

INDOOR AIR QUALITY HANDBOOK

JOHN D. SPENGLER, JONATHAN M. SAMET,
JOHN F. MCCARTHY

Table of Contents

Cover.....	1
Copyright.....	6
PART 1: INTRODUCTION.....	7
CHAPTER 1: INTRODUCTION TO THE IAQ HANDBOOK	9
CHAPTER 2: THE HISTORY AND FUTURE OF VENTILATION	27
CHAPTER 3: SICK BUILDING SYNDROME STUDIES AND THE COMPILATION OF NORMATIVE AND COMPARATIVE VALUES	43
CHAPTER 4: ESTIMATES OF POTENTIAL NATIONWIDE PRODUCTIVITY AND HEALTH BENEFITS FROM BETTER INDOOR ENVIRONMENTS: AN UPDATE.....	75
CHAPTER 5: INDOOR AIR QUALITY FACTORS IN DESIGNING A HEALTHY BUILDING.....	111
PART 2: BUILDING SYSTEMS	141
CHAPTER 6: AN OVERVIEW OF THE U.S. BUILDING STOCK.....	143
CHAPTER 7: HVAC SYSTEMS.....	159
CHAPTER 8: HVAC SUBSYSTEMS	177
CHAPTER 9: AIR CLEANING—PARTICLES	215
CHAPTER 10: REMOVAL OF GASES AND VAPORS.....	243
CHAPTER 11: DISINFECTING AIR.....	263
CHAPTER 12: CONTROLLING BUILDING FUNCTIONS	277
CHAPTER 13: VENTILATION STRATEGIES	295
CHAPTER 14: BUILDING FIRES AND SMOKE MANAGEMENT	319
PART 3: HUMAN RESPONSES.....	337
CHAPTER 15: THERMAL COMFORT CONCEPTS AND GUIDELINES	339
CHAPTER 16: THERMAL EFFECTS ON PERFORMANCE	353

CHAPTER 17: THE IRRITATED EYE IN THE INDOOR ENVIRONMENT— PHYSIOLOGY, PREVALENCE, AND CAUSES	369
CHAPTER 18: LIGHTING RECOMMENDATIONS.....	385
CHAPTER 19: THE ACOUSTIC ENVIRONMENT: RESPONSES TO SOUND	407
CHAPTER 20: PHYSICOCHEMICAL BASIS FOR ODOR AND IRRITATION POTENCY OF VOCs	431
CHAPTER 21: RESPONSE TO ODORS.....	453
CHAPTER 22: PERCEIVED AIR QUALITY AND VENTILATION REQUIREMENTS	465
CHAPTER 23: ANIMAL BIOASSAYS FOR EVALUATION OF INDOOR AIR QUALITY..	477
CHAPTER 24: COMPUTERIZED ANIMAL BIOASSAY TO EVALUATE THE EFFECTS OF AIRBORNE CHEMICALS ON THE RESPIRATORY TRACT	527
CHAPTER 25: SENSORY IRRITATION IN HUMANS CAUSED BY VOLATILE ORGANIC COMPOUNDS (VOCs) AS INDOOR AIR POLLUTANTS: A SUMMARY OF 12 EXPOSURE EXPERIMENTS	553
CHAPTER 26: METHODS FOR ASSESSING IRRITATION EFFECTS IN IAQ FIELD AND LABORATORY STUDIES.	581
CHAPTER 27: MULTIPLE CHEMICAL INTOLERANCE AND INDOOR AIR QUALITY	611
CHAPTER 28: ENVIRONMENTALLY INDUCED SKIN DISORDERS.....	643
PART 4: INDOOR POLUTANTS.....	655
CHAPTER 29: COMBUSTION PRODUCTS.....	657
CHAPTER 30: ENVIRONMENTAL TOBACCO SMOKE	681
CHAPTER 31: VOLATILE ORGANIC COMPOUNDS	711
CHAPTER 32: ALDEHYDES	731
CHAPTER 33: ASSESSING HUMAN	

EXPOSURE TO VOLATILE ORGANIC COMPOUNDS1	753
CHAPTER 34: POLYCYCLIC AROMATIC HYDROCARBONS, PHTHALATES, AND PHENOLS	789
CHAPTER 35: PESTICIDES.....	815
CHAPTER 36: POLYCHLORINATED BIPHENYLS	837
CHAPTER 37: FIBERS	867
CHAPTER 38: ASBESTOS.....	889
CHAPTER 39: SYNTHETIC VITREOUS FIBERS	907
CHAPTER 40: RADON	937
CHAPTER 41: LATEX.....	957
CHAPTER 42: ENDOTOXINS	973
CHAPTER 43: ALLERGENS DERIVED FROM ARTHROPODS AND DOMESTIC ANIMALS	987
CHAPTER 44: POLLEN IN INDOOR AIR: SOURCES, EXPOSURES, AND HEALTH EFFECTS.....	1003
CHAPTER 45: THE FUNGI.....	1021
CHAPTER 46: TOXIGENIC FUNGI IN THE INDOOR ENVIRONMENT	1055
CHAPTER 47: TUBERCULOSIS	1075
CHAPTER 48: LEGIONELLA.....	1089
PART 5: ASSESSING IAQ.....	1105
CHAPTER 49: STRATEGIES ANDMETHODODOLOGIES TOINVESTIGATE BUILDINGS.....	1107
CHAPTER 50: TRACKING ULTRAFINE PARTICLES IN BUILDING INVESTIGATIONS	1125
CHAPTER 51: INSTRUMENTS AND METHODS FOR MEASURING INDOOR AIR QUALITY	1143
CHAPTER 52: MEASURING VENTILATION PERFORMANCE.....	1181
CHAPTER 53: ASSESSING OCCUPANT REACTION TO INDOOR AIR QUALITY	1201
CHAPTER 54: BUILDING-RELATED DISEASES	1231
CHAPTER 55: METHODS TO ASSESS WORKPLACE STRESS AND PSYCHOSOCIAL FACTORS.....	1255

CHAPTER 56: COST OF RESPONDING TO COMPLAINTS.....	1279
CHAPTER 57: MODELING IAQ AND BUILDING DYNAMICS	1299
CHAPTER 58: INDOOR AIR QUALITY MODELING1.....	1311
CHAPTER 59: APPLICATION OF COMPUTATIONAL FLUID DYNAMICS FOR INDOOR AIR QUALITY STUDIES	1339
PART 6: PREVENTING INDOOR ENVIRONMENTAL PROBLEMS.....	1361
CHAPTER 60: INDOOR AIR QUALITYBY DESIGN	1363
CHAPTER 61: BUILDING COMMISSIONING FOR MECHANICAL SYSTEMS	1383
CHAPTER 62: PREVENTION DURING REMODELING RESTORATION...	1397
CHAPTER 63: PREVENTION AND MAINTENANCE OPERATIONS.....	1429
CHAPTER 64: PREVENTION WITH CLEANING.....	1441
PART 7: SPECIAL INDOOR ENVIRONMENTS	1459
CHAPTER 65: INDOOR ENVIRONMENTALQUALITY IN HOSPITALS	1461
CHAPTRE 66: RESIDENTIAL EXPOSURE TO VOLATILE ORGANIC COMPOUNDS FROM NEARBY COMMERCIAL FACILITIES.....	1475
CHAPTER 67: RECREATION BUILDINGS ..	1495
CHAPTER 68: TRANSPORTATION.....	1513
CHAPTER 69: DAY-CARE CENTERS AND HEALTH	1533
PART 8: RISK ASSESSMENT AND LITIGATION	1553
CHAPTER 70: THE RISK ANALYSISFRAMEWORK:RISK ASSESSMENT, RISKMANAGEMENT, AND RISKCOMMUNICATION	1555
CHAPTER 71: IAQ AND THE LAW	1591

Library of Congress Cataloging-in-Publication Data

Indoor air quality handbook / John D. Spengler, Jonathan M. Samet, John F. McCarthy, editors.

p. cm.

Includes index.

ISBN 0-07-445549-4

1. Housing and health—Handbooks, manuals, etc. 2. Indoor air pollution—Handbooks, manuals, etc. I. Spengler, John D. II. Samet, Jonathan M. III. McCarthy, John F., date.

Harvard School of Public Health
Boston, Massachusetts*

Jonathan M. Samet, M.D.

*Chairman, Department of Epidemiology
Johns Hopkins University
Baltimore, Maryland*

John F. McCarthy, Sc.D., C.I.H.

*President, Environmental Health & Engineering, Inc.
Newton, Massachusetts*

1.1 INTRODUCTION TO THE HANDBOOK

Our expectations are high for the indoor environments where we spend most of our time. Above all, we expect that these environments will not threaten our well-being and we anticipate acceptably low risks for injury and for damage to our health. One long-neglected aspect of indoor environments is the quality of the air and whether inadequate indoor air quality can actually pose a threat to health. Of course, we have long known that high levels of smoke can be unpleasant and irritating and that carbon monoxide can be acutely asphyxiating; but more recently we have learned of the more subtle, and sometimes delayed, threats of many other indoor pollutants—radon, tobacco smoke, allergens, and volatile organic compounds, for example. Complex and even disabling syndromes have also emerged that are linked to indoor air pollution: sick building syndrome (SBS) and building related illness (BRI).

We also expect that indoor environments will be comfortable, having appropriate temperature and humidity, lighting, and sound characteristics. This expectation extends to indoor air quality, one of the key determinants of the acceptability of indoor environments. Unacceptable indoor air quality (IAQ) may reduce well-being and contribute to lost productivity and absenteeism at work. Indoor pollution may cause diverse symptoms and

illnesses, including the symptom syndrome now most often referred to as SBS, which may lead to substantial time lost from work, medical costs, and even litigation. With the growing recognition of the problem of indoor air pollution, the need for a handbook on the topic for the many professionals dealing with IAQ issues became evident.

1.2 ORGANIZATION OF THE INDOOR AIR QUALITY HANDBOOK

Having reviewed the published literature and consulted with experts, McGraw-Hill Publishing Company in 1998 undertook an effort to compile the state of practice and knowledge concerning indoor air. The three editors expanded the coverage to some of the key additional factors related to total environmental quality for the built environment. In consultation with several of the contributing authors, this multisection handbook emerged. The sections and chapters are designed to inform professionals about the many factors that can and do influence the health, safety, and productivity of occupants, visitors, and users of the many built environments in our societies. As readers will learn, many of the problems in built environments are multifactorial, reflecting not only indoor air quality, but modifying factors like lighting and the level of stress in the workplace. Consequently, multidisciplinary approaches are typically needed not only for research but for problem solving. The problem of SBS is illustrative.

Over the past few decades, as SBS became a part of our lexicon, there has been a growing appreciation of interdisciplinary approaches to solve instances of SBS. For affected persons, the symptoms may be debilitating and refractory to medical management. For the building manager or employer, finding the cause(s) may be difficult and expensive, and claims for worker's compensation and litigation may be an unfortunate consequence. Complex cases of SBS may involve a multidimensional spectrum of impacts: social, political, health, and economic. Solving such problems may prove difficult and the costs may be high, as shown in the economic assessment of poor indoor environmental quality in U.S. office buildings presented by William Fisk in Chap. 4. The recognition of the costs of indoor air pollution and the growing interest in ecologically responsible architecture have led to a willingness of governmental agencies, municipalities, professional societies, and trade associations to engage in strategic, holistic thinking about integrated system designs in order to optimize multiple attributes of indoor environments. Whether it is designing vehicles, homes, or office buildings, attributes of safety, health promotion, energy efficiency, and material conservation are being recognized as components of performance and aesthetics. Long-term societal benefits are receiving consideration in the design, rehabilitation, furnishings, and operations in the new generation of sustainable buildings.

The *Indoor Air Quality Handbook* was written with an "eye to the future" but from a perspective informed by the realities of present conditions. Establishing good practice and specifications for high performance structures of the twenty-first century requires an understanding of the underlying causes of IAQ problems gained through experiences with buildings constructed across the last century and even earlier. In part, this understanding is solidly grounded in scientific research, but it is also based in experience gained in the field as professionals have addressed problems of specific buildings, much as physicians learn from caring for individual patients. Thus, the handbook assembles the experience and knowledge of many experts from around the world. Following five introductory chapters in Part 1, the handbook has seven additional parts. Part 2 describes the function of building systems and components that effect IAQ. Air distribution systems and ventilation strategies are covered. Air cleaning devices and fundamental physical/chemical principles behind

their performance are discussed in three chapters. A chapter on fire safety was included because fire codes in the United States dictate material specifications and ventilation design for many building types. Constraints imposed by fire codes will have to be negotiated before U.S. buildings can take full advantage of new energy-efficient design currently accepted within much of the European Community.

Part 3 focuses on the occupant response to indoor environmental quality conditions. Like the previous part on building components/systems, Part 3 describes how people interact with components of buildings through the diverse stimuli—visual, auditory, psychological, physical, dermal, olfactory, and respiratory—that are inherent to being within an indoor environment.

A pathophysiologic, or disease-oriented, perspective was not taken because useful texts that describe the medical aspects of environmental and occupational contaminants are available. The reader is referred to an early but still useful book, *Indoor Air Pollution: A Health Perspective* by Samet and Spengler, published in 1991, and to *Environmental and Occupational Medicine* (3d edition) by Rom, published in 1998, and to *Textbook of Clinical Occupational and Environmental Medicine* by Rosenstock and Cullen, published in 1994. Readers needing more detail on the etiology and symptoms of specific diseases are referred to *Robbins Pathologic Basis of Disease* (5th edition) (Cotran et al. 1994) or Amdur, Doull, and Klaassen's 4th edition of *Casarett and Doull's Toxicology*, published in 1991. Harber, Schenker, and Balmes (1995) address effects on the respiratory system in the 1995 book *Occupational and Environmental Respiratory Diseases*. Outdoor air pollutants penetrate indoors; the major pollutants are comprehensively addressed by Holgate and colleagues (1999).

In Part 3, concepts on comfort and the effects on performance are presented in Chaps. 15 and 16. Other chapters address lighting, acoustics, odor, and irritation. Odors and sensory irritation arising primarily from gases and vapors encountered indoors have been associated with a myriad of symptoms and undoubtedly associated with stress and discomfort. The understanding of the odor and irritation effects of mixtures continues to be advanced through clinical studies, laboratory assays, and sensor technology. Techniques, once restricted to the laboratory, have increasingly been applied in building investigations. We considered this area to be significant and have included six chapters on various aspects of odor and sensory irritation responses.

The term multiple chemical sensitivity (MCS) has become widely recognized as a condition of intolerance to low-level chemical exposures. Putting aside the controversy as to the underlying mechanisms and whether MCS constitutes a physiological or psychological disorder, MCS must be considered from the practical viewpoint when attempting to resolve building-related problems. Many managers, school principals, human resource personnel, medical professionals, and consultants will agree that occupants, teachers, tenants, and employees suffering with MCS require stringent remediation measures to minimize exposures to triggering agents. Professionals handling buildings where MCS cases occur should be aware of these needs, as should supervisors and health care professionals who deal with affected persons.

The fourth part is organized by contaminant groups. Handbooks are most often used to find guidance on procedures and equipment and as a source of concise information on specific subjects. We envisioned that comprehensive reviews of contaminant concentrations, exposures, and health effects would be useful to most readers and have constructed these chapters accordingly.

The fifth part of the *IAQ Handbook* deals with assessment methods, first offering a general approach to investigating building problems and providing instruments for that purpose. The following chapters cover assessment of ventilation performance, as well as the medical and stress conditions of occupants. This part also includes assessment of ventilation performance, and health status and workplace stress. Often IAQ investigations involve

only one building, which has been selected because occupants are known to be experiencing problems. Without comparison data, it may be difficult to interpret the symptom patterns and to gauge their severity, or to offer concrete remedial actions. Fortunately, there have been several European and U.S. studies involving a general sample of buildings. From these surveys, some information about expected prevalence of symptoms, as well as environmental conditions and physical status of the building, is obtained. The reader can find the summary descriptions of these U.S. and European building studies in Chap. 3. There, the findings of a National Institutes of Safety and Health (NIOSH) survey conducted in response to building complaints is compared to the U.S. Environmental Protection Agency (EPA) investigation of “noncomplaint” buildings. The common building-related symptoms are grouped in a physiologically coherent way and compared between these two large studies. The normative data derived from studies of noncomplaint buildings can be very useful in interpreting symptom survey results from occupants of a single “problem” building.

Earlier in the handbook (Chap. 4), the economic consequences of inadequate indoor air quality are presented. Estimates of the medical and labor cost for poor indoor air are estimated to range up to \$50 billion annually. Chapter 56 in Part 5 examines the cost associated with the most common IAQ complaint, thermal discomfort. Even without including improved performance, an economic case is made for improving the tolerance for HVAC thermal controls simply on the basis of decreased service calls. Changing HVAC performance, using higher-efficiency filters, and implementing enhanced cleaning programs are easily justified activities. The City of New York’s Department of Design and Construction recently published “High Performance Building Guidelines” (New York DDC 1999), which estimates annual savings from increased employee performance as a consequence of improved IAQ to range between \$2.87 and \$6.15 per square foot. This represents accumulative savings for city buildings of well in excess of \$200 million to New York City taxpayers. Quantifications of IAQ cost along with recovered energy, water, and materials have already accelerated the interest in high-performance buildings. Maintaining good indoor quality for these buildings is the shibboleth to economic benefits accrued from increasing productivity while reducing absenteeism, employee turnover, medical costs, and litigation.

Ventilation systems, pollutant dispersion and removal, and energy performance can be assessed with physical/chemical models. Three chapters provide readers with useful information on available models. The authors of these chapters are expert in the appropriate applications and limitations of models and provide guidance on these matters.

The sixth part of the *IAQ Handbook* addresses the critical issue of prevention. We understand that some IAQ problems originate with design and construction. In principle, SBS and other building-related problems would not occur if buildings were designed to optimize IAQ, built according to design specifications, and then appropriately maintained. In the series of five chapters, various issues related to prevention are presented. The guidance offered in these chapters would alleviate many IAQ problems common today.

Part 7 approaches IAQ in relation to specific groups of buildings that share functionality and have common patterns of IAQ problems. While some IAQ issues are common to many buildings, other buildings or built environments are distinguished by, among other attributes, the function they perform, occupant susceptibility, and uncommon sources, making them special indoor locations. Particular attention is given to five classes of indoor environments: health care facilities; special retail facilities; buildings designed for recreation; transportation vehicles such as cars, planes, trains, and buses; and schools. Each of these categories of facilities has special IAQ concerns. The occupants of hospitals and schools include special populations that are more susceptible to some contaminants. Hospitals and schools also have sources of contamination that distinguish them from the general office building. These sources pose risks from particular irritants, allergens, and microbiological agents that are less likely to be a concern in office buildings. Transportation vehicles are high-density spaces. Unlike office space or our homes where

there is 20 cubic meters or more per person, we must endure for hours in two cubic meters when flying. Of course, you can upgrade and have an additional cubic meter! Combustion exhaust along with the human-product- and furnishing-related emissions have to be contended with in these semiconfined environments (NRC 1986).

The final part (8) considers critical cross-cutting IAQ issues—risk assessment, risk communication, and litigation. Characterization of indoor exposures to chemical and biological agents is imperfect. Measurements are made over a limited time period and are only proxies for dose. Occupants can present a range of susceptibility, depending on genetic, personal, or behavioral risk factors. Health data are lacking for many of the contaminants that are now readily identifiable in subparts per billion by available analytical techniques. Risk assessment provides a framework for integrating environmental, demographic, and health information along with uncertainties to formulate an impression about the severity of an indoor exposure. While they are not presented here, the reader can find risk assessments published elsewhere on indoor pollutants, asbestos, lead, radon, and tobacco smoke. A vitally important skill for managing IAQ problems is risk communication. Effective communication skills and the ability to anticipate employee, management, tenant, and parental concerns are needed to manage any IAQ situation, especially one with a perceived health risk.

1.3 HISTORY OF RESEARCH ON INDOOR AIR QUALITY

For centuries, there has been a broad understanding of the threat posed by air pollution to the public's health. As early as the fourteenth century, the smoke laws in London were intended to reduce outdoor air pollution (Brimblecombe 1999). With the Industrial Revolution and the rise of cities, awareness of the threat posed by outdoor air pollution was recognized, and this potential was tragically demonstrated in a well-chronicled series of disasters across the twentieth century: the Meuse Valley in 1932; Donora, Pennsylvania, in 1948; and London in 1952. The London Fog of 1952 remains the most dramatic of these episodes, causing several thousand deaths, particularly in infants and the elderly, during the week of the fog. The modern era of air pollution research, in fact, begins with the London Fog, which prompted a wave of epidemiologic and other research to characterize the public health risks of outdoor air pollution. We now have a large body of evidence on the health effects of air pollution amassed through 50 years of research. Comprehensive, recent reviews should be consulted for the findings, including the summary statement on the health effects of air pollution prepared by the American Thoracic Society and published in 1996 (Bascom et al. 1996a, 1996b) and the 1999 monograph by Holgate and colleagues (Holgate et al. 1999).

The history and evolution of research on indoor air pollution is closely intertwined with investigation of outdoor air pollution. Recognition of the potential significance of sources of indoor air pollution for human health dates to the 1960s when some of the first measurements of indoor air quality were made; see the 1981 National Research Council report on indoor pollutants (NRC 1981b). For example, in 1965, the Dutch investigator, Biersteker, and his colleagues made measurements of nitrogen dioxide in homes, finding that this outdoor air pollutant was also present at high levels in homes with gas-fired combustion devices (Biersteker 1965). Some of the initial measurements of tobacco smoke components were made in the 1970s (Hinds and First 1975; Repace and Lowery 1980). In the 1980s, the U.S. EPA's Total Exposure Assessment Methodology (TEAM) Study provided a model for comprehensive assessment of the contributions of indoor and outdoor exposures to total personal exposure. This study yielded the then startling conclusion that

indoor pollution sources were generally a far more significant contributor to total personal exposure for toxic volatile organic compounds than are emissions released by some industrial sources into outdoor air. The Harvard Six-Cities Study, a landmark investigation of outdoor air pollution, also proved to be an invaluable platform for understanding residential indoor air pollution and its contribution to total personal exposures for a number of pollutants, including particles and nitrogen oxides, among others. In this community-based study, the investigators used the combination of outdoor and microenvironmental monitoring and personal exposure assessment to characterize the contributions of various indoor sources to total personal exposure.

Focused research on the health risks of indoor air pollution dates to the mid-1960s. Some of the early studies focused on the risks to respiratory health posed by smoking indoors. Cameron and colleagues provided cross-sectional findings on the respiratory health of persons living in homes with and without smokers in several reports published in the late 1960s. About the same time, a number of reports addressed the respiratory health of infants and children in relation to maternal smoking (Cameron et al. 1969; Colley 1971). Research on passive smoking and respiratory health continued through the 1990s, providing a large database on the effects on children and adults. In 1977, a report by Melia and colleagues in the United Kingdom brought attention to possible adverse effects of nitrogen dioxide indoors from gas cooking appliances. In a cross-sectional survey, children living in homes with gas stoves were found to have higher prevalence rates of respiratory symptoms and illnesses than those living in homes with electric stoves (Melia et al. 1977). A wave of cross-sectional and longitudinal studies on nitrogen dioxide indoors followed (Samet 1991). About the same time, formaldehyde was also intensively investigated as a potential cause of asthma. This interest was largely prompted by the release of formaldehyde from improperly installed urea formaldehyde foam insulation, which affected many homes particularly in the northeastern United States and Canada (see Chap. 32, “Aldehydes”).

Radon, a radioactive gas known to cause lung cancer in underground miners, is also a ubiquitous contaminant of indoor air. Its source is largely natural—primarily radon-contaminated soil gas, which leaks into homes through cracks and other openings in basements and around foundations. As early as the 1950s, radon was shown to be present in air in homes, but concern mounted in the late 1970s and early 1980s as the extent of the problem became evident in many countries in temperate and colder climates. In Sweden, there was early interest because building materials included a wallboard containing alum shale material with a high concentration of radium, the parent radioisotope for radon. In the United States, public and congressional concern was initiated in the early 1980s by the dramatic identification of a home in Pennsylvania with levels equal to those in underground uranium mines where miners had experienced excess lung cancer. Further homes with high levels were identified and programs of measurement and investigation of health risks were launched. See Chap. 40, “Radon.”

For approximately 20 years, research has been carried out on the problem of SBS. The initial investigations were essentially case reports, involving the description of symptoms of affected persons and the levels of some contaminants thought to be potentially responsible. A new generation of more informative, multibuilding studies have followed. The multibuilding design offered the possibility of comparing symptoms and contaminant levels in multiple buildings having differing characteristics. Chapter 3 reviews the major findings of investigating building conditions and occupants’ symptoms.

The result of over 30 years of inquiry is a substantial body of scientific evidence that has already served to guide policy making to reduce risks of indoor air pollution. The literature on many indoor air pollutants is immense in scope, and single pollutants have been the topic of substantial monographs and committee reports, for example, formaldehyde (NRC 1981a), indoor air pollution (NRC 1981b), radon (NRC 1999), indoor allergens

(NRC 1993), environmental tobacco smoke (U.S. Surgeon General 1986; Guerin et al. 1992), and several reports published by the World Health Organization and the European Collaborative Action group of the European Commission (Indoor Air Quality and Its Impact on Man).

Researchers have also addressed approaches to evaluating comfort and the acceptability of indoor air quality. During the first half of the twentieth century, Yaglou used an experimental approach to determine the amount of ventilation air that was needed to make air quality acceptable to an observer. In his experiments, panelists sniffed air coming from a chamber occupied by varying numbers of people and under varying rates of ventilation and judged the acceptability of the air quality (Yaglou et al. 1936). More recently, Fanger pioneered the use of panels of observers who are trained to evaluate acceptability of air quality in a standardized fashion (Fanger 1996). We recommend Chap. 2, which traces the development of ventilation systems and the concepts of adequate and healthy indoor air. Chapter 22 discusses how air temperature and humidity affect the perception of air quality in buildings.

Research on indoor air quality has been carried out by many different types of professionals, some moving into scientific territory outside their own discipline. The literature includes studies carried out by engineers, medical and nonmedical epidemiologists, industrial hygienists, occupational health physicians, psychologists, and indoor air quality professionals. The resulting literature is rich in approaches, but heterogeneous in its methods and some researchers may move too far from their core scientific backgrounds, and studies may be naïve as a result. Consequently, interdisciplinary studies are optimal as the investigative team may include:

1. Expertise in building design and operation
2. Expertise in study design and data analysis and interpretation
3. Expertise in exposure assessment
4. Medical expertise
5. Expertise in psychology and organizational dynamics.

For readers who may want to carry out a research project, we recommend careful consideration of the needed expertise. There are no ready templates for carrying out studies that can be implemented with assurance of proper measurement and standardization.

Some IAQ Research Needs

While the IAQ literature has grown significantly since the late 1970s, substantial uncertainties remain—uncertainties in a real-world understanding of the relationship between exposures to contaminants indoors and well-defined pathophysiologic, irritation, or sensory responses. For example, building materials must be studied as they are actually used in buildings, undergoing maintenance and degradation from use. The chemistry that occurs indoors results in complex mixtures that are poorly understood. Reactions that might occur in smog formation outdoors cannot simply be transferred to indoor conditions. Microorganisms growing indoors, such as fungi and bacteria, are capable of producing metabolites, protein and polysaccharide structures that are toxic, inflammatory, or irritating. The doses of these microorganisms or their derivatives required to produce a clinically meaningful response are largely unknown. Indoor residential concentrations of nitrogen dioxide (NO₂), carbon monoxide (CO), radon, formaldehyde, volatile organic compounds, and some allergens have been well studied in the United States, Europe, Australia, and Japan and, to a lesser extent, in a few other countries. Our knowledge

remains limited, however, about many other substances such as endocrine-disrupting chemicals, endotoxins, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), fibers, toxic metals, and pesticides for which indoor environments could very well play a critical role.

The IAQ research community is under pressure. Architects, builders, manufacturers, building managers, jurists, health officials, and the public seek easily interpretable axioms and guidelines to specify the “brightlines” that distinguish safe practice and safe indoor environments. Yet, uncomplicated outcomes are not always tractable when studying health outcomes in a heterogeneous population in possible association to conditions within a particular building. After all, we are in many buildings throughout the day and over our lives. So beyond the immediate practical need to study the offgassing of products, effectiveness of duct cleaning, or adequacy of ventilation, in our opinion, advances are needed in fundamental understanding of four key areas: *modeling*, *mixtures*, *microorganisms*, and *multiple-chemical sensitivity*.

More sophisticated IAQ exposure *models* need to integrate energy, economic, and health outcomes that predict performance of building and ventilation designs. While some useful models exist in both the IAQ and energy performance domains, a field-validated, user-friendly model that couples airflow, variable emissions, occupant behavior, and energy considerations is needed. Computational fluid dynamic (CFD) codes are commonly available now and will increasingly be used to predict heat and moisture transfer and, of course, air movements. Buildings have unplanned air pathways, partial internal mixing, sources with varying emission rates, and complex thermal gradients that comprise the poorly defined events affecting contaminant movements and exposure. Therefore, CFD models need to be validated with field and laboratory experiments. Advancement in CFD computational schemes and graphical displays will provide valuable testing of ventilation strategies or simply evaluation of room air cleaners. See Chaps. 57 to 59.

Life cycle analysis (LCA) is a methodology for evaluating the health and ecological impacts of product programs and designs. Models used for LCA currently do not consider indoor exposures that may result from the use of a product. For example, LCAs of paints assess manufacturing emissions and the loss of volatile organic compounds (VOCs) to the atmosphere, but not indoor exposures. LCA has indicators for greenhouse gases, air pollution, water pollution, toxic substances, acid deposition, and energy impacts. For many products, a substantial fraction of their emissions occurs indoors where the net exposure is 10 or more times higher than exposures to people residing near manufacturing sites. LCA models must be improved to include the potential health and discomfort occurring in populations exposed indoors.

Mixtures of gases, vapors, and particles are present in every breath we take. Hundreds to thousands of chemical compounds may be present simultaneously. The vast majority of our information on biological responses is derived from controlled exposures to cell cultures, animals, or humans of one or only a few compounds at a time. Where mixtures of VOC sources have actually been used in mouse bioassay (ASTM 1984; Nielsen 1991) and human studies (Cometto-Muñiz et al. 1997; Mølhave 1992), there is some evidence for additive and synergistic effects. In human studies, VOCs in combination have been shown to cause chemosensory irritation of eyes and nasal passages, even when each individual compound is substantially below its nominal irritant threshold. In the real world, the complexity of airborne exposures is further complicated by reactions in the presence of humidity, oxides of nitrogen, ozone, and hydroxyl radicals. Although considerably more complex than controlled assessments of single contaminants, studies of indoor air chemistry and mixtures of contaminants will likely yield more relevant information about potentially hazardous or irritating atmospheres.

Several recent studies have shown that ozone reacts with unsaturated hydrocarbons indoors to form submicrometer-size particles and a variety of hydroxyl and peroxy radicals.

Unsaturated hydrocarbons are emitted from cleaning agents (terpenes), building products, and furniture and flooring materials (Weschler and Shields 1997a, 1997b). Further, Wolkoff and colleagues (1999), using a mouse bioassay, demonstrated that the reaction products formed from terpenes and ozone are extremely irritating. Four chapters (25 to 28) of the handbook treat various aspects of chemical irritation.

Microorganisms are well recognized for contributing to irritation, allergies, disease, and other toxic effects indoors. When a disease can be histologically identified, it is possible to locate the indoor (or outdoor) source of the microorganism. Understanding exposure pathways and quantifying dose received by the infected or affected subject remains elusive in most cases. Further, our knowledge about a diverse array of noncellular agents associated with microorganisms, such as endotoxins, glucans, polypeptides, allergenic proteins, and mycotoxins, is limited. These components as well as bacteria, fungal spores, and viruses may be transported by air currents and ventilation systems to express health effects at some distance from their sources. Rapid identification of infectious, allergenic, and irritating microorganisms in air is currently limited to assays requiring culturing, laborious microscopy, or expensive gas chromatography/mass spectrometry (GC/MS) techniques. Concerns that terrorists will use biological weapons to attack buildings are now motivating the development of techniques to identify specific airborne organisms in real time. Microchip sensor arrays recognizing DNA or protein structures or responding to mass changes from specific antibody-antigen reactions will provide rapid detection technology. Many challenges remain to make the technology specific to microorganisms possibly causing more general and widespread illness, allergy, and irritation indoors.

Overall, a great deal more needs to be understood about the dose-response characteristics and host susceptibility factors for almost all microbiological agents. The lack of understanding of exposures (amount, duration, and timing) relevant to sensitization, infection, and allergy provocation is distorting public response and remediation. "Sporephobia" anxiety is increasing among the general public much the way "fiberphobia" and "chemophobia" have altered rational perspective about indoor air risks. For example, we know that mycotoxin from *Stachybotrys chartarum* in a high enough dose is a potent toxicant. However, it is extremely difficult to quantify how much mycotoxin is present in situ, and there is no well-substantiated guidance to predict the risk from airborne or surface spore samples. Seven chapters (42 to 48) discuss in considerable detail various microorganisms relevant to indoor environments.

*Multiple-chemical sensitivity (MCS)*¹ is a term that evokes skepticism, sympathy, hostility, and compassion. To distance the condition from emotionally and politically charged connotations, MCS is sometimes referred to as "chemically induced intolerance." The broad constellation of symptoms associated with MCS has also been called twentieth century disorder, darkroom disease, reactive airways dysfunction, Gulf War syndrome, environmental disease, or chemical hypersensitivity; in any guise, MCS presents a vexing problem for IAQ.

A review of the literature by Ashford and Miller (1998) cites indoor activities, including oil spills, pesticide applications, remodeling, new carpeting, film developing, and combustion leaks, among the more commonly reported initiating events for MCS. Decreased tolerance leads many individuals to report symptoms on exposure to products and sources common in indoor environments, such as perfumes, cleaning agents, cigarette smoke, and

¹Multiple-chemical sensitivity is an acquired disorder characterized by recurrent symptoms, affecting multiple organ systems. The symptoms occur in response to demonstrable exposure to a variety of chemically unrelated compounds at doses far below those established in the general population to cause harmful effects. No single widely accepted test of physiologic function can be shown to correlate with symptoms (Cullen 1987).

diesel exhaust. In the United States, if one believes the survey results, 5 percent of the population has been diagnosed by a physician as chemically sensitive, while the prevalence of a self-diagnosed sensitivity or allergy to chemicals and chemical odors ranges from 3 to 7 times this rate. Survey data related to MCS are not available from Europe, although, in Germany, a similar constellation of symptoms has been associated with “wood preservative syndrome” caused by pentachlorophenol exposures. In Greece, anesthetic agents have been reported as probable agents of chemical sensitivity, while reports from Denmark, Sweden, and Greece indicate that chemicals used by hairdressers may be agents of chemical sensitivity (Ashford and Miller 1998).

MCS is part of the indoor air landscape that needs to be addressed with scientifically defensible research. Ideally, objective measures of exposures and responses are needed in double-blind experiments. These studies will be difficult since exposures often evoke sensory stimulation and specific physiologic responses in MCS patients have been elusive. While these limitations present difficulties, the etiology of the MCS complex requires thorough investigation. Determining the environmental conditions that trigger MCS responses would give insight into the sources, compounds, and settings that need to be avoided to provide safe indoor environments for those affected by this vexing condition. MCS is presented by Miller and Ashford in Chap. 27.

The European Perspective

Mr. Christian Cochet, Head of the Health and Buildings Division, Centre Scientifique et Technique du Bâtiment, France, offered these comments on European indoor air research as part of an Electricité de France and Electric Power Research Institute workshop (Cochet 1998). This workshop was held December 15–17, 1998, in Boston, Massachusetts, and convened 25 leading scientists from Europe and the United States to discuss IAQ research needs.

European research on indoor environments cannot be defined by a single approach, but is really a complex mix of national and international interests and programs. Unlike research in North America, which is funded primarily on a national level by both public and private sources, European research is financed largely through public funding from both national and international agencies. Under authority of the European Commission (EC) and the European Collaborative Action (ECA), both international in nature, common research interests are encouraged and supported through international projects. By mutual agreement, research results that affect common regulatory and economic sectors, such as those involving free trade of goods and services, are implemented throughout the continent. However, individual countries (“member states”) are free to establish stricter health and environmental measures, to promote their own research programs, and to establish their own risk assessment and management policies. As a result, significant differences have developed from one country to another in indoor air standards and in health and environmental policies, such as those for asbestos and radon.

In recent years, however, several cost-shared European research programs have begun investigating indoor air quality issues that may ultimately provide some regulatory consistency on the continent. The IVth Framework Program, which directs all research and technological development activities of the EC, has sponsored the following projects:

- JOULE, a non-nuclear energy research program focusing on renewable, sustainable sources of energy
- SMT, the Standards Measurement and Testing program, which involved building audits of IAQ and the construction of a European database on indoor air pollution sources in buildings

- VOCEM, Volatile Organic Compounds Emission Measurements, focusing on improvement of building products
- EXPOLIS, a study of air pollution exposure of a European adult urban population.

In addition to the research being supported by the IVth Framework Program, the ECA has contributed significantly to the indoor air quality field since 1986 through the development of its "Indoor Air Quality and Its Impact on Man" (ECA-IAQ) program. Having no research funds of its own, the ECA steering committee primarily focuses on development and validation of guidelines and reference methods; collection, synthesis, and dissemination of knowledge and data; and organization of workshops, symposia, and seminars. To date, the ECA has issued 18 reports on various indoor air topics, including risk assessment of indoor air pollutants, sensory evaluation of indoor air, and interlaboratory comparison on VOC emissions measurements. The organization has also issued recommended guidelines for selected health and environmental building parameters. The ECA relies on a number of established working groups and also has plans in development for future task force topics.

The Vth Framework Program for research and development began in 1999. A broader research initiative has emerged for indoor air. The Kyoto objectives, which reinforce energy conservation in buildings, raise critical questions regarding limits on building ventilation requirements and potential concentration of indoor contaminant sources. Further, assessment of the health effects of atmospheric pollution will have to address how outdoor air impacts indoor air.

Research into indoor air pollution and its effects on health is becoming an increasing priority as we attempt to manipulate outdoor and indoor environmental conditions for the common good.

1.4 THE ROLES OF PROFESSIONALS IN INDOOR AIR QUALITY

Addressing problems of indoor air quality, whether for research, prevention, or problem-solving purposes, is inherently multidisciplinary. Involved professions include those who design buildings (architects and engineers), those who operate buildings (engineers and facilities managers), those who diagnose and treat health problems related to indoor air quality (physicians and other health professionals), and those who address problems of indoor air quality in buildings (industrial hygienists and the emerging discipline of indoor air quality professionals). In addition, research on indoor air quality is carried out by epidemiologists, physicians, industrial hygienists, psychologists, and other indoor air quality professionals. A research team may include expertise in building design and operations, occupational medicine, psychology, and exposure assessment, along with support from biostatisticians and specialized laboratories. Surprisingly, in spite of the inherently interdisciplinary nature of work on indoor air quality, there are very few forums for discussion across the disciplines and each may have limited knowledge of the capabilities of other involved groups. For example, our experience repeatedly shows that expectations of the medical community far exceed the general awareness of problems of indoor air quality.

The handbook provides a broad overview and specific content to the many professional disciplines who may become involved in indoor air quality problems, whether for research or other purposes. We have aimed this handbook at all of these communities to facilitate understanding among members of multidisciplinary teams. In this introduction, we highlight the professionals responsible for design, construction, and management of

buildings along with those in the health care community responsible for medical diagnosis and treatment.

Architects, Ventilation Engineers, and Builders

Building design, of course, is the domain of the architect, who works with the client in creating a building that will meet the client's needs and budgetary constraints. The architect's and client's decisions may be critical as tradeoffs are made between functionality and aesthetics, and comfort and costs. The materials selected for construction may have a lasting impact on indoor air quality. Unfortunately, neither the architect nor the client may be able to anticipate all future uses of the building and the consequences for maintaining healthy indoor air quality.

Delivering a building that works is key to preventing many IAQ problems. The process starts with design but the current practice followed in the United States can lead to defects that defeat the intentions of the architects and engineers who designed the building.

There are two common practices for construction of nonresidential buildings in the United States. The *design/bid/build* is the most common. A lead architect designs the basic structure but hires engineering firms for specific elements like the HVAC system, plumbing, and wiring. From the designs, detailed specification plans are drawn up for the bidding process. General contractors assemble subcontractors, again for specific components (sheet-metal work, plumbing, electrical, etc.) to bid on the project, which in many cases is awarded to the low bidder. There are variations where a contract manager might serve the owner to oversee the design-construction phases. A further and more common variant is the *design/build* format. In this case, the construction firm employs the architectural and structural engineering staff.

The system has somewhat perverse effects on the construction of buildings. These include:

- General contractor pressures subcontractors to contain cost. Cheaper materials are used, as well as less-skilled labor.
- Construction debris is left behind in ceilings, wall cavities, and elsewhere because less care is taken.
- Contractors make a substantial portion of fees on "change orders" because of mistakes on specifications or redesign. This is a disincentive for contractors to identify and avoid changes ahead of time.
- Concerns about legal liabilities encourage designers to distance themselves from the construction process, leaving construction details to contractors.
- With many subspecialists designing and constructing the building, it is difficult to maintain integration and eventual operation of many complex systems.
- Fee-based design and construction management arrangement provides no incentive for ensuring efficient design and performance.

Alternative systems have been proposed that hinge directly on the integration of a project team to provide coordination. The project team can assume responsibility for material specification and HVAC design to avoid many of the IAQ problems (moisture, noise, air intake placement, access for inspection and cleaning), and for lighting, acoustics, and many other features that are either taken for granted or ignored in the typical design-build process.

Building commissioning should be required to ensure all building components operate as designed before the building is turned over to the owner. Proper commissioning can also

provide training to building operators as well as establish maintenance procedures. See Chap. 61, “Building Commissioning for Mechanical Systems.”

Building Owner

Over the occupied life of a building, the owner has obvious responsibilities to maintain a building that complies with fire, safety, and building codes. Unfortunately, occupancy code requirements do not specify IAQ-related issues in detail. There are no indoor air quality guidelines except those applying to manufacturing facilities. Some states, however, are beginning to consider indoor air. Further, EPA and others have published guidelines for maintaining good indoor air quality in schools, homes, and office buildings. The owner has primary control over many aspects:

- Maintenance of ducts, cooling towers, and condensers. This is necessary to prevent microorganisms, dust, and fiber problems.
- Scheduling maintenance, repairs, cleaning, and refurbishing. With proper information given to occupants, this can reduce complaints.
- Developing a management plan and structure for IAQ complaints. This can head off many problems while keeping occupants more productive.

The key to a successfully operated building is a facility manager who is knowledgeable about how the building operates and the roles that inspection, maintenance, and cleaning have in preventing sources and pathways for contaminants. In addition, the manager must be sympathetic and responsive to the IAQ concerns of tenants and employees. Maintaining a complaint-free indoor environment may start with good design and comprehensive commissioning, but it requires vigilance of the facility manager. See Part 6 for insight on preventing indoor environmental problems.

The Role of Physicians and Other Health Care Providers

Unlike individual medical care, which lies with the practicing physician or other health care providers, day-to-day medical care at work-site clinic facilities may be provided largely by nurse practitioners or physician's assistants. Often, as the first point of contact for persons whose health is affected by indoor air pollution, health care professionals may play key roles in recognizing that indoor environmental exposures need consideration and evaluation. Some sentinel illnesses may quickly signal a potential role for indoor air pollution: hypersensitivity pneumonitis, carbon monoxide poisoning, or legionellosis. However, non-specific symptoms, associated for example with SBS, may not lead to any etiologic hypothesis related to indoor environments.

By specialty or subspecialty, health care providers will differ in their knowledge of the health consequences of indoor air pollution and in their skills in diagnosing and managing health problems arising from indoor air pollution. The bulk of primary care for adults is provided by family practitioners and general internists; for children, primary care is delivered by pediatricians and family practitioners. Most of these specialists have little or no specific training with regard to illnesses arising from indoor environments. Consequently, many problems related to indoor environments may be misdiagnosed or treated in a symptomatic fashion.

Some specialists and subspecialists may be more attuned to indoor air pollution: specifically allergists, pulmonary physicians, and physicians trained in occupational and environmental medicine. Allergists may focus on asthma and other allergic diseases, but

many have experience with a wider range of problems. Pulmonary physicians may also focus on asthma, but patients with nonspecific respiratory symptoms, such as coughing or wheezing, are often evaluated by pulmonary physicians, as well as those patients with respiratory infections, including various types of pneumonia and tuberculosis. Physicians trained in occupational and environmental medicine typically have a broad grounding in public health, and occasionally in toxicology, and clinical ecologists may become involved in the care of persons affected by indoor air pollution, particularly those with the syndrome referred to as MCS; however, clinical ecology is a nontraditional discipline and its methods have not yet been evaluated with the rigorous research methodology applied to conventional diagnostic and therapeutic approaches.

Regardless of professional background, physicians and other health care providers may be reluctant to become involved in issues that extend beyond care of the specific patient, such as contacting an employer to review concerns about indoor air quality. The time-consuming nature of such engagement and lack of knowledge regarding approaches are deterrents.

Patients may present physicians with specific complaints related to indoor environments or with a nonspecific picture that might reflect the actions of many different causal factors. This evaluation should invoke a detailed exposure assessment, perhaps drawing on the microenvironmental world.

The clinician's approach to assessing exposure in various microenvironments primarily involves interviewing the patient. Standardized instruments for collecting information on environmental and occupational exposures have been published (Cone and Hodgson 1989), but clinicians generally take exposure histories in idiosyncratic ways, the completeness of the history reflecting the clinician's training, fund of knowledge, and familiarity with the environments of concern to specific patients. The clinical history of exposures may touch on well-known hazards, e.g., asbestos, but rarely inventories the duties of specific jobs, the materials handled, the use of respiratory protection, or the quality of air in the workplace. Most physicians have limited knowledge of the exposures associated with specific occupations and little awareness of how buildings operate or of health-related indoor air contaminants. Exposures at home are rarely addressed. Often, however, it is the identification of a disease known to be caused by a specific agent that prompts full questioning of the patient concerning relevant exposures and, thus, routine medical records do not usually offer any more than a superficial assessment of inhaled exposures.

Biological markers of exposure are available on a routine clinical basis for only a few agents, including, for example, carboxyhemoglobin for carbon monoxide and blood or urine lead level for inhaled lead (NRC 1991). Serum antibodies or skin test reactivity to intradermal antigen injection can be measured to provide an indication of past exposure and the development of sensitivity to selected antigens; tests are available for the common sources of biological antigens, such as house dust mites, cockroaches, and cats. There are no routine tests for most chemicals found in indoor air that may represent a health threat, e.g., VOCs.

For the physician, the central problem in dealing with health problems arising from indoor air pollution is determining if that symptom, illness, or physiologic abnormality is caused by a particular agent. The starting point in any evaluation is careful and thorough history. Work, home, and other environments need to be considered for exposure to known allergens, irritants, chemicals, or organic dust. Careful inquiry is necessary about not only the materials the individual is working with, but also those being used by others in the workplace or at home. The occurrence of similar problems in family members and coworkers also should be assessed. Other clues in the history are useful. Of particular significance is the timing of the problem in relation to time spent in particular microenvironments. Occurrence of symptoms on exposure to, and improvement away from, suspect microen-

vironments indicate a potential causal factor. Often, however, clear temporal relation to exposure may not be evident.

The newer problems of SBS and BRI may be recognized if the patient presents an unmistakable clinical picture to an informed physician. The clinician is faced with an individual with a myriad of complaints, often including intractable upper respiratory symptoms, ill-defined central nervous system dysfunction, headache, fatigue, and low productivity. The patient may report odors, poor ventilation, or other problems in a building. Despite a careful physical evaluation, there may be no detectable abnormalities on examination.

An even more puzzling syndrome for clinicians is BRI, in which the individual can become "sensitized" to almost all organic and synthetic chemicals. The history is typically that of a healthy individual who after exposure to a solvent or irritant gas or fumes develops persistent symptoms with exposure to traces of the original agent or a variety of non-specific agents. The heart of the assessment lies in the clinical historical data, as the remainder of the evaluation is quite unremarkable. Often, a multidisciplinary evaluation is needed that may draw in a psychiatrist or psychologist, a clinical toxicologist or other specialist, and an industrial hygienist.

Summary

The responsibility for IAQ is shared by many professionals. Facility and human resource managers should be familiar with typical symptoms and sources of IAQ. However, they should recognize the limitation of capabilities of medical examinations or diagnostic tools to identify specific causes. Architects and engineers should appreciate the imperfections in our current system of constructing complex buildings that are expected to function properly the day they are turned over to owners. Owners should be more realistic and require verification of building performance. Owners should recognize that facility managers need to upgrade their training so they have the knowledge to prevent IAQ problems or to respond constructively should problems occur. It is only when the many professionals involved with the built environment appreciate the reality of IAQ problems that we, as a society, will begin to constructively avoid the disruption it causes. It is for all those many professions whose actions affect our indoor environments that we prepared this *Indoor Air Quality Handbook*.

CHAPTER 2

THE HISTORY AND FUTURE OF VENTILATION

D. Michelle Addington, Dr. Des., P.E.

*Harvard University Graduate School of Design
Cambridge, Massachusetts*

Recognition of the critical relationship between building ventilation and indoor air quality may seem to have occurred relatively recently. Not until 1989 did the American Society of Heating, Refrigeration and Air Conditioning Engineers (ASHRAE) modify their ventilation standard to address the growing concerns regarding degraded indoor air quality and sick buildings. The previous ventilation standard—ASHRAE Standard 62-1981—had recommended the reduction of ventilation rates so as to improve the energy efficiency of building systems. Although tobacco smoke had been singled out in the 1981 Standard as a contaminant requiring additional ventilation for its dissipation, the minimum standards were fundamentally based on balancing the two main constituents of human respiration: oxygen and carbon dioxide. Contamination of the indoor air from other substances ranging from volatile organics to microbial organisms did not begin to substantially influence recommended ventilation rates until after the World Health Organization provided a working definition of sick building syndrome in 1983 in response to widespread reports of work-related health complaints. The rise of symptoms seemed to most readily correlate with the advent of energy conservation procedures, including the reduction in ventilation rates, leading ASHRAE to dramatically increase its recommended rates by as much as fivefold.

This narrow time frame of events may lead one to conclude that the relationship between ventilation and indoor air quality is relevant only for post-energy crisis construction, and that implementation of the 1989 revisions to the ventilation standards should be sufficient to stem the rise in indoor air quality problems. A review of the history of ventilation, however, reveals that indoor air quality concerns played a significant role in the development of technologies and strategies for building ventilation and heating during the nineteenth century. The significance of this history cannot be overlooked as the heating, ventilation, and air conditioning (HVAC) system of the late twentieth century is conceptually and operationally

based on the technologies and requirements established nearly a century before. Future developments in ventilation therefore have the dual mandate of addressing today's indoor air quality concerns by challenging yesterday's technologies.

2.1 THE HISTORY OF BUILDING VENTILATION

Ventilation, both as a concept and in practice, was poorly understood before the nineteenth century. Although there was general awareness that "good" air was healthier than "foul" air, there was little consensus as to whether "good" air was indoor or outdoor air. Hippocrates, in *Airs, Waters, and Places*, postulated that decaying organic matter from marshes and wetlands created an infected air, or "miasma," that was the carrier of pestilence. In early treatises on building, from Vitruvius' first century B.C. *Ten Books of Architecture* to Leon Batista Alberti's fifteenth century *On the Art of Building*, foul air was thus considered as a natural condition to be avoided by proper city planning or careful selection of building sites away from marshes. The escalating urbanization of Western Europe after the Renaissance expanded the definition of foul air beyond an organic miasma to include "fuliginous vapour" and "horrid Smoake" when contaminants and fumes from fossil fuel combustion and toxic manufacturing processes created severe air pollution (Evelyn 1661). Exposure to the highly odiferous foul air was attributed as the cause of a number of epidemic and chronic diseases, including cholera, yellow fever, influenza, typhoid, consumption, and the plague, leading to the conscientious sealing of sick rooms and bedrooms to prevent the entry of outdoor air. In 1866, long after cholera had been determined to be transmitted by a form of waterborne contagion, public health officials in Savannah, Georgia, recommended that windows be bricked over to prevent the outside air from spreading the cholera epidemic (Chambers 1938). For respiratory diseases, night air was considered to be particularly pernicious, and the belief that exposure to night air caused tuberculosis persisted into this century (Ott 1996).

Within buildings, however, the air quality fared as poorly. Open fires were the predominant means for cooking, but the inability to effectively remove smoke tempered their use for heating. Fires were built in an open hearth in the center of buildings, away from combustible walls, and smoke exited through cracks, porous roofs, eaves and, eventually, louvers. Indeed, even today in many developing countries, open fires without flues are still used for cooking, often burning dung and other poor-quality fuels. Chimneys did not regularly begin to appear until the twelfth century, although these early chimneys did little to alleviate the interior smoke problem. The prevailing theories of combustion were based on the alchemical theory of phlogiston, in which fire was considered to be an elemental property. Bodies that contained phlogiston burned, whereas dephlogisticated bodies did not. Air was presumed to contribute to dephlogistication leading to the assumption that smoky, and thus poorly burning, fireplaces were due to the admission of too much air, particularly from down draught. Numerous modifications were made to the chimney flue, including the addition of bends and internal obstructions, many of which contributed to instead of alleviating the smokiness (McDonald 1984). The increasing reliance on poor-quality fuels also exacerbated the smoke problem, as all but the wealthiest were burning coal, dung, sawdust, and/or peat—fuels that produce large quantities of particulates. The deforestation of western Europe due to urbanization had severely depleted hardwood supplies—causing Elizabeth I to proclaim in 1558 that no oak, beech, or ash more than one foot square at the stub could be used for purposes other than building—and resulted in the further diminishment of increasingly expensive supplies of the dirtier-burning softwoods for fuel (Wright 1964). Charcoal became the preferred fuel of the wealthy; its smokelessness made it particularly appropriate for burning in braziers placed in closed rooms without any ventilation,

causing the deaths of many people in their sleep, including presumably that of Philip III of Spain, from carbon monoxide poisoning. Significant improvements in fireplace design did not occur until the end of the eighteenth century, when Benjamin Franklin's Pennsylvania Fireplace became the first closed stove to effectively heat an unsealed room, and after Benjamin Thompson (Count Rumford) introduced the smoke shelf to the open fireplace. These two inventions produced fireplaces that could reasonably heat without contaminating indoor air with smoke. Their impact was short-lived, however, as the late eighteenth century also ushered in new concerns about the organic contamination of indoor air that overshadowed the problem of smoke.

Carbonic Acid and Human Contamination

Developments in chemistry during the seventeenth and eighteenth centuries brought about the first substantial change in the theoretical understanding of air since Empedocles had designated air as one of the four primordial elements in the fifth century B.C. Beginning with Robert Boyle's atomist theory published in 1661 in *The Sceptical Chymist*, which led to the modern definition of an element, air was eventually understood as a chemical mixture rather than as a single element. Building on the research carried out by Henry Cavendish, Karl-Wilhelm Scheele, and particularly Antoine-Laurent Lavoisier, Joseph Priestly isolated oxygen in air in 1774. Priestly made the discovery while he was studying respiration; he had theorized that animal respiration was the means through which putrid emanations were expelled from the body (Bensuade-Vincent and Stengers 1996). He shared a common belief with many of his European colleagues that respired air was corrupted. The nature of the corruption and its potential harmful effects on human health would form the central debate in the ventilation of buildings until the early twentieth century.

With urbanization, the concern about contamination from putrefaction had shifted its focus from odors emanating from marshes and wetlands—the products of natural terrestrial processes—to the stench emitted by cesspools, refuse dumps, and overcrowded buildings—the results of dense human occupation. Paris was described as “an enclosed universe, breeding and trapping its own horrific odors” (Reid 1991). Close confinement and the rebreathing of expired air were presumed to be the generating causes of fever, an assumption seemingly supported by the greater disease rates in the lower classes whose housing density was much higher than that of the rich (Pickstone 1992). Lavoisier, who had been appointed to inspect French prisons, increasingly focused his research on determining the physiochemistry of air in public spaces. In 1787, he concluded that the air in crowded, confined spaces had an “abnormally strong carbonic gas content” (Corbin 1986). Carbonic acid gas (saturated carbon dioxide), as a product of respiration, emerged as a quantifiable and therefore potentially avoidable constituent of miasmatic contamination. By the beginning of the nineteenth century, other researchers were suggesting that asphyxiation by oxygen depletion was a greater concern than the buildup of carbonic acid. Regardless of which theory was propounded, however, the conclusion was the same: human respiration “vitiates” the air. Both factions also agreed that carbonic acid was a good marker for all putrid human emanations (Reid 1844). Lewis Leeds of Philadelphia summed up the nineteenth century's version of a human-generated miasma during a lecture given at the Franklin Institute in 1867: “It is not in the external atmosphere that we must look for the greatest impurities, but it is in our own houses that the blighting, withering curse of foul air is to be found.... We are thus led to the conclusion that *our own breath is our greatest enemy*” (Leeds 1869). Ventilation with outside air of any quality, even from a highly polluted urban environment, was seen as the only solution to preventing dullness, dementia, and perhaps death from human contaminated interior air.

The Development of Convection-Driven Ventilation

The burgeoning interest in ventilation took place just after theoretical advancements in the understanding of thermal behavior had overturned the material theory of heat, and coincided with the development of thermodynamics. Although “ventilators,” or fans, had been used to ventilate mines since the sixteenth century, the need for a prime mover, such as animal power, water, or steam, precluded their application in buildings. The emergence of thermodynamics led to new speculation and experimentation regarding the exploitation of the motive power of convection. The observation that heated air tended to rise encouraged numerous modifications to public buildings to take advantage of the natural ventilation induced by heat sources, particularly from fires, combustion-based lighting, and human bodies. The Houses of Parliament served as the initial and most prolific test ground for experiments in ventilation, beginning with Christopher Wren’s 1660 opening of holes in the ceiling to relieve the heat generated from candles, and continuing for over 2 centuries. Each successive ventilation expert, from John Desgauliers to Sir Humphrey Davy, added their often ill-fated modifications of shafts, towers, ducts, chambers, passageways, and perforations in their attempts to continually replace the air “vitiated” by the members of Parliament, although the available fresh air for ventilation passed over the malodorous Thames which was little more than a sewer during the nineteenth century (Elliott 1992). David Boswell Reid’s elaborate illustrations of convectively driven air movement were convincing enough to Parliament that they allowed him to renovate the House of Commons for nearly 20 years, leading Benjamin Disraeli to suggest in 1851 that “hanging... would put a stop to such blunders in the future” (Elliott 1992).

In the United States, Congress convened a committee devoted to ventilation of the Capitol building that, although criticizing the waste of the 200,000 pounds of sterling spent on Parliament in unsuccessful attempts to improve the ventilation, still solicited several proposals in 1871 from engineers (U.S. Congress 1871). Henry Gouge, one of the proposers, additionally came before the committee to demonstrate his apparatus, “Gouge’s Atmospheric Ventilator,” which depended on a primary current of air in a duct to induce air movement from the surroundings. A kerosene lamp or gas jet installed *inside* the duct was advertised as being sufficient to establish the convective current (Gouge 1881). Congress chose not to adopt Gouge’s system, but the use of a dedicated heat source inside of a duct gave rise to a host of “aspirating” ventilation designs. John Shaw Billings, Deputy Surgeon General of the U.S. Army, used aspirating ducts for ventilation in several of the systems he designed for public and institutional buildings, including Johns Hopkins Hospital, from the mid-1870s through the 1880s (Billings 1889). Unlike many of his predecessors, however, Billings was using steam for building heat. Rather than placing a combustion source directly in the aspirating shaft, he inserted steam coils and eventually proposed using the same shaft for both heating and ventilating—a single steam supply would perform both functions. By integrating the steam for the heating coils with the steam needed for aspiration, Billings was able to heat the delivery air instead of using the coils only to radiantly heat the room air, thus eliminating the redundancy of the separate heating and ventilating systems. This integration of heating and ventilation within the same distribution system established a precedent that was supported by two coincident developments. The first was the proliferation of district steam service in major U.S. cities, bringing steam supplies to urban buildings and facilitating the gradual phase-out of direct combustion systems for heating. The second was the development of small steam engines that could operate on low-pressure steam and therefore were ideally mated with the district steam service. Although fans were available throughout the nineteenth century, the engines necessary to drive them required steam systems more appropriate in industrial uses than in buildings. The smaller steam engine could be easily deployed in buildings, and resulted in the supplanting of convectively driven ventilation systems by mechanically driven fans during the

1890s. To encourage the expansion of the market to smaller users, the B. F. Sturtevant Company, one of the largest manufacturers of fans and steam engines, adopted Billings' approach and marketed a combination engine, fan, and heater packaged in a single unit. They advertised their "blower system" as providing free ventilation: the exhaust steam from driving the fan's engine served as the supply steam for the heating coils (Sturtevant 1896). This precedent became so well established that the integrated system was maintained even after steam engines were replaced by electrical drives at the beginning of the twentieth century.

Ventilation Laws and Health

Beginning with Thomas Tredgold's recommendation in 1824 that 4 cubic feet per minute (cfm) of "unvitiated" air per person should be the required ventilation rate, numerous experts in Britain and the United States proposed standards even though there were few working systems capable of providing a controlled amount of ventilation (Janssen 1994). The advent of mechanical ventilation brought a new interest in establishing standards and laws throughout the United States at the beginning of the twentieth century. Oddly, the development of the germ theory of disease during the 1870s had little impact on the debate about standards. The fear of carbonic acid generation and oxygen depletion in public spaces had been replaced by a more generalized concern about "crowd poison" during the latter half of the nineteenth century. This shift to crowd poison echoed the growing awareness about the socioeconomic conditions of immigrants and correlated with the shift of tuberculosis incidence away from the general populace to the lower classes (Tomes 1998). Even when the medical profession had accepted that infectious diseases were transmitted through physical contact or borne through water, food, or insects, there was still a pervasive belief that air was a carrier. In 1873, Frederick A. P. Barnard, president of Columbia University, lectured that *how* disease was carried—whether by germs or by the air—was unimportant, as the hygienic actions that should be taken were the same: disinfection, proper drainage, wholesome food, and fresh air (Barnard 1873). Billings, in his multiple roles as deputy surgeon general, chair of hygiene at the University of Pennsylvania, and director of the New York Public Library system, wielded the largest influence. Completely sidestepping the debate on germ theory, he wrote in 1893 that he had compiled statistics, comparing the death rates of men, horses, and monkeys in well-ventilated versus unventilated barracks, ships, prisons, and stables, proving that numerous diseases, including tuberculosis, were caused or exacerbated by insufficient ventilation (Billings 1893). He recommended that a minimum ventilation rate of 30 cfm per person be adopted. Engineers and manufacturers embraced this recommendation, as only mechanical systems were capable of providing buildings with such a high rate of ventilation (Cooper 1998). By 1915, twenty-one states had passed laws or ordinances requiring ventilation in public schools and/or factories, most using Billings' recommended rate as their standard, and four of those states, including New York, required ventilation in all classes of buildings (Ventilation Laws 1917).

As ventilation standards were being mandated across the country at the beginning of the twentieth century, a grass-roots effort to help tubercular children was nearly successful in dismantling the laws and eliminating mechanical ventilation systems from schools. Although the bacterial agent responsible for tuberculosis had been isolated by the German physician Robert Koch in 1882, the prevailing public sentiment maintained the association of the disease with damp, overcrowded dwellings and with urban pollution (Porter 1999). Fresh air was the preferred treatment for tubercular patients, and they would ideally be relocated to an "alpine-like" sanitarium for prolonged rest in a cool, dry mountainous environment. In 1904, however, the 600 existing sanitariums and tuberculosis hospitals were able to accommodate less than 5 percent of those suffering from the disease (Ott 1996). A cure

at a mountain retreat was also unreasonable for the urban poor and immigrants, the fastest growing segments of the population contracting the disease. Home cure was the only choice, and tuberculosis activists such as Adolphus Knopf exhorted the inner city patient to at least move outside tenement rooms and sleep on the balcony or the roof even in the winter (Knopf 1909). Tubercular children were sent to day camps, and in 1909, an open-air summer school was established in Chicago by the Board of Education and the Chicago Tuberculosis Institute (Cooper 1998). By that fall, a year round open-air school was built to serve sick children, and many other cities, including Providence, Detroit, and Cleveland, followed suit with open-air unheated, unventilated schools for tubercular children. Proponents of the open-air schools claimed that the children enrolled in open-air schools had better attendance, better scholastic performance, and lower drop-out rates than did children attending mechanically ventilated and heated schools, and suggested that open-air schools would be a good prophylactic measure for healthy children as well (Kingsley 1913). Throughout the major northern cities of the United States, windows began to be opened year round in many classrooms and mechanical systems were shut down in violation of state and city laws.

In 1913, Mrs. Elizabeth Milbank Anderson, a New York philanthropist, agreed to fund a study to resolve the question as to whether mechanical ventilation or open windows provided the best conditions for teachers and students. An investigatory commission was established—the New York State Commission on Ventilation—with Charles-Edward Amory Winslow as its chair, and included a biologist, a physiologist, a chemist, a psychologist, and a ventilating engineer (Cooper 1998). For 4 years, the Commission performed experiments in specially designed test facilities and also collected data in 134 classrooms in 20 different schools, evaluating the performance of nearly 5500 children (Milbank 1923). They concluded that temperature in the classroom was the most important variable to control, and that ventilation was necessary only insofar as it contributed to removing odors, a function that they determined was performed as well by opening the windows as by mechanical ventilation. For reasons not clear, the Commission's report was not published until 1923. During the 6-year gap between the conclusion of the study and its publication, ventilating engineers had the opportunity to develop countering data: in 1919, the American Society of Heating and Ventilating Engineers (ASH&VE) established a research laboratory in Pittsburgh (Cooper 1998). One of the primary products of the laboratory was a comfort chart that quantified the environmental determinants of comfort. In 1922, the Department of Ventilation and Illumination in the Harvard School of Public Health built a psychrometric chamber to further refine the standards for human comfort (Cooper 1998). The increasing precision with which engineers were able to define the ideal environment may have contributed to the lukewarm response that the Commission's report received when it was finally issued in 1923. More likely, however, was the unfortunate timing of the 1918–1919 influenza epidemic in which more deaths occurred than in World War I. The rapidity of its spread and its high rate of mortality resurrected old fears of miasmatic contamination. Indeed, undertakers were said to have sung the following ditty as they buried victims from the epidemic (Crosby 1997):

I had a little bird
And its name was Enza.
I opened the window
And influenza.

Winslow tried to rally support for the Commission's findings among 15,000 school superintendents, gathering them together in Washington, D.C., to denounce mechanical ventilation, but public sentiment had begun to sway toward the engineers' view that "there

was nothing fresh or natural about the fouled air of modern cities” (Cooper 1998). A concern with hygiene was sweeping the country, much of it stigmatizing immigrant and non-white urban dwellers, and the ability to conform to “antiseptic standards of cleanliness differentiated the rich from poor, American born from foreign born” (Tomes 1998). Mechanical ventilation systems, and particularly the integrated heating and ventilation blower systems, were easily incorporated with air washing systems, resulting in the development of the air handler. Engineers and manufacturers were quick to capitalize on the public’s concern with cleanliness, and pointed out that the air handler could produce “manufactured weather” that was cleaner and purer than what nature provided (Carrier 1919). In spite of the continued work of open-air enthusiasts such as Winslow and Dr. Leonard Hill during the next several decades to challenge mechanical systems, most of the early ventilation laws remained in place and the air-handler-based system became the standard for conditioning interior environments.

2.2 THE CONTEMPORARY APPROACH TO VENTILATION

During the first half of the twentieth century, building design and construction underwent a radical transformation in the developed countries because of the widespread influence of Modernism. The permeable masonry buildings of the nineteenth century were steadily replaced with impermeable curtain wall buildings constructed of unprecedented materials—glass, steel, plastics, as well as with lighter-weight masonry and concrete panels. The availability of mechanical systems and electric lighting allowed the deepening of the floor plate, which reduced the floor area ratio of perimeter space to core space and increased the portion of fully interior zones. Internal heat gains escalated dramatically—lighting standards in the United States had increased 200-fold from 1906 to 1972—and many buildings required cooling even in winter to relieve those gains. Nevertheless, mechanical ventilation underwent only negligible changes. Cooling coils had been regularly integrated into the air handler since the 1920s, and schemes for air distribution and secondary systems had become quite elaborate, particularly for high-rise buildings, but the conceptual operation of a mechanical system integrating ventilation with temperature control remained unchanged from its origins in the 1890s. Periodically, questions would arise as to whether the old ventilation codes required that the specified ventilation rate—typically 30 cfm per person—was necessarily to be supplied with outside air or by recirculated air. Constantine Yaglou, at Harvard University’s School of Public Health, conducted experiments during the 1930s to quantify the relationship between odor and ventilation with outside versus recirculated air. He concluded that if the recirculated air was treated through the air handler, then it could replace half of the outside air with no noticeable impact on odors (Janssen 1994). The issue waned, however, as the increasing lighting loads in buildings were more efficaciously removed through exhaust air, and thus the old ventilation standards went relatively unchallenged.

The Energy Crisis and New Ventilation Standards

The Arab Oil Embargo of 1973–1974, and the resulting energy supply shortages, dramatically changed the attitude toward environmental control as, suddenly, building energy usage had a significant monetary impact on every American. Turning back the thermostat was the seemingly most logical approach, but not necessarily the simplest. The larger the

building, and the more sophisticated the distribution system, the more likely that reheat systems or dual duct systems would be used. In these systems, cooling and heating were taking place simultaneously, and resetting the temperature would have little effect on the total energy consumed. As a result, the early energy conservation approaches tended to focus instead on strategies that simply turned off equipment and systems: peak demand scheduling, duty cycling, economizer operation, night shutdown, and occupancy determined start-up. The most strategic target, however, was ventilation: Introducing outside air brings the dual penalty of requiring energy to condition it to the level of the inside air as well as requiring additional fan energy for its distribution.

After absorbing ASH&VE (at the time: ASHAE—American Society of Heating and Air Conditioning Engineers) in 1958, ASHRAE concentrated on improving the calculation procedures for sizing equipment. In 1973, in a desire to give HVAC system designers more latitude in specifying equipment, ASHRAE proposed the first major modification to ventilation codes in nearly a century, and published *Standard 62-73 for Natural and Mechanical Ventilation* just before the energy crisis (Janssen 1994). This standard established minimum allowable rates and recommended ranges of rates for 271 different functional types, lowering the baseline minimum ventilation rate to 5 cfm per person, with 10 cfm per student as the minimum acceptable in schools and 15 cfm per occupant as the minimum in offices. The standard clarified that these rates were to be 100 percent outside air. The minimum rates could be calculated either for people—cfm per person—or for the building—cfm per square foot of floor area. The onset of the energy crisis a few months later spurred ASHRAE to write a standard on *Energy Conservation in New Building Design*, 90-75, specifying 5 cfm per person as the required ventilation rate across the board for new buildings. Concerns about tobacco smoke and formaldehyde in 1981 prompted a revision to the 1973 standard on ventilation, resulting in a two-tiered standard, 62-1981, *Ventilation for Control of Indoor Air Quality*, that reduced the general ventilation rate to 5 cfm per person in nonsmoking environments while raising it to 25 cfm in smoking environments. The low rate was deemed to be sufficient for diluting the human-generated contaminants: less than 1 cfm per person is needed to replace respired oxygen, 2.5 cfm is needed to dilute CO₂ to a concentration below 5000 ppm, leaving the remainder supposedly to dissipate odors, moisture, and heat (Spengler and Samet 1991). This standard allowed the use of air cleaning devices on recirculated air to control 34 specific contaminants and furthermore established a performance-based procedure in which ventilation rates could be determined from the concentrations of these contaminants (Stanke 1999). Research carried out by Ole Fanger and others, suggesting that at least 15 cfm per person was needed to dilute occupant odors, and increased knowledge about non-human-generated contaminants led ASHRAE to revise the standard yet again in 1989 (Janssen 1994). Standard 62-1989, *Ventilation for Acceptable Indoor Air Quality*, raised the baseline minimum rate to 15 cfm, and removed the differentiation due to smoking. The 1981 smoking ventilation rate had been based on an assumed prevalence of smokers and frequency of smoking, leading to confusion among many designers as to how to develop specifications from weighted averages. The 1989 standard did maintain the procedure that compliance could be achieved either by prescription—the adoption of the specified minimum rates—or by performance, but was made more complicated as the listed levels of specific indoor air contaminants had been eliminated (Stanke 1999). The complexity and ambiguity of the calculations prevented widespread acceptance of the standard, with the result that only one building code, the Southern Building Code, adopted the guidelines.

Figure 2.1 shows highlights of ventilation rate recommendations between 1800 and 2000.

Currently under review, Standard 62-1999 is written in language to facilitate building-code adoption and clarifies the methods for calculations (Stanke 1999). Most important, the standard distinguishes between human-generated contaminants and nonhuman sources.

FIGURE 2.1 History of recommended ventilation rates.

Rather than specifying either a minimum ventilation rate per person or for the building, both must be accommodated, with generally 6 to 7 cfm per person required as the minimum *plus* 0.06 to 0.14 cfm per square foot of building space, depending on the functional type (Stanke 1999). Interestingly, in the 1930s, Yaglou had concluded that the ventilation rate per person should be dependent on the size of the occupied space (Janssen 1994). The resulting calculations raise the total ventilation rate for some uses, such as retail spaces, and lower it for other uses, such as offices and schools. There are additionally several other standards being spun off to directly address residential uses, high-rise versus low-rise buildings, and health care facilities. Fundamentally, ASHRAE's struggle to develop ventilation standards over the past 20 years has been a product of the inherent conflict between the need to reduce energy, which minimizes ventilation, and the need to maintain acceptable indoor air quality, which tends to maximize ventilation.

Control Strategies and Energy Management Systems

In order to accommodate the reduction in outside air that the changing ventilation standards were mandating, a significant change in operating strategy needed to take place. Before the energy crisis, the predominant distribution strategy was termed *constant air volume* (CAV). In principle, CAV systems are designed to maintain ideal and continuous environmental conditions throughout the building by utilizing the thermal inertia of large volumes of air. A constant flow of air circulates through the spaces of the building, and the temperature of each zone is typically adjusted by reheat systems, requiring, in the most basic system, that all of the air be cooled to meet the requirements of the zone with the highest heat load. The high inertia of the overall air distribution system is able to moderate most transient loads,

with secondary systems compensating for extreme variations, particularly at the building perimeter. The resulting stability of the environmental conditions comes at a high price: systems operate continuously, regardless of the presence of occupants, and the temperature control scheme often causes the same air stream to be first cooled and then reheated. The much publicized wastefulness of this approach in federal buildings during the mid-1970s was particularly embarrassing to the U.S. government, whose energy conservation mandates were radically impacting the daily lives of individuals. A switch to variable air volume (VAV) systems seemed to be the logical and intelligent solution. In these systems, the temperature of the air stream is kept relatively constant, but the amount of airflow is varied, with room or zone thermostats determining how much is to be delivered. Essentially a demand scheme, variable air volume operation provides more air to zones with high thermal loads, and less air to low-load zones.

VAV systems, used since the 1960s for buildings with extreme differences in zonal loads, became the almost overnight solution to reducing energy use in buildings after the onset of the energy crisis. Most new buildings were installed with VAV instead of CAV systems, and many older buildings retrofitted their existing control systems for VAV operation (Sun 1991). One major problem of the basic operating strategy is that temperature readings in a zone do not differentiate between thermal loads generated by bodies or those produced by nonhuman sources such as lighting. Many of the VAV systems implemented in the 1970s and early '80s often cut off airflow to occupied zones if the net thermal loads were lower than in other zones. Later modifications ensured that a minimum airflow would be maintained, but the switch to VAV systems, coupled with the wide range of shutdown strategies that were also being implemented, clearly required additional sophistication in the design of control schemes. The prevailing VAV systems, with their already complex thermal interrelationships, were being expected to minimize energy usage, maximize air quality, meet growing individualized comfort requirements, and respond to highly variable loads. Computer analysis and control were deemed the solution for managing these contradictory demands.

In 1973, the Energy Research and Development Administration (ERDA), the forerunner to the Department of Energy, along with the U.S. Post Office and the Department of Defense, began funding the development of computerized energy calculation procedures, eventually releasing three programs into the public domain: BLAST in 1976, Cal-ERDA in 1977, and DOE-1 in 1978 (Ayes and Stamper 1995). These codes, along with many others developed by equipment manufacturers and consultants, could perform analyses and simulations where weather data and interior loading approximated transient conditions for more accurate sizing of equipment than the traditional peak loads analysis. As these programs continued to be developed and expanded, particularly in regard to the prediction of transient conditions, they began to be employed beyond their original scope of facilitating the energy-conscious selection between alternative HVAC systems. Energy analysis codes found additional applicability as architectural design advisors, particularly in regard to the building envelope design, and also enabled the testing of peak demand scheduling and conservation strategies. During the 1980s and '90s, versions of DOE-2 became progressively more sophisticated in the design of their simulation modules, leading to the ability to perform hourly simulations. These types of analysis codes, which had originally been conceived to optimize the design of HVAC systems, were increasingly considered for real-time analysis of building operation.

In the pre-energy crisis era, whole-building transfer functions that could be manually calculated were often sufficient for sizing HVAC equipment, and simple feedback analog controllers were more than adequate for system operation. The post-energy crisis VAV systems were not only inherently more unstable, but the requirement to continuously optimize energy usage while simultaneously meeting indoor air quality standards and maintaining occupant comfort demanded computerized decision-making ability. Energy management

systems (EMS) emerged from the simple time clock controllers that were originally used to implement the shutdown strategies and grew into sophisticated, intelligent systems that may monitor several thousand points and control numerous integrated functions. The energy analysis software was proposed as the “brain” for this system, continually calculating the thermal loads in a building and adjusting the setpoints for optimization, but the complexity of the algorithmic structure that was needed to both analyze and control an integrated transient system precluded widespread acceptance and adoption of the whole-building EMS. Instead direct digital control (DDC) has repackaged the EMS concept into discrete, distributed systems that independently control segments of the building operation, leaving the centralized EMS to monitor and detect faults. Interoperable systems with open protocols are the latest advance in digital controls, allowing designers and owners to specifically tailor HVAC control equipment to the particular needs and configuration of each building. The expanded distribution and more localized controls afforded by the development of DDC systems allowed further refinement to the operating strategy of VAV systems. Twenty-five years after the onset of the energy crisis, ventilation and energy use have found a tenuous compromise in the computer-controlled variable air volume system.

2.3 FUTURE DIRECTIONS IN VENTILATION

The almost overnight switch to variable air volume systems was clearly effective: Electrical consumption, of which buildings account for two-thirds of the total, increased only 7 percent in the 20-year period following the energy crisis, before substantial inroads had been made regarding digital controls (Penney and Althof 1992). The improvement in energy efficiency of building HVAC systems, however, has been paralleled by a substantial increase in occupant complaints, with a BOMA study revealing that more than half of the tenants in the United States are uncomfortable (Penney and Althof 1992). Furthermore, the incidence of specific and nonspecific illnesses related to building occupancy have brought a number of financial penalties, ranging from lower worker productivity to lawsuits (Cutter 1996). Although the reasons for the increase in complaints and illness are diverse and multimodal, including some, such as changing demographics, that are unrelated to building and HVAC system design, the most readily identifiable *solution* continues to be ventilation. If, during the past 20 years, the focus has been on determining the appropriate quantity of ventilation, then activity in the future will be devoted to improving the quality, or the efficacy, of ventilation.

Computational Fluid Dynamics and Demand-Controlled Ventilation

The existing energy analysis codes treat ventilation as conservative mass transfer. This approach is more than adequate for determining the energy use of a system, but is inadequate for determining air conditions at a point in the system. As such, although it is relatively easy to calculate how much ventilation air must be provided to a space to dilute contaminants generated at known rates, only empirical methods have been able to show how uniform or effective the dilution is *within* the space. New developments in the simulation of air behavior may soon give system designers an accurate tool for predicting and refining air movement.

Heat transfer and fluid mechanics were the last branches of classical physics to produce theoretical structures that could account for generally observable phenomena. The building blocks began with the codification by James Joule of the first law of thermodynamics in the 1840s, and were not complete until Ludwig Prandtl introduced the concept of the boundary

layer in 1904. The assembly of these blocks into an applicable theory was hampered by the insolubility of the governing equations. It was not until the 1950s that iterative methods were employed, leading to the eventual development of computational fluid dynamics (CFD). The use of CFD to predict convective heat transfer and fluid flow has revolutionized many fields, including aeronautics, nuclear power, and environmental engineering, and has significantly impacted the design of products such as turbomachinery, automobiles, and microelectronics. CFD is relatively new to the field of building air behavior, which has yet to be substantially influenced by this powerful analytical tool. Unlike most other problems in fluid dynamics, building air behavior is a true mixing pot of phenomena: wide-ranging velocities; temperature/density stratifications; conductive, convective, and radiant transfer; laminar and turbulent flows; buoyant plumes; and randomly moving (and randomly heat generating) objects. This mix of behaviors has prevented any substantial empirical data collection on building air movement, with the result that validation standards are not yet available. Nevertheless, the use of CFD for building simulation is rapidly spreading, particularly for the design of high-performance buildings and atria, and the development of standards for the use of CFD for simulating smoke and fire spread will spur its proliferation throughout the HVAC industry.

CFD simulation offers building and HVAC system designers an unprecedented window into the transient behavior of air inside of a building. At any given point, and at any given time, pressure, velocity, temperature, density, and concentration (humidity as well as chemical) can be determined. Trends can be tracked to determine patterns of distribution, and lagrangian models can be applied to follow a single particle on its journey through the ventilation system. With CFD simulation, designers can optimize the location of ventilation inlets and outlets, isolate problematic heat sources and contaminant sources, and test the impact of renovations on air distribution. Furthermore, the coupling of simulation with new developments in microtechnology, particularly sensors, may lead to the dynamic control of ventilation, in which ventilation is continuously and directly controlled to meet specific air quality criteria in real time.

Demand controlled ventilation (DCV) has long been proposed as a strategy for fine-tuning ventilation to further reduce energy consumption while maintaining good indoor air quality. In DCV, ventilation is adjusted in response to a measurable parameter that is indicative of the overall air quality at a given time. As occupancy is one of the most critical factors determining the necessary ventilation rate, then indicators of occupancy become the control variables for maintaining air quality, and related human bioeffluents, at an acceptable level. The indicator actually measured may range from the on/off position of a light switch to the concentration of carbon dioxide. Although conceptually sound, there are two major concerns with this approach: (1) the lack of predictive tools for properly locating sensors and (2) the inability of carbon dioxide to be a surrogate for nonhuman sources (Emmerich and Persily 1997). CFD simulation will eventually assist designers in determining the optimal locations for sensors, and the rapidly developing low-cost sensor technologies will allow the deployment of sensor systems capable of detecting and/or measuring multiple analytes.

The Impact of Developing Microtechnologies

Microtechnology has already revolutionized computing, communications, and electronic systems because of the unique electrical properties of silicon, but it is silicon's other properties that are spawning an even more dramatic revolution in mechanical equipment. Three times as strong as steel, but with a density less than half that of aluminum, silicon also has the near ideal combination of high thermal conductivity with low thermal expansion, making it a highly versatile mechanical material (Bryzek et al. 1994). Microelectromechanical

systems (MEMS), which combine electrical and mechanical performance in tiny chips, are one of the fastest-growing technologies of the decade. Sensors and actuators were among the first devices to demonstrate the potential of silicon-based micromachines, and the rapid proliferation of MEMS accelerometers into every new car sold in the United States demonstrates how readily these products can be commercialized and mass-produced. MEMS sensors, which are capable of 16-bit accuracy, offer high selectivity and low cost, enabling the direct measurement and control of many parameters that could previously only be estimated or determined from often exhaustive and time-consuming analyses: tracer gas studies, controlled sampling, and spectrometric/chromatographic characterization of individual contaminants. Inexpensive sensors that are highly sensitive to even single molecules will allow the real-time determination of the indoor air quality at any given location in an interior environment, and could be easily incorporated into the digital control schemes for the HVAC equipment. MEMS sensors will soon bring unprecedented accuracy and control to building systems.

Longer-term, but with potentially even greater impact than sensors, are MEMS energy systems. In 1995, the Department of Energy concluded that the development of MEMS for distributed energy conversion in buildings was its highest priority in microtechnology research, displacing sensors as the primary focus (PNL 1995). Microscopically sized gears, pumps, valves, compressors, evaporators, and steam engines have been demonstrated, and close to commercialization is a micro gas turbine weighing less than 1 gram (Ashley 1997). Already commercially available, and widely used for the cooling of electronics assemblies, are microchannels, micro and mini heat pipes, and thermoelectric (Peltier effect) coolers. For larger-scale applications, such as buildings, the same approaches and manufacturing methods that led to the miniaturization of MEMS systems are now being applied to the development of *mesomachines*. Mesomachines are mechanical devices that have a primary dimension at the scale of 1 centimeter, as compared to MEMS at 100 micrometers or less and conventional mechanical equipment at 1 meter. Mesomachines are more efficient than conventional machines, and an array of smaller machines operating in parallel can more reliably and economically replace a larger machine, while adding the bonus benefit of turn-down capability for load shedding (Warren et al. 1999). The real potential, however, may come from the ability to easily distribute these small machines throughout a building. Just as DDC has distributed control systems through a building, and DCV will distribute sensing throughout a building, then MEMS and mesomachines will enable the distribution of the energy conversion equipment throughout the building. The ability to locally act on a local condition will bring a new level of indoor air quality control, and may allow the reduction or elimination of some of the most energy-intensive equipment in a building: the air distribution system.

Alternative Strategies for Ventilation

Most of the current research and development has primarily been focused on the reduction of indoor air quality problems, with the secondary intention of further minimizing energy use. The basic operational concept of HVAC systems has not been challenged, even insofar as the control strategies and equipment have undergone enormous revisions during the last 25 years. Indeed, the HVAC system of today is still based on two premises from the nineteenth century. The first is the presumed necessity to integrate ventilation with other processes—heating, cooling, humidification—intended for the balancing of thermal loads. The second is the dependence on dilution to remove contaminants from occupied spaces. Both of these premises arose from the circumstances of their era: integration facilitated the use of the same steam supply, and dilution was the most appropriate strategy when society believed that bioeffluents were poisonous. Neither of these premises is valid

today. Among the most interesting research taking place in the field of ventilation and indoor air quality is the development of alternative strategies for ventilation that challenge these two premises.

The concept of dynamic insulation, or pore ventilation, proposes decoupling some of the ventilation from the HVAC system. A curious paradox emerged after the energy crisis when outside air infiltration through the building envelope was being reduced to control energy usage, and, simultaneously, the rate of outside air ventilation was being increased to improve indoor air quality. Replacing the sealed building envelope, permeable walls would allow cool air to flow from the exterior to the interior through a series of baffles, chambers or filters. The flow circuit and pressure differential across the wall are controlled to ensure that the infiltrating air picks up the heat that would normally be conducted outside (Taylor et al. 1999). This strategy potentially offers numerous advantages over conventional ventilation. The quantity of outside air that must be distributed through the HVAC system would be reduced, allowing the reduction of duct diameter and fan size and reducing the energy required for distribution, as well as minimizing contamination of the outside air in the ducts. The recovery of heat conduction through the envelope allows a size reduction in conversion equipment and reduces the energy exchanged with the air supply. One benefit currently being researched is that the permeable wall can double as an air filter for naturally ventilated buildings, making possible the replacement of mechanical systems in polluted urban areas (Taylor et al. 1999). Clearly, there is much work to be done on determining the characteristics of the interstitial contamination in the permeable wall and the health effects, but the concept demonstrates the energy-saving potential that may be reaped if ventilation can be decoupled from the thermal processes.

Displacement ventilation, or low sidewall delivery, is a low-inertia system that displaces contaminants instead of diluting them, therefore using less air, but more effectively. The concept is not new; the same Lewis Leeds who warned of deadly human breath also described the virtues of displacement ventilation in 1871: "The fresh air may enter cooler, and will naturally flow under the fouler air that has been longer in the room, and will rise toward the ceiling in unison with that warmer and fouler current that is always rising around and above the body" (Leeds 1871). By taking advantage of the body's convective plume, displacement ventilation ensures that the freshest, essentially the newest, air in a room reaches the breathing zone, resulting in the most efficacious removal of human-generated contaminants. Exposure to other contaminants may be reduced because the breathing air has a shorter residence time, but it also may be increased if the contaminants are generated upstream of the breathing zone, such as emissions from floor coverings and furniture. One of the difficulties preventing widespread adoption of displacement ventilation has been its inability to maintain thermal comfort; because it uses buoyancy to move air, thermal gradients along the human body are likely to be produced. In some applications, radiant panels have been tested to improve thermal comfort, harking back to Lewis Leeds' admonishment that displacement ventilation should serve only the purpose of removing contaminants, while some other means should provide heat.

At the start of the twenty-first century, building ventilation is poised to undergo its first major reconceptualization since its nineteenth-century origins. Whether based on the growing use of low-tech alternatives such as displacement ventilation and dynamic insulation, or due to the rapidly high-tech solutions emerging from microtechnology and computerized simulation, ventilation of the future will progressively be decoupled from thermal loads and made more responsive to local conditions. With separate systems providing for the requisite thermal environment for the human body, buildings may again be able to be permeable to the outside, allowing the free entry of fresh air, but also eliminating many of the most problematic synthetic building materials currently being used for insulation and sealing. The "smart" building will be able to discretely target and remove specific contaminants with selective ventilation before widespread contamination can take place. Ventilation,

which over a century ago was proposed as a generic solution to “crowd poison,” may, in the future, become a specific resource for improving the quality of human life.

3.1 INTRODUCTION

Occupational health professionals have made great strides in understanding the epidemiology of disease as it relates to contaminants and physical stressors found in industrial indoor environments. However, there is still limited knowledge regarding the causes of symptoms observed in nonindustrial indoor settings such as office buildings, recreational facilities, schools, and residences. Many countries have attempted to reduce industrial health hazards by adopting standards, such as the Occupational Safety and Health Administration's (OSHA's) Permissible Exposure Limits, or guidelines, such as the American Conference of Governmental Industrial Hygienists' Threshold Limits (ACGIH 1999a). However, only few such standards or guidelines apply to nonindustrial indoor settings. For example, the American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE) has established guidelines for ventilation rates (ASHRAE 1999) and thermal comfort (ASHRAE 1992) for a variety of indoor settings. OSHA has attempted to promulgate a standard that would apply to nonindustrial settings in the United States; however, to date it has been unsuccessful.

Faced with limited guidance, an indoor environmental quality (IEQ¹) investigator finds it difficult to evaluate symptom reports, air contaminants, physical stressors, and psychosocial issues. This presents a significant challenge because it is often impossible to describe what is “normal” in order to define that a problem exists. Normative data from buildings without known problems would provide useful baseline information for IEQ investigators and building managers. This chapter addresses the complexities of obtaining normative data by reviewing some of the larger IEQ studies conducted in Europe and the United States. We have summarized the findings of the studies, hoping to provide the reader with an overview of sick building syndrome (SBS), the inherent difficulties in defining such a syndrome, and its potential risk factors. For ease of presentation across the studies, the table formats have been standardized.

Health Outcomes

Development of standards that apply to the nonindustrial environment may be long in coming for many reasons. Epidemiologic evidence of an association between specific health effects and risk factors is needed to support such standards. Unfortunately, most of what we know about illnesses and symptoms related to nonindustrial indoor environments comes by way of case studies of complaint buildings. Only recently has the IEQ literature included more sophisticated epidemiologic studies such as randomized trials. Why don't we have a clear handle on SBS yet?

To begin with, health effects related to nonindustrial indoor environments are often measured subjectively and are difficult to quantify clinically. Although SBS is a commonly used term, it is defined differently across the literature and among scientists. Moreover, there is argument as to what chemical, physical, and psychosocial conditions are relevant to the health of individuals in indoor environments and how these conditions might interact. Contaminant concentrations in the nonindustrial indoor environment can be small and often require sophisticated and expensive monitoring methods. An individual's sensitivity may play a much greater role when the individual is exposed to low concentrations than to high concentrations. And, although we know psychosocial aspects significantly affect symptom reporting, current methods of quantifying psychosocial characteristics are limited. In short, symptoms related to nonindustrial indoor environments represent a complex issue. Because there are so many unknown factors regarding health effects and exposures, the results of even the most comprehensive studies can be questioned. Given these complexities, is this syndrome worthy of epidemiologic study and the effort to develop standards? Perhaps the best way to answer this is from an economic perspective.

As the United States moves toward a predominantly service economy—an estimated 75 percent in 1990 of private sector jobs are in services compared to 55 percent in the 1970s (Aronoff and Kaplan 1995), IEQ complaints from office buildings have increased. The literature contains strong evidence that symptoms occurring in the workplace significantly reduce productivity and tax health care systems. In a recent article (Fisk and Rosenfeld 1997), the authors estimate annual costs and productivity losses in the United States at \$1 to \$4 billion related to allergies and asthma, \$6 to \$19 billion related to respiratory disease, and \$10 to \$20 billion related to SBS symptoms. Fisk provides an update to this research in Chap. 4 of this handbook, “Estimates of Potential Nationwide Productivity and Health Benefits from Better Indoor Environments: An Update.” Although the estimates are crude, they indicate the impact of poor IEQ on the workplace and the importance of resolving

¹Throughout this chapter, we use the term IEQ rather than the more popular term *indoor air quality* to emphasize that the causes of SBS may not be limited to air quality.

factors contributing to these symptoms and illnesses. Money spent on improving the working environment may be cost-effective not only by improving health but also by significantly affecting productivity.

A logical starting point would be a clear definition of the health consequences of poor indoor environmental quality. In the absence of that, researchers have distinguished building-related illnesses from the more complex sick building syndrome.

Building-Related Illnesses Traditionally, SBS has been distinguished from well-defined building-related illnesses (BRI) that are caused by exposures to biological, physical, or chemical agents in indoor environments. Unlike SBS, BRI can be specifically diagnosed (ACGIH 1999b). BRI can be classified into three groups: airborne infectious diseases, hypersensitivity diseases, and toxic reactions (Kreiss 1996). Some building-related infectious diseases are transmitted through indoor air; for example, Pontiac fever, Legionnaires' disease, histoplasmosis, tuberculosis, measles, rubella, chicken pox, influenza, and the common cold caused by adenoviruses and some rhinoviruses. With the exception of Pontiac fever and Legionnaires' disease, which are spread from environmental sources, the risk of transmitting these diseases increases as office occupant densities increase. Members of the National Occupational Research Agenda have identified the relationship of occupant density to pathogen transmission as an important area in need of research.

Hypersensitivity diseases are illnesses resulting from an abnormal or maladaptive response of the immune system to a substance recognized as foreign to the body. In order to develop hypersensitivity disease, a person must be exposed to an antigen on at least two appropriately spaced occasions or in a sustained fashion (Cookingham and Solomon 1995). Such illnesses include allergic asthma, allergic rhinitis, and hypersensitivity pneumonitis, all of which have been associated with exposure to fungi and other bioaerosols. Certain skin disorders, such as dermatitis and hives, have also been associated with specific indoor exposures, including allergens (Redlich et al. 1997). Toxic reactions are perhaps the best-understood category of BRI because of extensive research in industrial environments. Toxic reactions involve exposures to contaminants, such as carbon monoxide and pesticides, that may lead to acute disruptions of a variety of organ functions and/or increased risk of chronic diseases, such as cancer.

In general, BRI differs from SBS in that BRI symptoms do not necessarily resolve when afflicted individuals leave the building. Moreover, an individual can be diagnosed with BRI without knowing the health status of other building occupants. This is currently not the case for SBS diagnosis.

Sick Building Syndrome Most researchers agree that sick building syndrome describes a constellation of symptoms that have no clear etiology and are attributable to exposure to a particular building environment. As information has amassed on this nonspecific complex, researchers (Levin 1989, Raw 1994) have attempted to clarify the use of differing definitions or ambiguous terms (e.g., "building sickness," "building-related occupant complaint syndrome," "nonspecific building-related illness," "office eye syndrome," "sick office syndrome," and "tight building syndrome"). Although objective measures are being developed, as described in Chap. 26, "Methods for Assessing Irritation Effects in IAQ Field and Laboratory Studies," diagnosis of SBS relies primarily on self-reporting.

In the early 1980s, the World Health Organization (WHO) compiled the common symptoms reported in what was defined as SBS (WHO 1982, 1984). These symptoms included: eye, nose, and throat irritation; sensation of dry mucous membranes; dry, itching, and red skin; headaches and mental fatigue; high frequency of airway infections and cough; hoarseness and wheezing; nausea and dizziness; and unspecific hypersensitivity. WHO suggested that the diagnosis of SBS would require a demonstration of an "elevated" complaint or symptom prevalence associated with a particular building;

however, they did not provide a standardized method for diagnosing SBS. The Commission of European Communities and the American Thoracic Society also attempted to define SBS. Common to each of the definitions are symptoms of the central nervous system (headaches, lethargy, and fatigue) and mucosal membranes (eye, nose, and throat irritation). Although both European panels identify skin symptoms as part of the SBS complex, the American panel does not. Further, the WHO panel lists odor and taste sensations, while the other two do not (Godish 1995).

Given the ambiguity of SBS diagnosis, what normative data can we turn to? Before we answer that question, let us review the risk factors potentially related to SBS.

Sick Building Syndrome Risk Factors

Although many observational and experimental studies have provided contradictory findings over the last 30 years, these studies have added much to our understanding of SBS. In 1993, Mendell reviewed the findings of 32 studies conducted between 1984 and 1992 that considered 37 factors potentially related to office worker symptoms. He prepared a summary of reported relationships between symptom prevalence and environmental measurements, building factors, workplace factors, and job or personal factors. A condensed version is given in Table 3.1.

Association with symptom prevalence was defined as statistically significant if an exposure variable was associated with at least one symptom related to: the eye, nose, throat, or skin; breathing or lower respiratory function; fatigue or tiredness; or headache. There were “consistent” findings of association with increased prevalence of symptoms with air conditioning, job stress/dissatisfaction, and allergies/asthma, and “mostly consistent” associations with low ventilation rate, carpets, occupant density, video display terminal (VDT) use, and female gender. Figure 3.1 provides an overview of studies investigating ventilation, showing that low ventilation rates [below 10 liters/second/person (L/s/person)] are significantly associated with more symptoms than higher ventilation rates. This contrasts with Menzies’s findings that increases in the supply of outdoor air do not appear to affect workers’ perceptions of their office environment or their reporting of SBS symptoms (Menzies et al. 1993).

These studies consistently showed no association with altered symptom prevalence for total fungi, viable bacteria, particles, air velocity, carbon monoxide, formaldehyde, and noise. For the other listed environmental measures, the findings of the various studies were inconsistent. However, possible indicators for these environmental measures (e.g., low ventilation rate, air conditioning, and carpeting) were shown to be associated with higher prevalence of symptoms. Ventilation is clearly important.

A 1996 review supports Mendell’s meta-analysis, while questioning the effectiveness of ventilation rates above 10 L/s/person to reduce SBS symptom prevalences (Godish and Spengler 1996). A recent review of 20 studies with approximately 30,000 subjects showed that ventilation rates above 10 L/s/person, up to approximately 20 L/s/person were associated with decreasing prevalence of SBS symptoms. About half of the carbon dioxide studies in this review indicated that the risk of SBS symptoms decreased with decreasing carbon dioxide concentrations below 800 ppm (Seppanen et al. 1999).

SBS is a complex and multifactorial problem. A combination of microbiologic, chemical, physical, and psychological mechanisms most likely explains the increased prevalence of symptom reports, although there is much to learn about SBS etiology. In subsequent sections, we review studies that both provide normative data and offer evidence for the possible exposures that elicit SBS symptoms. Although not comprehensive, this review summarizes a selection of relevant studies.

TABLE 3.1 Summary of Reported Associations between Work-Related Symptoms and Various Environmental Factors and Measurements from Studies Conducted between 1984 and 1992

Environmental measures	
Low ventilation rate	+
Carbon monoxide	○
Total VOCs	?
Formaldehyde	○
Total particles	○
Respirable particles	?
Floor dust	?
Total viable bacteria	○
Total viable fungi	○
Endotoxins	?
Beta-1,3-glucan	?
Low negative ions	?
High temperature	?
Low humidity	?
Air velocity	○
Light intensity	?
Noise	○
Building factors	
Air conditioning	++
Humidification	?
Mechanical ventilation, no AC	?
Newer building	?
Poor ventilation maintenance	?
Workspace factors	
Ionization	?
Improved office cleaning	?
Carpets	+
Fleecy materials/open shelves	?
Photocopier in room or near	?
Environmental tobacco smoke	?
More workers on the space	+
Job and personal factors	
Clerical job	?
Carbonless copy use	?
Photocopier use	?
VDT use	+
Job stress/dissatisfaction	++
Female gender	+
Smoker	?
Allergies/asthma	++

Legend: ++ = Consistent higher symptom reports; + = Mostly consistent higher symptom reports; ○ = Consistent lack of association with symptom reports; ? = Inconsistent findings.

FIGURE 3.1 Comparison of symptoms reported at various ventilation rates. [From Mendell (1993).]

3.2 EUROPEAN STUDIES

In the early 1980s, the Europeans pioneered field studies that have provided researchers with preliminary data on SBS. In the United Kingdom and throughout the European continent, survey instruments were refined and used to collect the first normative data on SBS symptoms. Efforts expanded in the 1990s to include extensive environmental and ventilation measurements in hopes of explaining this phenomenon.

British Office Environment Survey and Other U.K. Studies

In 1986, the British Office Environment Survey (BOES) was undertaken, covering buildings in England, Scotland, and Wales. The purpose of the study was to estimate the extent of the SBS problem in the United Kingdom and to identify SBS risk factors. A standardized protocol was developed to evaluate 4373 office workers in 42 buildings that had not been used in any prior study of SBS. Surveys collected information on symptoms as well as job, workplace, comfort, and personal factors. While environmental measures were not taken, the building ventilation systems were characterized (e.g., air change rates, percentage of fresh air, type of filtering, type of humidification, and position of supply and return air grills).

To summarize the general rate of symptom reports for each building, a building sickness index (BSI) was created. The BSI is defined as the average number of work-related symptoms (out of a possible 10 symptoms) in the last 12 months. The survey response rate was 92 percent, and the most common work-related symptom was lethargy (57 percent), closely followed by blocked nose (47 percent), dry throat (46 percent), and headache (46 percent). The least common symptoms were chest tightness and difficulty breathing (9 percent). Results indicated that symptom reports were common for all buildings and were

higher among women and employees in clerical job functions. For building factors, there was variation in BSI between buildings within each ventilation category. Symptoms increased when buildings had air conditioning or humidification. The researchers suggested that microbiological contamination of system components with allergic or endotoxin-related mechanisms might have been responsible (Burge et al. 1987).

Design characteristics of the buildings were associated with differences in symptom frequencies. The highest level of symptom reporting occurred in buildings with local induction unit ventilation, followed by buildings with central induction/fan coil units. The lowest rate of symptom reporting corresponded to buildings with natural ventilation. Prior work by Finnegan and his colleagues (Finnegan et al. 1984) supports this finding. Their study of nine buildings showed a repeated pattern of irritation and general symptoms reported in buildings with air conditioning as compared to those with natural ventilation. This was examined further in a study evaluating similarly ventilated pairs of buildings, one with a high prevalence of symptoms and one with a low prevalence of symptoms. A strong correlation between standards of maintenance and the prevalence of work-related symptoms was reported. The risk factors identified included the standard of maintenance, the standard of record keeping, and availability of good manuals describing the building's mechanical system (Burge et al. 1990a).

Burge and his colleagues conducted a study to determine the validity of using the self-administered BOES questionnaire to measure SBS symptoms. They found that the prevalence of work-related symptoms identified by medical opinion (28.6 percent) was approximately equivalent to that identified by self-administered questionnaires (33 percent) (Burge et al. 1990b). Later, they showed that a reduced list of five symptoms provided an equivalent BSI rank ordering of buildings. A BSI based on five symptoms is termed BSI₅. The symptoms used to measure BSI₅ are eye dryness, stuffy nose, dry throat, lethargy, and headache (Burge et al. 1993). Further modifications to the BOES questionnaire have improved its reliability and ease of administration. The Revised Office Environment Survey (ROES) questionnaire is described in greater detail in Chap. 53, "Assessing Occupant Reaction to Indoor Air Quality."

More recently, British researchers have extensively evaluated factors other than those related to building characteristics and indoor climate. Results from the White Hall study (Marmot et al. 1997) provide sound evidence that psychosocial variables have a significant influence on occupant reporting of symptoms. People who felt dissatisfied with their jobs or were physically or emotionally exhausted reported more symptoms than did others.

Danish Town Hall Study

The Danish Town Hall Study (Skov and Valbjorn 1987) was another large-scale project undertaken to examine the prevalence of SBS symptoms, providing more extensive environmental measures than the BOES Study. The Danish Town Hall Study evaluated a large and uniform population of individuals with approximately equivalent socioeconomic status and type of work but who were exposed to different indoor environmental conditions. In this study, over 4300 employees in 14 Danish town halls and associated buildings were surveyed and clinically evaluated.

The survey obtained information on employees' work: hours per week on the job, work function, number of occupants per office, past and current diseases, presence and timing of various symptoms, work-related complaints, and personal information, such as age, gender, exercise habits, smoking habits, and housing conditions.

The buildings varied in age from 1 to 80 years (mean 18 years) and were located in urban, residential, and rural settings. Six buildings had natural ventilation and eight had mechanical ventilation. Numerous indoor climate parameters were measured, such as

temperature, humidity, drafts, static electricity, noise, and lighting. A variety of indoor contaminants were also measured, such as airborne fungi, bacteria, particles, fibers, formaldehyde, and volatile organic compounds (VOCs).

The questionnaire response rate was 80 percent. Results showed a prevalence of work-related mucosal irritation (28 percent) and general symptoms, such as headache and fatigue (36 percent) (see Table 3.2), which varied greatly among buildings. Women had a higher prevalence of symptoms and complaints related to the quality of the indoor environment than did men. The study also showed that symptom reports were correlated with clerical level job function, high worker density, and the use of photocopiers, carbonless paper, and VDTs.

No single indoor environmental factor or contaminant was found to be correlated with any increased symptom prevalence. A summary of the environmental measurements is given in Table 3.3.

Although mucosal irritation and general symptom prevalence were higher in mechanically ventilated buildings, no statistically significant difference could be demonstrated between naturally and mechanically ventilated buildings (Skov and Valbjorn 1987; Skov et al. 1990). In 1989, Skov and his colleagues conducted a follow-up to the 1987 study to further examine possible associations between symptom prevalence and psychosocial factors (Skov et al. 1989). Strong correlations were found between symptom reports among office workers and factors such as dissatisfaction with superiors, fast work pace, high quantity of work, and feeling of having little influence on the organization of daily work.

Subsequent studies were conducted to further examine differences in symptom prevalences between buildings. The results of these efforts showed an association between symptom reports and a “fleece factor,”² a “shelf factor,”³ floor dust, and carpeting (Skov et

TABLE 3.2 Prevalence of Work-Related Symptoms in 14 Danish Town Halls

Symptom description	Women	Men
Fatigue	30.8	20.9
Headache	22.9	13.0
Nasal irritation	20.0	12.0
Throat irritation	17.9	10.9
Eye irritation	15.1	8.0
Malaise	9.2	4.9
Blocked runny nose	8.3	4.7
Dry skin	7.5	3.6
Irritability	6.3	5.4

al. 1990). Gyntelberg and his colleagues carried this further by examining the contents of the dust (Gyntelberg et al. 1994). Their concentrations are given in Table 3.4. They found correlations between symptom reports and specific dust components, such as Gram-negative bacteria, particle content, and microfungi. The investigators also tested the ability of varying concentrations of dust to stimulate histamine liberation in human blood-derived cell specimens. Results showed histamine liberation to be correlated with some general symptoms but not mucous membrane symptoms.

Other studies support the connection between bioaerosol exposure and SBS symptoms (Cooley et al. 1998, Rylander 1998, Rylander et al. 1992, Teeuw et al. 1994). This subject

is discussed in greater detail in Chap. 42, “Endotoxins,” Chap. 43, “Allergens Derived from Arthropods and Domestic Animals,” Chap. 45, “The Fungi,” and Chap. 46, “Toxigenic Fungi in the Indoor Environment.”

Office Illness Project and Other Swedish Studies

The Swedish Office Illness Project surveyed 5986 individuals over 210 buildings (Sundell 1994). The study compared buildings in which occupants exhibited either a high or low prevalence of SBS symptom reports. Consistent with other Swedish investigations, the study found personal and work factor risk indicators for SBS symptoms, including higher reports of general symptoms of women (35 percent) compared to men (21 percent). As

Table 3.5 depicts, history of allergy, VDT work, high level of paperwork, and low evaluation of psychosocial conditions at work were associated with elevated symptom prevalence. With respect to environmental and building factors, the risk indicators were buildings constructed or renovated after 1977 and buildings characterized as built either on concrete slab or with some combination of low-rise/light construction/horizontal roof. Outdoor air rates less than 13.6 L/s per person, the presence of copy machines, humidifiers, and fluorescent tube lighting with metal shields, and a low frequency of floor cleaning were also risk indicators for increased symptom reports. Increased symptoms were associated with perception of dry air, but not with physical air humidity. The measurements of airborne formaldehyde (11 to 59 $\mu\text{g}/\text{m}^3$) and total volatile organic compounds (TVOCs) (3 to 740 $\mu\text{g}/\text{m}^3$) were related to low outdoor air rates. Higher formaldehyde and lower TVOC concentrations were consistent risk indicators for SBS or individual SBS symptoms. This seeming disparity might be explained by VOCs reacting with other contaminants, such as ozone, to form even more irritant by-products, such as formaldehyde. This theory is often referred to as the “missing VOCs” theory.

In yet another Swedish study in the early 1990s, Norback (Norback and Edling 1991, Norback et al. 1993, Norback et al. 1990) studied the relationships between SBS symptoms and environmental exposures, both at work and at home. One thousand Swedes between ages 20 and 65 were surveyed on workplace symptoms and personal factors, such as smoking, allergies, education level, stress, and work satisfaction. Historical environmental exposures were also assessed, such as whether parents were smokers, subjects lived near possible industrial pollution sources, and child care was outside of the home. Building factors were evaluated, including age and size, presence of carpeting, recent renovation, moisture or dampness, and signs of mold growth.

Results of this large-scale survey showed that eye, airway, dermal, and general symptoms were commonly reported in the workplace. Minor seasonal variations were noticed. The historical information collected showed SBS symptoms, hay fever, and nickel allergy associated with childhood exposure to environmental tobacco smoke (ETS). Individuals who had spent their childhood near mining industry areas were found to have an increased frequency of hay fever, allergy to furry animals, and eye symptoms.

New dwellings and damp or moldy environments were significantly related to SBS symptom prevalence. Individuals in new buildings had an increase in reported dermal symptoms, and those in damp or moldy dwellings had an increase in reported eye, airway, dermal, and general symptoms. No correlation was found in this study among air humidity, type of building ventilation, presence of carpeting, ETS, or presence of pets in the home.

TABLE 3.5 Prevalence of Symptoms Reported Every Week during the Last 3 Months within 210 Office Buildings in Northern Sweden

Symptom	Women, mean %	Men, mean %
More than one general, mucous membrane, or skin symptom	56.2	36.1
General symptoms (fatigue, heavy headed, headache, nausea, or dizziness)	35.1	20.7
Skin symptoms (dry, flushed, itching, or scaling skin)	32.8	16.1
Mucous membrane symptoms (irritation of eyes, nose, or throat)	26.7	17.3

Source: Data from Sundell 1994.

Swedish investigators have also provided a useful way to summarize risk indicators and symptoms from their well-established “MM questionnaires.” The MM questionnaires were designed to be simple and short (no more than two pages). Various versions have been validated for the workplace, homes, schools, and day-care centers. The results of these surveys provide useful baseline data for a variety of environments and communities (Andersson 1998). Their method for summarizing the results of these surveys is shown in Fig. 3.2. For example, in Fig. 3.2 (left), frequent complaints about stuffy and dry air and a high prevalence of general symptoms indicate potential ventilation problems. In Fig. 3.2 (right), an increased prevalence of mucous membrane irritations and complaints about unpleasant odors suggest there may be a problem with emissions.

Displaying environmental and subjective data together in this manner allows an investigator to evaluate more information than a summary index, such as the BSI. Chapter 53, “Assessing Occupant Reaction to Indoor Air Quality,” compares the ROES and the MM questionnaires in greater detail.

The European Audit Study

Perhaps the most ambitious IEQ field study in Europe was conducted in the winter of 1994. Sponsored by the Commission of European Communities’ Joule II Programme, the European Audit Study investigated 56 buildings in nine countries: Denmark, Finland, France, Germany, Greece, the Netherlands, Norway, Switzerland, and the United Kingdom

FIGURE 3.2 Perceived indoor climate and symptoms in buildings with ventilation problems (left) and emission problems (right). The shadowed area signifies reference values for buildings without any indoor climate problems. [From Andersson (1998).]

(Groes 1995, Levin 1996). The study was the first to attempt a standardized protocol across such a large and varied population.

On the basis of the study results, Groes presented a multidimensional model to describe the potential relationships among building factors, environmental measures, personal factors, psychosocial conditions, and symptom responses (Fig. 3.3). As indicated by the gray boxes, the study did not include reliable measures of the psychosocial conditions or occupants' psychosocial perceptions.

Questionnaires were provided to at least 100 occupants in each building; response rates varied between 54 percent and 97 percent. As shown in Table 3.6, the most common work-related symptoms over the past month for all the buildings were lethargy or tiredness (28 percent), blocked or stuffy nose (22 percent), dry eyes (21 percent), dry or irritated throat (20 percent), and dry skin (20 percent). In addition, investigators took a "snapshot" of the air quality over the course of one day using air sampling instruments and a group of investigators, called "sensory panels," who were trained to perceive the air quality when they first enter office spaces.

The "mean sensory pollution load," as measured by the trained sensory panels in olf/m^2 ,⁴ did not differ among buildings in the nine countries. Although the sensory panels' measures of sensory pollution load were highly correlated with the percentage of occupants smoking in the buildings, the panels' measures did not correlate with the perceptions of the occupants. This could be because the sensory panels based their measurements on initial impressions of the environments, while occupants may have become habituated to their environments over longer periods of time.

Occupants' adverse perceptions of their environment were highly correlated to symptoms; dryness and stuffiness were especially correlated to mucosal and general symptoms. Adverse perceptions and symptoms were more associated with personal factors (e.g., gender and nationality) than to building factors and indoor environmental factors. Women, employees performing clerical work, employees working many hours at a video display unit, and those in offices with a high density of people reported more adverse perceptions and symptoms compared to others. Perceptions and symptoms differed significantly according to nationality.

FIGURE 3.3 Lisbet Groes's proposed model of symptom response. [From Groes (1995).]

⁴One olf is the sensory pollution load caused by a standard person, i.e., a typical sedentary adult living in the developed world.

TABLE 3.6 Percent of Work-Related Symptoms over the Last Month within 56 European Buildings

Symptom prevalence was highest in buildings with humidifiers, cooling systems, and recirculated air. Occupants of buildings supplied with a high degree of outdoor air assessed their air quality as significantly better than those with a low outdoor air supply. Roughly 30 percent of the occupants were dissatisfied with the air quality even though the average outdoor air supply was 23 ± 5 L/s/person. The authors found no association between energy consumption and either measures of IEQ or outdoor airflow rates. They concluded that a potential exists for optimizing IEQ without consuming more energy (Bluyssen et al. 1996).

Many of the environmental measures were not found to be associated with symptoms, perhaps because of the low concentrations found in these buildings (e.g., dust was less than 0.1 mg/m^3 in most of the buildings). Unlike the Danish Town Hall Study, the shelf and fleece factors could not explain the differences in symptom prevalence among buildings. Occupants, however, reported higher symptom prevalence in buildings with lower TVOC concentrations, as evidenced by Sundell (1994). Occupants in buildings near busy roads and with loud background noise reported more adverse perceptions and symptoms than did others. And, although occupants in buildings with a low relative humidity did not show a higher prevalence of mucosal irritation, they had a higher prevalence of skin symptoms (Groes 1995).

German ProKlima Study

The Project Klima und Arbeit (ProKlima) Study, one of the more recent European efforts, was initiated in Germany in 1994 by the German Ministry of Education, Science, Research and Technology and is still ongoing. The study is a cross-sectional investigation of 16 German office buildings (10 predominantly air-conditioned and 6 naturally ventilated) with intervention studies conducted in a subset of buildings. Moreover, its design improved upon preceding European IEQ studies by including extensive clinical validation of reported symptoms. Clinical measurements included: ophthalmologic tests (break-up time, foam formation, lipid layer of tear film, epithelial desiccation, and Schirmer's test); dermatological tests (skin moisture and sebum); and allergenic tests [lung function, oximetry, rhinomanometry, and immunoglobulin E (IgE) antibody].

Between 1995 and 1998, a cross-sectional investigation of 14 buildings was conducted, and interventions were initiated in two of them. Preliminary results were recently published (Bischof et al. 1999, Brasche et al. 1999, Witthauer et al. 1999). The investigation occurred in two phases for each building. In the first phase, the investigators characterized the ventilation systems and administered questionnaires to a sample of approximately 120 occupants in each building; this typically took 1 day. Then, over the course of 5 business days, the investigators took extensive environmental measurements. The authors highlighted the dynamic range of measurements among buildings, as shown in Table 3.7.

As in other studies, the initial results showed a higher prevalence of nose, throat, and nervous system symptoms among individuals working in air-conditioned rooms. Risks

TABLE 3.7 Results of Indoor Measurements in Sampling Spaces within 14 German Office Buildings

Variable	Units	Mean	Single building median (lowest value)	Single building median (highest value)
TVOC	$\mu\text{g}/\text{m}^3$	379.6	74.0	707.5

were higher in each symptom category (especially skin symptoms) for women, individuals with acute illnesses (especially nose and throat symptoms), and individuals with low job satisfaction. The investigators showed that respondents working at computers with poor software also reported more symptoms. There was also a slight trend of increased symptoms (especially eye and throat symptoms) in nonwinter conditions. Low education was associated only with nervous system symptoms, and age (less than 30 years) was associated only with mouth symptoms (Brasche et al. 1999).

Environmental measurements were also tested for association with symptoms, after adjusting for ventilation type and personal characteristics. The levels of VOC concentrations were associated with symptoms of the eyes, skin, nose, and nervous system. Mouth-related symptom reports were linked to exposure to endotoxins and low operative temperature, and eye complaints were related to nitrogen dioxide levels. Ozone and sulfur dioxide concentrations were lower indoors than outdoors and were not thought to play a part in the building's IEQ. Finally, two apparent anomalies were identified, an inverse relationship between symptoms and CO₂ and an inverse relationship between symptoms and mold exposure. The authors could not explain these apparent discrepancies. As this study is further analyzed, undoubtedly its results will contribute significantly to the IEQ literature.

3.3 UNITED STATES STUDIES

The California Healthy Buildings Study

The California Healthy Buildings Study was the first extensive IEQ investigation in the United States of buildings not selected on the basis of complaints. Like the European studies, it examined the multifactorial relationships between workers' health symptoms and building, workspace, job, and personal factors. A variety of indoor environmental parameters were also measured. The study included 12 buildings with 880 occupants (Fisk et al. 1993a, 1993b). Survey results showed that for the entire sample, symptoms of eye, nose, and throat irritation were most frequent (40 percent); however, the symptoms varied greatly among buildings. Further, occupants in mechanically ventilated and air-conditioned office buildings had significantly more symptoms than occupants of naturally ventilated buildings did. Increased symptom reports were associated with job and workspace factors, such as presence of carpet, use of photocopiers and carbonless paper, space sharing, and distance from windows. The environmental parameters measured also varied greatly between locations in the same building and as a function of the ventilation system, as shown in Table 3.8. Total viable fungi was lower in the air-conditioned spaces, most likely because the filtered air supply and sealed windows reduced the entry of outdoor fungi. TVOC was higher in some locations because of the use of wet process copiers but did not cause an increase in VOC-related irritancy when first analyzed. Carbon monoxide levels were low and carbon dioxide levels were generally found to be within ASHRAE guidelines. Humidity ranged from 32 percent to 58 percent and was not thought to have had a major impact on thermal comfort.

The investigators offered several possible explanations for the symptom associations. It has been speculated that the reason for increased symptoms related to the presence of carpeting may be the release of VOCs. However, in the buildings examined in this study, the carpeting had been in place for over 1 year. The authors thought the VOC levels would have decreased rapidly after installation and been insignificant after the first few months. It is possible that the carpeting could have been a reservoir for microbiological materials, dust, or fibers, and that episodic resuspension of the materials from foot traffic resulted in

TABLE 3.8 Space-Average Environmental Parameters as a Function of Ventilation Type within 12 California Buildings

Source: Data from Fisk et al. 1993.

inhalation or direct contact exposures. Carbonless paper has also been linked to increased symptom reports in other studies, perhaps related to inhalation or physical contact exposure to the organic chemicals in the inks or paper coatings. The authors proposed that the association between symptoms and mechanical ventilation, and between symptoms and air-conditioning, could result from ventilation systems harboring contaminants, such as microbiological organisms, VOCs, or fibers. Alternatively, the type of ventilation system may be a surrogate for building age, interior finishing materials, and/or furnishings, which may affect symptom frequency.

The California Healthy Buildings Study has been a source of several reanalyses. Joanne TenBrinke and others (1998) reexamined these data to test potential associations between VOCs and SBS symptoms. The authors created a merged VOC and symptom database (containing 517 individuals located in 12 buildings with 22 VOC samples) and developed seven exposure metrics to test methods of combining VOC concentrations. The authors drew on a comprehensive literature review to develop a relative irritancy scale, referenced to toluene, for the 22 VOCs. They also tested associations among the measured VOCs: four VOC groups, statistically known as principle components, were identified and hypothesized to represent VOC sources within the buildings. After adjustment for demographic and other environmental characteristics, a combination of irritancy and principle components provided the strongest correlations with symptoms (Ten Brinke et al. 1998).

The results of these analyses showed for the first time a link between low-level VOC exposures from specific indoor sources and SBS symptoms. The authors were honored at the 1999 Indoor Air Conference for their study's unique methodology. The small number of samples and the sparse diversity of VOC analytes limited the study, however, and analyses of larger datasets are currently under way to test the proposed VOC metrics (Apte and Daisey 1999).

Library of Congress Study

In the winter of 1989, a study was conducted of 6771 employees of the Environmental Protection Agency (EPA) and the Library of Congress, occupying four buildings in the Washington, D.C., area (Wallace et al. 1991). All buildings in the study were mechanically ventilated. A questionnaire was administered to collect information on symptoms, workplace odors, air quality comfort, workplace environment, psychosocial factors, and personal characteristics. Table 3.9 shows the prevalence of 32 symptoms among participants during the week before completing the questionnaire. The most common symptoms reported were headaches, stuffy nose, and sleepiness for both genders. Other common symptoms overall were fatigue, dry/itchy eyes, sore eyes, runny nose, and sneezing. Approximately two-thirds of these symptoms were classified as job-related (i.e., they improved on leaving work).

Source: Data from Wallace et al. 1995.

Principal components analysis reduced the 32 original symptoms to 12 health factors (Wallace et al. 1993a) : (1) headache, nausea; (2) stuffy nose/sinus congestion, runny nose, sneezing, cough, (3) wheezing, shortness of breath, chest tightness; (4) dry, itching, tearing eyes, sore eyes, burning eyes, blurry vision, (5) sore throat, hoarseness, dry throat; (6) sleepiness, unusual fatigue; (7) chills, fever; (8) aching muscles, lower back pain, upper back pain, shoulder/neck pain, hand/wrist pain; (9) difficulty concentrating, difficulty remembering, tension, depression; (10) dizziness; (11) dry itchy skin; and (12) problems with contact lenses. This was the first U.S. attempt to test associations among SBS symptoms using a substantial number of respondents. Variables with the strongest associations with these health factors are given in Table 3.10.

The variables found to be most closely associated with the health factors included comfort characteristics (dry air/dusty office and hot, stuffy air), odor factors (paint/chemical and fabric odor), and individual susceptibility factors (dust/mold allergies and sensitivity to chemicals). Glare was the workplace variable most commonly associated with eye irritation and shoulder/neck pain. Among the psychological variables, job pressure and career frustration were strongly associated with depression, tension, and difficulty concentrating. The identified health factors supported grouping symptoms by single body systems and helped to reduce the number of SBS symptom questions in future studies (Wallace et al. 1991, 1993a, 1993b, 1995). The authors suggested treating each gender separately to reduce the high collinearity between gender and other personal and job-related variables.

TABLE 3.10 Variables Associated with at Least Four of the 12 Health Factors Evaluated within the Environmental Protection Agency and Library of Congress Buildings

Workplace characteristics	
Dust	Headache; nasal, chest, eye, throat symptoms; fatigue; chills; difficulty concentrating; dizziness; dry skin; contact lens problems
Glare	Headache; eye symptoms; fatigue; difficulty concentrating; pain
Personal characteristics	
Chemical sensitivity	Headache; nasal, chest, eye, throat symptoms; fatigue; pain; difficulty concentrating; pain
Mold allergies	Headache; nasal, eye, throat symptoms; fatigue; pain; dry skin
No college	Headache; chest symptoms; fatigue; chills and fever; dizziness
Measures of stress	
Workload	Headache; eye symptoms; pain; difficulty concentrating; dizziness
Conflicting demands	Nasal, chest symptoms; chills and fever; pain; difficulty concentrating; dizziness
Comfort and odor characteristics	
Hot stuffy air	Headache; nasal, eye, chest symptoms; fatigue; difficulty concentrating; dizziness
Dry air	Nasal, eye, throat symptoms; dry skin
Odor of paint, chemicals	Headache; nasal, chest, throat symptoms; fatigue; chills; difficulty concentrating; dizziness
Odor of cosmetics	Eye symptoms; chills; pain; difficulty concentrating

National Institute for Occupational Safety and Health Studies

Throughout the 1980s, the National Institute for Occupational Safety and Health (NIOSH) responded to thousands of requests to investigate “problem” or “complaint” buildings (Fine et al. 1990). In 1993, in response to a national news program that discussed health effects associated with nonindustrial indoor environments, NIOSH received approximately 500 requests for IEQ health hazard evaluations. A subset of these buildings was selected, and between April and July 1993, NIOSH investigated 160 offices, schools, and other nonindustrial work settings (Crandall and Sieber 1996). Each investigation included a description of building characteristics and a self-administered questionnaire for occupants. A total of 2435 questionnaires from 80 office buildings were analyzed (Malkin et al. 1996), and associations with building and personal characteristics were tested (Sieber et al. 1996). The authors’ analysis focused on symptoms that occurred over the last month and that improved when the occupants were away from work. Symptom prevalence for both genders is shown in Table 3.11.

Three symptom scores were also calculated for each respondent: multiple lower respiratory,⁵ multiple atopic,⁶ and diagnosed asthma.⁷ Female gender, age over 40, and conflict at work were associated with increases in each symptom group, and the managerial job category was associated with less diagnosed asthma.

In total, 67 environmental and demographic variables were tested in models corrected for age, gender, and smoking status. The investigators found that although multiple lower respiratory symptoms were positively associated with outdoor intakes located close to

⁵At least three of the following were required: shortness of breath, cough, chest tightness, or wheezing.
⁶All of the following were required: sneezing, nasal congestion, and eye irritation.
⁷Asthma was diagnosed after the beginning of work in the building.

pollutant sources,⁸ neither multiple atopic symptoms nor diagnosed asthma was strongly associated with these exposures. Evaluation of the HVAC maintenance programs showed similar results: multiple lower respiratory symptoms were positively associated with nearly all measures of uncleanliness.⁹ Analysis of building maintenance¹⁰ showed a decrease in multiple lower respiratory symptoms, but in some cases, an increase in multiple atopic symptoms and diagnosed asthma. This may be because cleaning can both reduce pollutants and resuspend them. Fabric coverings were evaluated; however, the results were not entirely consistent with those shown in the Danish Town Hall Study. Although diagnosed asthma was more prevalent in the presence of cloth partitions, lower respiratory symptoms were less prevalent in the presence of fabric wall coverings (Sieber et al. 1996).

This study provided the first comprehensive normative IEQ data for the United States. However, because the buildings were selected on the basis of complaints from at least three employees, one manager, or one union representative, these data most likely do not represent normal IEQ conditions. Hoping to measure IEQ in more representative building samples, EPA launched a similar study in buildings randomly selected throughout the United States.

Building Assessment Survey Evaluation Study

Concurrent with NIOSH's IEQ investigations, EPA sponsored a series of workshops at which more than 40 IEQ experts developed a standardized sampling protocol to measure IEQ in noncomplaint office buildings (Womble et al. 1993). EPA created the Building Assessment Survey Evaluation (BASE) Study to collect data on 100 representative U.S. buildings between 1994 and 1998. It is the largest and most comprehensive IEQ field study ever undertaken in U.S. office buildings and provides valuable IEQ baseline information. The BASE Study included private and public office buildings, randomly selected from cities with populations greater than 100,000 in ten climatic regions throughout the continental United States (Womble et al. 1995). Climatic regions were defined by ASHRAE winter and summer design dew points and temperatures, as listed in Table 3.12 and depicted in Figure 3.4.

Buildings were selected according to certain criteria, such as having more than 50 employees and being serviced by no more than two air-handling units. Buildings that had been highly publicized as "complaint" or "problem" buildings (i.e., occupants or management had requested that their buildings be investigated before EPA's contact) were excluded. Evaluation areas within the BASE buildings were randomly selected from a list of acceptable areas provided by the building owner or manager. This differed from spaces selected for the NIOSH study, which were defined at the discretion of the NIOSH investigators and primarily based on reported complaints. Extensive data were collected over a 1-week period in each of the BASE buildings, as described in Table 3.13.

What makes this study uniquely valuable for those interested in normative IEQ values is that the data are available to the public on the Internet at <http://www.epa.gov/iaq/base/index.html>. Summaries have been published on subsets of these data as they have become available (Brightman et al. 1996, 1997; Girman et al. 1995, 1999; Hadwen et al. 1997; Womble et al. 1996, 1999). At present, the data for 56 buildings are avail-

⁸Outdoor air intakes were within 25 feet of standing water, exhaust vents, sanitary vents, vehicle traffic, and trash dumpsters.

⁹Measures of uncleanliness included, among others: no scheduled air handler inspection, dirty filters, dirty ductwork, and presence of moisture in the HVAC system.

¹⁰Maintenance measures included, among others: daily vacuuming, daily surface dusting, use of pesticides inside, and monthly floor stripping and waxing.

TABLE 3.13 BASE Core Parameters

Environmental measures	Building checklist	HVAC checklist	Occupant questionnaire
Temperature	Use	Type	Workplace physical information
Relative humidity	Occupancy	Specifications (air handler, exhaust fans)	Health and well-being

between 7 and 58 L/s/person with a mean of 21 L/s/person. With few exceptions, these buildings provided fresh air above ASHRAE’s minimum requirement of 9 L/s/person.

Airborne and dustborne measurements are listed in Tables 3.16 and 3.17. Outdoor fungi concentrations were less than those measured indoors, and allergen levels were less than those found in homes (Chew et al. 1998).

In the 86 buildings presented in Table 3.17, 30 different fungal groups were identified indoors in quantifiable concentrations. Four genera, at low concentration and frequency, were unique to the indoor samples: *Thysanophora*, *Oedocephalum*, *Rhinocladiella*-like, and *Verticillium*. In the outdoor samples, 28 different fungal groups were identified in quantifiable concentrations (Womble et al. 1999).

Both PM₁₀ and PM_{2.5} particle sizes were measured in the BASE buildings. Outdoor concentrations were higher than indoor concentrations for both PM₁₀ (geometric mean of 26 versus 12 µg/m³) and PM_{2.5} (geometric mean of 16 versus 8 µg/m³), indicating a sink effect (Ligman et al. 1999).

Over 200 VOC samples were collected on multisorbent samplers in 56 buildings. The distributions of the 12 VOCs with the highest indoor median concentrations are shown in Figure 3.5. Acetone, toluene, d-limonene, m- and p-xylenes, 2-butoxyethanol, and n-undecane had the highest median concentrations: 29, 9, 7, 5, 5, and 4 µg/m³, respectively. The maximum concentrations for these were 220, 370, 140, 96, 78, and 58 µg/m³, respectively (Girman et al. 1999).

TABLE 3.14 Prevalence of Symptoms Occurring at Least Once a Week over the Last 4 Weeks and Improving Away from Work within 56 BASE Buildings

Symptom	Prevalence within all buildings, %, 2535 respondents	
	Women	Men

Figure 3.6 shows the distribution of indoor to outdoor concentration ratios for the 12 VOCs with the highest median concentrations. All the ratios were greater than 1, and ratios for five of the VOCs (d-limonene, 2-butoxyethanol, n-undecane, n-dodecane, and hexanal) were near or greater than 10. This indicates that all detectable VOCs had indoor sources in these buildings (Girman et al. 1999). Apte et al. (1999) and others are drawing on these data to test the associations between low-level VOC concentrations and symptoms in hopes of validating the methods used by TenBrinke et al. (1998) in the California Healthy Buildings reanalysis.

The BASE study used nearly the same questionnaire, as did the NIOSH study, thus affording a comparison between occupant responses from noncomplaint and complaint

TABLE 3.15 Thermal Comfort and Ventilation Measurements within 56 BASE Buildings

Measurement	Units	Range	Mean
Thermal comfort

buildings. A study published in 1997 (Brightman et al. 1997) showed that demographics measured by the survey (e.g., gender, age, asthma) did not significantly differ between the two samples; however, symptoms, perceptions, and psychosocial aspects did. In nearly all cases, the NIOSH respondents described their work environment less favorably. Symptom prevalences in the NIOSH sample (shown in Table 3.11) were higher than the BASE sample (shown in Table 3.14), yet the symptom ranking was roughly the same in each.

Another study (Brightman 1999) drew on the NIOSH data (2435 respondents) and BASE data (4326 respondents) to examine associations among the symptoms. The hypothesis was that etiologic mechanisms would differ between complaint and randomly selected buildings. Exploratory factor analysis, similar to the principle component methods employed in the Library of Congress analysis, identified five symptom groups, shown in Figure 3.7. These biologically plausible symptom groups were consistent in both the NIOSH and BASE samples. The robustness of the symptom groups was examined by using a sensitivity analysis. In this analysis, buildings with few respondents were selectively dropped, the number of factors was varied, and the data were stratified by gender and by season, but the results remained the same. There seemed to be no significant difference between the symptom groups of the two samples. These results support etiologic grouping of symptoms for further data analyses.

As the BASE data become available, more in-depth analyses will be possible. In addition, the BASE data will complement the Temporal Indoor Monitoring Exposure (TIME) study, also sponsored by EPA. The TIME study, which used a protocol similar to the BASE study, repeatedly measured IEQ in government buildings. Although the TIME data are not

TABLE 3.17 Distribution of the Concentration in cfu/m³ of Most Commonly Identified Taxa in 86 BASE Buildings

FIGURE 3.6 Indoor versus outdoor VOC concentrations within 56 BASE buildings. Minimum, 5th, 25th, 50th, 75th, 95th percentiles, and maximum ratios of 12 VOCs within 56 BASE buildings. [From Girman et al. (1999).]

FIGURE 3.7 A comparison of symptom prevalences measured in the BASE (B) and NIOSH (N) studies. A frequent work-related symptom was defined as one that was reported at least once per week in the previous four weeks and that improved when the employee was away from the work site. Upper and lower lines for each box plot represent maximum and minimum building prevalence, and each box indicates the 25, 50, and 75 percent building prevalence for 100 BASE and 80 NIOSH buildings. [From Brightman et al. (1999).]

available at the time of this printing, the combination of the NIOSH and the two EPA data sets will provide extensive normative IEQ data for complaint, noncomplaint, and government buildings in the United States.

3.4 DISCUSSION

Throughout this chapter, we have provided an overview of studies that can be used as sources of referent normative data. We hope that the summaries provide both useful normative measures and an understanding of the complexity of the normative values issue. The data presented include both complaint and noncomplaint environments (ranging from the complaint-driven NIOSH study to the mostly randomly selected BASE study). When choosing a reference data set, demographics (e.g., nationality), building characteristics (e.g., age and size), and geography (e.g., climatic region and population density) should be matched as closely as possible.

Most studies reviewed in this chapter measure SBS symptoms by using a self-administered questionnaire. In order to compare responses, the same questionnaire must be administered in the same manner to all respondents. Comparing measures of SBS symptoms is further complicated by how symptoms are defined by different investigators. For example, in the BOES, Burge et al. (1987) defined a work-related symptom as one that occurred more than twice in the last 12 months and improved away from the office. In the Danish Town Hall Study, Skov et al. (1987) defined a work-related symptom as one that occurred “some times

a week” or “daily,” but improved “on days off/during weekends or vacations.” The BASE and NIOSH studies used similar definitions for frequent work-related symptoms but considered only symptoms experienced over the last month. Lastly, investigators have chosen different methods to group symptoms, with some investigators drawing on statistical associations among the symptoms to define symptom groups.

No matter how symptoms are defined in a study, there is a nonzero baseline of work-related symptoms that differs by symptom. This is important for ascertaining whether a symptom is “elevated.” For investigators interested in administering a questionnaire to measure symptom prevalences, we advise employing one that is well established (e.g., the British ROES questionnaire, the Swedish MM questionnaire, or the BASE/NIOSH questionnaires) and using the same method to codify symptoms.

Many personal characteristics have been associated with increased symptoms. Evidence shows that nonmanagerial women in densely occupied work areas report more symptoms (Soine 1995, Stenberg and Wall 1995). For this reason, whenever possible, the genders should be treated separately. Moreover, the studies that attempted to measure psychosocial variables showed that respondents who are unhappy or dissatisfied with their job reported higher symptom rates. Results such as those presented in the White Hall study (Marmot et al. 1997) indicate that psychosocial aspects are not easily measured but are perhaps the most important variables in an analysis. Researchers have only begun to standardize measures for these important variables (Hurrell and Murphy 1992; Karasek et al. 1981, 1982), and much work is still to be done.

Most of the studies presented in this chapter are cross-sectional. Cross-sectional studies are valuable as they provide clues to what risk factors are important. However, more controlled studies, such as chamber studies to test dose response and field intervention studies to test environmental conditions, are needed. Few studies collected extensive environmental measurements, and those that did showed a variety of associations with symptoms. This may be because of the lack of personal exposure measurements. Although no one exposure is clearly the cause of SBS, environmental measures presented in this chapter provide a normative reference for chemical and physical parameters thought to be associated with SBS. Ensuing chapters throughout the handbook will offer the details necessary to further evaluate the strengths of these associations.

CHAPTER 4

ESTIMATES OF POTENTIAL NATIONWIDE PRODUCTIVITY AND HEALTH BENEFITS FROM BETTER INDOOR ENVIRONMENTS: AN UPDATE

William J. Fisk, M.S.

*Indoor Environment Department
Lawrence Berkeley National Laboratory
Berkeley, California*

The existing literature offers relatively strong evidence that characteristics of buildings and indoor environments significantly influence prevalences of respiratory disease, allergy and asthma symptoms, symptoms of sick building syndrome, and worker performance. Theoretical considerations, and limited empirical data, suggest that existing technologies and procedures can improve indoor environments in a manner that significantly increases health and productivity. At present, we can develop only crude estimates of the magnitude of productivity gains that may be obtained by providing better indoor environments; however, the projected gains are very large. For the United States, we estimate potential annual savings and productivity gains in 1996 dollars of \$6 to \$14 billion from reduced respiratory disease; \$2 to \$4 billion from reduced allergies and asthma; \$15 to \$40 billion from reduced symptoms of sick building syndrome; and \$20 to \$200 billion from direct improvements in worker performance that are unrelated to health. In two example calculations, the potential financial benefits of improving indoor environments exceed costs by factors of 9 and 14. Further research is recommended to develop more precise and compelling benefit-cost data that are needed to motivate changes in building codes, designs, and operation and maintenance policies.

4.1 INTRODUCTION

In office buildings, the salaries of workers exceed the building energy and maintenance costs by approximately a factor of 100 and salaries exceed annualized construction or rental costs by almost as much (Woods 1989). Thus, even a 1 percent increase in productivity should be sufficient to justify an expenditure equivalent to a doubling of energy or maintenance costs, or large increases in construction costs or rents. Productivity increases for a worker of 1 percent correspond to reduced sick leave of 2 days per year, reduced breaks from work or increased time at work of 5 minutes per day, or a 1 percent increase in the effectiveness of physical and mental work.

Current evidence suggests at least four major links between people's health and productivity and the quality of indoor environments, where we spend 90 percent of our lives. Three of these links involve the following health effects influenced by the indoor environment: (1) infectious disease, (2) allergies and asthma, and (3) acute building-related health symptoms commonly called *sick building syndrome symptoms*. The fourth link is the direct impact of indoor environmental conditions on worker performance, without any change in health. Most of the prior literature on the relationship between indoor environments and productivity has focused on the fourth link—potential direct improvements in worker's cognitive or physical performance. Possible productivity gains and savings in health care costs from reductions in adverse health effects have received much less attention despite the very high costs of adverse health effects. This paper will consider both direct productivity gains and gains associated with reducing adverse health effects.

The primary purpose of this paper is to synthesize available information pertaining to the linkage between the indoor environment and health and productivity and, on the basis of this synthesis, to develop credible estimates of the total productivity gains that might result from better indoor environments. We recognize that existing data and knowledge are inadequate for precise estimates of potential productivity gains from better indoor environments; however, even imprecise unbiased estimates should be of considerable value to policy makers, researchers, and those responsible for decisions about the design and operation of buildings.

4.2 APPROACH

The approach used for this analysis is illustrated in Fig. 4.1. Computer-based literature searches and personal contacts were used to identify relevant papers, and the evidence supporting or refuting the hypothesized linkages was synthesized. Evidence from small studies without sufficient statistical power, or from studies judged to be of poor quality,¹ was disregarded. The potential economic significance of adverse health effects linked to the indoor environment was estimated, primarily by synthesizing and updating the results of previously published estimates. The economic results of previous analyses were updated to 1996 to account for general inflation, health care inflation, and increases in population (U.S. Department of Commerce 1997). The next and most uncertain step in the analysis was to estimate the magnitude of the decrease in adverse health effects and the magnitude of direct improvements in productivity that might result from improved indoor environments. These estimates are based on findings reported in the literature (e.g., the strength of associations between indoor environmental characteristics and health outcomes) and on our

¹Reasons for neglecting a study included suspected major uncontrolled sources of confounding due to missing data or incomplete data analyses and very limited statistical power. Only one article from the archival refereed literature was neglected.

understanding from building science of the degree to which relevant indoor environmental conditions could practically be improved. Nationwide health and productivity gains were then computed by multiplying the potential percentage decrease in illness (or percent direct increase in productivity) by the associated cost of the illness (or by the associated magnitude of the economic activity). In two example calculations, the costs of improving indoor environments are compared with the value of potential productivity gains and savings in health care costs. A final section discusses policy implications.

This article is based on the results of many studies that have used statistical models to analyze research data and that report findings in statistical terms. To make this article understandable to a relatively broad audience, the use of potentially unfamiliar statistical terminology has been minimized. For example, the odds ratio is a statistical parameter commonly used to indicate the statistical association between an outcome (e.g., a health effect) and a risk factor suspected to increase the proportion of the population that experiences the outcome. Published odds ratios plus data on the fraction of the populations that experienced the outcomes were used to calculate *estimates* of the percentage increase or decrease in the outcomes when the suspected risk factors are present or absent.² Additionally, measures of statistical significance have been excluded from the text. The findings reported in this paper would generally be considered to be statistically significant (e.g., the probability that the findings are due to chance or coincidence is generally less than 5 percent). For the statistically inclined, measures of statistical significance are included in footnotes.

This article draws heavily on a previously published paper (Fisk and Rosenfeld 1997). Relative to the previous paper, the current article has been updated to reflect new research findings, more recent statistical data, and 1996 prices. Also, tables have been added that summarize some key published findings, and a section on odors and productivity has been added.

4.3 LINKAGE OF BUILDING AND INDOOR ENVIRONMENTAL QUALITY CHARACTERISTICS TO HEALTH AND PRODUCTIVITY

In this section, the magnitude of potential productivity gains is estimated for the four previously identified links between the indoor environment and productivity. For each link, the estimate is preceded by a synthesis of the literature.

Infectious Disease Transmission

Linkage. The relationship of building and indoor environmental characteristics to infectious disease transmission among building occupants likely depends on the mechanisms of transmission. If disease transmission occurs because of airborne transport of infectious aerosols³ over distances of many meters between the source and the recipient, then measures that reduce or interrupt this long-range transport would be expected to reduce disease transmission. Examples of such measures include more efficient or increased rates of air filtration, increased ventilation (i.e., increased supply of outside air), and reduced air recirculation in ventilation systems. If disease transmission is primarily a consequence of short-

²Because of the definition of odds, the ratio of symptom prevalences is smaller than the odds ratio by an amount that depends on the proportion of the population that experiences symptoms.

³Examples of infectious aerosols are small aerosols produced by coughing and sneezing that contain a high virus concentration.

FIGURE 4.1 Flowchart illustrating method of estimating health and productivity gains from better indoor environments.

range transport of infectious aerosols over distances of only a few meters (because the aerosols settle on surfaces or quickly become noninfectious), then measures that increase the separation between individuals may help to reduce disease transmission; e.g., reductions in occupant density and increased use of private work spaces⁴ may be helpful. However, more efficient filtration of infectious aerosols in the recirculated airstreams of ventilation systems and decreased air recirculation by ventilation systems may not signifi-

⁴Separating workers with walls or partitions will generally increase the path that infectious aerosols must travel between their source (infected worker) and a nearby uninfected individual.

cantly reduce short-range airborne disease transmission. Regardless of the range of transport, disease transmission by infectious aerosols may also be influenced by environmental-condition aerosols (e.g., air temperature and humidity) that affect the period of viability of infectious materials. Finally, if disease transmission is primarily due to direct person-to-person contact or to indirect contact via contaminated objects, many indoor environmental and building characteristics may have a very small influence on transmission. However, temperatures and humidities at surfaces may affect the survival of infectious organisms on surfaces, and the associated disease transmission.

In addition to direct effects of building factors on the transmission of respiratory infections among occupants, indoor environmental conditions may influence occupants' susceptibility to these infections. For example, there is some evidence, discussed subsequently, that increased exposures to molds are associated with substantially increased numbers of respiratory infections.

Numerous laboratory experiments and field-based epidemiological studies have attempted to determine the significance of different potential routes of transmission of common infectious diseases. Most laboratory research has focused on selected viral infections, such as rhinovirus infections that are responsible for an estimated 30 to 50 percent of acute respiratory illness (Jennings and Dick 1987). For rhinovirus infections, laboratory experiments demonstrate that transmission is possible as a consequence of both direct and indirect contact (e.g., Gwaltney et al. 1978; Gwaltney and Hendley 1982) and also from infectious aerosols (e.g., Dick et al. 1987; Jennings and Dick 1987; Couch et al. 1966); however, there is contradictory evidence regarding the relative significance of the transmission routes. The airborne route of transport is also known or thought to be significant for a number of other respiratory infections including adenovirus infections, coxsackievirus infections, influenza, measles, and tuberculosis (Couch et al. 1966; Couch 1981; Knight 1980; Sattar and Ijaz 1987; Nardell et al. 1991). In general, however, the relative importance of transmission mechanisms for many common respiratory illnesses remains controversial.

Several field studies provide evidence that building characteristics significantly influence the incidence of respiratory illness among building occupants. Most important is a multi-year study performed by the U.S. Army that involved a large number of subjects (Brundage et al. 1988). This study showed that rates of acute respiratory illness with fever (illness confirmed clinically) were 50 percent higher among recruits housed in newer barracks with closed windows, low rates of outside air supply, and extensive air recirculation compared to recruits in older barracks with frequently opened windows, more outside air, and less recirculation.⁵ This study provides strong evidence that some building-related factors can have a large influence on rates of illness transmission. Because of potential confounding, this study does not prove that low ventilation rates or mechanical air recirculation increase illness transmission. However, low ventilation and recirculation are suspected risk factors because of their theoretical impact on exposures to infectious aerosols (Nardell 1991).

Another study in U.S. Navy barracks (Langmuir et al. 1948) also compared the rate of respiratory illness with fever among recruits housed in two types of barracks. One set of barracks contained ultraviolet (UV) lights that irradiated the indoor air near the ceiling—a technology designed to kill infectious bioaerosols. The second set of barracks, housing the control group, had no UV lights. An epidemic of influenza occurred during the study. Rates of respiratory illness with fever were lower in the population with UV irradiated air by 48, 19, and 13 percent during the preepidemic, epidemic, and postepidemic periods, respectively. For the entire study period, there was a 23 percent lower rate of respiratory illness in the population housed in barracks with UV irradiated air.

Several additional studies provide relevant information on this topic. In a study by Jaakkola et al. (1993), office workers with one or more roommates were about 20 percent

⁵Adjusted relative risk = 1.51, 95% confidence interval (CI) 1.46 to 1.56.

more likely to have more than two cases of the common cold during the previous year than office workers with no roommates.⁶ At an Antarctic station, the incidence of respiratory illness was twice as high in the population housed in smaller (presumably more densely populated) living units (Warshauer et al. 1989). In an older study of New York schools (New York State Commission on Ventilation 1923), there were 170 percent as many respiratory illnesses⁷ and 118 percent as many absences from illness⁸ in fan-ventilated⁹ classrooms compared to window-ventilated classrooms, despite a lower occupant density in the fan-ventilated rooms. Unfortunately, ventilation rates were not measured in the classrooms. Another study investigated symptoms associated with infectious illness among 2598 combat troops stationed in Saudia Arabia during the Gulf War (Richards et al. 1993). The study results suggest that the type of housing (air-conditioned buildings, non-air-conditioned buildings, open warehouses, and tents) influenced the prevalence of symptoms associated with respiratory illness. Housing in air-conditioned buildings (ever versus never housed in an air-conditioned building while in Saudia Arabia) was associated with approximately a 37 percent greater prevalence of sore throat¹⁰ and a 19 percent greater prevalence of cough.¹¹ For housing in non-air-conditioned buildings (ever versus never), which had a lower occupant density and presumably a higher ventilation rate than air-conditioned buildings, the corresponding increases in the prevalences of sore throat and cough were smaller, approximately 24 and 12 percent, respectively.¹² For housing in tents and warehouses (ever versus never), which presumably had much higher ventilation rates than buildings, there were no statistically significant increases in sore throat or cough.

Jails are not representative of other buildings because of severe crowding and residents who are not representative of the general public. However, disease transmission in such facilities is an important public health issue and indoor-environment factors that influence disease transmission in jails may also be important, but less easily recognized, in other environments. An epidemic of pneumococcal disease in a Houston jail was studied by Hoge et al. (1994). There were significantly fewer cases of disease among inmates with 7.4 m² (80 ft²) or more of space¹³ relative to inmates with less space. The disease attack rate was about 95 percent higher in the types of jail cells with the highest carbon dioxide concentrations and the lowest volume of outside air supply.¹⁴

Nursing homes are also densely populated. Drinka et al. (1996) studied an outbreak of influenza in four nursing homes located on a single campus. The total number of residents was 690. Influenza, confirmed by analyses of nasopharyngeal and throat swab samples, was isolated in 2 percent of the residents of Building A versus an average of 13 percent in the other three buildings¹⁵ (16, 9, and 14 percent in Buildings B, C, and D, respectively). After correction for the higher proportion of respiratory illnesses that were not cultured in Building A, an estimated 3 percent of the residents of Building A had influenza, a rate 76 percent lower than observed in the other buildings.¹⁶ The total number of respiratory illnesses (i.e., influenza plus other respiratory illnesses) per resident was also 50 percent lower in Building A. Vaccination rates and levels of nursing care did not differ among the buildings. The authors of this study suspect that architectural factors may be the cause of

⁶Adjusted odds ratio = 1.35 (95% CI 1.00–1.82).

⁷Difference more than 3 times probable error.

⁸Difference greater than probable error.

⁹In fan-ventilated classrooms, fans are used to bring outside air into the classrooms.

¹⁰Adjusted odds ratio = 1.57 (95% CI 1.32–1.88).

¹¹Adjusted odds ratio = 1.33 (95% CI 1.01–1.46).

¹²For sore throat, adjusted odds ratio = 1.36 (95% CI 1.13–1.64). For cough, adjusted odds ratio = 1.21 (95% CI 1.01–1.46).

¹³ $p = 0.03$.

¹⁴Relative risk = 1.95 (95% CI 1.08–3.48).

¹⁵ $p < 0.001$, Cochran-Mantel-Haenszel statistics.

¹⁶ $p < 0.001$, chi-square.

the lower infection rate in Building A. The ventilation system of Building A supplied 100 percent outside air to the building (eliminating mechanical recirculation) while the ventilation systems of the other buildings provided 30 or 70 percent recirculated air. The Building A ventilation system also had additional air filters. Finally, the public areas of Building A were larger (per resident), reducing crowding that may facilitate disease transmission.

Milton et al. (1998) investigated the association of absence from work caused by illness in 4119 workers (located in 40 buildings) with the rate of outside air supply and the presence of humidification systems. While absence is clearly not synonymous with respiratory disease, it is a useful surrogate and a substantial proportion of short-term absence from work caused by illness results from acute respiratory illness. Estimates of ventilation rates were based on ventilation system design, occupancy, and selected end-of-day carbon dioxide measurements, and buildings were classified as normal ventilation (about 12 L/s per occupant) or high ventilation (about 22 L/s per occupant). The total absence rate was 34 percent lower in the high-ventilation buildings. The estimated rate of short-term absence, which excludes lengthy absences and those not associated with respiratory conditions, was 17 percent lower in the high-ventilation buildings. Absence rates were 25 percent and 18 percent lower, for total and short-term absence, respectively, in spaces without humidification. The associations of low ventilation and humidification with absence remained significant after controlling for age, gender, work shift, seniority, and job type.

The association of mold problems in buildings with the incidence of respiratory infections has been investigated in a few studies. One study (Husman et al. 1993; Husman 1996) compared the rates of acute respiratory infection in 158 residents of apartments with verified¹⁷ mold problems to the rates of infection in 139 residents of apartments without mold problems. Approximately twice as many residents of the moldy apartments reported at least one acute respiratory infection during the previous year.¹⁸ A complex multistage study examined the association of high mold exposures within day-care centers with common colds as well as other health outcomes in children (Koskinen et al. 1995, 1997) with inconclusive results (i.e., one comparison suggests that mold significantly increased serious persistent respiratory infections while other comparisons found small statistically insignificant decreases in common colds with higher mold exposure). The recent evidence that mold exposures may adversely affect immune system function (Dales et al. 1998) is consistent with the findings of a positive association between molds and respiratory infections.

Table 4.1 summarizes the key features and findings from these studies (excluding the inconclusive results from the studies of mold and respiratory illness in day-care centers). Taken together, these studies provide relatively strong and consistent evidence that building and IEQ factors can influence rates of respiratory disease. Only one paper was identified with a null finding of no association of building factors with respiratory disease (Rowe et al. 1992), and this paper is based on a study with important methodological limitations.

Cost of Infectious Respiratory Illness. The obvious direct costs of respiratory illness include health care expenses and the costs of absence from work. Additionally, there is evidence that respiratory illnesses cause a performance decrement at work. In controlled experiments, Smith (1990) has shown that viral respiratory illnesses, even subclinical infections, can adversely affect performance on several computerized and paper-based tests that simulate work activities. The decrement in performance can start before the onset of symptoms and persist after symptoms are no longer evident.

To estimate the productivity losses associated with respiratory illness, we consider periods of absence from work and restricted activity days as defined in the National Health

¹⁷Visible mold growth was recorded. Also, measured airborne mold levels were higher in six moldy homes relative to six control homes.

¹⁸Relative risk is 2.2, 95% CI is 1.2 to 4.4, adjusted for age, sex, smoking, and atopy.

TABLE 4.1 Summary Information from Studies of the Association of Building Characteristics with Acute Respiratory Illness

Setting	Populations compared	Health outcome	Findings
U.S. Army Barracks (Brundage 1988)	Recruits in modern (low ventilation) barracks versus recruits in older barracks	Respiratory illness with fever	50% higher incidence of respiratory illness in modern barracks
U.S. Navy Barracks (Langmuir 1948)	Recruits in barracks with UV irradiation of air versus those in barracks without UV irradiation	Respiratory illness with fever	23% decrease in respiratory illness with UV irradiation
Finnish Office (Jaakkola 1993)	Office workers with ≥ 1 roommate versus office workers without roommates	Common cold	Worker with roommates had 20% higher risk of more than two common colds per year
Antarctic station (Warshauer 1989)	Residents of smaller versus larger quarters	Respiratory illness	100% higher incidence of respiratory illness for residents of smaller quarters
N.Y. state schools (N.Y. State Commission on Ventilation 1923)	Students in fan-ventilated versus window-ventilated classrooms	Respiratory illness and absence	70% more illness and 18% more absence in fan-ventilated classrooms
Four U.S. nursing homes (Drinka 1996)	Residents of single nursing home with no recirculation of ventilation air and less crowding of common areas versus residents in three homes with recirculation and more crowding	Culture-confirmed type A influenza and total respiratory illness	76% less influenza and 50% less total respiratory illness in nursing home with no recirculation and less crowding

Gulf War troops (Richards 1993)	Troops ever versus never housed in different types of buildings during Gulf War	Symptoms of respiratory illness	37% more cough and 19% more sore throat if housed in air-conditioned buildings
U.S. jail (Hoge 1994)	>80 ft ² versus <80 ft ² space per occupant and high versus low CO ₂ (i.e., low versus high ventilation per occupant)	Pneumococcal disease	Significantly higher incidence if <80 ft ² space, 95% higher incidence if in cell type with high CO ₂ concentration (i.e., with low ventilation)
40 buildings with office, trade, manufacturing workers (Milton 1998)	Workers in buildings with high versus low ventilation and workers in buildings with and without humidification	Short-term absence	17% less short-term absence in high-ventilation buildings and 18% less short-term absence in spaces without humidification
Dwellings in Finland (Husman 1993, 1996)	168 residents of moldy apartments versus 139 residents of nonmoldy apartments	Acute respiratory infection	Approximately twice as many residents of moldy apartments had at least one respiratory infection during prior year

Interview Survey (U.S. Department of Health and Human Services 1994). In the United States, four common respiratory illnesses (common cold, influenza, pneumonia, and bronchitis) cause about 176 million days lost from work and an additional 121 million work days of substantially restricted activity (Dixon 1985, adjusted for population gain). Assuming a 100 and 25 percent decrease in productivity on lost-work and restricted-activity days, respectively, and a \$39,200 average annual compensation (U.S. Department of Commerce 1997), the annual value of lost work is approximately \$34 billion.¹⁹ The annual health care costs for upper and lower respiratory tract infections total about \$36 billion (Dixon 1985, adjusted for population gain and health care inflation). Thus, the total annual cost of respiratory infections is approximately \$70 billion. This estimate may be less than the true cost, as neglected costs include the economic value of reduced housework and of absence from school. Also, these estimates reflect lost work and restricted activity from only four common respiratory illnesses.

Potential Savings from Changes in Building Factors. Without being able to substantially change the building-related factors that influence disease transmission, we cannot realize these health care cost savings and productivity gains. A number of existing, relatively practical building technologies, such as increased ventilation, reduced air recirculation, improved filtration, ultraviolet disinfection of air, and reduced space sharing (e.g., shared office) have the theoretical potential of reducing inhalation exposures to infectious aerosols by a factor of more than 2. Also, occupant density can be decreased if future studies confirm that less density reduces the incidence of respiratory illness. (Attempts to reduce the costs of workspace by increasing occupant density may be counterproductive.) Changes in building codes could help to stimulate widespread adoption of technologies that have been proved to be effective.

Based on the previous analyses, each 1 percent decrease in the incidence of respiratory illness in the United States would result in approximately \$0.7 billion in annual savings. The studies cited above suggest that changes in building characteristics and ventilation could reduce indexes of respiratory illness by 15 percent (absence from school) to 76 percent (influenza in nursing homes), with the strongest study (Brundage et al. 1988) suggesting that a 33 percent reduction is possible.²⁰

While the evidence is compelling that the incidence of common respiratory infections is associated with indoor environmental conditions, the complexity of disease transmission makes it difficult to estimate the magnitude of practical reduction for the U.S. population. For example, reducing disease transmission in one setting, such as an office or school, should lead to reduced disease in other settings, e.g., at home; however, we do not attempt to account for these indirect effects.

The amount of time spent in a building should influence the probability of disease transmission within the building. The period of occupancy in the studies cited above ranged from approximately 25 percent of time in offices and schools to 100 percent of time in nursing homes and jails. If efforts to reduce disease transmission were implemented primarily in commercial and institutional buildings²¹ that people occupy approximately 25 percent of the time, smaller reductions in respiratory illness would be expected in the general population than indicated by the building-specific studies. To adjust the reported decreases in respiratory illness for time spent in buildings, we estimated the percentage of time that occupants spend in each type of building (100 percent of time in jails and nursing homes, 66 percent in barracks

¹⁹A similar estimate, \$39 billion, is based on the information in Garabaldi (1985).

²⁰For example, the observed 50 percent increase in disease in the modern army barracks suggests that a 33 percent decrease in disease is possible, i.e., $(1.5 - 1.0)/1.5 = 0.33$.

²¹There are no technical barriers to implementation of similar measures in residences; however, business owners will have a stronger financial incentive to take action than home owners.

and housing, and 25 percent in offices and schools) and assumed that the magnitude of the influence of a building factor on the incidence of respiratory illness varies linearly with time spent in the building. After this adjustment (Table 4.2), the 10 studies yield 14 estimates of potential decreases in metrics for respiratory illness (some studies had multiple outcomes such as influenza and total respiratory infections), ranging from 6 to 41 percent with an average of 16 percent. Considering only the studies with explicit respiratory illness outcomes (i.e., excluding studies with absence or individual symptoms as outcomes) results in nine estimates of decreases in respiratory illness, adjusted for time in building, ranging from 9 to 41 percent with an average of 18 percent. The range is much smaller, 9 to 20 percent, if the outlier value of 41 percent (illness in schools) is excluded. This narrower range is adopted, i.e., 9 to 20 percent, for the potential reduction in respiratory illness. With this estimate and statistics on the frequency of common colds and influenza (0.69 cases per year²²), approximately, 16 to 37 million cases of common cold or influenza would be avoided each year. The corresponding range in the annual economic benefit is \$6 to \$14 billion.

Allergies and Asthma

Linkage. In the United States, approximately 20 percent of the U.S. population has allergies to environmental antigens (Committee on Health Effects of Indoor Allergens 1993) and approximately 6 percent have asthma (Rappaport and Boodram 1998). Over the last two decades, the prevalences of asthma, asthma-related hospitalization, and asthma-related mortality have risen substantially (Committee on Health Effects of Indoor Allergens 1993). The symptoms of allergies and of asthma may be triggered by a number of allergens in indoor air including fragments of house dust mites; allergens from pets, fungi, and insects; and pollens that enter buildings from outdoors (Committee on Health Effects of Indoor Allergens 1993). Allergens are considered to be a primary cause of the inflammation that underlies asthma (Platts-Mills 1994). Viral infections, which may be influenced by building factors, also appear to be strongly linked to exacerbations of asthma, at least in school children (Johnston et al. 1995). Asthma symptoms may also be evoked by irritating chemicals in indoor air, including environmental tobacco smoke (Evans et al. 1987). For example, in a study of children (Garrett et al. 1996), higher formaldehyde concentrations were associated with diagnosed asthma,²³ asthma symptoms,²⁴ and positive responses to skin prick allergy tests.²⁵ There is evidence (e.g., Arshad et al. 1992, Wahn et al. 1997) that lower exposures to allergens during infancy or childhood can reduce the sensitization to allergens.

The building factors most consistently and strongly associated with asthma and allergic respiratory symptoms are moisture problems, molds, and house dust mites. Many studies indicate that occupants of homes or schools with evidence of dampness or presence of molds have approximately a 30 to 60 percent higher prevalence of asthma or of lower respiratory symptoms associated with asthma (e.g., Brunekreef 1992, Bjornsson et al. 1995, Dales et al. 1991, Li and Hsu 1996, Smedje et al. 1996, Spengler et al. 1993). Bjornson et al. (1995) also found detectable levels of house dust mites and increased concentrations of bacteria were associated with asthma-related symptoms.²⁶ Platts-Mills and Chapman (1987) provide a detailed review of the role of dust mites in allergic disease.

²² Averaging data from 1992 through 1994, the civilian noninstitutional population experienced 43.3 common colds and 25.7 cases of influenza per 100 population (U.S. Department of Commerce 1997).

²³ $p = 0.035$.

²⁴ Adjusted odds ratios for symptoms ranged from 1.57 to 2.21, 95% CI excluded 1.0 only for cough.

²⁵ The reference was children in homes with <16 ppb formaldehyde. A higher proportion of children in homes with 16–40 ppb had positive skin prick tests ($p < 0.05$). An even higher percentage of children in homes with >40 ppb formaldehyde had positive skin prick tests ($p < 0.05$).

TABLE 4.2 Percentage Reduction in Respiratory Illness or Surrogate Metrics before and after Adjustment for Time Spent in Building

Setting	Estimated % time in building	Outcome (observed % reduction*)	Adjusted % reduction in outcome assuming 25% time in building
U.S. Army barracks (Brundage 1988)	66	Respiratory illness (33)	12.5
U.S. Navy barracks (Langmuir 1948)	66	Respiratory illness (23)	9
Finnish office (Jaakkola 1993)	25	Common colds (17)	17
Antarctic station (Warshauer 1989)	66	Respiratory illness (50)	19
N.Y. state schools (N.Y. State Commission on Ventilation 1923)	25	Illness (41)	Illness (41)
Four U.S. nursing homes (Drinka 1996)	100	Absence (15)	Absence (15)
		Influenza (76)	Influenza (19)
Gulf War troops (Richards 1993)	66	Total respiratory illness (50)	Total respiratory illness (12.5)
		Cough (27)	Cough (10)
		Sore throat (16)	Sore throat (6)
U.S. jail (Hoge 1994)	100	Pneumococcal disease (49)	12
40 buildings with office, trade, manufacturing workers (Milton 1998)	25	Short-term absence with high Ventilation (17)	17 (high ventilation)
		Short-term absence without humidification (18)	18 (without humidification)
Dwellings in Finland (Husman 1993, 1996)	66	Respiratory illness (54)	20

*Some studies report the increase in the health outcome while other studies indicate the degree of reduction. All percentage increases have been converted to a percentage reduction, e.g., if some risk factor is associated with a 50% increase in illness, the percentage reduction from eliminating that risk factor is 33% [(1.5 - 1.0)/1.5].

Smedje et al. (1997) investigated the proportion of school children within 28 classrooms who were diagnosed as asthmatic and also had current asthma (i.e., experienced asthma symptoms or used asthma medication within the past 12 months). As shown in Table 4.3, several classroom and indoor environmental quality factors were associated with the rate of current asthma, suggesting that improvements in the classroom factors might substantially reduce current asthma.

Fewer office-based studies data are available for asthma and allergy associations with indoor environmental conditions. In case studies, moisture and related microbiological problems have been linked to respiratory symptoms in office workers (Division of Respiratory Disease Studies 1984). In a study of office workers²⁷ (Menzies 1988), higher relative humidity, higher concentrations of alternaria (a mold) allergen in air, and higher dust mite antigen in floor dust were associated with a higher prevalence of respiratory symptoms.

Various measures have been found effective in reducing indoor concentrations of allergens in buildings (Harving et al. 1991, Ingram and Heymann 1993, Pollart et al. 1987). Unfortunately, except for studies involving air cleaners, we have identified relatively few published experimental studies of the effect of changes in building conditions on the symptoms of allergies and asthma. Measures to reduce exposures to dust mite allergen, such as improved cleaning and encasement of mattresses in nonpermeable materials, have reduced symptoms in some but not all studies (Ingram and Heymann 1993, Pollart et al. 1987, Harving et al. 1991, Antonicelli 1991, Platts-Mills and Chapman 1987).

Numerous studies have examined the influence of air cleaners that remove particles from indoor air on symptoms of allergies and asthma. Many of these studies have important limitations. Some studies have used small air cleaners that would not be expected to significantly reduce airborne allergen concentrations. Many studies have involved a small number (e.g., 20) of subjects so that moderate (e.g., 20 percent) improvements in symptoms cannot be distinguished from random variations in symptoms. Many of the studies have focused on dust mite allergies, and dust mite allergens that may be poorly controlled with air cleaners due to their large size and high settling velocities.

Nelson et al. (1988) reviewed research on the use of residential air cleaning devices to treat allergic respiratory disease. All nine of the studies reviewed indicated that air filtration devices and air conditioning reduced seasonal allergic symptoms, but the subjects of most of the studies were not blinded. For perennial allergic disease, six of eight studies reviewed by Nelson et al. (1988) suggested improvement with air filtration. Despite these generally positive results, Nelson et al. (1988) indicated that current data were inadequate to support recommendations for the use of air cleaners.

Since the review by Nelson et al. (1988), a few new studies of the benefits of air cleaners have been completed. In a double-blind study by Van der Heide et al. (1997), air cleaner operation combined with allergen-impermeable mattress covers was associated with an improvement²⁸ in a measure of lung function used as a test for asthma (but a combination of both measures was required). In a double-blind study of dust mite-sensitive individuals (Reisman et al. 1990), operation of efficient air filters (compared to placebo filters) was associated with a lower (better) score for several allergy symptoms²⁹ but only during the period of the study without respiratory infections. In a similar study (Antonicelli et al. 1991), again involving individuals sensitive to dust mites (but with only nine subjects),

²⁶For the association of asthma-related symptoms and bacteria, adjusted odds ratios and 95% CI are 5.1 (1.3 to 20). For the association of asthma-related symptoms and detection of house dust mites, adjusted odds ratios and 95% CI are 7.9 (1.2 to 55). House dust mite levels were positively associated with humidity ($p < 0.05$) and increasing age of the house ($p < 0.001$).

²⁷This was a case-control study of ~17 percent of all workers in the buildings.

²⁸ $p < 0.05$.

²⁹Several p values < 0.05 and others close to 0.05.

TABLE 4.3 Association between Classroom Factors and Current Asthma in Swedish Pupils, 13 to 14 Years Old

Classroom factor [*]	Change in current asthma [†] associated with increase in the classroom factor	Observed range in the classroom factor
Unit increase in shelf factor (measure of area of open shelves)		
1.0°C increase in air temperature	40% increase	Not provided
10% relative humidity (RH) increase	40% decrease	21.0 to 27.5°C
1 µg/m ³ increase in formaldehyde	80% increase	22 to 61% RH
10 µg/m ³ increase in VOC concentration	10% increase	<5 to 10 µg/m ³
100 per m ³ increase in airborne viable bacteria concentration	30% increase	4 to 93 µg/m ³
Increase in airborne viable mold concentration of 1000 per m ³	40% increase	100 to 1100 per m ³
100 ng/g fine dust increase in cat allergen	50% increase	8000 to 170,000 per m ³
	80% increase	<16 to 391 ng/g

^{*}Factors not associated with current asthma include age of building, type of ventilation system, air exchange rate, carbon dioxide concentration, visible signs of dampness, fleece factor, respirable dust, settled dust, total molds, total bacteria, volatile organic compounds (VOCs) from short-term sampling, nitrogen dioxide, endotoxin, dog allergen.

[†]P values as follows: <0.001 for shelf factor, 0.003 for temperature, 0.014 for RH, 0.042 for formaldehyde, <0.001 for VOCs, 0.01 for bacteria, <0.001 for mold, 0.001 for cat allergen.

Source: From Smedje et al. 1997.

operation of filtration units did not significantly influence dust mite allergen concentrations or measures of allergic response.

Overall, the evidence of a linkage between the quality of the indoor environment, particularly moisture problems, molds, and dust mites, and the incidence of allergic and asthma symptoms is relatively strong. Additionally, the exposures that cause allergic sensitization often occur early in life and are likely to occur indoors; consequently, the quality of indoor environments may also influence the proportion of the population that is allergic or asthmatic.

Cost of Allergies and Asthma. Table 4.4 summarizes the results of several recent estimates of the annual costs of allergies and asthma in the United States, updated to 1996. The authors of these studies have generally characterized their estimates as conservative because some cost elements could not be quantified. Differences between cost estimates are due to reliance on different underlying data, different assumptions, and inclusion of different cost elements. For the purposes of this paper, the averages of the cost estimates for each outcome and cost category, provided in the last row of Table 4.4, have been summed, yielding a total estimated annual cost for allergies and asthma of \$15 billion. A significant portion of the costs of allergies and asthma reflects the burden of these diseases in children.

Potential Savings from Changes in Building Factors. There are three general approaches for reducing allergy and asthma symptoms by changes in buildings and indoor environments. First, one can control the indoor sources of the allergens and chemical compounds that cause symptoms (or that cause initial sensitization to allergens). For example, indoor tobacco smoking can be restricted to isolated, separately ventilated rooms or prohibited entirely. Sources of other irritating chemicals can be decreased by changing building materials and consumer products. Pets can be maintained outside of the homes of individuals that react to pet allergens. Perhaps even more effective are measures that reduce the growth of microorganisms indoors. Changes in building design, construction, operation, and maintenance could reduce water leaks and moisture problems and decrease indoor humidities (where humidities are normally high). Known reservoirs for microorganisms, such as carpets for dust mites, can be eliminated or modified. Improved cleaning of building interiors and HVAC systems can also limit the growth or accumulation of microorganisms indoors. There are no major technical obstacles to these measures, but the costs and benefits of implementation are not well quantified.

The second general approach for reducing allergy and asthma symptoms is to use air cleaning systems or increased ventilation to decrease the indoor concentrations of the relevant pollutants. Many of the exposures that contribute to allergies and asthma are allergens in the form of airborne particles. Technologies are readily available for reducing indoor concentrations of airborne particles generated indoors (e.g., better air filtration). Better filtration of the outside air entering mechanically ventilated buildings can also diminish the entry of outdoor allergens into buildings. Filtration is likely to be most effective for the smaller allergenic particles such as cat allergens. Allergens that are large particles, e.g., from dust mites, have high gravitational settling velocities and are less effectively controlled by air filtration.

Because viral respiratory infections will often exacerbate asthma symptoms, a third approach for reducing asthma symptoms is to modify buildings and IEQ in a manner that reduces viral respiratory infections among occupants. A recent study of 108 children, ages 9 to 11, found a strong association of viral infections with asthma exacerbation (Johnston et al. 1995). Viral infections were detected in 80 to 85 percent of asthmatic children during periods of asthma exacerbation. During periods without exacerbation of asthma symptoms, only 12 percent of the children had detectable viral infections.³⁰

³⁰The difference between infection rates is statistically significant, $p < 0.001$.

TABLE 4.4 Estimates of Annual Costs of Asthma and Allergic Disease in Billions of Dollars, Updated to 1996

Study	Cost of asthma		Cost of allergic rhinitis		Cost of other associated airway diseases*	
	Health care	Indirect†	Health care	Indirect	Health care	Indirect
Weiss et al. 1992	5.0	3.1	NA	NA	NA	NA
McMenamin 1995	3.7	2.7	1.2	1.2	2.7	0.2
Fireman 1997	NA	NA	NA	>4.3	NA	NA

Average	4.7	2.2	2.3	2.8	2.7	0.2

*Portion of costs of chronic sinusitis, otitis media with effusion, and nasal polyps attributed to allergies.

†Components of indirect costs vary among the studies; indirect costs account for lost work, lost school days, and in some cases, mortality.

With the available data, the magnitude of the potential reduction in allergy and asthma symptoms is quite uncertain, but some reduction is clearly possible by using practical measures. The subsequent estimate is based on two considerations: (1) the degree to which changeable building and IEQ factors have been associated with symptoms and (2) the degree to which indoor allergen concentrations and concentrations of irritating chemicals can be reduced. As discussed, several cross-sectional studies have found that building-related risk factors such as moisture problems and mold or dust mite concentrations are associated with 30 to 60 percent increases or decreases in allergy and asthma symptoms. Several, but not all, studies have found that use of particle air cleaners reduced symptoms, but the magnitude of the improvement is generally not well characterized.

Significant reductions in allergy and asthma symptoms would not be expected unless it were possible to substantially reduce indoor concentrations of the associated allergens and irritants. From engineering considerations, it is clear that indoor allergen concentrations, for many allergens, can be reduced very substantially. Filtration systems, appropriately sized,³¹ should be capable of reducing concentrations of the smaller airborne allergens by more than 75 percent. Some of the source control measures, such as elimination of water leaks, control of indoor humidities, reduction or elimination of indoor smoking, and improved cleaning and maintenance, are likely to result in much larger reductions in the pollutants that contribute to allergies and asthma.

Based primarily on the strength of reported associations of changeable building and IEQ factors to allergy and asthma symptoms, we estimate that a 10 to 30 percent reduction in symptoms and associated costs is feasible and practical. With this estimate, the annual savings would be about \$2 to \$4 billion. Control measures can be targeted at the homes or offices of susceptible individuals, reducing the societal cost.

Sick Building Syndrome Symptoms

Linkage. Characteristics of buildings and indoor environments have been linked to the prevalence of acute building-related health symptoms, often called sick building syndrome (SBS) symptoms, experienced by building occupants. SBS symptoms are most commonly reported by office workers and teachers, who make up about 50 percent of the total workforce (64 million workers³²).

SBS symptoms include irritation of eyes, nose, and skin, headache, fatigue, and difficulty breathing. In a modest fraction of buildings, often referred to as “sick buildings,” symptoms become severe or widespread, prompting investigations and remedial actions. The term “sick building syndrome” is widely used in reference to the health problems in these buildings. However, sick building syndrome appears to be the visible portion of a broader phenomenon. These same symptoms are experienced by a significant fraction of workers in “normal” office buildings that have no history of widespread complaints or investigations (e.g., Fisk et al. 1993, Nelson et al. 1995, Brightman et al. 1998), although symptom prevalences vary widely among buildings. The most representative data from U.S. buildings, obtained in a 56-building survey that excluding only buildings with prior SBS investigations, found that 23 percent of office workers reported two or more frequent symptoms that improved when they were away from the workplace (Brightman et al 1998).

³¹ Many of the commonly used portable air cleaners will be ineffective because they do not remove pollutants at a sufficient rate.

³² According to statistical data on employed civilians by occupation (U.S. Department of Commerce 1997), there are approximately 63 million civilian office workers plus teachers (49.6 percent of the civilian workforce). Assuming that 50 percent of the 1.06 million active duty military personnel are also office workers, the total is approximately 63.5 million.

Applying this percentage to the estimated number of U.S. office workers and teachers (64 million), the number of workers frequently affected by at least two SBS symptoms is 15 million.

Although psychosocial factors such as the level of job stress are known to influence SBS symptoms, building factors are also known or suspected to influence these symptoms: e.g., type of building ventilation; type or existence of humidification system; rate of outside air ventilation; level of chemical and microbiological pollution; and indoor temperature and humidity (see the reviews by Mendell 1993, Sundell 1994, Menzies and Bourbeau 1997). In one set of problem buildings, SBS symptoms were associated with evidence of poorer ventilation system maintenance or cleanliness (Sieber et al. 1996). For example, debris inside the air intake and poor drainage from coil drain pans were associated with a factor of 3 increase in lower respiratory symptoms.³³ In the same study, daily vacuuming was associated with a 50 percent decrease in lower respiratory symptoms.³⁴ In some, but not all, controlled experiments, SBS symptoms have been reduced through practical changes in the environment such as increased ventilation, decreased temperature, and improved cleaning of floors and chairs (Mendell 1993, Menzies and Bourbeau 1997). Therefore, there is little doubt that SBS symptoms are linked to features of buildings and indoor environments. The building-related factors most consistently associated with increased SBS symptoms include sealed air-conditioned buildings, humidification, higher air temperature, and lower outside air ventilation rate.

Cost of SBS Symptoms. SBS symptoms are a hindrance to work and can cause absences from work (Preller et al. 1990) and visits to doctors. When SBS symptoms are particularly disruptive, investigations and maintenance may be required. There are financial costs to support the investigations and considerable effort is typically expended by building management staff, by health and safety personnel, and by building engineers. Responses to SBS have included costly changes in the building, such as replacement of carpeting or removal of wall coverings to remove molds, and changes in the building ventilation systems. Some cases of SBS lead to protracted and expensive litigation. Moving employees or students imposes additional costs and disruptions. Clearly, SBS imposes a significant societal cost, but quantification of this cost is very difficult. However, it is possible to make some estimates of potential productivity losses from SBS.

Our calculations indicate that the costs of small decreases in productivity from SBS symptoms are likely to dominate the total SBS cost. Limited information is available in the literature that provides an indication of the influence of SBS symptoms on worker productivity. In a New England survey, described in EPA's 1989 report to Congress (U.S. Environmental Protection Agency 1989), the average self-reported productivity loss due to poor indoor air quality was 3 percent. Woods et al. (1987) completed a telephone survey of 600 U.S. office workers and 20 percent of the workers reported that their performance was hampered by indoor air quality, but the study provided no indication of the magnitude of the productivity decrement. In a study of 4373 office workers in the United Kingdom by Raw et al. (1990), workers who reported higher numbers of SBS symptoms during the past year also indicated that physical conditions at work had an adverse influence on their productivity. According to the data from this study, the average self-reported productivity decrement was about 4 percent.³⁵ In an experimental study (Menzies et al. 1997), workers provided with

³³For debris in air intake, relative risk = 3.1 and 95% CI = 1.8 to 5.2. For poor or no drainage from drain pans, relative risk = 3.0 and 95% CI = 1.7 to 5.2.

³⁴Relative risk = 0.5, 95% CI = 0.3 to 0.9.

³⁵The data indicate a linear relationship between the number of SBS symptoms reported and the self-reported influence of physical conditions on productivity. A unit increase in the number of symptoms (above two symptoms) was associated with approximately a 2 percent decrease in productivity. Approximately 50 percent of the workers reported that physical conditions caused a productivity decrease of 10 percent or greater; 25 percent of workers reported a productivity decrease of 20 percent or more. Based on the reported distribution of productivity decrement (and productivity increase) caused by physical conditions at work, the average self-reported productivity decrement is about 4 percent.

individually controlled ventilation systems reported fewer SBS symptoms and also reported that indoor air quality at their workstation improved productivity by 11 percent relative to a 4 percent decrease in productivity for the control population of workers.³⁶

In addition to these self-reported productivity decrements, measured data on the relationship between SBS symptoms and worker performance are provided by Nunes et al. (1993). Workers who reported any SBS symptoms took 7 percent longer to respond in a computerized neurobehavioral test³⁷ and had a 30 percent higher error rate in a second computerized neurobehavioral test.³⁸ Similar findings were obtained in a study of 35 Norwegian classrooms. Higher concentrations of carbon dioxide, which indicate a lower rate of ventilation, were associated with increases in SBS symptoms and also with poorer performance in a computerized test of reaction time³⁹ (Myhrvold et al. 1996). Renovations of classrooms with initially poor indoor environments, relative to classrooms without renovations, were associated with reduced SBS symptoms and with improved performance in the reaction time tests⁴⁰ (Myhrvold and Olsen 1997).

Another investigation (Wargocki 1998) providing evidence that SBS symptoms reduce productivity was a laboratory-based blinded, controlled, randomized experimental study with all indoor environmental conditions constant except for the presence or absence of a 20-year-old carpet that was not visible to study participants. In this study, subjects (30 females ages 20 to 31) rated the quality and acceptability of air, reported the current intensity of their SBS symptoms, completed a standardized performance-assessment battery, performed simulated office work, and completed a self-assessment of performance. These tests and assessments were completed several times with and without the presence of carpet. The study design and data analyses controlled for the effects on performance of learning when tasks were repeated. As a result of the complexity of this fascinating study, there were numerous findings. The major relevant findings were that removing the carpet was associated with the following outcomes⁴¹: (a) small decreases in selected pollutants; (b) better perceived air quality; (c) increased intensity of some SBS symptoms, particularly headache; (d) 6.5 percent increase in amount of text typed in the simulated office work; (e) a 7 percent increase in performance in a column addition test; (f) a 4 percent increase in performance in a logical reasoning test; (g) a 2.5 percent increase in performance in a serial addition test; (h) a 4 percent increase in performance in an addition test; (i) a 6.5 percent increase in performance in a reaction time test; and (j) one conflicting finding—a 2 percent decrease in performance in a code substitution test. The self-assessments of performance suggested that performance increases may be a consequence, in part, of increased effort by the workers when the carpet was absent. The author's interpretation was that performance increases in the typing test were most likely a consequence of the reductions in headache. The other performance increases were not associated with a reduction in SBS symptoms.

We must base our estimate of the productivity loss from SBS symptoms on the limited information available. The measured data (described above) of Nunes et al. (1993), the studies of classrooms in Norway (Myhrvold et al. 1996, Myhrvold and Olsen 1997), and the laboratory-based studies by Wargocki (1998) provide substantial evidence that SBS symptoms actually decrease performance; however, it is not clear how to translate the increases in

³⁶ $p < 0.05$ for the reduction in SBS symptoms and $p < 0.001$ for the self-reported change in productivity.

³⁷ $p < 0.001$.

³⁸ $p = 0.07$.

³⁹Correlation coefficient = 0.1111 and p value = 0.009 for performance versus carbon dioxide. Correlation coefficient = 0.1976 and p value = 0.000 for performance versus a score for headache, heavy headed, tiredness, difficulty concentrating, and unpleasant odor. Correlation coefficient = 0.1136 and p value = 0.008 for performance versus a score for throat irritation, nose irritation, runny nose, fit of coughing, short winded, runny eyes. Correlation coefficients are controlled for age.

⁴⁰Measures of statistical significance are not included in paper.

⁴¹The associated p values for outcomes c through j are as follows: (c) $p < 0.04$ [severe headache]; (d, e, h, i, and j) $p < 0.05$; (f and g) $p < 0.10$.

response times and error rates and decreases in typing performance measured in specific tests with the magnitude of an overall productivity decrement from SBS symptoms. The self-reports discussed above suggest a productivity decrease of approximately 4 percent due to poor indoor air quality and physical conditions at work. Although SBS symptoms seem to be the most common work-related health concern of office workers, some of this self-reported productivity decrement may be a consequence of factors other than SBS symptoms. Also, workers who are dissatisfied with the indoor environment may have provided exaggerated estimates of productivity decreases. To account for these factors, we will discount the 4 percent productivity decrease cited above by a factor of 2, leading to an estimate of the productivity decrease caused by SBS equal to 2 percent, recognizing that this estimate is highly uncertain. The objective data of Nunes (1993) and Wargocki (1998) suggest that, for specific tasks, performance decrements from SBS symptoms may be considerably larger.

SBS symptoms are primarily associated with office buildings and other nonindustrial indoor workplaces such as schools. According to Traynor et al. (1993), office workers are responsible for approximately 50 percent of the U.S. annual gross national product. Statistical data on the occupations of the civilian labor force are roughly consistent with this estimate (U.S. Department of Commerce 1997); i.e., 50 percent of workers have occupations that would normally be considered office work or teaching. Since the gross domestic product⁴² (GDP) of the United States in 1996 was \$7.6 trillion (U.S. Department of Commerce 1997), the GDP associated with office-type work is approximately \$3.8 trillion. On the basis of the estimated 2 percent decrease in productivity caused by SBS symptoms, the annual nationwide cost of SBS symptoms is \$76 billion.

Potential Savings from Changes in Building Factors. Because multiple factors, including psychosocial factors, contribute to SBS symptoms, we cannot expect to eliminate SBS symptoms and SBS-related costs by improving indoor environments. However, strong evidence cited by Mendell (1993) and Sundell (1994) of associations between SBS symptoms and building environmental factors, together with our knowledge of methods to change building and environmental conditions, indicate that SBS symptoms can be reduced. Many SBS studies⁴³ have found individual environmental factors and building characteristics to be associated with changes of about 20 to 50 percent in the prevalence of individual SBS symptoms or groups of related symptoms.⁴⁴ A smaller number of studies have identified a few building-related factors to be associated with an increase in symptoms by a factor of 2 or 3 (e.g., Jaakkola and Miettinen 1995, Sieber et al. 1996). In a few blinded experimental studies (reviewed in Mendell 1993, Sundell 1994), specific indoor environmental conditions have been changed to investigate their influence on symptoms. Some of these studies have also demonstrated that increased ventilation rate, decreased temperature, better surface cleaning, and use of ionizers can diminish SBS symptoms, while no significant benefit was evident in other studies. In summary, the existing evidence suggests that substantial reductions in SBS symptoms, on the order of 20 to 50 percent, should be possible through improvement in individual indoor environmental conditions. Multiple indoor environmental factors can be improved within the same building. For the estimate of cost savings, we will assume that a 20 to 50 percent reduction in SBS symptoms is practical in office buildings. The corresponding annual productivity increase is of the order of \$15 to \$38 billion.

⁴²GDP is approximately equal to GNP.

⁴³Most of these studies have taken place in buildings without unusual SBS problems; thus, we assume that the reported changes in symptom prevalences with building factors apply for typical buildings.

⁴⁴Adjusted odds ratios (ORs) for the association of symptom prevalences to individual environmental factors and building characteristics are frequently in the range of 1.2 to 1.6. Assuming a typical symptom prevalence of 20 percent, these ORs translate to risk ratios of approximately 1.2 to 1.5, suggesting that 20 percent to 50 percent reductions in prevalences of individual SBS symptoms or groups of symptoms should be possible through changes in single building or indoor environmental features.

Direct Impacts of Indoor Environments on Human Performance

Background. The previous discussion has focused on the potential to enhance worker productivity by improving the indoor environment in a manner that reduces illness and health symptoms. However, indoor environmental conditions may influence the performance of physical and mental work, without influencing health. This section discusses the evidence of a direct connection between worker performance and three characteristics of the indoor environment: thermal conditions, lighting, and odors. Existing standards define the boundaries of recommended thermal and lighting conditions in buildings. These standards exist, in part, because conditions far from optimal have an obvious adverse influence on worker performance.

Research on this topic is difficult because of the complexity of defining and measuring human performance in real-world environments and because many factors influence performance. Additionally, worker motivation affects the relationship between performance and environmental conditions (e.g., highly motivated workers are less likely to have reduced performance in unfavorable environments). Indicators of human performance have included measures of actual work performance, results of special tests of component skills (e.g., reading comprehension) deemed relevant to work, and subjective self-estimates of performance changes.

A large number of papers, including many older papers, provide information pertinent to an assessment of the direct influence of environmental factors on human performance. A review of all identified papers was not possible; therefore, the following discussion is based on a review of selected papers, emphasizing more recent research with performance measures that are more closely related to actual work performance, and with environmental conditions more typical of those found in nonindustrial buildings.

Linkage between Thermal Environment and Performance. Several papers contain reviews of the literature on the linkage between the thermal environment (primarily air temperature) and selected indices of work performance. On the basis of these literature reviews and on original reports of research, there is substantial evidence of an association between work performance and air temperature, for the range of temperatures commonly experienced in buildings. However, not all studies have found such associations. Emphasizing the relationship of temperature to mental performance and light manual work, a brief summary of positive findings follows:

1. Laboratory studies by the New York State Commission on Ventilation (1923) found that performance of manual work was significantly influenced by air temperature but that performance of mental work was not affected by temperature. However, a reanalysis of a portion of the Commission's data (Wyon 1974) found that subjects performed 18 to 49 percent more typewriting work⁴⁵ at 20°C compared to 24°C.
2. Meese et al. (1982) investigated factory workers' performance on 14 tasks that simulate factory work. Workers' performance on eight of the tasks differed significantly⁴⁶ (generally lower performance) at an 18°C air temperature compared to 24°C.
3. Automobile drivers of a special test vehicle missed 50 percent more of the signals introduced via instruments and rear view mirrors at 27°C compared to 21°C and response time was 22 percent slower at 27°C (Wyon 1993).
4. Pepler and Warner (1968) investigated the learning performance of university students at six temperatures ranging from 16.7 to 33.3°C. Students studied a programmed text and were required to respond to questions on critical points. Air temperature signifi-

⁴⁵ $p < 0.05$.

⁴⁶ $p < 0.002$ to $p < 0.01$.

cantly influenced two out of four measures of learning performance: errors per unit time and times required to complete assignments. Error rates were about 20 percent smaller at 26.7°C than at 20°C or 33.3°C.⁴⁷ However, the time to complete assignments was 5 to 10 percent higher at 26.7°C compared to the temperature extremes. These results suggest that overall effect of temperature on performance would depend on the importance of errors relative to speed of work.

5. Existing literature suggests a complex relationship between temperature and mental work performance that varies with the type of work. In a study of reading speed and comprehension, performance was superior at 20 and 30°C compared to 27°C (Wyon 1976). Similarly, on the basis of simulated high-school classroom conditions the following findings were reported (Wyon et al. 1979): Reading speed was 20 percent better at 23 and 29°C compared to 26°C; multiplication speed in males was about 20 percent higher⁴⁸ at temperatures above and below 27 to 28°C; word memory in males was best (about 20 percent higher) at an intermediate temperature of around 26°C⁴⁹; and word memory performance for females increased with temperature between 24 and 26°C, but did not fall as temperatures increased further to 29°C.

The previous discussion suggests that temperature can influence mental performance in some settings. For some types of mental work (e.g., complex or creative mental work), optimal thermal comfort and optimum performance may approximately coincide. For other types of mental work, slight thermal discomfort that increases arousal (e.g., slightly cool temperatures) may increase performance. Temperatures just below the point that causes sweating may cause workers to relax and work less to prevent sweating. Given that the optimum temperature for a task depends on the nature of the task, varies among individuals (e.g., with gender, age, and clothing), and varies over time (e.g., tasks may change), some papers have advocated or investigated the provision of individual control of temperature as a practical method to increase productivity (Kroner and Stark-Martin 1992; Wyon 1993, 1996; Menzies et al. 1997). A study in an insurance office, using the number of files processed per week as a measure of productivity, suggested that provision of individual temperature control increased productivity by approximately 2 percent. However, studies of individual control may be criticized because these studies cannot be performed blindly; i.e., occupants know if they have individual control. With assumptions about workers' use of individual control, Wyon (1996) has estimated that providing workers $\pm 3^\circ\text{C}$ of individual control should lead to about a 3 percent increase in performance for both logical thinking and very skilled manual work, and approximately a 7 percent increase in performance for typing relative to performance in a building maintained at the population-average neutral temperature. Larger productivity increases would be predicted if the reference building did not maintain the average neutral temperature.

Linkage between Lighting and Human Performance. As discussed by the National Electrical Manufacturers Association (NEMA 1989), lighting has at least the theoretical potential to influence performance directly, because work performance depends on vision, and indirectly, because lighting may direct attention, or influence arousal or motivation. Several characteristics of lighting, e.g., illuminance (the intensity of light that impinges on a surface), amount of glare, and the spectrum of light, may theoretically affect work performance. Obviously, lighting extremes will adversely influence performance; however, the potential to improve performance by changing the lighting normally experienced within buildings is the most relevant question for this paper.

⁴⁷ $p < 0.05$.

⁴⁸ $p < 0.05$.

⁴⁹ $p < 0.05$ for the performance improvement between 24 and 26°C.

It is expected that performance of work that depends very highly on excellent vision, such as difficult inspections of products, will vary with lighting levels and quality. The published literature, while limited, is consistent with this expectation. For example, Romm (1994) reports a 6 percent increase in the performance of postal workers during mail sorting after a lighting retrofit that improved lighting quality and also saved energy. A review of the relationship between lighting and human performance (NEMA 1989) provides additional examples, such as more rapid production of drawings by a drafting group after bright reflections were reduced.

Many laboratory studies have investigated subjects' performance on special visual tests as a function of illuminance, spectral distribution of light, and the contrast and size of the visual subject. As an example, in one visual test subjects must identify the location of an open section in a circle (called a Landolt C) that is briefly shown on a computer monitor. Many of these studies have identified statistically significant differences in people's performance on these visual tests with changes in lighting (e.g., Berman et al. 1993, 1994; NEMA 1989); however, the relationship between performance in these visually demanding laboratory tests and performance in typical work (e.g., office work) remains unclear.

Several studies have examined the influence of illuminance on aspects of reading performance, such as reading comprehension, reading speed, or accuracy of proofreading. Some of these studies have failed to identify statistically significant effects of illuminance (Veitch 1990, Smith and Rea 1982). Other studies have found illuminance to significantly influence reading performance; however, performance reductions were primarily associated with unusually low light levels or reading material with small, poor-quality, or low-contrast type (Smith and Rea 1979, Tinker 1952). Low levels of illuminance seem to have a more definite adverse influence on the performance of older people (Smith and Rea 1979, NEMA 1989), a finding that may become increasingly important as the workforce becomes older.

Clear and Berman (1993) explored economically optimum lighting levels by incorporating equations that relate illumination to performance within a cost-benefit model. Their resulting recommended illumination levels varied a great deal with the visual subject (size and contrast), the age of the person, and the model used to relate illumination to performance. It is not possible to generalize from the findings; however, the variability in optimum illumination indicates that occupant-controllable task lighting may be helpful in increasing productivity.

There have been anecdotal reports of the benefits of full-spectrum lighting on morale and performance, relative to the typical fluorescent lighting. However, according to the published literature (Boray et al. 1989, Veitch et al. 1991, NEMA 1989) there seems to be no strong or consistent scientific evidence of benefits of full-spectrum lighting.

Berman et al. (1993, 1994) have found that changes in the spectrum of light (with illuminance unchanged) influence both pupil size and performance in visual tests. They suggest that the smaller pupil size when light is rich in the blue-green portion of the spectrum reduced the adverse effects of optical aberrations. Additionally, Berman (1992) argues that the required illuminance to maintain work performance, hence the required lighting energy use, could be decreased by 24 percent if standard cool-white lamps were replaced by those with a larger portion of light output in the blue-green spectrum. The associated annual reduction in energy use for the United States would be \$4.2 billion.

A few studies have examined the influence of different lighting *systems* on self-reported productivity or on cognitive task performance. The lighting systems compared resulted in different illuminance and also different lighting quality (e.g., differences in reflections and glare). In a study by Hedge et al. (1995), occupants reported that both lensed-indirect and parabolic downlighting supported reading and writing on paper and on the computer screen better than a recessed lighting system with translucent prismatic diffusers.⁵⁰ Katzev (1992) studied the mood and cognitive performance of subjects in laboratories with four different

⁵⁰ $p < 0.01$.

lighting systems (both conventional and energy-efficient). The type of lighting system influenced occupant satisfaction and one energy-efficient system was associated with better reading comprehension.⁵¹ Performance in other cognitive tasks (detecting errors in written materials, typing, and entering data into a spreadsheet) was not significantly associated with the type of lighting system. In a recent laboratory study, Veitch and Newsham (1998) found that the type of luminaire influenced performance of computer-based work. Also, energy-efficient electronic ballasts, which result in less lighting flicker than magnetic ballasts, were associated with improvements in verbal-intellectual task performance.

Based on this review, the most obvious opportunities to improve performance through changes in lighting are work situations that are very visually demanding. The potential to use improved lighting to significantly improve the performance of office workers seems to be largely unproved; however, it appears that occupant satisfaction and the self-reported suitability of lighting for work can be increased with changes in lighting systems. Most of the studies that incorporated measurements of performance had few subjects, hence, these studies were not able to identify small (e.g., few percent) increases in performance that would be economically very significant. Also, a majority of research subjects have been young adults and lighting is expected to have a larger influence on the performance of older adults.

Linkage between Odor or Scents and Human Performance. Substantial research has been undertaken to evaluate the relationship of work performance with odors and scents, e.g., pleasant odors, unpleasant odors, stimulating or relaxing odors. The rationale behind these studies is that odors may potentially affect mood, or arousal, or increase relaxation which, in turn, influences work performance. Odors, especially unpleasant odors, could also distract workers or cause workers to be afraid of health effects. Additionally, the temporal coincidence of odors, even unconscious odors, with an emotionally significant (e.g., anxiety-producing) event could result in conditioning so that the emotions reoccur on subsequent exposure to the odors.

Researchers have investigated the influence of odors on moods, attitudes, self-reported health effects, self-reported work performance, and measured task performance. Some findings of associations between odors and measured task performance are summarized below:

1. Rotton (1983) used groups of approximately 80 subjects to investigate the influence of malodors on performance in a simple mental task (arithmetic) and a complex task (proofreading). The experimental periods were 15 to 30 minutes. He found that the presence or lack of malodor was associated with significant⁵² changes in the number or errors identified during proofreading. About 50 percent more errors were detected in the no-odor situation. Performance on the arithmetic task was not significantly changed by the presence or lack of the odor. The intensity of the odor was uncharacterized, and may have exceeded the intensity of odors normally experienced in buildings.
2. Dember et al. (1995) summarize four fascinating short-term laboratory experiments involving intermittent odors of peppermint (considered arousing), muguet (considered relaxing), and normal air (for reference). In each case, the performance test was the detection of signals on a computer screen. The test was characterized as tedious and demanding vigilance, similar to the real work of air traffic controllers and other workers who must monitor displays and detect occasional events. In the first experiment (Warm et al. 1991), the percent of signals that were detected increased by approximately a factor of 1.4 with exposure to 30-second pulses of either odor⁵³ (the pulses

⁵¹ $p < 0.01$.

⁵² $p < 0.01$ to 0.1 .

⁵³ $p = 0.05$.

occurred every 5 minutes). In the second experiment, the subjects had control over delivery of the odor, and only the performance of women improved with exposure to the odors. A third experiment found that peppermint odor significantly improved the performance of subjects judged to be inattentive (attentiveness based on a self-administered test), but that the performance of attentive subjects was not improved. The final experiment showed that exposure to peppermint odors improved signal detection and also had a significant effect on the amplitude of voltage changes measured from the scalp. The amplitude of these voltage changes had previously been linked to the extent of attention to a stimulus.

3. Knasco (1993) assessed performance on simple and difficult math and verbal tasks during exposure to pleasant, unpleasant, and no odors. The odors were rated as moderately strong. No significant influence of odors on performance was identified. Knasco (1992) also found that odors of weak to moderate intensity did not influence performance on a test that measured creativity.
4. Baron (1990) found that positive odors from commercial air fresheners had no significant influence on performance in a clerical coding task; however, in the pleasant-odor condition subjects more often used an efficient approach to complete the task.⁵⁴
5. In one of two sessions of a study, Ludvigson and Rottman (1989) found a significant association between exposure to lavender odor (considered relaxing) and reduced performance in a test of arithmetic reasoning. No significant associations were found between other measures of cognitive performance and lavender or clove odors. The odors were described as subjectively quite strong.
6. One additional study (Kirk-Smith et al. 1983) employed a neutral odor with low intensity so that subjects were not conscious of the odor. The odor did not significantly influence the subjects' ability to assemble a pattern from a set of blocks.

Several, but not all, studies have found that odors can influence moods and attitudes, which, in turn, may influence work performance. For example, the data from the study by Baron (1990) suggests that positive scents may lead to higher goal setting and improved methods of conflict resolution.⁵⁵ Even feigned (suggested but nonexistent) odors influenced moods (Knasco et al. 1990). A significant association⁵⁶ between exposure to lemon scents and reduced self-reported health effects, such as SBS symptoms, was found by Knasco (1992) but not in a subsequent study (Knasco 1993).

On the basis of this review, the results of research on odors and performance range from findings of no effect to findings of large statistically significant effects. The variability in results is not surprising, since the research has included many different odors, odor intensities, and measured or reported outcomes. Overall, the literature provides substantial evidence that some odors can affect some aspects of cognitive performance. Each of the studies cited above has relied on special laboratory-based tests of cognitive performance. The implications for the overall performance of workers in the actual workplace are not readily quantified. Also, intentionally exposing workers to chemicals that have scents could be considered unethical.

Summary of Findings Regarding Direct Impacts of Environments on Human Performance. Much of the research on the direct linkage between human performance and environmental conditions is from laboratory experiments, and the relevance of laboratory findings to real-world settings is uncertain. Numerous studies suggest that the thermal

⁵⁴ $p < 0.07$.

⁵⁵ $p < 0.05$ for both goal setting and conflict resolution.

⁵⁶ $p = 0.02$.

environment can influence performance of some aspects of mental work by a few percent to approximately 20 percent; however, other studies suggest that modest changes in environmental conditions will not influence performance. There is also evidence that improved lighting quality can have a strong positive influence (e.g., 6 percent) on work performance when the work requires excellent vision; however, the potential to improve the performance of more typical, largely cognitive work by changing the lighting within buildings remains unclear. The literature provides substantial evidence that some odors can affect some aspects of cognitive performance.

Estimate of Potential Productivity Gains. Once again, the limited existing information makes it very difficult to estimate the magnitude of direct work performance improvements that could be obtained from improvements in indoor environments. Extrapolations from the results of laboratory studies to the real workforce are the only avenues presently available for estimating the potential values of productivity gains. There are reasons for estimating that the potential productivity increases in practice will be smaller than the percentage changes in performance reported within the research literature. First, some of the measures of performance used by researchers, such as error rates and numbers of missed signals, will not directly reflect the magnitudes of overall changes in productivity (e.g., decreasing an error rate by 50 percent usually does not increase productivity by 50 percent). Second, research has often focused on work that requires excellent concentration, quick responses, or excellent vision while most workers spend only a fraction of their time on these types of tasks. Third, changes in environmental conditions (e.g., temperatures and illuminance) within many studies are larger than average changes in conditions that would be made in the building stock to improve productivity.

To estimate potential productivity gains, we consider only reported changes in performance that are related to overall productivity in a straightforward manner; e.g., reading speed and time to complete assignments are considered but not error rates. The research literature reviewed above reports performance changes of 2 to 20 percent (with one outlier value excluded, a 49 percent improvement). Assuming that only half of people's work is on tasks likely to be significantly influenced by practical variations of temperature or lighting, the range of performance improvement would be 1 to 10 percent. Because research has generally been based on differences in temperature and lighting about a factor of 2 larger than the changes likely to be made in most buildings, the estimated range of performance improvement was divided by another factor of 2. The result is an estimated range for potential productivity increases in the building stock of 0.5 to 5 percent. Considering only U.S. office workers, responsible for an annual GNP of approximately \$3.8 trillion (as discussed above), the 0.5 to 5 percent estimated performance gain translates into an annual productivity increase of \$19 to \$190 billion.

4.4 EXAMPLE COST-BENEFIT ANALYSES

To illustrate the costs of improving indoor environments relative to the potential productivity gains and health care cost savings discussed previously, two methods of improving indoor air quality are considered: increased outside air ventilation and improved particle filtration. These two cost-benefit analyses serve as examples. A comprehensive assessment would consider many additional changes in technologies or practices such as improved lighting, changes in air temperature, improved building maintenance, and reduced occupant density.

Increased Outside Air Supply

Increasing the rate of outside air ventilation is one obvious method of reducing indoor exposures to indoor-generated air pollutants contributing to infectious disease, allergies, dissatisfaction with air quality, and a variety of sick building syndrome symptoms. The costs of increased ventilation, estimated on the basis of model predictions, have been reported in a variety of papers. The findings vary considerably with the type of building, type of heating, ventilating, and air conditioning (HVAC) system, occupant density, and climate. For example, if minimum ventilation rates are increased to 10 liters per second per occupant [$\text{L}/(\text{s} \cdot \text{occupant})$] [20 cubic feet per minute (cfm) per occupant] from 5 $\text{L}/(\text{s} \cdot \text{occupant})$ (10 cfm/occupant), the estimated increase in building HVAC energy used for fans, heating, and cooling, varies from less than 1 percent to approximately 50 percent. In office buildings with HVAC systems that have an economizer,⁵⁷ increasing the average minimum ventilation rates to approximately 10 $\text{L}/(\text{s} \cdot \text{occupant})$ (20 cfm/occupant) from 2.5 $\text{L}/(\text{s} \cdot \text{occupant})$ (5 cfm/occupant) is likely to change building energy use by only a few percent to 10 percent (Eto and Meyer 1988, Eto 1990, Mudarri and Hall 1993). The larger increases in energy use (e.g., 30 to 50 percent) are expected only in buildings with a high occupant density such as schools (Ventresca 1991, Mudarri and Hall 1996, Steele and Brown 1990). Since workers' salaries in office buildings exceed total building energy use by approximately a factor of 100 (Woods 1989), the cost of modest (e.g., 10 percent) increases in HVAC energy will be small compared to the potential savings cited above. However, to reduce adverse environmental impacts of energy use, energy-efficient options for increasing ventilation (e.g., adding economizer systems where they are absent or ventilation with heat recovery) should be considered preferred options.

As an example of costs, we consider the results of analyses of Eto and Meyer (1988) involving a large 55,500 m^2 (597,000 ft^2) office building. Eto and Meyer (1988) do not indicate building occupancy; therefore, we will assume a default occupancy for offices of 7 persons per 100 m^2 (ASHRAE 1989) resulting in an estimated 3880 occupants. Results from the Washington, DC, temperate climate are used. Increasing the minimum ventilation rates from 2.5 $\text{L}/(\text{s} \cdot \text{occupant})$ (5 cfm/occupant) to 10 $\text{L}/(\text{s} \cdot \text{occupant})$ (20 cfm/occupant) increased the projected annual energy costs by \$24,100 or \$6.20 per person in 1996 prices (\$20,400 in 1988 prices).⁵⁸ The estimated incremental first cost of the HVAC system was \$154,000 or 2.1 percent (\$116,000 in 1988 prices).^{59,60} Spreading this first cost over a 15-year period using a 6 percent real capital recovery factor results in an additional annual cost of about \$15,800 (\$4.10 per person); thus, the total estimated annual cost is about \$40,000, or \$10.30 per person. The annual total compensation for the 3880 office workers in this building will be approximately \$152 million (3880 persons $\times$ \$39,200 per person). If the increased ventilation leads to a 10 percent reduction in respiratory infections, the days of lost work and reduced performance at work will decrease by 10 percent. Since respiratory infections cause workers to miss work about 1.3 days per year and to have 2.2 days of restricted activity, the annual value to the employer of the 10 percent reduction in respiratory disease would be \$117,000⁶¹ (\$30.20 per person), or 3 times the projected annual cost.

⁵⁷To save energy, economizer systems automatically increase the rate of outside air supply above the minimum set point during mild weather.

⁵⁸Since the increased energy costs are dominated by electricity used for cooling, data on the price of electricity for commercial establishments were used to update costs (Table 752, U.S. Department of Commerce 1997).

⁵⁹In many existing office buildings, there will be no incremental HVAC costs because oversized HVAC equipment will handle increased loads.

⁶⁰Cost updated to 1996 using the ratio of the CPI (for all items) in 1996 to the CPI in 1988, which equals 1.33 (Table 752, U.S. Department of Commerce 1997).

⁶¹We assume a 25 percent reduction in productivity on restricted-activity days. We also scale the days in bed and restricted activity days reported by Dixon (1985) by the ratio of work days to total days.

Additionally, health care costs for the workers would be reduced by roughly \$49,000 annually⁶² (\$12.60 per person). If the increased ventilation decreases symptoms of SBS by 25 percent and SBS symptoms are responsible for a 1 percent drop in productivity, the associated annual productivity increase is \$380,000 ($0.0025 \times 3880 \text{ persons} \times \$39,200 \text{ per person}$), or \$97.90 per person. Combining the three savings elements yields an annual savings of \$545,000 (\$140 per person), 14 times the projected annual cost.

Improved Air Filtration

As discussed previously, improved air filtration has the potential to reduce disease transmission, allergies and asthma, and SBS symptoms. In a recent field study, high-efficiency air filters were installed in an office building (Fisk et al. 1998). Product literature indicates that these filters remove 95 percent of particles with an aerodynamic diameter of 0.3 μm and a higher percentage of smaller and larger particles. According to measured data, the high-efficiency filters reduced the total indoor concentration of particles 0.3 (μm and larger by a factor of 20. Many of these particles have an outdoor origin. The estimated reduction in the concentration of submicrometer indoor-generated particles is a factor of 4. The annual cost of purchasing the high-efficiency filters used in this study is approximately \$23 per person, assuming the filters must be replaced annually.⁶³ The incremental cost of labor for installing an extra set of filters once per year is negligible compared to the cost of the filters. (Upstream low-efficiency prefilters are often used to extend the life of the high-efficiency filters.) The increased airflow resistance of high-efficiency filters, compared to typical filters, can increase the required fan power if HVAC airflow rates are maintained unchanged. The increased cost of fan energy was estimated to be about \$1.00 per person-year using standard relationships between fan power requirements and airflow resistance, assuming that the average airflow resistance increases by 60 Pa. However, in many retrofit applications the flow rate in the HVAC system can decrease substantially without adverse effects because existing flow rates are excessive. In these applications, installation of high-efficiency filters will actually save fan energy.

In the previous example, the total estimated annual per person cost of improved air filtration is \$24. If the improved filtration resulted in a 10 percent reduction in respiratory disease, the annual savings would be \$43 per worker (see calculation in the previous example on increased ventilation). If the improved filtration reduced allergic symptoms experienced by the 20 percent of the workforce that have environmental allergies and this reduction in allergic symptoms resulted in a 1 percent increase in the productivity of allergic workers, the annual productivity gain would be \$78 per person averaged over all workers ($0.01 \times \$39,200 \text{ annual compensation} \times 0.2 \text{ of workers affected}$). If the improved filtration decreased the productivity loss from SBS symptoms from 1 percent to 0.75 percent, the annual productivity gain would be \$98 per person. If all of these benefits were realized, the annual savings of about \$220 per worker would exceed the annual cost per worker by a factor of 9.

⁶²The direct health care costs of respiratory infection for the U.S. population were estimated to be \$36.4 billion (see prior text). The incidence of acute respiratory conditions (common cold and influenza) is approximately 63 per 100 for people of working age (18–64) and 80 per 100 for others (Tables 16 and 217, U.S. Department of Commerce 1997, estimate based on average influenza rate for 1990–1994). The total number of acute respiratory conditions per year is 180 million. The number of people in the workforce is 135 million and outside of the workforce is 131 million. If health care costs per respiratory infection are approximately the same for workers and nonworkers (relevant data were not identified), the annual health care cost per worker per respiratory illness is \$200. Multiplying by the incidence of respiratory infections for workers yields an annual health care cost per worker of \$126 or \$489,000 for 3880 workers. A 10 percent reduction is \$49,000.

⁶³Calculations indicate that the high-efficiency filters should have a lifetime of at least a year, before they need to be changed because of an increase in airflow resistance.

4.5 CONCLUSIONS

1. On the basis of a review of existing literature, there is relatively strong evidence that characteristics of buildings and indoor environments significantly influence the occurrence of respiratory disease, allergy and asthma symptoms, sick building symptoms, and worker performance.
2. Theoretical and limited empirical evidence indicate that existing technologies and procedures can improve indoor environments in a manner that increases health and productivity. Estimates of the potential reductions in adverse health effects are provided in Table 4.5.
3. Existing data and knowledge allow only crude estimates of the magnitudes of productivity gains that may be obtained by providing better indoor environments; however, the projected gains are very large. For the United States, the estimated potential annual savings plus productivity gains, in 1996 dollars, are approximately \$40 billion to \$250 billion, with a breakdown as indicated in Table 4.5.
4. In two example calculations, the potential financial benefits of improving indoor environments exceed costs by large factors of 9 and 14.

4.6 IMPLICATIONS

Strong evidence that better indoor environments can cost-effectively increase health and productivity would justify changes in the components of building codes pertinent to indoor environmental quality, such as the prescribed minimum ventilation rates and minimum efficiencies of air filtration systems. Additionally, strong evidence of benefits would justify changes in company and institutional policies related to building design, operation, and maintenance. Health maintenance organizations and insurance companies might also be motivated to reduce rates charged to organizations that maintain superior indoor environments.

We do not presently have the specific and compelling cost-benefit data that are necessary to motivate these changes in building codes, designs, and operation and maintenance policies. The existing evidence of potential productivity gains of tens of billions of dollars per year is, however, clearly sufficient to justify a program of research designed to obtain these cost-benefit data. The primary objectives of the research should be to develop more specific and accurate estimates of the benefits and costs of technologies and policies that improve indoor environments. Wright and Rosenfeld (1996) describe the required program of research and identify research priorities.

TABLE 4.5 Estimated Potential Productivity Gains from Improvements in Indoor Environments

Source of productivity gain	Potential annual health benefits	Potential U.S. annual savings or productivity gain (1996 \$US)
Reduced respiratory disease	16 to 37 million avoided cases of common cold or influenza	\$6–\$14 billion
Reduced allergies and asthma	10 to 30% decrease in symptoms within 53 million allergy sufferers and 16 million asthmatics	\$2–\$4 billion
Reduced sick building syndrome symptoms	20 to 50% reduction in SBS health symptoms experienced frequently at work by approximately 15 million workers	\$15–\$38 billion
Improved worker performance from changes in thermal environment and lighting	Not applicable	\$20–\$200 billion

This work was supported by the Assistant Secretary of Energy Efficiency and Renewable Energy, Office of Building Technology, State, and Community Programs, Office of Building Systems of the U.S. Department of Energy under contract No. DE-AC03-76SF00098.

5.1 INTRODUCTION

At the beginning of the twenty-first century, “green building design” can be seen as being at the confluence of emerging societal interests, all seeking to use resources wisely in the design of health-promoting environments. The last decade saw the concept of the “global village” emerge through terms such as “sustainable development,” “ecotourism,” “ecotaxation,” “socially responsible investment,” and “green architecture,” among others. Organizations representing private and public sector interests lay claim to these terms and attempt to establish the consensus to operational definitions, often suited to their perspective and constraints. Others are asking for a civil society that promotes social justice, equality, and conservation through the actions of the public and private sectors. Green building concepts are simply a manifestation of these changes in our western society (see list of Internet references at the end of this chapter).

Are “healthy buildings” a subset of “green buildings”? In the absence of widely accepted definition criteria, the answer is unclear at this time. The concept of a “healthy building” is still polemic, with no consistent guidelines. It is important to recognize that, although indoor air quality (IAQ) is an important determinant of healthy design, it is not the sole determinant, as occupants experience the full sensory world. Other parameters include lighting, acoustics, vibration, aesthetics, comfort, and security, along with safety and ergonomic design factors. Drawing on contemporary accounts of inner city asthma rates and cases of sick buildings, the building professions need more than cursory and inadequate guidance to incorporate IAQ considerations into their “healthy building” design.

Problems with IAQ have traditionally been associated with older and poorly maintained construction (e.g., threats arising from the degradation of asbestos fireproofing or from *Legionella* contamination in cooling towers). Increasingly, however, building-related illnesses caused by poor air quality are being documented in newly constructed or recently renovated buildings. Poor IAQ is being blamed for a host of problems ranging from low worker productivity to increased cancer risk, and the resulting responses have produced action as severe as building demolition. Our building interiors, once thought of as providing safe havens from the pernicious effects of outdoor air pollution and harsh climates, may actually be more polluted than the surrounding ambient environment.

As recently as 1994, the Building Owners and Managers Association (BOMA, Washington, DC) considered concerns with IAQ as “overblown” by activists who “continue to portray IAQ as an epidemic sweeping the nation.” OSHA’s proposed rule on nonindustrial workplace air quality was published in the U.S. Federal Register April 5, 1994. BOMA, in response, said that reports of IAQ problems were overplayed in the media, and that current concern for IAQ represents “mass hysteria...fueled by misinformation rather than conclusive scientific evidence (BOMA 1994).¹ Instead of being the product of a newly vocal minority, however, the increased publicity regarding IAQ at *this* time is representative of the convergence of many factors. These multifaceted attributes include a heightened public perception, litigation trends, and the current regulatory status, as well as long-term changes in construction systems, coupled with a shift in building occupancy and functional types.

Rising expectations of occupants for healthy work environments are forcing building owners, operators, and managers to reconsider the importance of IAQ. In a more recent survey conducted by the International Facility Managers Association, IAQ and thermal comfort were the top operational issues in all types of buildings (Tatum 1998). According to a recent telephone survey of building tenants commissioned by BOMA, “control and quality of air” was the fourth most important criterion for attracting and retaining tenants. The study also showed that quality heating, ventilating, and air conditioning (HVAC) is extremely important for retaining tenants (BOMA 1999).

The problems with defining good IAQ are both multimodal and unprecedented, requiring a multidisciplinary approach for their investigation and resolution. This article begins with a description of several factors that lead to the wide acceptance that buildings and their IAQ can adversely impact occupants’ health. It continues with an offering of design guidance and evaluation tools to advance the state of practice. The article concludes with practical advice for evaluating the healthfulness of IAQ.

¹BOMA seemed to reflect concerns from building owners and construction professionals, who pointed to the need for source control by manufacturers. At the time BOMA urged federal efforts looking at causes, such as carpets, paints and coatings, and emissions from office equipment. Fundamentally BOMA’s argument emphasized prevention at the manufacturing level, not management once the sources were in the building.

5.2 IAQ HEALTH FACTORS

Trends in Public Perception

The members of the general public have become much more aware of their own risk, the risks they are willing to accept for their children,² and the risks they expect to encounter in public buildings such as schools and hospitals. Much of this increased awareness is an offshoot from the widespread “fiberphobia” that swept through this country at the height of the asbestos debacle. The original concerns were justified in that asbestos materials in many school buildings were degrading and producing an exposure hazard, but many non-hazardous installations were also summarily replaced at great expense. Although in the subsequent 15 years asbestos policy has been refined to more reasonably address actual risk, the public fear of fiber contamination from construction materials has not abated.

Recognition of hazardous waste sites in our communities heightened by the widely celebrated Love Canal and Times Beach cases have added “chemophobia” to our lexicon. Now “sporophobia,” or the fear of microbial agents and their infectious, allergenic, and toxigenic effects, is emerging. One example is that of *Stachybotrys chartarum* (also referred to as *S. atra*), a fungal spore associated with widely publicized infant mortality cases in Cleveland, which evokes fear regardless of how much is present or the potential for exposure (NIOSH 1995). The popular press is featuring the “toxic mold” phenomenon with stories such as the one that appeared in USA Weekend December 3–5, 1999, reaching millions of households. Radon and formaldehyde are but a few of the chemical substances that were little known not too many years ago and are now part of the vocabulary of the average homeowner, who is increasingly wary of widespread “silent” contamination.

One of the great medical achievements of the twentieth century was the extension of life expectancy, but this has resulted in an overall increase in the age of the population, particularly in North America, Japan, and northern Europe. An aging population brings with it all of the diseases of the elderly (cancer, immunological disorders, cardiovascular problems, bone frailty, and skeletal and muscular structure degeneration). Therefore, the people who are generally least aware of the risks posed to their health are also the ones most susceptible to hazards. This situation is further exacerbated by the increased amount of time elders spend indoors. To the extent that the workforce is also aging, indoor environmental quality and safety will continue to become more important in the design and construction of facilities.

Representative of another general change in the health of the populace is the dramatic rise in allergic diseases. The first documented case of hay fever was recorded 150 years ago by a British physician, who had to collect data for another 10 years before he could find seven additional cases.³ By 1980, it was estimated that 20 percent of the population suffers from some form of allergic disease (Burge 1980). Estimates now appear even higher (Institute of Medicine 1993). This tremendous increase in adverse health effects is a relatively new phenomenon, and it is implicated as a risk factor associated with the reported symptoms that occur in buildings.

Fundamentally, however, occupants still trust their eyes and nose to sense what is in the surrounding environment. The presence of displaced odors (e.g., a smell normally associated with a chemical process, but noticed in an occupied space) is increasingly observed, questioned, and reported. Many unrecognizable odors may produce a chemical input to the

²Concern for children’s health has become the shield against Congressional budget cutting or interference with promulgating clean air standards for particles and ozone. EPA now has an office on children’s health. NIEHS is sponsoring several centers focusing on children. The recently passed Food Quality Protection Act requires pesticide manufacturers to assess multipathway, multicontaminant impacts on children.

³Reported at NIH Conference, Washington, DC.

fifth cranial nerve, thereby resulting in a protective gag reflex. The connection between the sensory awareness and the body's protective responses mandate that the simple sensory awareness of the presence of an atypical chemical in the surroundings will initiate other symptomatic responses. Stress adds a further complication when the urge to flee a perceived environment is overridden by social conditioning, and often, by economic need.

Basically, the concept of health is no longer thought of as simply the absence of disease. The World Health Organization has done much to advance a definition of health that encompasses mental and physical well-being, access to clean and safe environments, and health care (World Health Organization 1999).

Trends in Ventilation Design Philosophy

Changes in construction, materials, energy cost, and health concerns are shifting ventilation philosophy once again. Buildings are now a source of contamination. Health, economics, and aesthetics are becoming more important than comfort in determining the specification for ventilation. Figure 5.1 is an extension of the concept originally presented by Fanger in 1996. The debate over ventilation is very contentious, as exemplified by ASHRAE conceding Standard 62-1999 to a status of "continued maintenance," rather than an accepted standard by consensus. We expect to be in a transition period over the next 5 to 10 years as the design industry struggles to incorporate qualitative attributes into prescriptive standards. Performance criteria based on developing indices for quantifying the health hazard of air composed of a mixture of contaminants or subjective rating schemes are likely to emerge.

Interestingly, these tenets are beginning to shift the paradigm for ventilation design. As described by Fanger (1996), in the nineteenth century poisonous vapors were attributed to foul air. Bensuade-Vincent and Stengers (1996) retell the pre-germ-theory beliefs that putrid emanations were expelled from the body. In 1869 Lewis Leeds told the Franklin Institute that "We are thus to conclude that our own breath is our greatest enemy."

In the earliest part of the twentieth century, the concern for contagious airborne infection prevailed. Tuberculosis and influenza epidemics fueled the debate between

	Paradigm	Pollution Sources
2050	Personal aesthetics	People Buildings Outside Environment
2025	Health, productivity, comfort	
2000	Comfort (+ health)	People + Buildings
1975	Comfort	People
1935	Contagion	
1900	Poison	
1800		

FIGURE 5.1 Paradigm shifts in the philosophy of ventilation since 1800 [extension of Fanger (1996)].

mechanical and natural ventilation requirements. Still, the concern was health, and the source was people. Only when heating, ventilating, and air conditioning became widely available, and Yaglou published his work on acceptable ventilation to control body odors, did the focus shift to comfort and productivity (Yaglou et al. 1936). By the middle of the twentieth century, vaccines were available and many communicable diseases were better understood. Health concerns were no longer motivating ventilation requirements, while people remained the primary source. (For a detailed history of ventilation, see Chapter 2 by M. Addington.)

In the future, advancements in sensor technology, microengineered machines, and computerized simulation will position ventilation to be more customized to personal desires. This will lead to further shifts in ventilation philosophy because the bulk properties of building air will not be managed for the mean preference among occupants. Some will enjoy an “indoor spring day” while others acclimatize for their tropical vacation.

Litigation Trends

In general, we are in an increasingly litigious society; i.e., there is more aggressive action by lawyers, individuals, and small groups. Fueled in part by the constant media exposure of IAQ problems, occupants are no longer taking a “wait and see” attitude toward suspect reactions.

Several multimillion dollar settlements or awards have been won by plaintiffs. Several EPA employees working in the Washington, DC, headquarters claimed chronic exposures to air toxins released from furnishings, including carpeting during renovation (Buhura versus SSW Investors, Inc., 1993). Similar claims of exposure to offgassing materials from recent construction or renovation, along with inadequate ventilation, have been the basis for IAQ lawsuits in courthouses, homes, schools, hospitals, ice skating rinks, and office buildings. Other claims have included pesticides in carpets, molds from water-damaged materials, chlorine from swimming pools, and faulty combustion systems. Contractors, building owners, manufacturers, and designers have been named as defendants in lawsuits, together whose awards have ranged in excess of \$25 million.

A new wave of class action suits has appeared since the numerous asbestos suits filed in the 1980s and early 1990s. These include lawsuits filed against manufacturers of paint containing lead, as well as manufacturers of latex gloves. In both cases, the route of exposure asserted is contaminated dust indoors. In the lead case, direct ingestion as well as inhalation of lead paint dust in homes placed children at risk. The cases involving latex exposure followed a marked increase in the use of latex gloves in the health care professions as well as in other service jobs. This increase was a direct result of requirements for universal protection against bloodborne pathogens (HIV, hepatitis B, and others). The first clinical case of latex allergy was documented in 1970. To date, it is estimated that upward of 7 percent of medical-related personnel are allergic to latex (Hamann 1993; Bubak et al. 1992).

Concerns about potential labor unrest and workforce troubles have prompted many pre-trial awards with respect to sick buildings, and for those cases that do go to trial, juries have been generous with both blame and awards. Large settlements have been awarded to occupants complaining about multiple chemical reactions resulting from exposure to commonplace materials, such as carpets, paints, and even computer workstations. In addition, there is an increased willingness to link nonspecific causes with indirect effects. For instance, indoor air pollution is even being blamed for a host of nonphysical complaints, including poor school performance, for which no direct epidemiological relationship has yet been established.⁴

⁴Personal observation following extensive remediation of IAQ problems in a local high school. Legal aftermath included workers' compensation cases and lawsuits brought by parents, claiming disruption of schooling during a critical time hindered children's performance, thus depriving them of competitive college applications to some schools.

Current Regulations

The rise of IAQ-driven litigation has yet to result in any substantial change in the U.S. government's involvement in developing and enforcing regulations. Federal standards are limited to those under the jurisdiction of the U.S. Environmental Protection Agency (EPA), the Department of Housing and Urban Development (HUD), the Consumer Product Safety Commission, and the Occupational Safety and Health Administration (OSHA), most of which focus on specific situations or particular materials. Given the wide scope of these agencies' health and safety activities, it may seem surprising that their regulations significantly penetrate the building industry in only three areas: asbestos, lead, and formaldehyde.

EPA's efforts have been on building surveys, product testing, model development, and education. HUD has the Partnership for Advancing Technology in Housing (PATH) program to advance technologies into housing. With appropriations from Congress, HUD has a Healthy Homes Initiative run out of its lead safety office. Public education and survey demonstration projects will form the basis of HUD's efforts (www.hud.gov). The one attempt at comprehensive regulations for IAQ was unsuccessful. In 1994, OSHA proposed rules governing ventilation, maintenance, IAQ reporting, and restrictions on tobacco smoke in office buildings. The *Federal Register* (April 5, 1994) proposed rule making elicited voluminous responses from tobacco, HVAC, and real estate industries. Changes in the U.S. Congress at that time made it inopportune to expand the regulatory reach of government, and OSHA never pursued final IAQ rules.

While the federal government's activities have mostly been directed at education and research, some states have pursued IAQ through codes and regulations. The California Proposition 65, enacted in the early 1990s, bans the use of carcinogenic substances in building materials, and through labels and warnings, accelerated the growth of smoke-free workplaces. Minnesota had the first IAQ standards for ice skating arenas, followed by Rhode Island and Massachusetts. Washington state, following an initiative to specify low-emission office furnishings for a new state office building, proposed new statewide requirements for ventilation, inspection, and maintenance to improve IAQ. Quite recently, New York City's Department of Design and Construction has issued guidelines for the design and construction of high-performance buildings that include many IAQ-enhancing features (New York City Department of Design and Construction 1999).

From within the industry there are numerous activities addressing various aspects of IAQ. Industrial associations, like the North American Insulation Manufacturers Association, the National Association of Home Builders, BOMA, and Sheet Metal and Air Conditioning Contractors National Association, among others, are also becoming increasingly involved in the IAQ aspects of building design (www.naima.net, www.nahb.org, www.boma.org, www.smacna.org, www.paint.org, www.acgih.org). The American Society of Heating, Refrigerating, and Air Conditioning Engineers, Inc. (ASHRAE) has recently revised its Standard 62-1999, Ventilation for Acceptable Indoor Air Quality. This latest version of "model" ventilation standards distinguishes between human-generated contaminants and nonhuman sources. ASHRAE is struggling to accommodate the conflicting objectives of reducing energy use (lower ventilation), while simultaneously maintaining an acceptable IAQ (increasing ventilation). Prescriptive codes requiring the calculation of source strength and dilution to achieve target concentrations will never work to the satisfaction of heterogeneous occupants, particularly given the scientific uncertainties about the effects of mixtures and mechanisms leading to sensitization, hormonal disruption, or carcinogenicity. Performance-based concepts for ventilation standards that acknowledge the primacy of healthy indoor air will prevail in the twenty-first century, especially as linkages between healthy building design and business profitability become increasingly apparent (Fisk and Rosenfeld 1997; Wargocki et al. 1999, 2000; Lagercrantz et al. 2000).

Guidance for Building Systems

Among the first to explore the relationship between occupant complaints and building conditions was the work of Black and Milroy on air-conditioned offices in 1966. Concern about IAQ grew throughout the 1970s with the emergence of sealed buildings and pressures to reduce energy. By the early 1980s, the prevalence of building-related problems had most researchers agreeing there was a phenomenon that is now called “sick building syndrome” (SBS). A working group of experts for WHO in 1982 provided a definition describing SBS. By the mid-1980s, Akimenko et al. (1986), reporting on another WHO international expert group, estimated that “up to 30 percent of new or re-modeled buildings may have an unusually high rate of complaints.” The report acknowledges between-country variability and the somewhat arbitrary definition of what constitutes building-related complaints. By this time, investigators in the United Kingdom, Denmark, and Sweden had begun systematic studies on the prevalence of symptoms among office workers and the possible relationship between design, mechanical, managerial, and environmental factors. Mendell (1993) reviewed these and other studies in an attempt to identify common identifying factors. Howard Brightman and Nanette Moss in Chapter 3 summarize the findings of these early studies involving multiple buildings and extend the review to the important European and U.S. studies of the late 1990s.

One tautology is that IAQ problems are a consequence of the energy crisis and the subsequent tightening of buildings to reduce infiltration. Although it is true that ASHRAE revised ventilation guidelines suggesting that 5 cfm/person did contribute to poor IAQ in some instances, the more significant influences have occurred over the last 40 years as basic envelope systems transitioned from heavy site-built construction to lightweight pre-manufactured systems. Many of the materials and systems used in older construction were more forgiving of variations in temperature and humidity, and they often acted as filters or sponges for absorbing contaminants. Today’s lightweight systems with their gaskets, seals, and tight tolerances are intended to function as a barrier to both indoor and outdoor conditions rather than as a floating filter permeable to moisture and gaseous compounds. As a result, these systems not only tend to exacerbate the precursor conditions for poor air quality, but also have resulted in a reduction of the sink area for contaminant absorption. These impervious surfaces are then covered with a wide array of nonnatural finish products (synthetic fiber carpets, vinyl wall coverings, and plastic moldings) that are glued in place rather than mechanically fastened. The unforgiving envelope is now sealing in complex chemical formulations, many of which we have little experience with. The chemical composition of our modern interior environment is substantially different from that of the first half of this century.

As a different mix of pollutants is accumulating in our interiors, the quality and quantity of the supply air has also been degrading (Brown et al. 1994). The proliferation of information technology into even the smallest businesses has resulted in the ceding of infrastructure space to electronic communication. Ceiling plenums are quickly being filled with cables, adding outgasing sources while reducing the airflow area. Duct liners, which are steadily replacing external duct insulation, result in supply air exposure to large surface areas of synthetic and occasionally friable materials. These changes are coupled with the general shift in HVAC systems from constant air volume (CAV) to variable air volume (VAV), which was spawned by the energy crisis of the 1970s. VAV systems are more energy-efficient precisely because of an overall reduction in supply air. Less dilution and absorption of contaminants is taking place, while contaminant generation is increasing.

This unforgiving combination of materials and systems has then been increasingly deployed in speculative construction for which the interiors must be more flexible to accommodate a greater range of possible functions. Unprecedented, and often irreconcilable, many contemporary building systems combine activities that have historically been

separate. For instance, shopping malls may have ice-skating rinks as features, and the routine of cleaning ice with gasoline- or propane-powered machines introduces nitrogen dioxide and carbon monoxide into the air. Small dental clinics may be located inside high-rise office towers, introducing a variety of controlled chemicals with rigorous ventilation requirements into a building that is ill-equipped to support such specific needs. The trend toward light manufacturing and small biotech laboratories has resulted in these functions being distributed into office-like environments. More widespread, however, is the reconfiguration of today's standard office environment arising from the proliferation of information technology. With its computers, copiers, and printers, the typical office resembles a traditional manufacturing facility in terms of thermal and environmental conditions. The heat generated from personal computers alone is estimated to contribute more than half of a building's total heat gain.⁵ HVAC systems designed for generic office spaces can no longer meet the varying and complex demands posed by new occupancy types.

Interior fit-outs in speculative construction, particularly to support the trend toward smaller tenants with high turnover, have capitalized on finish materials to provide the visible amenities desired by these new occupants. Rapidly entering the market are a wide variety of composite surface materials and wall systems, as well as the new trend for integrated office furniture, that attempt to meet several different criteria within a single unit. Surface texture and finish for the client's amenity will often be coupled with insulation for thermal and acoustic purposes and then further stiffened to allow installation as a stand-alone partition. These combinations of materials often introduce new problems; for example, a common combination mates impervious surface materials with cellulose backing, creating ideal breeding grounds for molds and fungi. Of even greater concern is the chemical interactivity between these sandwiches of foams, adhesives, plastics, and fabric. Fleeced and porous surfaces in offices have most certainly increased over the last 2 decades, with fabric-covered partitions and acoustical ceiling tiles. Levin (1987) states that large amounts of surfaces in office buildings never get cleaned. Free-standing partitions are more than 3 times the floor area.

Unducted air supply often uses the ceiling space as a plenum. The surface area in contact with air can be twice the floor area. These surfaces may include unfinished wallboard, fireproofing, fiberglass, acoustical insulation, power and communication cables, and the top sides of ceiling tiles. While there is some experience with the individual materials, there is limited knowledge of how emissions from many materials may interact with each other in our interior environments.

The American Institute of Architects provides a reference, the *Environmental Resource Guide*, to assist designers and specify various building materials (www.aiaonline.org). This guide, while useful, does not provide specific recommendations, nor does it propose a methodology for selecting among a variety of manufactured products. Other schema are under development. The National Paint and Coatings Association (www.paint.org) offers a Hazard Material Identification System (HMIS) developed for shipping, fire fighting, and emergency spill response, modified for IAQ application. The American Conference of Governmental Industrial Hygienists (www.acgih.org) has a formula for assigning a threshold limit value for chemical mixtures. With modification to reflect product formulation from material safety data sheets (MSDSs) (OSHA 29 CFR 1910.1200), a hazard index for a specific product is obtained.

Currently, there is no widely applicable procedure for evaluating the IAQ potential of products, or the combination of materials and systems in operation. The physical/chemical complexities of emissions from composite materials, sinks, and reemission from furnishings, floor, wall, and ceiling components, as well as in plenums and ducts, challenge the

⁵Personal computer power wattage has increased with computational capacity, where 100 to 400 watts might be typical of office PCs today.

formulation of a simple discriminating selection scheme. The typical construction practices in the United States almost ensure that these complex issues will not be addressed beyond the simplistic specification to use low-emission paints. Although substantial progress has been made to characterize emissions from building products, paints and equipment, predictive models reflecting complexity of interactions, variability and human response lags behind (ECA-IAQ 1997; Chang 1999; Brown 1999).

5.3 THE BUILDING CONSTRUCTION PROCESS

The process by which buildings are actually constructed can contribute to the indoor air quality problems, arising in part by the separation of responsibility among professions participating in the design and build teams. Financing and bidding constraints can also contribute to lack of construction quality resulting in buildings that simply do not perform well. In 1995, the American Thoracic Society, Medical Section of the American Lung Association, assembled an interdisciplinary group to assess the underlying causes of poor IAQ (American Thoracic Society 1995). Participating in the Santa Fe workshop were architects, HVAC engineers, contractors, physicians, and industrial hygienists, among others. The process of designing, bidding, and building structures, and the role this played in the etiology of SBS was evaluated. It was concluded that the common design/bid/build system and its variants in the United States had a high likelihood of contributing to the problem.

The design/construction teams are not necessarily interactive. Each has distinct responsibilities with different financial arrangements, and each participates in only part of the project. Prime architects and general contractors rely on subcontractors hired usually on the basis of the low bid. Further, contractors make most of their profits on *change orders*. Change orders occur under several circumstances, including improper or inadequate plans and specifications. With the *design/build* approach, the architectural and design professionals usually work for the construction firm. The construction company has an interest in containing costs by reducing the customization. Components such as HVAC systems have been standardized and repeatedly used for buildings constructed in different climate zones. To operate properly, the emerging, more sophisticated HVAC systems and control systems require more competence in design and construction. Large firms do not innovate quickly in part because it requires more expensive professional staff in building component design. On-site construction work is generally managed by the lead firm, but performed by subcontractors. Here again, the incentives are misplaced and deficiencies in some aspects of the building jeopardize performance in other areas. Even when high-performance systems are designed, they may operate suboptimally because of poor-quality construction.

The preceding discussion, although lengthy, was necessary to convey that improved IAQ cannot be achieved by directing attention only on sources or ventilation. In some sense, SBS is symptomatic of a complex system involving manufactured materials, construction practices, and legal and financial constraints, as well as human susceptibility, perceptions, and behaviors. This chapter alone cannot address all these aspects. Instead, we discuss one class of indoor contaminants, volatile organic compounds (VOCs), and various strategies to deal with them. We assert that there are tools (models) available to assess the consequences of sources and various ventilation designs. Further, these models can be used to predict thermal, moisture, and contaminant conditions inside buildings. The implication of architectural features (e.g. atria, windows, parking garages, loading docks, etc.), material specifications, and ventilation design on air quality can be known long before occupancy. With the tools described, along with others addressing moisture, air, and thermal transfer through building envelopes, as well as lighting and acoustics, it is now possible to predict various IAQ-related aspects of building performance.

Designing high-performance buildings that provide healthful indoor environmental conditions will come to rely more on sophisticated source-ventilation models. So too, product “ecolabeling” and “building green” certification protocols will eventually increase the effectiveness of the predictive aspects of these models.

5.4 HEALTHY BUILDING DESIGN

There have been many attempts recently to describe the attributes and process for achieving green buildings. The design, construction, and use stages as well as the functional components of buildings, from the envelope to furnishings, have been addressed quite comprehensively in books and guidelines (New York City Department of Design and Construction 1999; Wilson et al. 1998). Table 5.1 reflects the standard list of design issues encountered in most building developments. Here, we annotated the relationship of these decisions to potential IAQ issues. The list demonstrates the point that a designer has a myriad of choices that will potentially contribute to IAQ through either the location and strength of sources or the ventilation component that influences exposure pathways and dilution.

Contaminant Sources

Table 5.2 is a partial list of chemical sources found indoors. Specification of coatings, adhesives, surface finishing, and furnishings is among a few actions used by architects determining the mixture of compounds and the frequency and rates of their emissions. However, for many other building materials, finishings, furnishings, and cleaners, information about chemical composition and emissions are less well known and beyond the architect’s reasonable ability to specify acceptable alternatives. Phthalates and PCBs, for instance, are a class of compounds and/or endocrine disruptors. Ruthann Rudel in Chap. 34 summarizes the literature on these compounds, indicating substantial indoor exposures.

Pesticides are widely used indoors or around the outside of homes. In either circumstance, elevated levels are reported indoors in a review by Robert Lewis (see Chap. 35). The use of pesticides decided on by the homeowner or facility manager and is not subject to design review. Similarly, decisions about cleaning services and specific cleaning materials determine chemical loading indoors. Cleaning compounds introduced indoors are becoming more recognized for potential contribution to occupant symptoms. Adverse outcomes include adult onset asthma and acute irritation of the eyes and the respiratory tract (McCoach et al. 1999, Kreiss et al. 1982, Wolkoff et al. 1998). Suspected is acquired sensitization to the various ingredients and the reaction products formed when citric-based solvents react with ozone (Weschler and Shield 1997, Weschler et al. 1992, Wolkoff et al. 1999). The reactions of ozone with unsaturated hydrocarbons common in citrus-based cleaners, or added for scent to many consumer products, is just a recent example of how complex indoor air chemistry is, and of unanticipated changes to IAQ from new formulations, new products, or equipment.

The next section discusses modeling indoor VOC emission sources. These models will eventually be improved and coupled to ventilation models to predict indoor concentrations. Until then, “green building” recommendations suggest avoiding VOC emitting sources or substituting materials with lower VOC emissions. We cannot expect architects, unfamiliar with the health literature and product testing protocols, to understand the subtle nuances behind product claims. When chamber tests are used to evaluate offgassing emission rates, usually the values are expressed as total VOC or are compound-specific (e.g., formalde-

TABLE 5.1 Building Components Potentially Affecting IAQ

Planning and construction	Potential contributors to IAQ
Siting	• Traffic, parking • Upwind sources or change of airflow • Soil emissions of radon • Moisture/drainage
Building envelope	• Moisture intrusions • Cooling/heating loads affecting dilution, condensation (if cooling capacity is overdesigned) • Unintended infiltration of untreated air
Waste services loading dock entrances served by vehicles (hotels, emergency rooms, convention/recreational centers, schools)	• Odors from waste and diesel service trucks drawn in through loading dock and/or window vents • Particle intake and possible health risk (e.g., soot)
HVAC system Plumbing system Electrical systems	• Filters, condensation traps, wet insulation, dirty return air ducts as sources of odor, microbiologicals • Air intakes, venting, potential of reentrainment • Operating set points can cause cool surfaces and unwanted condensation • Unintended pathways • Sweaty and leaking pipes, valves, joints, gaskets provide moisture leading to material damage and microbiological growth • Electromagnetic fields causing interference to equipment (e.g., computers), exposures, and noise.
Sanitation vents, kitchen exhausts, fume hoods, cooling towers	• Potential chemical biological exposures to workers on roof or to pedestrians around building • Entrainment into air intakes of present and neighboring buildings
Communications	• Excessive wiring in ceiling space restricts repairs, offgasses VOCs • Wire, drainage, pipe chase provide unwanted pathways for airflow • Electromagnetic exposures near antennae
Materials used for internal finishings, furnishings, equipment, and cleaning	• Sources of VOC, aldehydes, phthalates, and particles • Sources of nutrients for microorganisms

hyde). Interpreting results requires knowledge about test protocols (De Bortoli et al. 1995; American Society for Testing and Materials 1997).

Manufacturers reformulating products to test “environmentally friendly” may lower the total VOC emissions in the short-term test by substituting longer-chained hydrocarbons. Cometto-Muñiz and Cain (1992) and Cometto-Muñiz et al. (1998) show that, within families of organic compounds (i.e., acetates, ketones, alkylbenzenes, aldehydes), more carbon atoms usually translate to an increased odor and irritation potential. These larger molecules generally have lower vapor pressures, but continue to offgas over long periods of time. Hence, focusing only on the short-term total volatility may have a perverse effect by making indoor environments worse.

TABLE 5.2 Indoor Sources of Selected VOCs

VOC	Possible sources
Acetaldehyde	Perfumes, dyes, tobacco smoke
Benzaldehyde	Fiberboard, particleboard
Benzene	Adhesives, spot cleaners, paint removers, particleboard, tobacco smoke, silicone caulk, gasoline, fuel combustion
Carbon tetrachloride	Grease cleaners
Chloroform	Chlorinated water
<i>p</i> -Dichlorobenzene	Deodorizers, moth crystals
Ethylbenzene	Floor/wall coverings, insulation foam, chipboard, fiberboard, caulking, adhesives, lacquer, grease cleaners
Formaldehyde	Plywood, particleboard, fiberboard, chipboard, gypsum board, urea foam insulation, carpets, linoleum, upholstery, latex-backed fabric, new clothing, wallpaper, fiberglass, gas space heaters, range-top gas burners, gas ovens, caulking, floor varnish, floor lacquer, adhesives, tobacco smoke
Methylene chloride	Paint remover, aerosol finishers
Styrene	Plastics, paints
Tetrachloroethylene	Dry-cleaned fabrics/ upholstery
Toluene	Adhesives, edge-sealing, molding tape wallpaper, floor coverings, silicone caulk, paint, chipboard, linoleum, kerosene heaters, tobacco smoke
1,1,1-Trichloroethane	Dry-cleaned fabrics/upholstery
Trichloroethylene	Paints and varnishes, degreasing, dry-cleaned materials
Xylenes	Adhesives, wallpaper, caulking, floor coverings, floor lacquer, grease cleaners, tobacco smoke, varnish, kerosene heaters

Modeling Indoor VOC Emission Sources

Quantifying the VOC emissions from the building materials and furnishings is both challenging and important, because the emissions account for a major part of the indoor pollutants (De Bellis et al. 1995). To design a healthy indoor environment, one requires accurate VOC emission models.

At present, most models for building materials assume that emissions are exclusively dominated by internal diffusion. These models, called *diffusion models*, use Fick's law to solve VOC diffusions in a solid under simple initial and boundary conditions. For example, Dunn (1987) calculated diffusion-controlled compound emissions from a semi-infinite source. Little et al. (1994) simulated the VOC emissions from new carpets on the assumption that the VOCs originate predominately in a uniform slab of polymer backing material. These models, though based on the sound mass transfer mechanisms of the VOC species, still have limitations. They presume that the only mass transfer mechanism is the diffusion through the source material. The models neglect the mass transfer resistance through the air phase boundary layer, and also the air phase concentration of emissions. Although this may be true for some building materials, the assumption as a general one has not been well justified. The models also tend to solve the VOC diffusion problem analytically, assuming a one-dimensional diffusion process with a simple boundary and initial conditions. In practice, emissions can be three-dimensional with complicated initial and boundary conditions.

Recently, Yang et al. (1998) developed a numerical model with the following four parameters—initial VOC concentrations in the material, a solid-phase diffusion coefficient, a material-air partition coefficient, and the age of the material—to predict both short- and long-term emissions. The model can predict the VOC emissions, if those four parameters

are known. Since there are thousands of products on the market, it is not easy to obtain the four parameters for most of the products.

In addition to being primary sources of emissions, building materials can also affect the transport and removal of indoor VOCs by sorption (adsorption and desorption) on the interior surface. The reemission of adsorbed VOCs from building materials can elevate VOC concentrations in the indoor environment (Tichenor et al. 1988, Berglund et al. 1988). Materials capable of depositing, adsorbing, and/or accumulating pollutants can influence the IAQ during the entire service life of a building (Nielsen 1987). A low-emitting material at the beginning does not necessarily mean a clean one, because the material may emit a large amount of VOC over its useful life. Therefore, prediction of IAQ must take sorption into account.

All sorption models can be generally classified into two classes (Guo 1993): statistical models and theoretical models. The classification is based on different understandings and assumptions regarding sorption. Statistical models view sorption as a two-way process in which the adsorption and desorption processes occur simultaneously and the interface between the air and the material is not always at equilibrium. In contrast, theoretical models always assume sorption as an instantaneous process and the interface between the air and the material is always at equilibrium. Hence, statistical models focus on the kinetics of the sorption process, whereas theoretical models focus on the overall effect, ignoring the kinetics of the sorption process.

A major shortcoming of statistical models lies in the fact that they have to obtain multiple model parameters by curve fitting (nonlinear regression) with measured data, often from a small test chamber. Though the principles of the models are reasonable, the model parameters that are obtained from curve fitting may not represent what is intended. Furthermore, they may not be generalizable. The other problem with this kind of curve fitting method is that it is difficult to validate the model. For example, the sorption-diffusion hybrid model (Dunn 1993) has some problems with the boundary condition, however, the model can still fit the experimental data well.

In contrast, theoretical models are more reliable, in that they can be validated. The model parameters have solid physical significance and can be measured *directly* from experiments, thereby eliminating the problem of curve fitting. The numerical model proposed by Yang et al. (1998) can consider both the transport of VOCs in the room and the diffusion of VOCs inside the materials. It can predict the VOC concentration reasonably well solely on the basis of the material and compound properties, without resorting to expensive sorption measurements. Therefore, the numerical model has predictive capabilities. The disadvantage of this model is that it can be used only for homogeneous materials.

Given the complexity of indoor sources and the modeling limitations, quantifying the source strength for many indoor contaminants is not a straightforward task. There are still uncertainties in obtaining reliable data from contaminant sources, and more research in this area is needed.

Source Elimination

Even without the quantitative source information, it is still possible to design a healthy building through proper control of the indoor contaminants. The control strategies are to reduce the concentration of the contaminant in an indoor space below the threshold defined by standards and codes. Unfortunately, there are very few recognized indoor air quality standards. Applying ambient air standards from the United States, WHO, or elsewhere covers very few chemical compounds (less than 50).⁶ There is no guidance from recognized

⁶WHO European Air Quality Guidelines from Copenhagen have been recently reviewed and updated (WHO 1999). U.S. EPA National Ambient Air Quality Standards cover SO₂, NO₂, CO, O₃, Pb, and particulate matter.

authorities for hundreds of chemicals. Even for those known or suspected to be human carcinogens, an “acceptable” level of indoor risk has not been established. Often occupants or parents of school children invoke the “precautionary principle” on a compound-specific basis, requiring levels to be below detection limits, or essentially removed from indoor environments.

Professional microbiologists have resisted sanctioning guidelines for airborne fungal counts (Yang et al. 1998). Short of identifying and removing specific organisms (e.g., *Aspergillus*, *Stachybotris*, *Penicillium*, and others), the absence of hard evidence associating exposure to health risk precludes setting guidelines. The same limitation extends to glucans and endotoxin. In the biological context, only cat and mite allergens have guidelines for comparing measurements.

The lack of IAQ standards for microbiological components limits assessing the degree of hazard for occupants. Even if such standards existed, however, they could not be used in predictive models. Emission rates for spores, bacteria, allergens, and endotoxin are completely unknown. By comparison, VOC modeling is relatively advanced.

Essentially, there are three control strategies used to improve the IAQ in a building (ASHRAE 1999): source elimination, local source control, and dilution of the indoor contaminants by ventilation. Hadlich and Grimsrud (1999) also recommend the three control strategies for residential buildings.

Source elimination is the most effective and often the least expensive method to improve IAQ. For example, prohibition and isolation of smoking can greatly reduce indoor pollution (Lee et al. 1986). Source elimination may also be achieved through control of environmental parameters, such as temperature and relative humidity. For instance, VOC emissions and sorption are related to temperature and relative humidity. Similarly, conditions that regulate fungal growth depend on temperature and moisture conditions of materials and nutrients. Source elimination can also be achieved by using an alternative product. Products treated with sealants and/or antimicrobial coatings (e.g., silver) can also lower or eliminate sources. This approach is especially effective for building materials, because building materials are major indoor pollutant sources. To modify Levin’s (1999) suggestions, building material characteristics ideal for better IAQ include durability, hard smooth surfaces, long service life with clean nontoxic materials, low VOC emissions, low moisture content, low moisture absorptivity, and low toxic chemical and fiber content.

Local Source Control

In addition to source elimination control, local source control is also very effective. This technique limits pollutant transport within a building. In chemical and biological laboratories, the use of fume hoods to exhaust toxic and hazardous gases, after filtration, to the outdoors is essential. Even office spaces can benefit from local exhaust. For example, local exhaust systems can be installed in spaces with copiers and printers. This would reduce the risk of the pollutant transport and dispersion from the sources to the other part of the building. In residential buildings, the use of exhaust systems in kitchens and bathrooms are also preferred design features to improve IAQ.

Dilution of Indoor Contaminants by Ventilation

Another commonly used control strategy is dilution of the indoor contaminants by ventilation, defined by ASHRAE as “the process of supplying or removing air by natural or mechanical means to or from any space.” Ventilation systems are used to maintain a good thermal comfort level and acceptable IAQ in an indoor environment, at a reasonable cost.

Today, although IAQ attracts more and more attention, thermal comfort is still the major concern of the HVAC industry.

The major parameters that have an impact on thermal comfort are air temperature, relative humidity, air velocity, and environment temperature. Other parameters, such as turbulence intensity and radiant temperature asymmetry, are also important to thermal comfort. To design a thermally comfortable indoor environment, the comfort parameters should fall within a tolerable range. The most commonly used standard for thermal comfort design is ASHRAE Standard 55-1992. The standard stipulates an operative air temperature between 20 and 27°C and a relative humidity between 30 and 60 percent. The temperature varies with different seasons, the clothing level, and the metabolism of occupants.

By design, the ventilation should be sufficient to dilute the contaminant sources so that the concentrations of the contaminants will be below the thresholds. There are two ways to achieve ventilation in a building: natural ventilation and mechanical ventilation.

Natural ventilation has two components: daytime ventilation and nighttime cooling. Daytime ventilation is the most common natural ventilation system. The system uses outdoor air during daytime to remove the heat gains and contaminants indoors in a way shown in Figure 5.2*a*. The system increases the occupants' thermal comfort by increasing convective and evaporative heat transfer between the occupants and the room air. The maximum indoor air velocity is approximately 2 m/s (Givoni 1998). If the outside temperature is high, the indoor air temperature will then be too high to be acceptable for the occupants. This system works better in climates with a mild summer.

Nighttime cooling uses cooler outdoor air during the night to cool the building thermal mass (building internal partitions and structure) and to flush out indoor contaminants. The thermal mass functions as a heat sink during the day, absorbing the internal heat gains. Figure 5.2*b* and *c* shows the operation principles of night cooling. In order to reduce the heat gains due to ventilation during the day, the windows should be kept closed. In this period, infiltration should provide sufficient fresh air for an acceptable IAQ. The lower the outdoor air temperature during the night, the more effective the night cooling system. This system works better for a climate with a minimum temperature below 22°C during the night.

Compared to mechanical ventilation systems, natural ventilation systems consume little energy, require little maintenance, have low first costs, and are environmentally friendly. Occupants can expect a high air temperature in naturally ventilated buildings in summer, compared with that in the mechanical ventilated buildings. Busch (1992) conducted thermal comfort surveys in Bangkok offices. He divided more than 1100 Bangkok office workers into two groups: one acclimatized to air-conditioned offices and the other to a naturally ventilated office. The study found that, on the basis of 80 percent satisfied workers, the acceptable effective temperature is 28°C in the air-conditioned buildings, and 31°C in the naturally ventilated buildings. Comparing the responses from the naturally ventilated buildings with those from the air-conditioned buildings provides convincing evidence of

FIGURE 5.2 Principle of daytime ventilation (*a*) and nighttime cooling (*b* and *c*). (*a*) Outdoor air removes the heat gained indoor, (*b*) outdoor air cools the thermal mass during the night, and (*c*) the thermal mass absorbs heat during the day.

acclimatization. If a building is designed to use natural ventilation, the period of air conditioning use can be significantly reduced because of the high acceptable temperature. This has a major impact on the building energy consumption and first costs.

Because natural ventilation generally provides a larger amount of fresh air than mechanical ventilation, the increased air supply would improve IAQ, provided the outside air were clean. The United States has a great potential to use natural ventilation. This is shown in Table 5.3, in which the U.S. climate is divided into 17 regions (Lechner 1992). In many regions, no air-conditioning system is needed during the summer with proper natural ventilation.

It should be noted that natural ventilation could be used where outdoor air quality would be acceptable as indoor air. It is almost impossible to filter outdoor air in naturally ventilated buildings. However, passive diffusion of gases and particles, along with ultraviolet catalytic irradiation, could clean outdoor air substantially without imposing a significant pressure drop.

However, it is not easy to design and control natural ventilation. Natural ventilation is related to wind speed and direction, building shape and density, surrounding landscape and buildings, thermal conditions in and around buildings, window size and location, and the internal spatial arrangement in a building. Outdoor noise can easily be transferred into the indoors with natural ventilation. In a hot and cold climate, natural ventilation alone cannot provide an acceptable thermal comfort level indoors. Therefore, the use of mechanical ventilation is inevitable.

Mechanical ventilation can be classified into mixing, displacement, and localized ventilation systems.

Mixing ventilation is the most popular system in the United States. In mixing systems, conditioned air is normally supplied from air diffusers at a high velocity with a suitable temperature for heating or cooling. The diffuser jet mixes the conditioned air with the ambient room air through entrainment. Thus, the air velocity is reduced and the temperature will become close to the room air temperature. At the same time, the conditioned air dilutes the contaminant concentrations in the indoor space.

ASHRAE (1997) has classified the mixing ventilation system into four groups:

- Conditioned air is discharged horizontally at or near the ceiling (Fig. 5.3*a* and *b*)
- Conditioned air is discharged vertically at or near the floor (Fig. 5.3*c*)
- Conditioned air is discharged horizontally at or near the floor
- Conditioned air is discharged vertically at or near the ceiling (Fig. 5.3*d*)

Figure 5.3 shows the airflow pattern in a typical section in an office. These patterns do not reflect the presence or movement of persons or objects within the workspace, and the turbulent flow they generate. Thousands of air diffusers can be used to achieve the airflow pattern. However, in the most effective scenario, mixing ventilation creates relatively uniform contaminant concentrations in the occupied zone. Ventilation effectiveness, defined as the ratio of exhaust concentration to concentration in the occupied zone, can reach a maximum value of only 1.0, one that is not very high. Other forms of ventilation (e.g., displacement) can have ratios of 1.3 or higher.

Displacement ventilation has been used quite commonly in Scandinavia during the past 20 years. It has been increasingly used in Scandinavia as a means of ventilation in industrial facilities to provide good IAQ while saving energy. More recently, its use has been extended to ventilation in offices and other commercial spaces where, in addition to IAQ, comfort is an important consideration. In the Nordic countries in 1989, it was estimated that displacement ventilation accounted for a 50 percent market share in industrial applications and a 25 percent market share in office applications (Svensson 1989).

A typical displacement ventilation system, as shown in Fig. 5.4, supplies conditioned air from a low sidewall diffuser. The supply air temperature is slightly lower than the

The velocity in the upper-left corner of (a) and upper-right corner of (c) are large so that the arrows are very long. However, they do not imply the flow is going through the ceiling.)

FIGURE 5.4 A typical displacement ventilation system.

desired room air temperature and the supply air velocity is low (lower than 0.5 m/s). Through the diffuser, the conditioned air is introduced directly to the occupied zone, where the occupants stay. Exhausts are located at or close to the ceiling through which the warm room air is exhausted from the room. Because it is cooler than the room air, the supply air is spread over the floor and then rises as it is heated by the heat sources in the occupied zone. These heat sources (e.g., persons and computers) create upward convective flows in the form of thermal plumes. The plumes remove heat and contaminants that are less dense than the air from the surrounding occupied zone. When properly designed, displacement ventilation can take advantage of the thermal plumes to carry away contaminants, and thus can increase the ventilation efficiency. If the indoor space needs heating, a separate heating system, such as baseboard heaters, can be used.

Traditionally, the amount of supply air in a displacement ventilation system has been less than that of the mixing-type systems. This necessitates a careful design of the system configuration and operation to adequately handle the space cooling loads. The supply air temperature, velocity, and vertical temperature gradient in the occupied zone are all very important, comfort-related design parameters. However, one must comply with the specification of ASHRAE Standard 55-1992 for an acceptable vertical temperature difference in the occupied zone. This places limitations on the magnitudes of the temperature difference between supply air and room air. It also places limitations on the space cooling loads for a given supply airflow rate. This is especially important when the system is applied to a building in the United States, in which the cooling load can be high and the weather can be hot. Yuan et al. (1999) have developed a design guide for displacement ventilation systems in U.S. buildings.

The third type of ventilation system is localized ventilation. A localized ventilation system supplies conditioned air to areas close to the building occupants. The system creates a microclimate (local area) within a macroclimate (entire indoor space). The building occupants can regulate the air supply device to achieve a desired thermal comfort and IAQ level. Localized ventilation systems have a higher air supply volume, higher supply velocity, and smaller diffusers than the displacement ventilation systems (ASHRAE 1997). An attractive localized ventilation system is a task-conditioning system (Bauman and Arens 1996).

Ventilation Rate and Energy Efficiency

In addition to the ventilation system type, ventilation rate is crucial to IAQ. Before the energy crisis in the 1970s, the ventilation rate was generally large and the IAQ problems were not as severe as today. Fisk (2000) found that, with a doubling of minimum ventilation rates, building energy use would increase modestly (e.g., 5 percent) in most buildings except in schools (e.g., 10 to 20 percent) because of a high occupant density. In general, energy used to heat or cool ventilation air is a small portion of total building energy consumption. Fisk (2000) suggested increasing the ventilation rate because of a strong correlation between ventilation rate and productivity. In most nonindustrial workplaces, the costs of salaries and benefits exceed energy costs, maintenance costs, and annualized construction costs or rent by a large factor, e.g., 100 (Woods 1989).

5.5 TOOLS FOR DESIGNING VENTILATION

Increased awareness of the potential health risks associated with indoor air pollutants (Nero 1988, Morris 1986, Brundage et al. 1988) has stimulated interest in improving our understanding of how ventilation air is distributed and how pollutants are transported in buildings.

Pollutant transportation and distribution depend in general on the ventilation system, building geometry, pollutant source characteristics, and thermal/fluid boundary conditions, such as the flow rate, locations of supply outlets and return inlets, and diffuser characteristics. The task of predicting the pollutant transport by ventilation systems is not a simple one. For a certain kind of building geometry and pollutant source, IAQ may be improved by increasing the ventilation rate. However, the increase of ventilation results in higher energy consumption and sometimes increases equipment cost. Although recirculated air and air treatment devices can be used, they may not be economically feasible.

In addition to energy consumption and the first costs, a good ventilation system can be evaluated by the indoor environmental parameters, such as the distributions of contaminant concentrations, air velocity, air temperature, relative humidity, and turbulence intensity. Another important parameter for evaluating the performance of a ventilation system is the mean age of air. The mean age of air is defined as the averaged time for all air molecules to travel from the supply device to that certain point. The younger the mean age of air, the fresher the air. Ventilation effectiveness is also widely used to evaluate the ventilation system performance. Many definitions have been used to describe how effectively the ventilation system removes the contaminant from the space. The most original definition was from Sandberg and Sjöberg (1983).

The air distribution by ventilation in building interiors is complicated by the geometry of the interiors. Partitions, furniture, and passageways between indoor spaces all distort the airflow. The air motion in the building may be a strong function of the air velocity (kinetic energy) as it enters. This, in turn, may be a function of the wind flow pattern around the outside of the building or the variability of the fan controls for the mechanical ventilation system. In many building interiors, the airflow may be strongly influenced by buoyancy effects: light hotter air moving up and cooler air moving down. The temperature pattern of the air will change with the temperature of the air delivered by mechanical systems. Equally important may be solar energy entering through windows and temperature patterns on walls due to external weather conditions.

IAQ problems may involve the multiple areas in a building, where the problems can be attributed to the transfer of ventilation air carrying pollutants from one indoor space to another. This interspace transfer may be set up by the ventilation system, but most likely, it also involves the exchange of air between different rooms and public spaces in the building. At this level of understanding, a first approximation to the air and pollutant flows may be gained by assuming the gases in each room are well mixed. The flow between rooms is represented as a simple flow resistance between two elements at different pressures. The pressures and driving flows may be set up by the mechanical ventilation systems, the wind-driven flows from the outside, and the buoyancy-driven flows, or a combination of all three.

In many cases, this level of understanding is insufficient to deal with the building design or to solve an existing IAQ problem. The air circulation pattern within an individual space must be understood. The circulation pattern within one space may influence the exchange between neighboring spaces as well as the overall flow for the building.

Two approaches are available for the study of IAQ problems—experimental investigation and computer simulation. In principle, direct measurements of the building interior give the most realistic information concerning the IAQ. Because of the nonuniform distributions of the flow and pollutant, measurements must be made at many locations. Taking direct measurements of the air velocity, flow direction, contaminant concentrations, and the air temperature at many locations is very expensive and time-consuming. Furthermore, to obtain conclusive results, the airflow and temperature from the ventilation systems and the temperatures of room enclosures should be maintained unchanged during the experiment. This is especially difficult because, as outdoor conditions change, they cause the temperatures of the room enclosures and the airflow and air temperature from the ventilation systems to vary with time. For proposed building designs, direct measurements from previous

buildings can be misleading. Some information can be gained by experiments carried out on scaled-down models.

An environmental chamber may be used to simulate IAQ, for it completely isolates the measured system from the external world. Such an environmental chamber, with necessary equipment for measuring air velocity, temperature, relative humidity, and contaminant concentrations, costs more than \$300,000. Also, complete measurements are tedious, time-consuming, and costly. This technique is not an efficient way to examine a variety of designs or conditions. Furthermore, it may not be easy to change from one spatial configuration to another in such an environmental chamber. The experimental approach is still used since it is considered most reliable. In many cases, the parameters are normally measured at only a few points in a space.

Computational Tools

The computational approach, based on computational fluid dynamics (CFD), is used more often than the experimental approach to study IAQ problems. It consists of computing numerical solutions of the flow behavior with a computer. CFD involves the solutions of the equations that govern the physics of the flow. Because of the limitations of the experimental approach and the increase in the performance and affordability of computers, CFD provides a practical option for computing the airflow and pollutant distributions in buildings. The next section will describe how the problem is formulated for a numerical solution. The succeeding sections will present typical CFD results and describe the future of this technique. Although CFD has become the most popular method of predicting airflow associated with IAQ, it is essential to validate the model results with a few experiments carefully carried out over the range of conditions that are under consideration. Results from CFD techniques that have not been validated should be used with caution.

The flow transport of air and contaminants is governed by the geometry of the space and the forces present to move the material through the space. To deal with this numerically, there are two points of view that could be followed. In the first view, one could follow each packet of gas or particles as it moves around the space, like following billiard balls as they collide and move around a table. This turns out to be impractical for airflows in a room, since the packets divide, mix, and constantly change their location, velocity, and mixture concentration.

A more practical approach is to subdivide the space inside the room into a number of imaginary subvolumes, or elements. The subvolumes usually do not have solid boundaries; rather, they are open to allow gases to flow through their bounding surfaces. Each of the subvolumes has a single temperature associated with it; this is the average temperature of all of its contents. It also has a single concentration of air and other components. Finally, it has a single average velocity, although in this case the velocity components in the two vertical and horizontal directions must be included (to account for the velocity magnitude and its orientation in a three-dimensional room). In the beginning of the CFD problem, the temperature, concentrations of contaminants, and velocity are unknown for most of the subvolumes. The values at the boundaries of the room, let's say at the outlet of a duct or a window, may be known. Similarly, the wall temperatures and the concentration of a pollutant source at its origin may be known. The goal of the CFD program is to find the temperature, concentrations of contaminants, and the velocity throughout the room, for each of the subvolumes. This will reveal the flow patterns and the pollution migration throughout the room.

To produce a solution, the CFD program solves the equations describing the process in the room. Each of the subvolumes involve the conservation of

- Mass
- Energy

- Momentum
- Chemical/biological species

Since each of the equations for the conservation of mass, energy, momentum, and chemical/biological species involves the pressure, temperature, velocity, and chemical/biological concentration of an element and its neighbors, the equations for all of the elements must be solved simultaneously. The smaller the subvolumes, the larger the number of equations that must be solved. For a three-dimensional problem, halving the size of an element's width, length, and height increases the total number of elements by a factor of 8. For fast calculation, the element size should not be too small. On the other hand, the use of a few large elements, each with a single average velocity, temperature, and concentration, may not capture the true pattern of conditions within the space. In fact, it may sometimes lead to a very erroneous overall flow prediction with air moving in a direction opposite to its true value.

The presence of turbulent flow complicates matters, and improper handling of this is one of the prime causes of inaccurate CFD predictions. Turbulent flow, which exists in most room flow situations, involves a mixture of eddies of widely different sizes. To accurately capture the behavior of the smallest eddies would require a very fine subdivision of the space. The computational resources to solve for the flow this way, known as direct numerical simulation, are stupendous. It is not practical with today's computers. Rather, investigators have adopted a number of ways to approximate the turbulent behavior without using very fine subdivisions. The problem with this approach is the absence of a single approximation for turbulent flow that works well in all situations. Techniques developed for predicting high-speed turbulent flow over airplane wings do not necessarily yield good results in large rooms where the buoyancy effect may be important. Although most commercial CFD codes will yield a solution to an IAQ problem, there is no guarantee it is the right solution.

The most common CFD techniques are direct numerical simulation (DNS), large-eddy simulation (LES), and the Reynolds averaged Navier-Stokes (RANS) equations with turbulence models. Each technique handles turbulence in a different manner.

Simulation Techniques

Direct numerical simulation solves the Navier-Stokes equations without approximations. DNS requires a very fine grid resolution to catch the smallest eddies in the flow. An eddy, a small element of flow in an indoor space, is typically 0.1 to 1 mm in size. In order to include the smallest eddies in the flow in the computations, the total grid number for a three-dimensional indoor airflow is around 10^{11} to 10^{12} . Current supercomputers can have a grid resolution as fine as 512^3 , that is around 10^8 . The computer capacity is still far too small to solve such a flow. In addition, the DNS method solves the time-dependent flow with very small time steps to account for eddy breakup and reforming which occurs in a flow that on average is "steady." This makes the calculation extremely time-consuming. DNS for indoor environment simulation is not realistic in the near future.

Large-eddy simulation was developed in the early 1970s by Deardorff (1970) for meteorological applications. He separated turbulent motion into large eddies and small eddies. The theory assumes that the separation between the two does not have a significant effect on the evolution of large eddies. LES accurately solves the large-eddy motion for a three-dimensional, time-dependent flow. Turbulent transport approximations are used for small eddies. The small eddies are modeled independently from the flow geometry, eliminating the need for a very fine spatial grid and short time steps. LES is successful because the main contribution to the turbulent transport comes from the large-eddy motion. LES is also a

more practical technique than DNS. LES can be performed on a large, fast workstation. Figure 5.5*a* and *b* shows an instantaneous flow field around a simple building with single-side natural ventilation, calculated by LES. Thousands of the instantaneous flow images can be averaged to obtain a mean flow, as shown in Fig. 5.5*c* and *d*. For a single-side natural ventilation system design, LES produces the most realistic results. Nevertheless, LES is still too time-consuming because it calculates a time-dependent flow. In addition, such a large, fast workstation is not available in most designers' offices.

The Reynolds averaged Navier-Stokes method is the fastest but maybe the least accurate method. RANS solves the time-averaged Navier-Stokes equations by using approximations to simplify the calculation of the turbulent flow. The approximations can sometimes generate serious problems that will be discussed later. The number of grids used for the simulation with RANS (10^5) is normally much less than that for LES (10^6). Most important, a steady flow can be solved as time-independent flow. Therefore, the computing costs are the cheapest compared to those for LES and DNS. The latest generation of PCs has the speed and capacity to utilize this CFD technique. The CFD method with RANS is a very promising and popular tool for IAQ prediction. The most popular RANS model is the standard k - ϵ model developed by Launder and Spalding (1974). Recently, the RNG k - ϵ model (Yahkot et al. 1992) has become widely used. The computational method can provide informative results inexpensively. Most CFD computations of a three-dimensional indoor airflow and pollutant transport can be done on a PC with 64 MB of memory and a Pentium processor.

Figure 5.6 shows CFD results for a section of an ice rink arena, although the results are available three-dimensionally in the entire space. The results were obtained with the RNG

FIGURE 5.5 Airflow in and around a building with single-side ventilation computed by LES. (a) Instantaneous velocity in a vertical section; (b) instantaneous velocity in a horizontal section; (c) mean velocity in a vertical section; (d) mean velocity in a horizontal section.

FIGURE 5.6 The CFD-computed distributions of (a) airflow, (b) temperature, (c) CO concentration, and (d) the mean age of air at the symmetric section of an ice rink (black = low, dark gray = low moderate, light gray = high moderate, white = high).

k - ϵ turbulence model. Although this model is not universal, the model gives stable and reasonable results for many indoor airflows in buildings such as offices, classrooms, etc. (Chen 1995). In CFD simulations, it is necessary to provide boundary conditions as inputs, such as wall surface temperature and flow characteristics from diffusers. In many cases, experimental measurements or numerical computations with a heat transfer program are necessary to obtain these boundary conditions. In the present study, the fresh, heated outdoor air is supplied from an air diffuser on the upper part of the left wall, as shown in Fig. 5.6a. The warm air can reach to the opposite wall because of its high momentum. Figure 5.6b illustrates a strong thermal stratification in the arena because of the thermal buoyancy from the warm supply air and the cold ice sheet on the floor. The air velocity and temper-

ature distributions provide important information for evaluating the thermal comfort in the space. This particular study assumes a resurfacer produces a certain amount of carbon monoxide when it resurfaces the ice. Figure 5.6c shows the carbon monoxide concentration distribution in the section through the air supply diffuser. Because of the stratified flow, the ventilation system does not effectively deliver the fresh air into the occupied zone on the ice. This ineffectiveness can also be seen from the distribution of the mean age of air (Figure 5.6d). The mean age of the air is oldest on the ice and is very young at the region close to the air diffuser.

With the CFD tool, it is possible to improve the ventilation system design for better indoor air quality. For example, by changing the return exhausts on the upper right wall to the screen wall near the ice sheet, the CFD results indicate that the ventilation effectiveness can be 50 percent higher (Yang et al. 2000).

The two examples indicate that CFD is a powerful tool to study indoor environment (thermal comfort and IAQ). With the tool, different design alternatives can be carefully studied and analyzed with little cost. However, it is very difficult to obtain reliable CFD results since the CFD method uses many approximations and requires good knowledge of fluid dynamics and numerical skill. Because of the development in CFD modeling and computer technology, the CFD tool becomes more and more popular for IAQ and thermal comfort studies.

5.6 CONCLUSION

In the absence of widely accepted definition criteria or consistent guidelines, the concept and definition of a “healthy building” is still evolving. What is known is that IAQ is an important determinant of healthy design. There are numerous factors that lead to the wide acceptance that buildings and their IAQ can adversely impact occupants’ health. Several IAQ design guidance and evaluation tools are in development to advance the state of practice. Evaluating the healthfulness is a particular challenge, given the truly multidisciplinary nature of both the problem and the solution.

Trends in public perception, litigation, current regulations, and new building materials and systems pose new challenges to providing good IAQ. Building ventilation is a good measure, being linked to not only health and thermal comfort but also to productivity. The trend in ventilation considers the people, the building, and the outdoor environment as a whole, would be linked to personal aesthetics in the next few decades.

As a result of changes in building materials (including recycled content) and construction technologies, new contaminants are being introduced to workplaces, schools, hospitals, and homes. Even known contaminants, such as volatile organic compounds from building materials, are not easily quantifiable. Our ability to model VOC emissions is further developed than our other simulation capabilities, such as modeling indoor chemical reactions or determining emission rates for biological contaminants. Many other potentially harmful components, such as endocrine-disrupting chemicals, latex, and ultrafine particles, are just beginning to be assessed.

Three strategies are available to control indoor contaminants: source elimination, local source control, and dilution of the indoor contaminants by ventilation. Since the first two have their limits, ventilation becomes very important for achieving an acceptable level of IAQ. Compared to mechanical ventilation, natural ventilation consumes little energy, requires little maintenance, has low first costs, and is environmentally friendly. Natural ventilation should be used wherever and whenever possible. Among the three mechanical ventilation systems (mixing ventilation, displacement ventilation, and localized ventilation), the displacement ventilation systems seem to be the most promising for creating a better IAQ and an acceptable thermal comfort level indoors.

Although both experimental and computer approaches are available for studying and designing IAQ, a computer-based approach using CFD is a powerful design tool of the future.

BUILDING SYSTEMS

CHAPTER 6

AN OVERVIEW OF THE U.S. BUILDING STOCK

Richard C. Diamond, Ph.D.
Lawrence Berkeley National Laboratory
Berkeley, California

6.1 INTRODUCTION TO THE U.S. BUILDING STOCK

From the skyscrapers of Manhattan to the Victorian houses of San Francisco and the shopping malls of Anytown, USA, buildings in the United States are remarkable for their variety. Variety in the type of building (commercial warehouse, manufacturing facility, institutional and office buildings, apartment buildings, condos, single-family dwellings, mobile homes, etc.) translates to variety in occupancy and use, which, in turn, means differences in energy requirements and indoor air quality concerns.

Since the late 1950s, energy prices in the United States have been so low that there has been little concern for energy-efficient design. With the oil shocks of the 1970s, an increased awareness of energy and the environment led to greater interest and research in the use of energy and its environmental consequences. Since the mid-1970s, increasing attention has been given to the indoor environment—and with good reason: Americans reportedly spend up to 90 percent of their time in homes, shopping malls, and workplaces and have come to expect that temperatures, humidities, and lighting conditions will be appropriate to their needs and desires for comfort, safety, ease of use, and health. Indeed, technological advances in air conditioning and lighting, in particular, have enabled us to create uniform indoor environmental conditions wherever we are—whether in cold Northern cities, hot humid regions of the South, or the hot arid conditions of the Southwest.

This re-creation of acceptable indoor climates that surmount external conditions comes at a price, however. In 1996, for example, over 34 quadrillion British thermal units of energy, at a cost of \$232 billion, was expended on the energy resources associated with the heating, cooling, lighting, and equipment in buildings. Buildings account for 36 percent of the total primary energy use in the United States, compared to 36 percent for industry and 28 percent for transportation (Fig. 6.1).

It is no surprise, then, that the building construction industry accounts for 7 percent of the U.S. gross domestic product (GDP)—nearly \$564 billion in 1996. Over one-third (38 percent) of the building construction activity is in remodeling and renovation (USDOE 1998a). Over 130,000 builders employ more than 163,000 architects and nearly 4 million

6.4

BUILDING SYSTEMS

FIGURE 6.1 U.S. primary energy use by sector, 1996. [From USDOE (1998a).]

construction workers, a significant fraction of the workforce. For these reasons the construction industry serves as an indicator of economic activity, and the number of new housing starts is used as an index of the nation's overall economic health.

Despite the key role that the construction industry plays in our economy and the advances it has made in materials and methods of building, the construction process, in many respects, remained largely unchanged in the twentieth century. The large number of players and specialized trades means that very little coordination occurs between the design, construction, and operation of buildings. The outcome is that buildings do not always perform according to design intent, and optimal indoor environmental conditions are not always achieved, including indoor air quality.

Commercial buildings, for example, are typically built under a *design/bid/build* approach, in which the owner retains an architect to lead the project through the design stage. Following the design phase, the project is let out for bid by general contractors. After award of the project, the general contractor usually subcontracts most or all of the work to subcontractors. A drawback of this system is that, in a competitive environment, projects are awarded on the basis of the lowest bid, and contractors must then find ways to cut costs during construction, often at the expense of HVAC systems and controls.

In the case of commercial buildings, there is an alternative: the *design/build* approach, where the designer works for the contractor. A design/build contractor usually has in-house staff handle the architecture and engineering as well as other specialties.

Unlike commercial buildings, residential housing is typically "designed" once and built several times, in different locations and with slight modifications. These new houses are built on site using a variety of specialized trades and craftspeople, but increasingly, more factory-assembled components are being used to lower on-site construction costs. Only a few percent of the housing stock are custom designed by architects for specific clients.

One of the major differences between housing construction in the United States and that of other industrialized nations is the decentralized nature of the U.S. building industry. Compared to Sweden, where the large majority of new housing is built by a few large builders, the five largest residential home builders in the United States (Pulte, Centex, Ryland, JPI, and Kaufman & Broad) built only 50,000 new homes in 1995, less than 4 per-

cent of the total new houses. For that year, the top 100 builders built 16 percent of all new homes. Habitat for Humanity, a nonprofit builder serving low-income households, built 3280 homes in 1995—less than 1 percent of the new housing construction (USDOE 1998a).

6.2 CHARACTERISTICS OF THE EXISTING U.S. HOUSING STOCK¹

This section first describes the number, location, type, ownership, age, size, and household characteristics of the residential sector. The remainder of the section reviews the energy use characteristics, looking at both overall household consumption and individual components.

Number and Location of U.S. Households

In 1997 there were 101 million households in the United States, 19 percent of which were located in the Northeast, 24 percent in the Midwest, 35 percent in the South, and 21 percent in the West. Over three-quarters of the households (77 percent) are in urban areas, with 36 percent in the central city and 41 percent in suburbia. The remaining households (22 percent) are in rural areas.

Type and Ownership of U.S. Households

The three basic categories of housing type are (1) single-family units (both as detached units and in row houses), (2) multifamily (both low-rise and high-rise apartments), and (3) mobile homes. In 1997 the stock was predominantly single-family units (73 percent), with apartments accounting for 21 percent of the total households and 6 percent for mobile homes (Fig. 6.2). The United States is a nation of primarily homeowners, with 67 percent of the households owner-occupied and the remaining 33 percent rented.

Age, Size, and Equipment Characteristics of U.S. Households

Over 90 percent of the current U.S. housing stock were built before 1990; only 18 percent was built before 1940. The 1970s was the decade with the largest amount of housing built, with 19 percent of the current stock built during that period. The oldest housing stock is in the Northeast and Midwest, and the newest is in the South.

The average existing single-family home has 3.0 bedrooms and 1.5 full bathrooms, for a total of 2280 ft² of floorspace, of which 1950 ft² was heated space; the rest consisted of unheated garage and basement areas. Air conditioning is installed in 70 percent of single-family households, with 47 percent having central units and 25 percent having wall or window units. Clothes washers are present in 93 percent of the units, and 88 percent have clothes dryers.

The average existing multifamily dwelling consists of 1.6 bedrooms and 1.1 full bathrooms, for a total of 970 ft², of which 920 ft² was fully conditioned space. Air conditioning

¹Unless otherwise noted, the information on the residential sector comes from a single reference, the 1997 *Residential Energy Consumption Survey*, a representative sample of all U.S. households (USDOE 1997). For readers interested in perusing the data in more detail, the information can be found on the following Website: <http://www.eia.doe.gov/emeu/recs/contents.html>.

FIGURE 6.2 Distribution of U.S. households, 1997. [From USDOE (1998a).]

is installed in 65 percent of apartment households, with 36 percent having central units and 30 percent having wall or window units. Clothes washers are less common than in single-family households, and are found in 31 percent of the units and 25 percent use clothes dryers.

Over 11 million apartment households—nearly half the sector (48 percent)—were eligible for *weatherization* or for the Low-Income Home Energy Assistance Program, a federal subsidy for utility payments of low-income households. The average annual income of federally eligible households in 1994 was \$11,245. Over 3 million rental units, nearly 10 percent of the rental stock (both single- and multifamily) are defined as “inadequate,” which refers to the absence of heating and plumbing equipment as well as information on upkeep and maintenance (Harvard 1997).

The average existing mobile home has 1.6 bedrooms and 1.1 full bathrooms, for a total of 980 ft², of which 940 ft² was conditioned space. Air conditioning is installed in 70 percent of mobile homes; 43 percent have central units and 29 percent have wall or window units. Clothes washers are found in 84 percent of the units, and 75 percent have clothes dryers. Forty percent of the households in mobile homes were eligible for the Low-Income Home Energy Assistance Program.

Basement and foundation types are important in studying migration of moisture, radon, and soil gas into housing. In 1995 nearly half (45 percent) of all single-family housing had a full or partial basement. About one-quarter (26 percent) of the single-family houses were built over crawlspaces, and 27 percent were built on concrete slabs (USDOC 1997a).

Energy Use Characteristics

In 1997, over half of all households (52 percent) used natural gas as their primary fuel for space heating, 30 percent used electricity, 9 percent used fuel oil, 4 percent used liquefied petroleum gas (LPG), 2 percent used wood, and 2 percent used some other fuel (Fig. 6.3). Of the 52 million households using natural gas for space heating, 71 percent had a central, warm-air furnace, 13 percent had a steam or hot-water system, and 8 percent had a wall or floor furnace. Of the 30 million households using electricity for space heating, 37 percent

FIGURE 6.3 Fuel used for U.S. residential space heating, 1997. [From USDOE (1998a).]

had a central, warm-air furnace, 32 percent had heat pumps, and 25 percent had built-in resistance units. Portable space heaters are used in 12 percent of all households, the majority (88 percent) of which are electric. The remainder of the portable heaters are kerosene or fuel oil—a potential source of indoor air pollution.

In 1997, air conditioning was present in 74 percent of U.S. households. Central air-conditioning (A/C) systems were installed in 48 percent of the households, and 27 percent had window units. Of the households with central A/C that were surveyed by the Residential Energy Conservation Survey (RECS), 33 percent said that they used the system “all summer”; 14 percent, “quite a bit”; and 17 percent, “only a few times.” In contrast, of the households with window A/C units, only 8 percent said they used the unit “all summer”; 9 percent, “quite a bit”; and 18 percent, “only a few times.” More than half the U.S. households use some type of portable fan for cooling.

Humidifiers are used to increase the relative humidity in 14 percent of all households; the highest use (26 percent) is in the Midwest. Dehumidifiers are used in 9 percent of all households. Again, the highest percentage is in the Midwest, where 22 percent of the households use these devices routinely. Six percent of U.S. households reported using some type of air-cleaning device in 1993.

ASHRAE Standard 62-1989 sets minimum ventilation rates for providing acceptable air quality in buildings (ASHRAE 1989). For residential buildings the standard specifies 0.35 air changes per hour (ACH). This standard is a general guideline and does not anticipate health risk from acute and chronic exposure to a variety of sources or materials found in homes. Also, since most houses rely on infiltration to provide adequate ventilation, the ACH will vary by geographic location, orientation of the home, surrounding structures, vegetation, and, of course, the season and weather conditions. The behavior of occupants, design of heating system, use of fans, and other factors play an important role leading to variation in ACH, both between and within homes.

Information on the actual air exchange rates of the residential housing stock is sketchy at best, but estimates of air leakage based on blower-door measurements suggest that the existing single-family housing stock has, on average, 1.0 air changes per hour (Sherman and Matson 1996). Because of code changes and other mandates for more energy-efficient

construction, new housing is considerably tighter than existing residences, with air exchange rates reported to average 0.5 ACH for new construction.

Although most single-family housing meets the ASHRAE standard of 0.35 ACH through infiltration and natural ventilation, new, tighter housing may require mechanical ventilation. Multifamily housing can have much lower infiltration rates, and mechanical ventilation is frequently required to provide acceptable ventilation. Unfortunately, the mechanical ventilation systems in apartment buildings often fail to perform, because of poor design, construction, operation, and maintenance (DeCicco et al. 1996).

Following the energy shocks of the 1970s there was increased awareness of the importance of improving the energy efficiency of new housing. Since the late 1970s, homeowners have improved the thermal integrity of their homes. For instance, 81 percent of single-family houses have insulation in the roof or ceiling, and 70 percent have insulation in the walls. Double- or triple-pane windows are found in 36 percent of all households, and 61 percent of replacement windows are double- or triple-pane glass.

Energy Use Consumption

The average U.S. household consumed 136 million British thermal units (MBtu) of primary energy in 1996. Energy consumption varies regionally and by housing type. For the average single-family household, 39 percent of the energy use is attributable to space heating, 14 percent to water heating, 9 percent to refrigeration, 8 percent to cooling, 6 percent to lighting, 3 percent to cooking, 3 percent to clothes drying, and the rest (20 percent) to other uses (see Fig. 6.4). In 1996 the average U.S. household spent \$1355 for their residential energy needs (USD OE 1998a).

Although public interest in renewable energy sources, such as energy from sun and wind, is increasing, only 1 percent of U.S. households use solar energy directly for space or water heating.

FIGURE 6.4 U.S. residential primary energy use by end use, 1996 (193 MBtu per household). [From USD OE (1998a).]

6.3 CHARACTERISTICS OF THE NEW U.S. HOUSING STOCK

Newer homes share many of the characteristics of the existing housing stock. The latest RECS conducted in 1993 included a series of questions about single-family homes built between 1988 and 1993 (USDOE 1995b) to look at changes in the newest additions to the housing stock.

Over one million new single-family housing units were completed in 1995, with an average floor area of 2095 ft², 17 percent larger than a new house in 1980. In 1995, 247,000 new multifamily housing units were also completed. The average floor area of these units was 1080 ft², 9 percent larger than a new apartment unit in 1980. As for new mobile homes, 311,000 were placed in 1995 (USDOE 1998a).

Between 1978 and 1993, the number of homes with central air conditioning rose from 18 million homes to 42 million homes. The use of air conditioning varied among the four census regions. In the South, where A/C needs are the greatest, 89 percent of all households had some type of air conditioning in 1993, double the number from 1978.

The 1993 data also showed an increase in the number of households using window or ceiling fans, personal computers, color televisions, microwave ovens, and electric clothes dryers. The appliances that decreased in use include black-and-white television sets, portable kerosene heaters, and well-water pumps.

6.4 TRENDS IN NEW HOUSING CONSTRUCTION

Several factors drive changes in new housing construction. First, the changing demographics of the U.S. population is bound to affect the size and location of new housing. Beyond that, the increased costs of disposing of construction wastes in urban landfills will lead to efforts to minimize construction waste, and new materials and construction techniques will be introduced to improve the efficiency of housing production. Finally, the industry itself is changing; through mergers and acquisitions, many large housing companies are absorbing smaller, more innovative firms. The implications of this transformation may be that changes could occur more quickly across the new housing stock.

Changing Demographics

Even as households continue to decrease in size, from an average household size of 2.7 people per household in 1995 to a projected 2.5 in 2015, the trend in new houses is toward more, not less, floor area. This trend signals an increase not only in floor area per capita but also in energy consumption per capita.

As the population ages, it is reflected in changes in energy use. The elderly, for example, often prefer higher indoor temperatures during the heating season than do their younger counterparts. The first one or two decades of the twenty-first century will also see the first generation of elderly growing old in suburbia and thus increasingly dependent on the automobile for access to health care and other services.

Minimizing Construction Wastes

Despite the strong environmental concerns of an increasingly vocal public, it is more likely to be economic factors that motivate builders to curb construction waste. Rising landfill

costs have already persuaded builders to reduce the wastestream associated with residential construction. Construction of a typical 2000-ft², new, single-family, detached house creates an average of 4 tons (U.S.) of construction waste, generally consisting of wood/paper (45 percent), drywall (25 percent), masonry (13 percent), and miscellaneous other (17 percent). Annual construction and demolition waste accounts for roughly 24 percent of the municipal solid wastestream. As much as 95 percent of building-related construction waste is recyclable, and most construction materials are clean and unmixed (USDOE 1998a).

Even though less than 1 percent of residential construction waste is classified as hazardous material (NAHB 1996), 15 to 70 lb of hazardous waste is generated during the construction of a single-family house. Hazardous wastes include paint, caulk, roofing cement, aerosols, solvents, adhesives, oils, and greases.

New Materials and Construction Techniques

The trend toward increased use of factory-built and assembled components will likely continue, both as an efficiency measure and as a way to satisfy individual requirements of prospective home buyers. On-site construction will consist primarily of assembling these components and modules rather than fabricating them from raw materials. Data from 1991 indicate that manufactured housing now accounts for 30 to 40 percent of new housing in parts of the West and South (Harvard 1997).

Already, new materials and construction techniques such as are involved in steel framing, modular wall panels, advanced windows, and integrated wiring and electronics are becoming widespread across the United States. Advanced materials such as building-integrated photovoltaic roof tiles may become common as their price decreases. These tiles convert sunlight to electricity, that can be battery-stored or fed back to the utility grid when the electricity is not needed. Improved windows designed for solar control, and advanced lighting systems and controls will also see increased use in routine building. In addition, building materials will need to meet higher standards for reduced emissions and for recycling and reuse.

Consumers will increasingly demand houses that are comfortable and healthy, and mechanical ventilation systems will be increasingly common to ensure adequate ventilation. Smart controls and sensors designed to respond to either occupancy or carbon dioxide levels will operate the ventilation systems. Ventilation air will also be filtered to remove infectious agents and allergens.

6.5 CHARACTERISTICS OF EXISTING U.S. COMMERCIAL BUILDINGS²

In 1995, there were 4,580,000 commercial buildings in the United States representing 60 billion ft² of floorspace. The total number of commercial buildings in 1995 was only 6 percent of the total number of residential buildings in 1993, but commercial floorspace was equivalent to 32 percent of total residential floorspace.

²The U.S. Department of Energy's *Commercial Buildings Energy Consumption Survey* (CBECS) collects information on physical characteristics of commercial buildings, building use and occupancy patterns, equipment use, energy-conservation features and practices, and types and uses of energy in buildings (USDOE 1998b). For additional information see their Website at <http://www.eia.doe.gov/emeu/cbecs/char95/profile.html>.

Primary Activities in Commercial Buildings

The commercial buildings sector is dominated by four types of activity: retail and service, office, warehouse and storage, and education (Fig. 6.5). Together they represented 67 percent of commercial floorspace and constituted 63 percent of all commercial buildings in 1995. Retail and service buildings were by far the most numerous type (more than 28 percent), but they account for less in floorspace (22 percent) compared to other activity types.

Comparison of the percentage of floorspace and buildings for a given activity category gives an indication of the mean, or average, size of building in the category. For example, knowing that education buildings accounted for 13 percent of total floorspace and 7 percent of total buildings tells us that those buildings were larger in average size. At 25,100 ft² per building, education buildings were, in fact, the largest type, much larger than that of all other commercial buildings (12,840 ft² per building). Two other building activities, lodging and health care (22,900 and 22,200 ft² per building, respectively), were significantly larger than the average size of all buildings.

Both food sales and food service buildings, which include convenience stores, retail bakeries, fast-food restaurants, and bars, were significantly smaller in average size (fewer than 5000 ft² per building).

FIGURE 6.5 U.S. commercial buildings and their floorspace by type of activity, 1995. [From USDOE (1998b).]

Office buildings, which included some of the largest commercial buildings in the United States, had an average size of 14,900 ft². A common image of an office building is the multistory building that dominates the skyline of major urban cities. Actually, this category is dominated by smaller buildings, such as banks, real estate offices, and insurance offices. Collectively, they bring the overall office building average close to the mean of the total commercial population of buildings.

Geographic Location of Commercial Buildings

The U.S. Census Bureau divides the United States into four census regions, each having 9 to 16 states. For 1995, commercial buildings, floorspace, and population were distributed in a similar pattern for the four regions (Fig. 6.6). The high correlation of buildings and floorspace with population was not surprising since commercial activity is mostly the provision of services to people.

There were slight regional differences in the average floorspace of commercial buildings. Those in the Northeast were larger on average (16,400 ft² per building) than those in the other three regions (11,900 to 12,600 ft² per building).

Building Size

As evident in Fig. 6.7, the vast majority of commercial buildings nationwide are in the smallest size categories. More than half (52 percent) are in the smallest category, and three-quarters are in the two smallest categories.

FIGURE 6.6 Commercial buildings and their floorspace by region, 1995. [From USDOE (1998b).]

FIGURE 6.7 Distribution of U.S. commercial buildings by size of building, 1995. [From USDOE (1998b).]

Fewer than 5 percent of the nation's commercial buildings (188,000 buildings at the time of writing) were larger than 50,000 ft² and less than 2 percent (73,000 buildings) were larger than 100,000 ft². However, large buildings represent a significant percentage of total floorspace (44 percent for buildings larger than 50,000 ft²; 30 percent for buildings larger than 100,000 ft²).

The energy-use characteristics of small and large commercial buildings are quite different, as might be expected. In smaller buildings, heating and cooling systems are employed primarily to moderate outside air temperatures (as they are in residential buildings). In larger commercial buildings, outside air conditions have less impact on heating and cooling systems than do activities within the buildings—equipment used, lighting levels, number of people, and hours of operation. For example, one part of a building might need to be heated and ventilated to provide comfortable conditions for employees, whereas a computer room might need to be cooled because of excess heat given off by the computer equipment.

Age of Commercial Building Stock

Most commercial buildings, once constructed, are expected to last for decades or longer. New buildings are constructed each year, and older buildings are demolished, but the commercial building stock at any point in time remains dominated by older buildings. More than 70 percent of buildings and total floorspace in 1995 were constructed prior to 1980 and more than 50 percent of buildings and floorspace, prior to 1970 (Fig. 6.8).

The 420,000 buildings and their more than 4.6 billion ft² of floorspace added to the commercial buildings sector in the 1990s represented less than 10 percent of both buildings and floorspace in the 1995 buildings stock.

FIGURE 6.8 Distribution of U.S. commercial floorspace by year constructed, 1995. [From USDOE (1998a).]

Major Energy Sources Used in Commercial Buildings

Electricity and natural gas are used widely in commercial buildings. Electricity use is nearly universal (97 percent of floorspace and 95 percent of buildings). Natural gas is used for 66 percent of floorspace and 55 percent of buildings.

Of the other major energy sources, only fuel oil is used for as much as a quarter of total floorspace (but in less than 14 percent of buildings). The other energy sources (district heat, chilled water, propane) are used for no more than 11 percent of floorspace (or in 13 percent of buildings).

Major End Uses of Energy in Commercial Buildings

The types of activity within commercial buildings determine what specific energy-consuming services will be needed. The vast majority of commercial buildings used energy for lighting, space heating, water heating, and cooling (each of these end uses exceeded 73 percent of buildings and 60 percent of floorspace).

Electricity is the most flexible energy source in commercial buildings, as well as the sole source for ventilation equipment, office equipment, and all other electrical equipment used in commercial buildings. Electricity was by far the dominant energy source for cooling (97.4 percent of cooled buildings and 95.0 percent of cooled floorspace).

In 1995, the average commercial building in the United States consumed 203 thousand British thermal units (kBtu) of primary energy per square foot (see Fig. 6.9). Although energy consumption varies regionally and by commercial building type, on average, 27 percent of primary energy use goes for lighting, 15 percent for space heating, 13 percent for cooling,

6 percent for office equipment, 4 percent for ventilation, and the rest (35 percent) for refrigeration, water heating, and miscellaneous other uses. The average amount spent on energy costs associated with the buildings operation was \$1.33 per square foot of floorspace (USDOE 1998a).

Energy Conservation Features and Practices

Energy conservation was widely practiced in commercial buildings. In an overwhelming majority of buildings (89 percent), some type of conservation feature had been installed or energy-efficient practice implemented.

Most commercial buildings report some type of building shell conservation feature (85 percent of buildings, 91 percent of floorspace). The type most often found was roof or ceiling insulation (74 percent of buildings, 79 percent of floorspace). HVAC conservation features were, in general, less common than building shell features. HVAC maintenance, the most widely practiced of the HVAC categories, was performed in about half of buildings and three-fourths of floorspace.

Some type of lighting conservation feature is found in 46 percent of buildings and 66 percent of floorspace. The most widely used lighting system conservation feature was the energy-efficient ballast, used in 30 percent of buildings and 48 percent of floorspace.

6.6 CHARACTERISTICS OF NEW U.S. COMMERCIAL BUILDINGS

The profiles of new commercial buildings showed no statistically significant changes in the major characteristics from 1989 to 1992 to 1995, the 3 years in which the last CBECS were conducted. Changes in the absolute numbers of buildings and floorspace were noted within

FIGURE 6.9 Primary energy consumption in U.S. commercial buildings by end use, 1995 (203 kBtu/ft²). [From USDOE (1998b).]

categories, but when each category was expressed as a percentage of the total, no significant differences were found from one to another.

6.7 TRENDS IN NEW COMMERCIAL CONSTRUCTION

At the time of writing, most of the changes in commercial buildings over the next 10 to 20 years are expected to be incremental in nature—increasingly improved environmental controls, more efficient equipment and systems (e.g., in lighting), and advanced construction methods. One policy trend will be the “certification” or labeling of buildings that meet environmental or “green” criteria. We can also expect the widespread adoption of telecommunication technologies and other “information” technologies. Another trend is the increasing importance of “commissioning” the building to ensure that the systems operate as intended.

Advanced Construction Methods and Materials

The increased use of computer-aided design and computer-aided manufacturing (CAD/CAM) will result in the more efficient use of time and materials in the design and construction of buildings. Automated systems will lead to the more efficient use of materials. Modular components and systems that can be assembled on site will be increasingly available.

Engineered materials, such as wood composites, stressed-skin panels, and lightweight steel components, together with adhesive assembly techniques, will be increasingly more common in building construction. Concerns for indoor air quality may drive the increased use of low-emission materials, and environmental and economic concerns are likely to increase the use of recycled and reused components.

Improved Building Envelopes

Improvements in window technology, which use selective glazings and gas fills, will develop into fully integrated building envelopes that take advantage of natural daylight and provide optimal solar control. Photosensors and other daylight controls designed to reduce electric lighting are becoming increasingly common and will continue to be used in a wide range of commercial buildings. Dynamic control of solar and thermal loads by “smart” materials and systems will play an increasingly important role in building operation.

Integrated Building Controls

The trend toward increased automation and control of a building’s mechanical and electrical systems will develop into fully integrated systems that rely on information technologies for their operation. Sensors that respond to occupants’ programmed preferences for temperature, lighting, and ventilation will relay information to appropriate systems. Sophisticated design tools are now available to optimize the sizing of these systems and provide feedback mechanisms to building operators.

Labeling and Rating Schemes

One way to advance the development of energy-efficient and environmentally responsible buildings is to acknowledge their performance with a label or rating system. Several such schemes, such as LEED, BREEAM, and EnergyStar, developed in the United States, Canada, and Europe, certify the presence of sustainable design, materials, and systems. These rating schemes have been developed for both new and existing commercial buildings.

High-Performance Buildings

It is possible that all phases of the design, construction, and operation of commercial buildings will ultimately be linked electronically to ensure high levels of performance. No longer will design intent be lost in the construction phase. Electronic documentation of design intent and building construction will allow building owners and operators to optimize the performance of their buildings. A driving force for these changes is the continued expectation by the owners and occupants of buildings for comfortable, safe, and healthy indoor environments.

CHAPTER 7

HVAC SYSTEMS

David W. Bearg, P.E., C.I.H.

AIRxpert Systems, Inc.

Lowell, Massachusetts

This chapter of the *IAQ Handbook* deals with the relationship between the achievement of good IAQ and the specifics of the design, installation, operation, and condition of the HVAC system serving that building.

7.1 DESCRIPTIONS OF HVAC SYSTEMS

The acronym *HVAC* stands for heating, ventilation, and air conditioning. These mechanical systems are designed to provide for both the thermal conditioning and introduction of adequate amounts of outdoor air to be supplied and delivered to the occupied spaces of buildings. Additionally, these systems are designed to control pressure relationships of occupied areas with the outdoors and surrounding spaces. A typical system consists of controls, a minimum of one fan to move the air, a provision for introducing outdoor air, a filter medium to reduce the concentration of particulate matter in the air, coils for heating and cooling the air, and a distribution system. The distribution system typically consists of ductwork connected to supply registers and a pathway for air leaving the occupied space to return to the air-handling unit (AHU).

In its simplest form, the basic HVAC system described is commonly called a *unit ventilator* or *univent*. Because of the simplicity of the limited distribution components of univents, they are frequently used where “first costs” dominate and are therefore present in many schools across the United States. Unfortunately, they still require maintenance. All too often, the upkeep of these units is neglected, and they become noisy or fail to operate. Since these univents are supposed to provide ventilation as well as thermal conditioning, this failure to operate as designed can result in less than the recommended amount of ventilation.

The complexity of AHUs can increase; the next level of equipment consists of “packaged” units that are installed as a single unit as received from the factory. These can be located either on the roof (RTU = rooftop units) or at some other location. As the size or need for more custom capabilities increase, the next step in the evolution of AHUs is the “built-up” unit, where individual components are combined to achieve the desired result. These individual components are described and discussed in greater detail in Chap. 8. An additional resource in this area is the book *Indoor Air Quality and HVAC Systems* (Bearg 1993).

7.2 INDIVIDUAL COMPONENTS OF HVAC SYSTEMS

Figure 7.1 presents the basic components of an HVAC system. Each component of the HVAC system makes a specific contribution to the resulting IAQ that the total system provides. This section discusses the role that these individual components play in achieving good IAQ. One challenge of performing IAQ evaluations is that, to be thorough, all aspects of the system, including equipment and performance, need to be examined. The performance of the overall system is dependent on the proper design and functioning of each individual component.

Outdoor Air Intake

When designing or evaluating a building, one of the first IAQ considerations that can affect the ability of the HVAC system to provide good IAQ over the life of the building is the location of the outdoor air intakes. The choice of this location is very important because of its potential to permit the introduction of air contaminants from nearby sources. Air intakes located one-third of the way up the side of the building tend to work best. Yet all too often

FIGURE 7.1 Basic components of an HVAC system. [Reprinted from EPA (1994). *Orientation to Indoor Air Quality*. Washington, DC: U.S. Environmental Protection Agency.]

air intakes are found next to loading docks, at ground level near roadways, below grade in areaways, or on roofs near exhausts.

It should also be noted that frequently there are unintentional “outdoor air” intakes in addition to the intentional ones. For instance, air can be drawn into the air-handling equipment directly from the mechanical room.

Mechanical Room

In view of the potential for the mechanical room to be part of the pathway for air and for possible air contaminants to reach occupied spaces, certain factors regarding this space with respect to IAQ should be considered. These include its location, its other uses, and its pressure relationship with respect to adjacent areas. It seems that from the perspective of architects, mechanical rooms and loading docks are both building support services, and are treated very differently from prime occupant space. Consequently, mechanical rooms frequently end up adjacent to loading docks or other sources of air contaminants. This is unfortunate because mechanical rooms tend to be under a negative pressure with respect to their surroundings. This negative pressurization is a result of leakage into AHUs or at times part of the design where the mechanical room is used as part of the return-air system. In addition, mechanical rooms also frequently house other potential sources of air contaminants such as chemical storage, sumps with standing water, and condensate vents for boiler water containing additives. These factors together can cause situations of degraded IAQ if the air contaminants are inadvertently drawn into an AHU and then delivered to occupied space.

Outdoor Air Dampers

The outdoor air (OA) dampers are a critical component of the HVAC system in terms of their ability to provide adequate ventilation for the building occupants. The basic requirement for providing ventilation when the building is occupied means that the OA dampers are open. The only exception to this is during a *warmup cycle*, in which the OA dampers remain closed for an interval at the start of the day to allow a more rapid rise in the temperature of the occupied space. This will not be a problem if the building has been adequately purged overnight, and there is still a volume of air available to dilute the air contaminants associated with human occupancy. Unfortunately, OA dampers are a mechanical component with moving parts, and things can and do go wrong, thus depriving occupants of adequate ventilation.

Mixing Plenum

The mixing plenum is the location where the return and outdoor airstreams meet and are combined. The ratio of mixing is a function of the pressure relationships in the area and the positions of the OA, return air, and mixed-air dampers. Since rain or snow may be sucked in along with the outdoor air, there should be a floor drain to prevent water accumulation. If this floor drain is connected to a sewer line, it needs to have a functional water trap, with water present, so that sewer odors will not be drawn into the airstream.

If the system has a mixed-air temperature control, both its setting and calibration might be off, thus affecting the amount of outdoor air being admitted. Similarly, a freeze stat sensor may also be located here, to protect the coils from damage due to cold air below the freezing point of water. Improperly set or calibrated freeze stats can also decrease the amount of ventilation provided.

Air Filters

The condition and quality of the filtering media and its installation are a very important determinant of the HVAC system's ability to protect system components, deliver clean air, and achieve good IAQ. An inspection of the filter installation should first determine whether they are grossly clogged or blown out and how completely they fill the cross section available to them in the AHU. The absence of leaks around the perimeter, or gaps between the filters, is critical for the rated effectiveness of the filters to be achieved.

Filters are rated according to the requirements of ASHRAE Standard 52-76 (ASHRAE 52-76) to yield a dust spot percentage and an arrestance percentage. Of these two criteria, the dust spot is a more meaningful indicator of efficiency. This is because the arrestance merely refers to the amount collected by weight. Since the larger, easier-to-capture particles will represent most of the weight of the dust in the air, filters with high arrestance values can still have low dust spot ratings. For instance, according to their literature, a Farr 30/30 filter, which can be considered a medium-efficiency filter, has an arrestance of 94 to 96 percent and a dust spot efficiency of 30 percent. Another aspect of filters is that their collection efficiency increases over time as the filter cake builds up. According to Farr (Farr Company 1992) the efficiency of the RIGA-FLO 10 and XL filters, a 0.3- μm diameter particle, starts at 5 percent and increases to 55 percent, with a weighted average of 34 percent. This particle size is perhaps the hardest size to capture with a filter, and so filters are typically tested against particles of this size. These filters are rated to have a 96 percent arrestance and 40 to 45 percent dust spot efficiency. Similarly, their RIGA-FLO 100 filters have a 0.3 μm efficiency that starts at 48 percent and increases to a final value of 86 percent, with a weighted average efficiency of 68 percent. These filters are rated with an arrestance of 98 percent and a dust spot efficiency of 80 to 85 percent.

As the amount of material collected on a filter increases, the collection efficiency also increases, as does the pressure drop across the filter. Since manufacturers provide a value for the maximum pressure drop that the filter can safely withstand, the monitoring of the filter's pressure drop provides a metric on which to base when the filters should be replaced.

Low-efficiency filters (ASHRAE dust spot 10 to 20 percent) are effective in removing coarse particulate. However, removal of pollens, bacteria, fungi, and dust at an acceptable level for host building occupancies requires a medium-efficiency filter with an ASHRAE dust spot rating of 30 to 60 percent. According to Morey (1988), "a 50 percent atmospheric dust spot efficiency filter will remove most microbial particulate." At a minimum, there should be a 1- to 2-in. extended surface (i.e., pleated) filter that approaches this dust spot efficiency rating. Higher-efficiency extended-surface filters with a dust spot rating of 85 percent are recommended by some manufacturers to provide the optimum balance between filter efficiency and energy conservation.

Greater detail about filter design, selection, and performance is in Chapter 9.

Face and Bypass Dampers

Various components within a given air handler unit, especially the coils, can add a significant amount of pressure drop against which the fan must work to move air. Therefore, when these coils are not needed to thermally condition the air being handled, some AHUs contain the geometry and dampers to permit these coils to be bypassed. The significance of this fact is that another pathway for the introduction, or leakage, of outdoor air into the system can now exist.

Cooling Coils

Heating and cooling coils are used to regulate the temperature of the air being delivered to the space. The effectiveness of their design and maintenance is critical in maintaining

thermal comfort in the space. The purpose of cooling coils is to lower the temperature of the air passing through them, as part of the thermal conditioning function of the HVAC system, as well as providing dehumidification as water condenses from the airstream. This can be achieved by the flow of chilled liquids such as water, brine, glycol, or various refrigerants. Coils cooled by a refrigerant can be either of the direct-expansion or flooded types.

In terms of IAQ, one aspect of the cooling coils is the capacity of the system relative to the needs of the space being served. If the capacity of the cooling system is too large for the load, it will cycle on and off frequently, resulting in poor dehumidification. If the system is too small for the current load, then poor thermal comfort will be provided.

The issues involved with heating coils are much the same as those for cooling coils: the need for access, the need to be kept clean, and the need to have sufficient capacity in order to provide thermal comfort in the occupied spaces. Here, they need to be able to provide a sufficient amount of adequately heated air during the winter design conditions. They can be located either centrally, as part of the AHU, or distributed throughout the building to help achieve more control in providing thermal comfort to the building occupants. In this distributed application, they are referred to as *reheat coils* and require maintenance for both periodic cleaning and calibration checks. The need for periodic cleaning is mentioned because these coils can become clogged and thus reduce the quantity of supply air passing through them. The need for periodic calibration is mentioned because improperly operating reheat coils can cause comfort problems and wasted energy.

In the heating mode, it is essential to maintain the coils at sufficient temperature to ensure thermal comfort. If the coil temperature is too low to appropriately condition the outdoor air, the quantity of outdoor air may be reduced, possibly resulting in decreased ventilation rates.

Condensate Drain Pans

The purpose of the condensate drain pans is to initially collect moisture from below the cooling coils and then transfer this water out of the AHU. When the air passing through the cooling coils is sufficiently humid that the temperature to which it is cooled is below its dew point, dehumidification of this airstream will occur and liquid water will form on the cooling coils. This water will then drain down by gravity to the collection pan below. Spores and dirt can also be collected in this pan, causing a significant decrease in IAQ due to the growth of microorganisms at this location. Chapters 45 and 46 discuss microorganisms.

It is therefore very important that this drain pan be designed and installed so that it will drain completely, and not leave any standing water. For this to be achieved, the drain pan needs to be properly sloped toward its connection to its drain line or lines, and these connections must be at the lowest level of the pan so that no water residue remains. This connection between the drain pan and its drain line thus becomes a critical detail in the system.

Because of the importance of the condensate drain pan, it should be included in an inspection of IAQ conditions. This can be a challenge because some AHU designs do not permit the ease of viewing and cleaning of this component. This pan should be maintained in a clean condition, not only to minimize the source of spores and nutrients but also because debris can block the drain connection and lead to standing water.

For AHUs where the cooling coil section is under a negative pressure, there should be a water trap in the drain line. This water trap will isolate this portion of the AHU from ambient pressure and let the water siphon out of the system despite the operation of the fan. To be properly designed, the effective height of the water trap should be 40 percent greater than the expected peak static pressure of the supply-air fan.

Supply-Air Fans

The supply-air fans provide the driving force to move the air through the distribution system to the occupied spaces in the building. A given HVAC system can contain just a supply fan, or the combination of a supply fan and a return fan or relief fan. There will be, of course, separate exhaust fans for the toilet exhaust and any other identifiable sources of air contaminants, such as from a kitchen. An inspection of the supply fan should make sure the fan is operating and include a check of the condition of the fan belts, the fan housing, and louvers which could be restricting the flow of air into the fan.

Humidification

In some buildings or areas within buildings, it may be necessary to control relative humidity more precisely. Generally, this means adding moisture to the airstream. The addition of moisture can also represent a potential source of air contaminants (microbiological agents, anti-corrosive agents, etc.) in HVAC systems. Therefore, the moisture introduced should be from a potable-water supply; it preferably should not have a chance to reside in a stagnant reservoir, and it should not be introduced in a way that could wet surfaces in the HVAC system.

In addition, the absence or the lack of the operation of humidifiers can adversely affect the comfort of individuals in buildings where outdoor conditions are dry and cold. Although it can be an added factor in achieving comfortable conditions in buildings with cold and dry winters, humidification should not be added to any building until after the details of the building envelope have been reviewed to make sure that they can accommodate an indoor to outdoor moisture difference without leading to damage to any of the envelope components.

The Distribution System

The role of the distribution system, which consists of the ductwork, mixing boxes, terminal units, and connectors, is to convey the conditioned air from the conditioning equipment and deliver it to the occupied spaces in the building. Unfortunately, this distribution system may not always perform as intended, because of leakage of air from the ductwork itself, light-troffer-type diffusers, and return ducts. The components of the distribution system can also serve as sources of contaminants due to internal linings, collection of dust, and microbiological material.

Terminal Equipment

In addition to concerns about the clogging of coils in terminal reheat boxes, terminal equipment with the potential for adversely affecting IAQ includes induction fan-coil units and fan-powered terminal boxes.

Induction units use the movement of supply air to induce the movement of air in the space to achieve a larger combined total airflow. This way, the actual ductwork dimensions required for the delivery of conditioned air can be reduced. Induction units are usually under a window or at a perimeter wall, with the centrally conditioned primary air supplied to the induction nozzles of the unit at high pressure. This flow then induces movement of the adjacent air from the room to achieve the desired result. The advantage of this approach is that smaller volumes of air need to be distributed.

Room Configuration

The configuration of the room, especially one where cubicles are installed in a space originally designed and intended to remain as open space, can have consequences on IAQ because the supply diffuser and exhaust grille locations may no longer achieve an appropriate ventilation effectiveness in that space.

Return-Air Plenum

Another portion of the distribution system is how the air is returned to the AHU in those systems where recirculated air is permitted. While some installations have ductwork above exhaust grilles over the occupied space all the way back to the AHU, many installations rely solely on the ceiling *plenum*, the space between a suspended ceiling and the real ceiling, for this return flow. Because the return air can move through this space, it can pick up air contaminants that it would not be exposed to in a ducted return system. One example of a potential air contaminant is pieces of insulation from fiberglass batts around the perimeter being drawn into the return system.

Return-Air Fan

The function of the return-air fan is to draw air out of the occupied spaces and deliver it back to the AHU. Air leaving the return-air fan can also be exhausted directly to the outdoors. The correct operation of the return-air fan is critically tied to the operation of the supply-air fan because the resulting pressure relationship can affect the introduction of outdoor air into the AHU. If, for instance, the return-air fan is moving more air than the supply-air fan, the quantity of air being exhausted can spill over to the outdoor air intake, and create a building exhaust instead of an air intake.

Stairwells and Elevator Shafts

Stairwells and elevator shafts can become important in terms of IAQ because of the vertical penetrations they create within buildings. This vertical communication, in conjunction with the pressure forces in and on the building, can preclude the presence of operable windows in tall buildings. Opening and closing windows would create an impossible situation for the designers and operators of buildings due to their unpredictable nature of changing pressure relationships.

One approach to providing operable windows is therefore to create compartments on each floor that would isolate the occupied floorspace from any such vertical chases in the building.

Building Exhausts

The quantity of outdoor air entering the building will be exactly equal to the quantity of air leaving the building. Therefore, in the absence of either fan-powered exhaust at the AHU or pressure-relief fans in the building, the upper limit to the amount of outdoor air that can be brought into the building will be equal to the sum of the building exhausts and exfiltration. Therefore, in relatively tight buildings with only limited exhausts (i.e., only for bathrooms) the amount of outdoor air for ventilation may be similarly limited and may be insufficient for adequate IAQ.

Boilers

Boilers that generate the heated water for either thermal conditioning or domestic hot-water needs may burn fossil fuels or use electricity. The burning of fossil fuels generates combustion products that can become indoor air contaminants if they have a pathway to the occupied spaces of the building. These combustion products may contain carbon monoxide; if the combustion appliance is starved for air, the potential consequences may be fatal to any exposed occupants.

Another aspect of boiler operation that can adversely affect IAQ is the use of boiler additives that were added to control corrosion in the piping system. These chemicals, typically morpholine or diethylaminoethanol (DEAE), are strong irritants, and can therefore contaminate the air if they end up being distributed to the building occupants. This can happen; in one building, evaporation from a condensate return line occurred near an AHU in a basement mechanical room. Leakage into the AHU then resulted in the transport of air contaminants to the building occupants through pathways from the mechanical room into the AHU.

Cooling Towers

There are several important relationships between cooling towers and the IAQ in buildings. One relationship is a function of the cooling capacity of the cooling tower in rejecting heat to the atmosphere. This capacity, in turn, is a controlling factor in the cooling capacity for the building, and the resulting ability to maintain thermally comfortable conditions.

Another area of importance to be evaluated when considering the potential contribution of cooling towers to degraded IAQ is that they can be a source of microbiological growth. This is because cooling towers usually have reservoirs of standing water. The presence of this water, in conjunction with nutrients from dirt and spores from the wind, can provide a suitable habitat for the proliferation of microorganisms. Therefore, the distance between cooling towers and air intakes should be reviewed for the potential of mist from the tower to reach the outdoor air intake. Chapter 48 focuses on *Legionella*.

Chillers

Chillers have an indirect role in the maintenance of good IAQ. In addition to being able to provide sufficient quantities of chilled water to meet cooling loads necessary for providing thermally comfortable conditions, the improper operation of this equipment can adversely affect the quantity of outdoor air entering the building for ventilation.

In one building, for instance, the operational need to keep an adequate load on the chiller (to prevent the chiller discharge temperature from becoming too low) also prevented the economizer capability from being utilized. This mode of operation kept the outdoor air dampers at their minimum position, even when the outdoor air temperature would otherwise permit the use of increased ventilation. This situation is a good example of the need to fully understand the details of the operation of all components of the HVAC when performing an IAQ investigation.

7.3 FUNCTIONS OF HVAC SYSTEMS

The functions of HVAC systems can be divided into those of conditioning the air, those related to ventilation, and those related to pressurization of the building. Since those functions

pertaining to conditioning of the air for both thermal comfort and the removal of particulate matter are discussed elsewhere in this handbook, the immediate discussion here focuses on ventilation and building pressurization.

Ventilation

The primary purpose of *ventilation* is to provide acceptable IAQ by diluting and removing air contaminants. Natural means, mechanical means, or a combination of the two can achieve desired ventilation. For most buildings without operable windows, ventilation is accomplished by mechanical means as described above. A mechanical ventilation system will need to draw in outdoor air, deliver it to where the people are in the building, and also have provisions for the removal of stale air to make room for the outdoor air. One widely used criterion for the minimum amount of ventilation sufficient for acceptable IAQ is ASHRAE Standard 62-1989 (ASHRAE 62-1989). This edition of the standard recommends a minimum of 20 cubic feet per minute (ft³/min; cfm) of outdoor air per person in offices, and offers different requirements for other settings, but recommends at least 15 cfm of outdoor air per person in nonresidential buildings. Table 7.1 presents some selected prescriptive guidelines from this standard. Chapter 13 presents ventilation strategies.

Building Pressurization

Building pressurization refers to the pressure difference that can exist across the building envelope between the indoors and outdoors. Pressures can occur in response to both natural and mechanical forces. An example of natural forces is that of the *stack effect*, which occurs when it is warmer indoors than outdoors. In this situation, the warmer indoor air is less dense (i.e., more buoyant) than the outdoor air. This results in a combination of leakage at the top of the building and a positive pressure between the indoors and outdoors at the building envelope. The leakage of air at the top of a building then causes a negative pressure at the lower levels of the building in order to draw replacement air into the building. The level at which air exfiltration equals air infiltration is known as the *neutral buoyancy plane* (see Fig. 7.2).

Mechanical systems can also influence the distribution of pressures across the building envelope due to the action of fans. Fans, after all, move air by the creation of pressure differences in airstreams. Ideally, the mechanical system should be able to neutralize the forces created by leakage and the stack effect. If successful, this will prevent the infiltration of unconditioned air into the lower levels of the building. Even if the occupied areas of the building are maintained at a positive pressure with respect to the outdoors (typically 0.05 in. of water column, or 12.5 Pa), unoccupied plenum spaces may be at a negative pressure with respect to the outdoors because of the action of the return fan. If this occurs, it can provide for the transport of air contaminants into the building from the outside. This occurs especially with HVAC systems that have return-air fans and plenum return systems. An approach that can achieve positive pressurization across the entire building envelope, and not just the occupied areas, can be achieved with the use of relief fans, instead of return fans.

7.4 OVERVIEW OF TYPES OF HVAC SYSTEMS

Different approaches exist for achieving the various goals of HVAC systems. Each of these options contains a means for providing for both thermal comfort and ventilation.

TABLE 7.1 Outdoor Air Requirements for Ventilation for Commercial* and Institutional† Facilities

Application	Estimated Maximum‡ Occupancy P/1000 ft ² or 100 m ²	Outdoor Air Requirements			
		cfm/ person	L/s* person	cfm/ft ²	L (l/s·m ²)
Dry cleaners, laundries					Dry cleaning processes may require more air.
Commercial laundry	10	25	13		
Commercial dry cleaner	30	30	15		
Storage, pickup	30	35	18		
Coin-operated laundries	20	15	8		
Coin-operated dry cleaner	20	15	8		Supplementary smoke-removal equipment may be required; makeup air for hood exhaust may require more ventilating air; sum of the outdoor air and transfer air of acceptable quality from adjacent spaces shall be sufficient to provide an exhaust rate of not less than 1.5 cfm/ft ² (7.5 L/s·m ²)
Food and beverage service					
Dining rooms	70	20	10		
Cafeteria, fast food	100	20	10		
Bars, cocktail lounges	100	30	15		
Kitchens (cooking)	20	15	8		Distribution among people must consider worker location and concentration of running engines; stands where engines are run must incorporate systems for positive engine exhaust withdrawal; contaminant sensors may be used to control ventilation
Garages, repair, service stations				1.50	
Enclosed parking garage				1.50	
Auto repair rooms				7.5	7.5
Hotels, motels, resorts, dormitories				cfm/room	L/(s·room)
Bedrooms				30	15
Living rooms				30	15
Baths				35	18
Lobbies	30	15	8		Installed capacity for intermittent use.

Room type	Area, ft ²	Volume, ft ³	Supply air, cfm	Exhaust air, cfm	Notes
Conference rooms	50	20	10		See also food and beverage services, merchandising, barber and beauty shops, garages Supplementary smoke-removal equipment may be required
Assembly rooms	120	15	8		
Dormitory sleeping areas	20	15	8		
Gambling casinos	120	30	15		
Offices					
Office space	7	20	10		Some office equipment may require local exhaust.
Reception areas	60	15	8		
Telecommunications centers and data entry areas	60	20	10		
Conference rooms	50	20	10		Supplementary smoke-removal equipment may be required
Public spaces					
Corridors and utilities					
Public restrooms, cfm/WC§ or cfm/urinal		50	25		Normally supplied by transfer air; local mechanical exhaust with no recirculation recommended
Locker and dressing rooms		60	30		Normally supplied by transfer air
Smoking lounge	70				
Elevators					
Education					
Classroom	50	15	8		Special contaminant control systems may be required for processes or functions including laboratory animal occupancy
Laboratories	30	20	10		
Training shop	30	20	10		
Music rooms	50	15	8		
Libraries	20	15	8		
Locker rooms					
Corridors					
Auditoriums	150	15	8		Normally supplied by transfer air; local mechanical exhaust with no recirculation recommended
Smoking lounges	70	60	30

Constant-Air-Volume HVAC Systems

With constant-air-volume systems the temperature of the airstream varies over time while the volume stays the same in its effort to provide thermal comfort within the building. Within the overall approach of constant-volume systems, the temperature of the supply air can vary by cycling the addition of air warmer or cooler than the space, or by use of a dual duct system where the supply air to various zones is composed of a blending of air of two temperatures in a mixing box. Since the volume of supply air remains constant over time, the provisions for ventilation are more straightforward than with variable-air-volume (VAV) systems, because the system can be set up to provide a constant minimum percent of outdoor air in the supply air.

Variable-Air-Volume HVAC Systems

With VAV systems, it is the volume of air that is varied among zones, rather than by changing airstream temperature, to provide for thermal comfort. Therefore, as conditions in the building decrease from the extremes of design conditions (i.e., the hottest, most humid day, with the sun shining, all the equipment on, and the maximum expected number of people present), thermal comfort can be achieved with less and less cooling air required. As the amount of supply air at individual supply diffusers decreases, the total quantity of supply air handled by the AHU also decreases. While this can result in energy savings, it also creates the potential for IAQ problems due to the delivery of inadequate amounts of ventilation. Unlike constant-volume systems where adequate ventilation can be maintained with outdoor air as a constant percentage of the total supply air, VAV systems require that the percentage of outdoor air in the supply air increase while the total supply-air quantity decreases. While various approaches are available to maintain adequate ventilation to the occupants despite decreases in the total supply-air quantity, these approaches typically require more complexity and sophistication for the HVAC system, and therefore require greater vigilance and maintenance to ensure proper operation.

Hybrid HVAC Systems

Sometimes the designer of the HVAC system for a given building varies the specifics of the components within that building. This is particularly true in buildings where the thermal challenges at the perimeter of the building are very different from those in the core areas. It can therefore be useful to compare and contrast how the HVAC systems attempt to deal with these differing requirements for achieving thermally comfortable conditions. The concept of *hybrid HVAC systems* also refers to approaches that are a cross between constant volume and VAV equipment. One type of system, for instance, is constant volume with respect to the air handler, but involves the use of mixing boxes with the ability to discharge a portion of the supply air directly to the return plenum to prevent overcooling the space being served.

Heat-Pump HVAC Systems

Another category of HVAC systems relies on heat-pump units, typically of the water source type. These units are typically located in the ceiling plenum space (above the suspended ceiling) and are distributed around the building. With this approach, thermal comfort is dealt with separately for each zone served by each individual heat-pump unit. In some buildings, this would permit cooling of some interior zones, while providing heat to some perimeter zone with a lot of heat loss.

These heat-pump installations are most often constant minimum outdoor air setups. These require mechanisms to both bring in the appropriate quantity of outdoor air for ventilation and deliver it to the array of heat-pump units. This introduction of outdoor air varies from ducted systems that actually deliver it to each heat-pump unit to simpler systems where the outdoor air is merely dumped into the plenum space and is drawn from them into individual heat pumps. From the IAQ perspective, the issue then becomes how well, and how uniformly, the occupied space is ventilated. A related issue can be the introduction of unconditioned outdoor air into the return plenum, and how it can contribute to indoor moisture problems and possible microbiological growth problems if that air is humid.

Heat pumps are also typically distributed throughout buildings at many locations. This can limit their accessibility for inspection, making maintenance difficult at times. Increased labor is often required to maintain these heat pumps appropriately to ensure that the condensate drain pans are functioning properly and filters are changed on an appropriate schedule. In addition, the filters in heat-pump units are frequently of low efficiency in removing particulate matter as compared with the potential sometimes achieved in centralized systems. Another problem observed with heat pumps, and fan-powered mixing boxes to some degree, are poorly installed filters that permit unfiltered leakage of particle-laden air from the return plenum.

Displacement Ventilation Systems

A *displacement ventilation system* (DVS) differs from the more typically observed turbulent mixing system primarily by how it moves the air through the occupied space. The measure of how a given geometry of supply diffusers and exhaust grilles removes the air contaminants in a space is referred to by the term *ventilation effectiveness* (Skaaret 1984). One of the basic advantages of a DVS approach is that in many situations it can be more efficient in terms of the removal of air contaminants than a turbulent mixing ventilation system for a given quantity of air. One key difference between these two approaches is the amount of mixing that is intended to occur between the conditioned supply air entering the space, and

the air that is in the room and has already begun to become contaminated from sources within the space.

The achievement in ventilation effectiveness is a function of the following parameters: the location of the components that deliver supply air and remove air from a space, the relative temperatures of the air supplied, the air and any objects in the room, and the injection velocity of the supply air. A review of displacement ventilation (Yuan et al. 1988) indicates that they present certain challenges in terms of thermal comfort. Uncomfortable conditions can occur if the temperature at the foot level is significantly lower than at the head level.

Unlike more traditional mixed-air systems where the goal of the supply-air diffusers is to achieve rapid mixing of the delivered supply air with the room air, the goal in displacement ventilation systems is to have as little mixing as possible. In one approach to achieving displacement ventilation, the supply air is released low in the space, either at the corners or from the floor, and the air is removed from the space at the ceiling. In addition, the air is introduced at a temperature slightly below that of the space so that it can slowly push the air up through the space as the air increases in temperature around heat sources such as people, electrical equipment, and lights.

7.5 CONTROL OF THE HVAC SYSTEM

The control of the HVAC system is an aspect of its operation, which, along with its design, installation, and maintenance, has potential ramifications for the ultimate IAQ provided. Chapter 15 and 16 discuss the rationale for thermal comfort controls and Chap. 12 presents building control functions in more detail.

Thermal Control Approaches

A basic control option for achieving thermal comfort in spaces is the use of thermostats. With this approach, the thermostat can call for either heating, or cooling, of the air that is supplied to a space. In addition, the operation of the fan can either be turned on only when the thermostat is activated or may remain on independently. This cycling of the fan not only can eliminate the ventilation provision of the HVAC system but can also aggravate thermal comfort issues since the air motion experienced in the space varies dramatically as the fan cycles on and off over time. It is therefore recommended that thermostats that offer the choice of ON or AUTO for FAN operation have the ON option selected to maintain ventilation during those intervals when heat is being neither added or removed from the air going through the AHU.

Controls Affecting the Quantity of Outdoor Air

Decisions are made during the design of a building that affect the ability of the HVAC equipment to deliver adequate quantities of outdoor air to the building's ultimate occupants. Some building design decisions are dictated by maximizing the amount of prime rental space to be available rather than with the ultimate IAQ achieved. Examples of this are systems with provisions for only a constant minimum amount of outdoor air for ventilation. The advantages of this type of system are the simplicity of their controls and the ease with which they can be evaluated with respect to the amount of ventilation provided. In comparison, other control approaches can be more sophisticated in that they can vary the amount of outdoor air as a function of the outdoor temperature, or the number of people actually in the building and save energy while doing so.

Economizer Cycles

The term *economizer* refers to the HVAC system approach where the quantity of outdoor air is a function of the outdoor air temperature. In HVAC equipment with economizer capability, as the outdoor air temperature warms up to the temperature desired for the supply air, more and more outdoor air is brought in to achieve “free cooling.” One control approach typically used with economizer operation is that of a constant mixed-air temperature. With this approach the quantity of outdoor air is varied so the combination of the outdoor air and return air, when blended, yields a mixed-air temperature close to that of the desired supply-air temperature. When the outdoor temperature is very cold, a limit on the dampers establishes a minimum amount for ventilation. Similarly, when the temperature, or temperature and humidity (enthalpy), of the outdoor air exceeds that of the recirculated air, the damper positions also revert to that for providing only minimum ventilation amounts (see Fig. 7.3).

Feedback Information on Ventilation Performance

Considering the importance of the distribution system to actually deliver air to the building occupants, it may be useful to provide feedback data, such as space carbon dioxide (CO_2) measurements to supplement the direct measuring of the quantity of outdoor air entering the air-handling unit. The continual monitoring of IAQ parameters, such as CO_2 concentrations, can provide information not only about the adequacy of ventilation (as a function of peak values) but also on related performance criteria as to the uniformity of distribution within a given AHU, how well this ventilation distribution mirrors the distribution of people, and the effectiveness of the overnight purge of air contaminants of human origin (Bearg 1997, 1998a).

FIGURE 7.3 Variation of outdoor air fraction in the return-air temperature economizer cycle. [Reprinted from R. Johnson (1999). *Fundamentals of HVAC Systems*, ASHRAE Continuing Education. Atlanta, GA: American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. This material is reprinted with permission of the American Society of Heating, Refrigerating, and Air Conditioning Engineers, Inc. (1791 Tullie Circle, Atlanta, GA 30329).]

Adding the monitoring of dew point (absolute humidity) and carbon monoxide to a multipoint monitoring system such as this can provide further specific information on HVAC performance in the areas of infiltration control, humidity control, and the presence of moisture sources (Bearg 1998b).

Demand-Controlled Ventilation (DCV)

Beyond the passive evaluation of ventilation, there is the option of using ventilation performance data to actively control the amount of outdoor air entering the AHU. In systems utilizing DCV, the amount of outdoor air delivered can vary in accordance with the actual number of people in the building. In one typical approach DCV is achieved by the monitoring of carbon dioxide because this parameter can reflect the dynamic interaction between the amount of ventilation being provided and the number and duration of people in a given space (Bearg 1995). If CO₂ concentrations are used in this capacity, then people need to be the predominant source of air contaminants present. There are two key advantages of a DCV application where ventilation is based on actual occupancy. First, it can automatically modify the operation of the HVAC system to increase the amount of ventilation provided during peak intervals of maximum occupancy. It can also achieve energy savings during intervals of reduced or minimal occupancy by permitting the setting of more accurate minimum ventilation rates for the HVAC system. It can help achieve this because few buildings have a provision for feedback on ventilation performance.

DCV systems can vary in complexity from just a single sensor in the return airstream to multiple sampling locations throughout both the air-handling equipment and the occupied spaces. One problem observed with monitoring only the return airstream is that this location, at best, only reflects an average of all the spaces being served. If there

FIGURE 7.4 Monitoring data for locations served by AHU-2 on July 2, 1997. [Reprinted with permission from AIRxpert Systems, Inc. (1997).]

is a distribution problem and the DCV system is monitoring only the return-air value, the amount of ventilation provided at some locations cannot meet ASHRAE minimum requirements even though the return-air value indicates that a generous amount of ventilation is being provided. Figure 7.4 presents data from a building where such a distribution problem exists.

CHAPTER 8

HVAC SUBSYSTEMS

Jerry F. Ludwig, Ph.D., P.E.
Environmental Health & Engineering, Inc.
Newton, Massachusetts

The following section discusses the several common heating, ventilating, and air-conditioning (HVAC) subsystems that can be found in a commercial building. These subsystems are often integrated into the building so well that building occupants are able to enjoy their contribution to the building's environment while being unaware of these important design elements.

The subsystems that are discussed in this chapter include ducts, plenums, and diffusers; heat exchangers; cooling towers; dryers; and humidifiers.

8.1 DUCTS, PLENUMS, AND DIFFUSERS

This section discusses the use and construction of various physical elements of air conveyance systems, such as ducts, plenums, and diffusers. It also discusses the elements of design that determine performance. While maintenance and cleaning of system components is described later, it is worthwhile to include some discussion in this section.

Concept Statement: Ducts and Plenums

Ducts and *plenums* are conduits used to convey air from one place to another through a building. Sometimes the air is being conveyed because of desirable properties of purity and its thermal conditioning, while at other times the air being conveyed contains undesirable elements or thermal properties that need to be removed and exhausted from the building environment.

Duct systems in modern buildings are usually constructed of sheet metal, fiberglass material that has been pressed into sheets, cast-in-place concrete, masonry enclosures, and various polymer materials. In some instances, structural cores are utilized as ducts, such as the hollow areas in some precast building elements. To limit the amount of combustible material in a building and smoke spread, most building codes require that material used to form ducts in nonresidential buildings be made from materials that are noncombustible.

An intersection of many ducts is commonly referred to as a *plenum*. In many nonresidential buildings, the air being returned from the occupied space in order to heat or cool that space flows through a *return-air plenum*, which is typically formed by the installation of a false ceiling under the bottom side of the deck of the floor or roof above the space.

Common Design Parameters for Duct Systems

The design parameters for duct systems in buildings are guided by a variety of factors that affect the habitability, operability, and cost of the building. Duct systems, while necessary elements for proper ventilation and air-conditioning systems in most commercial buildings, are often viewed more as an architectural constraint rather than an architectural element and are generally hidden from view. Sizing and installation of ducts must be considered carefully because they impact so many different areas of building operation, such as

- Space ventilation effectiveness
- Amount of rentable space
- Generation of noise and noise levels in occupant space
- Load on the building structure
- Amount of fan power required by the ventilation system
- Amount of energy needed to operate the system and provide ventilation
- Costs of installation, operation, and maintenance

Ducts must be sized and installed in a building in a manner that assures proper ventilation of the space, while optimizing the other elements listed above. The optimization process is often more complicated on major renovation projects rather than new construction.

The need to meet these constraints for most commercial office buildings in the United States has narrowed the generally accepted design options. The most common design for these systems is to utilize galvanized sheet metal for the duct material, often lined either internally or externally with fiberglass. Galvanized sheet metal is fireproof and relatively lightweight. Utilizing skilled labor, galvanized sheet metal can be readily formed to the sizes and shapes required for the project, either on site or at a local fabrication shop. A fiberglass lining serves to isolate and insulate the ductwork, both thermally and acoustically, from the occupied volume of the space.

The size of the ducts in a building will be determined in part by the required airflow rates. As noise, total duct pressure, and required fan horsepower increase with the square of the airspeed within the duct, and fan energy consumption with the cube of the airspeed, the airspeed in ducts is generally less than 5000 feet per minute (ft/min; fpm). Generally, most duct systems in buildings for reasons of fan power requirements, space constraints, and noise considerations operate at velocities between 1000 and 3000 fpm.

Return-Air Plenums

To minimize the use of duct material and to maximize the rentable volume of the building, often only the conditioned supply air, and air exhausted from bathrooms, kitchens, and special capture devices utilizes ductwork, which generally runs between the top of a suspended false ceiling and the bottom of the roof deck or deck of the next floor. The remaining volume of the space between the false ceiling and the floor/roof deck not contained within the ductwork and other conduits for electrical, plumbing, and fire protection utilities can be used to form a return-air plenum (see Fig. 8.1). Another result of utilizing this space for supply air ductwork, return air, and exhaust air is that it dictates the design of the supply-

FIGURE 8.1 Cross-section view of typical return-air plenum system in a commercial office building. (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 79.)

air diffuser system, and return-air and exhaust-air extraction systems. In most office buildings supply air is introduced into the occupied areas of the building through ceiling mounted diffusers; and return air and exhaust air is gathered from grilles mounted in the ceiling plane.

Supply-Air Plenums

In some instances, the volume enclosed between the top of the suspended false ceiling and the bottom of the floor/roof deck is used as a supply-air plenum. This configuration is seldom applied in commercial office space. However, some designs that utilize heat pumps may provide outdoor air to the plenum as the primary air to the heat pumps. The use of supply-air plenums may also find application in specialized rooms used for clean processes (cleanrooms), used in the manufacture of semiconductors and other microtechnologies. In these instances, the cleanroom will have an air circulation rate that may be as much as 100 air changes per hour (ACH), as opposed to the more typically observed air exchange rate of approximately 6 ACH in commercial office space (i.e., approximately 1 cfm/ft²). In some cases, in high-technology facilities, the entire false ceiling serves as both a particulate filtration system and an air diffusion system for the occupied space.

Fibrous Insulation

Fibrous insulation, typically fiberglass, is commonly used inside building HVAC systems and in plenums. This insulation is relied on for both its thermal insulating and sound adsorption properties.

If properly installed and maintained, fiberglass insulation inside ducts and plenums is not a problem. However, improperly installed or wet, dirty fiberglass insulation may detrimentally impact the indoor environment. Wet and dirty fiberglass can provide a medium for microbiological growth. Improperly installed or maintained fiberglass can also cause indoor air quality (IAQ) problems when it delaminates and erodes by allowing fibers to be transported into occupied areas of the building. Contact with fiberglass may produce a number of health symptoms. Skin irritation, primarily itching and dermatitis, can be caused by glass fiber exposure. Eye irritation is also common. Although rare, upper respiratory irritation has been reported. There is some limited evidence that some man-made mineral fibers produce an increase in lung cancers, but this has not been established for fiberglass (Wiese and Lockey 1992, HEI-AR 1991).

Fiberglass insulation materials on the interior portions of ductwork must be securely installed. Edges should be protected during installation to avoid fraying, erosion, and delamination on system start-up. In some instances, it has been observed that fiberglass that is not properly secured to the ductwork begins to “sail” into the airstream. After reaching a critical angle, the air pressure on the bottom side can cause the fiberglass to break off and travel through the duct out of the diffuser.

Other vulnerable areas for fiberglass damage and erosion include access doors in air handler systems and ducts. In these areas, the fiberglass requires periodic inspection and maintenance to avoid erosion. Although most studies have shown that the steady-state rate of fiber erosion from fiberglass in good repair is negligible, glass fibers from damaged ductwork do occasionally find their way into occupied areas of a building. This usually occurs because pieces of fiberglass erode from frayed and delaminated edges of the lining and will be transported through the system. The size of the material transported depends on where these pieces originate in the system. For instance, chunks of glass lining originating upstream of the ventilation system’s fan will likely be pulverized into many small pieces when they pass through the fan, whereas fiberglass chunks originating downstream of the

fan can be expected to remain more intact yet continue to serve as a source through continuation in the airstream.

Once glass fibers have eroded and been transported into the occupied areas of the building, occupants are likely to touch surfaces that are contaminated and then transfer the fibers from their hands to their face and eyes. Fiber contact with building occupants via airborne vectors is usually limited as the fiber release usually occurs in short bursts, and the fibers are of an aerodynamic size that tends to quickly settle. However, they can often be resuspended and create additional intermittent exposures through normal occupant activities.

Properly installed insulation does not erode over time. In the absence of liquid water and accumulated dirt, fiberglass insulation should pose little risk for contact with building occupants. Figure 8.2 shows a commonly specified detail to minimize fiber erosion from the edges of the internal lining of ducts.

Air Diffusion Principles

The introduction of supply air into an occupied space for purposes of heating or cooling is a more complex problem than it might initially appear. Improperly designed supply-air diffusion systems may result in areas that are cold and drafty, while at the same time, only a few feet away, occupants may be subjected to hot and stagnant conditions. Improperly

FIGURE 8.2 A commonly specified detail for securing internal duct liner, including edge treatment detail.

designed supply-air diffusion systems may also impose excessive noise on the occupants of the space.

Supply air is often as much as 20°F colder to 50°F warmer than would be considered acceptable for room air and travels from the ductwork into the space at speeds much greater than would be acceptable to building occupants. Therefore, introducing this air into the space in a manner that does not cause a draft requires consideration of mixing and thermal comfort principals. Proper air diffusion entrains room air into the supply-air jet, causing mixing to occur, making the conditions in the occupied zone homogenous in both temperature and air motion.

Diffusers are devices used to distribute air of desirable quality into the occupied areas of the building. Common practice in most nonresidential environments in U.S. buildings is to specify diffusers that completely mix the air supplied through the diffuser into the occupied space so that there are no discernible gradients in temperature or contaminant concentrations in the space.

Thermal Comfort Constraints

For a building occupant to achieve acceptable thermal comfort conditions, the occupant must be at thermal equilibrium (i.e., one is losing thermal energy at the same rate of one's metabolism and any thermal gains from one's environment), and heat transfer from all areas of the body must be relatively uniform. The thermal conditions within the occupied space are generally a complex interaction of dry-bulb temperature, water vapor content (humidity), air movement, and thermal radiant environment (surface temperatures of the surroundings as seen by the occupant) with the thermal insulating properties of the occupants' clothing activity levels.

Considerable care is required to introduce air into the occupied space of a building, since in most nonresidential buildings, diffusers introduce air into the occupied space that is much cooler (15 to 20°F) than the air in the occupied space. Assuming that an occupant is in an otherwise thermally comfortable environment, an occupant's acceptance of draft conditions generally depends on the difference of temperature of the air flowing locally over the body from the local air temperature, and the speed at which it flows. Generally, 80 percent of human occupants will be satisfied with a thermal environment in which the effective draft temperature as defined by Nevins (1976) is -3 to $+2^\circ\text{F}$. The effective temperature is defined as

$$\phi = (t - t_c) - 0.07 (V_x - 30) \quad (8.1)$$

where ϕ = effective draft temperature, °F

t = local temperature, °F

t_c = control temperature, °F

V = local air velocity, fpm

Using the effective draft temperature, Nevins (1976) defined the *air diffusion performance index* (ADPI), which is the percentage of points at which the draft temperature, uniformly distributed throughout the occupied space, satisfies the 80 percent comfort criterion (i.e., $-3^\circ\text{F} < \phi < +2^\circ\text{F}$). This index has proved to be a valid, single-number rating of an air diffusion system, and is commonly used when selecting diffusers and diffusion systems.

Figure 8.3 illustrates results of studies performed to determine acceptable draft conditions at the neck and ankle regions of humans. Figure 8.4 graphically depicts the ADPI envelope.

FIGURE 8.3 Percentage of occupants objecting to drafts in air-conditioned rooms. (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 8.)

FIGURE 8.4 Comfort criteria used to evaluate the air diffusion performance index (ADPI). (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 9.)

Momentum Transfer from Supply Air

Supply air, when traveling within ductwork, possesses considerable momentum. When the supply-air duct empties its air into the air-conditioned space, this momentum is utilized to help mix this air with the air in the space, which is intended to ensure homogenous temperature and air movement within the occupied zone of the air-conditioned space.

The momentum of the air jet where the supply duct empties into the air-conditioned space is utilized to mix the air in the occupied space by careful understanding and manipulation of its throw, drop, and spread as illustrated in Fig. 8.5.

“Throw” is the horizontal and vertical distance a supply-air jet travels after leaving the discharge point before its velocity is reduced to a specified terminal value. “Drop” is the vertical distance that the lower edge of the air jet travels at the end of the jet’s “throw.” “Spread” is the divergence of the airstream in the horizontal or vertical plane after it leaves the outlet.

The characteristics of a supply-air jet entering a much larger air-conditioned space is often understood, and engineered on the basis of the following description of the jet’s four zones of expansion (see Fig. 8.6).

Zone 1 is a short zone, extending approximately four duct diameters from the duct termination point. In this zone, the centerline velocity of the supply-air jet remains approximately unchanged.

Zone 2 is a transition zone, extending to approximately eight duct diameters from the duct termination point. In this zone the centerline velocity of the jet varies inversely

VERTICAL CROSS SECTION

PLAN VIEW

FIGURE 8.5 Characteristics of air jets introduced into air-conditioned rooms. (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 12.)

with the square root of the distance from the outlet. In this zone, the jet is just beginning to spread, and entrain air from the space.

Zone 3 is a long zone in which the maximum velocity varies as the inverse of the distance to the outlet. In this zone, the turbulence caused by the supply-air jet is fully established, and significant amounts of entrainment with the air in the zone occur. This zone may be as long as 100 duct diameters, depending on the initial jet velocity and shape.

Zone 4 is the final transition zone; here, the centerline velocity of the jet varies inversely to the square of the distance from the outlet.

Supply-air jets discharging near obstructions such as walls, ceilings, or other discharge jets may be influenced in several ways. Jets flowing parallel to a ceiling or wall will attach to the surface, thus limiting the possibility of entrainment from one side of the jet. This phenomenon, known as the *Coanda effect* (see Fig. 8.7), is often utilized to affect the supply-air distribution characteristics of the air diffuser.

Effect of Diffuser Location on Air Mixing and Thermal Comfort

Building designers usually locate diffusers in a building's sidewalls, ceilings, or sills. The size and type of diffuser should always be selected to overcome stagnant zones that could be created by the natural convection process and internal loading. Diffusers should be chosen to provide proper coverage of the area (diffuser "throw") in a manner that does not produce drafts. Normally, the diffuser should be installed so that the primary supply-air jet

FIGURE 8.7 Jet characteristics when projected parallel and within a few inches of a surface (i.e., Coanda effect). (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 15.)

attaches itself to an adjacent ceiling or wall and entrains air from the occupied space. This entrainment causes the usually cooler supply air to induce a flow of relatively warmer air from the occupied zone of the space. This mixing of the different temperature air sources prevents drafts that would occur if the cool supply-air jet were focused directly on the occupants. Since this design relies on momentum transfer to induce mixing, care must be taken to ensure acceptable noise levels. Criteria have been developed and are presented in the ASHRAE 1997 *Fundamentals Handbook*, Chap. 7 (ASHRAE 1997).

Without the proper throw, the supply-air jet is no longer attached to the adjacent surface. This effect, often referred to as “dumping,” can be expected to cause occupants of the space to complain that the air near the diffuser is drafty and cold, while occupants farther away from the diffuser(s) will complain that the air is too warm and stuffy or stagnant.

Generally, ceiling diffusers are quite effective for cooling but are poor for heating. The return-air intake affects the room air motion only in its immediate vicinity. On the other hand, locating the intake in the stagnant zone returns the warmest air during cooling and the coolest air during heating to the air-handling units (AHUs) (see Fig. 8.8). Likewise, diffusers mounted on the floor with their Coanda jet attached to a wall perform much better in the heating mode than in the cooling mode of operation (see Fig. 8.9).

Return Air

While the location of return air grilles has relatively little impact on the air movement and mixing of air in an air-conditioned space, the location of return-air and exhaust-air inlets are nonetheless important. To illustrate the relative difference between the effect on air movement that a return or exhaust air inlet has compared to a supply-air diffuser, one needs only remember the candles on a birthday cake. While it is relatively easy to blow the candles out, it is virtually impossible to extinguish them by inhaling.

When air conditioning a space, it is often desirable to draw return air from the space that avoids exposing occupants of the space to sources of air that contain excessive heat or pollutants generated by a point source. For instance, in modern office design, return air is often drawn through light fixtures in a manner that does not subject the occupants of the space to the heat source that these fixtures represent.

Likewise, when exhausting air from a space that contains a local source of air pollution, it is desirable to draw this exhaust as close to the pollutant release point as possible, in a manner that prevents the pollutants from mixing into the occupied space, and ensures that it is captured before it comes in contact with any occupants of the space. Figure 8.10 illustrates an example of good practice when locating an exhaust for a point-source pollutant generator.

Sound Control

The introduction of supply air into the air-conditioned space, if not carefully executed, can generate excessive noise in the occupied space. Noise is generated when the air from the duct is allowed to expand into the air-conditioned space. Often, noise is generated in terminal control devices such as variable-air-volume (VAV) or dual-duct (DD) mixing boxes. The opening in the supply-air duct at the diffuser also provides a sound conduit back to the air handler unit fan, which is itself a noise generator. Additionally, the supply-air duct may act as a sound conduit from the building's mechanical room or other areas where noise is generated.

Generally, the treatment of the noise generation and transmission through the ductwork is a major design consideration in any HVAC system. The manufacturers of air diffusers and terminal control devices generally provide data that allow the designer to assess the noise performance of the installed system.

FIGURE 8.8 Performance of a correctly designed and installed ceiling diffusers in both the cooling and heating modes of operation. Note the influence of natural convection currents on the total air pattern, and temperature stratification relative to height. (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 26.)

FIGURE 8.10 Examples of good practice when locating exhaust air inlets to capture locally generated air pollutants. (Reprinted from *Industrial Ventilation*, 22d ed., ACGIH, Cincinnati, OH, 1995, pp. 2-4.)

Sound is defined as a vibration in an elastic medium. At a given point, sound is a rapid variation of pressure of the medium (usually air) about a steady-state value. *Noise* is unwanted or objectionable sound. Sound becomes noisy when it is distracting or loud, when its frequency is objectionable, or when it interferes with communication.

The absence of sound can also be annoying. The use of sound of moderate strength and good quality can mask conversation or unpleasant, distracting sounds to create the desired acoustical environment. The masking sound or noise source should be loud enough to mask other sounds, but not loud enough to be disturbing or prevent communication.

While humans are generally sensitive to acoustical vibrations (sound) between 20 and 20,000 cycles per second (Hz), their sensitivity to sound changes as the frequency of a sound changes. For purposes of design, it is often desirable to use a method of rating sound that incorporates the sound intensity at the various frequencies into a single sound rating number.

For HVAC design applications, the acoustical quality of the environment is often judged by either a noise criterion (NC) or a room criterion (RC). Both of these criteria provide a single-number method of providing information about the sound level throughout the human sound spectrum (i.e., frequencies between 20 and 20,000 Hz). Figures 8.11 and 8.12 display the NC and RC ratings, respectively. Table 8.1 shows recommended design goals for various building occupancies using the NC and RC ratings.

Manufacturers of diffusers, and terminal control devices such as VAV boxes, typically provide NC or RC ratings for their devices. These ratings assume that specific installation recommendations have been followed, and that the product is installed in applications that reflect typical sound adsorption characteristics.

Diffuser Characteristics

For today's buildings, diffusers are available in a wide variety of types, to suit many different applications. Ceiling diffusers, which are probably the most common diffuser used in commercial office buildings, are available in many styles to blend with the chosen

FIGURE 8.11 Noise criterion curves for specifying the design level in terms of the maximum permissible sound pressure level for each frequency band. (Reprinted from Ralph G. Nevins, *Air Diffusion Dynamics*, Business News Publishing Co., 1976, p. 46.)

FIGURE 8.12 Room criterion curves for specifying the design level in terms of the maximum permissible sound pressure level for each frequency band. Region A: High probability that noise-induced vibration levels in lightweight wall and ceiling constructions will be felt; anticipate audible rattles in light fixtures, doors, windows, etc. Region B: Noise-induced vibration levels in lightweight wall and ceiling constructions may be felt; slight possibility of rattles in light fixtures, doors, windows, etc. Region C: Below threshold of hearing for continuous noise. ceiling and can be conveniently mounted into a suspended grid ceiling system. Likewise, other types of diffusers, such as sidewall diffusers, are available. Since the ceiling diffuser is the predominant type of diffuser specified and installed, the choice of styles for sidewall diffusers is relatively limited.

Figures 8.13 through 8.18 illustrate diffusers typically observed in commercial office buildings. Table 8.2 illustrates typical catalog performance data for a circular ceiling diffuser, while Table 8.3 provides guidance as to the correct specification of terminal airflow

length versus room dimensions to maximize the ADPI for various types of air diffusers, as a function of internal cooling.

Note from Table 8.2, that typical catalog data for a diffuser include information pertaining to the throw of the diffuser and noise information [in this case in terms of the noise criteria. Note also that throw, discharge pressure drop, and NC vary as a function of airflow through the device.

Variable-Air-Volume Systems

To avoid creating drafty areas or areas of stagnant air, the design of VAV systems must accommodate the sensitivity of the throw characteristics of the diffuser to the change in airflow and the geometry of the room. This is a most critical design area; the diffuser must be carefully selected and the “turndown” of the VAV terminal limited. Note that ADPI performance of some diffuser types is much less sensitive to the diffuser throw characteristics than other types. This is illustrated by Figs. 8.19 and 8.20.

VAV systems are most vulnerable to these complaints when the local control zone sets the amount of supply air to its minimum flow. In some buildings, the minimum flow of the control zone may allow no flow through the diffuser, especially for internal areas that have no method of supplying heat. To avoid this problem, fan-powered boxes are often installed.

These boxes mix primary supply air from the building's air-handling units with local return air from the building's return-air plenum, thus assuring constant air velocity through the diffusers, and therefore stable mixing and air distribution in the occupied space. Fan-powered boxes are often equipped with the means to add heat to the air discharged through the air diffusers.

At least one study (Taylor 1996) has questioned the economics of this practice because of the requirements for many small inefficient fans and fan motors to move air versus larger and more efficient fans and fan motors at the air handler, the additional capital expense of the fan-powered box, installation cost such as wiring, and maintenance of the fan-powered devices. However, the use of fan-powered VAV boxes to minimize the drafts and stagnant

conditions in localized areas to which VAV systems are prone is nonetheless finding its way into practice.

8.2 HEAT EXCHANGERS

Heat is transferred whenever there is a differential in the thermal energy state of a substance. In nature, heat migrates from higher energy to lower energy. The temperature of a substance is one measure of its thermal energy potential. Another measure of the ther-

mal energy state of a substance is the quality of that substance—that is, the percentage of the total amount of that material within a control volume that is a solid, liquid, or gaseous state.

In a building, as in nature, heat transfer occurs nearly continuously. Many elements of the built environment have been designed solely for heat exchange so that a comfortable thermal environment can be maintained. Such components, commonly referred to as *heat exchangers*, are specifically designed to transfer or exchange thermal energy (i.e., heat) from one process to another to attain the desirable thermal properties released in that process. Often this heat exchanger isolates the building's environment from other elements of that process.

Heat exchangers are found in warm-air furnaces, allowing the air of the building to obtain the desired thermal characteristics from the combustion occurring in the furnace while shielding this air from the combustion products generated in the combustion process. Figure 8.21 illustrates this concept.

Heat exchangers are also commonly used in refrigeration or air-conditioning systems to transfer heat from the areas to be cooled (i.e., the occupied space) into a refrigerant. In the system, heat that is adsorbed is used to replace heat that is lost in the endothermic process of evaporation of the refrigerant. As the system's evaporator is a part of a closed-loop system containing only the refrigerant, heat is exchanged via convection and conduction through the system's evaporator, a heat exchanger specifically designed for this purpose. In some cases, an intermediary fluid (usually water) is used to transfer heat from the air to be cooled to the evaporator. In this design, two heat exchangers are used: one to transfer heat from the air to the water, and another to transfer heat from the water to the evaporating refrigerant (see Fig. 8.22).

Likewise, heat exchangers are utilized on the condensers of refrigeration systems to reject heat into the ambient environment. In this case, the condensing refrigerant rejects

FIGURE 8.21 The heat exchanger is an essential element of a warm air furnace. The heat exchanger extracts the heat from the combustion process, while segregating the indoor environment from the gaseous products of combustion. (Reprinted by permission from Richard R. Johnson, Ph.D., *Fundamentals of HVAC Systems*, ASHRAE, Atlanta, GA, 1999, p. 6.5.)

heat through a heat exchanger, either directly to ambient air or to an intermediate fluid (e.g., water), which then rejects the heat either through a water to air heat exchanger or to a cooling tower.

Heat exchangers can be classified in many different ways, depending on their configuration and flow characteristics. Figures 8.23 to 8.25 show schematic representations of various heat exchanger configurations commonly specified to transfer thermal energy between water, steam, or refrigerants. Figure 8.26 schematically illustrates heat exchangers designed specifically to transfer heat from water or refrigerant to or from air (*a*), or to transfer heat from two different airstreams (*b*).

8.3 HUMIDIFICATION AND BUILDING ENVELOPE

It is commonly acknowledged that it is desirable to maintain a building's humidity level within certain limits. Generally, low humidities in buildings are associated with static discharge problems, which can trigger other problems with electronic equipment. Persistent low humidities are also commonly thought to dry mucous membrane tissues of occupants

FIGURE 8.22 Shell and tube condenser. Heat exchangers as components in packaged air-conditioning systems.

FIGURE 8.23 Heat exchangers. (a) Parallel flow; (b) counter flow; (c) cross flow. (Reprinted by permission from Karlekar and Desmond, *Engineering Heat Transfer*, West Publishing Company, St. Paul, MN, 1977, p. 482.)

to the point where discomfort occurs because of nasal irritation. Nosebleeds (epistases) are often reported as a symptom associated with dry environments. To avoid these problems, building designers and owners sometimes install humidification systems in a building.

Generally, experience has shown that in many climates, it is better not to install a humidification system, rather than install a system with a design that does not thoroughly address its potential impact on the building in which it is installed. Generally the design should consider the method of moisture dispersion into the air, the control sequences for maintaining the humidity levels, and the limitations of the building envelope due to moisture migration and possible condensation and freezing problems.

Review of Available Humidification Systems

Generally, humidification systems that are available for commercial office buildings utilize one of five different methods of turning liquid water into water vapor and injecting it into

FIGURE 8.24 Heat exchangers. (a) Two-tube pass, one-shell pass; (b) four-tube pass, two-shell pass. (Reprinted by permission from Karlekar and Desmond, *Engineering Heat Transfer*, West Publishing Company, St. Paul, MN, 1977, p. 483.)

FIGURE 8.26 (a) Extended surfaces used to promote heat transfer. (b) Cross-flow compact exchanger. (Reprinted by permission from Karlekar and Desmond, *Engineering Heat Transfer*, West Publishing Company, St. Paul, MN, 1977, p. 485.)

the building's supply air through its HVAC systems. These methods include use of (1) plant steam, (2) steam produced by boiling domestic water, (3) ultrasonic vibrations to atomize liquid water into a fine water aerosol mist, (4) compressed air to force water through a nozzle that generates a fine water aerosol mist, and (5) pan-type humidifiers, in which water is evaporated into the airstream.

Generally humidification systems that rely on steam are least problematic for commercial building use. This is because water that is heated to steam temperatures generally kills all living organisms that may have been present in the water used to make the steam. Steam generated by boiling domestic water directly at the humidifier is probably best because it greatly minimizes the possibility that chemicals used to treat a large boiler and steam distribution system are injected into a building's HVAC systems.

Humidification systems that rely on plant steam generally contain chemicals used to treat plant steam to minimize corrosion. These chemicals commonly are in the form of amines. In general, they are measurable in indoor spaces in which plant steam humidification systems are used, but the concentrations are at very low levels. In a steam plant that is continuously treated with these chemicals at low levels and not shock-treated, the presence of these amines is not known to cause IAQ symptoms among building occupants. However, the use of plant steam for purposes of humidification does allow the possibility that water and steam treatment practices that might be acceptable for other reasons may in fact pose an IAQ risk.

One concern with any humidification system is that the water injected into the HVAC system or room should have minimal concentrations of microbiologicals or chemicals. Steam generated from domestic water is the medium that is least likely to cause environmental problems. Even for steam humidifiers, domestic water is commonly treated to protect system components from metals and salts.

Where steam is not used, cool mist, atomizing, evaporative pans, and ultrasonic humidifiers have all been shown to have a higher potential to be a source of microbiological contaminants in some situations (Oie et al. 1990, 1992; Shuie et al. 1990; Tyndall et al. 1995; Highsmith et al. 1988). Pan humidifiers are particularly a cause for concern because they contain water basins where microbiological growth may occur without inhibition. When pan humidifiers are used, their basins should be drained down and cleaned weekly and the water supply subjected to the same treatment and filtration requirements discussed later in this section for atomizing humidifiers. Generally, it is recommended that unless strict attention can be paid to a weekly maintenance program, pan humidifiers should be replaced with less maintenance-intensive systems such as steam humidifiers.

In general for atomizing humidifiers, water may be stagnant inside piping when the system is not operating. For this reason, and the fact that these pipes may be stagnant in areas that would produce optimal temperatures for the proliferation of *Legionella pneumophila* bacteria, automatic draindown of the pipes is advised whenever the humidification system has not been operating for approximately one day.

Even though the domestic water for the atomizing humidifiers is not stagnant, the water invariably has some level of microbiological contaminants, metals, salts, and chemicals. Municipal water supplies can contain bacteria, such as *Legionella*, in sufficient number to be of concern when the water is sprayed into the air (Burge 1995). Furthermore, metals and salts may damage the humidifier or HVAC components, generate an irritating "white dust," or create an airborne exposure hazard. Therefore, further water treatment when using domestic water for humidification in systems that do not boil water is recommended.

Treatment of Domestic Water for Atomizing Humidifiers

Analysis of water samples collected as close to the humidifiers as possible may help determine the extent to which filtration or water treatment is necessary. However, water samples

may not provide relevant data or may not be indicative of the content on any given day. Therefore, it is generally recommended that a filtration option that can provide suitable water over a wide range of incoming water quality be specified as part of the equipment.

This section briefly describes common technologies that are available for treatment of domestic water supplying the atomizing humidifiers in the building.

Ion-exchange methods, including softening and deionization, remove dissolved inorganics by percolating water through ion-exchange resins. This method does not remove particles or bacteria, and the beds can generate resin particles and provide a culture medium for bacteria.

Carbon adsorption is commonly used to protect ion-exchange resins from nonionic organics that may coat the resin and decrease life and capacity. This method effectively removes nonionic organics as well as chloramines and free chlorine, but it does not effectively remove dissolved inorganics, particles, and bacteria.

Filtration removes material larger than the rated pore size for a given filter. By using a 0.2- μm filter, essentially all bacteria can be removed. However, dissolved inorganics, dissolved organics, viruses, endotoxins, and some colloids can still pass through a 0.2- μm filter. Finer filters may remove much of this material, but pressure drop across the filter greatly limits the feasibility of using filtration as a treatment method to remove these contaminants.

Reverse-osmosis systems pass water tangentially at high pressure across a very tight membrane, with about 20 percent of the input water yielded as high-purity water. Reverse osmosis can be effective at removing all types of contaminant, including particles, endotoxins, microorganisms, colloids, dissolved inorganics, and dissolved organics. Reverse-osmosis membrane manufacturers claim greater than 99 percent removal of particles, bacteria, and organics with molecular weights greater than 100, as well as at least 94 percent removal of dissolved inorganic ionic compounds. Prefiltration by carbon absorption and a 5- μm prefilter is recommended to remove chlorine and particles in the water in order to extend the life of a reverse-osmosis system. The high-quality water produced by reverse-osmosis systems may be corrosive to piping systems. Therefore, the effect of the pure water on humidifier and piping components should be evaluated. Stainless-steel components may be appropriate.

Ultraviolet (UV) radiation can be an effective killer of microorganisms, given sufficient residence time and appropriate sizing, maintenance, and prefiltration (Makin and Hart 1995). Prefiltration is important because particulate material in the water can shield microorganisms from the effects of UV radiation. With UV radiation alone, particles and nonviable biological matter, including endotoxins, are not removed. Endotoxins and nonviable biological matter that are not removed by UV radiation may still cause health effects (Burge 1995).

Chemical treatment of water supplies is used to control microbial growth. Continuous hyperchlorination of domestic water to control the growth of *Legionella* has been used, but has not always proved effective (Kutch a et al 1995). Furthermore, excess water chlorination can cause secondary problems such as corroding metals or production of toxic compounds in the water (Makin and Hart 1995).

Reverse-osmosis treatment of domestic water for use with atomizing humidifiers has been shown to be an effective system. The initial cost of one reverse-osmosis system containing all necessary prefiltration components that can produce 5 to 6 gal (enough to humidify a 250,000-ft² office building in the Boston area) of water per minute, is about \$20,000 in 1997 dollars. This cost does not include the cost to bring water service to the system or to pipe water to the humidifiers. Using more than one system may be desirable to limit the

amount of piping required, particularly since the pure water produced by reverse osmosis can corrode some piping systems.

Any time humidification is used, including steam humidifiers, care must be taken to avoid stagnant water or wet insulation inside HVAC systems and to avoid wetting of building materials if dew points are reached inside the building envelope.

Generally the manufacturer of any humidifier system installed in a building's HVAC system should be relied on to advise clients of the proper location of the humidity injection point to avoid wetting of the electric heating coil or pooling of water. The sequence of operations for the humidifier should specify that airflow be proved before the humidification system will operate. Furthermore, sloped water drainage should be provided not only at the cooling coil but also below the spray nozzles. Experience shows that even in well-designed humidification systems, the area below the nozzles often becomes wet.

A common problem is the preinstallation of humidifiers in HVAC systems without adequate attention to the vapor trail lengths required. This is an important consideration to ensure that the water vapor is completely vaporized before any flow perturbation, which may cause the vapor to condense. "Humidifiers should be connected to airflow proving switches that prevent humidification unless the required volume of airflow is present or high limit humidistats are provided. All duct takeoff should be sufficiently downstream of the humidifier to ensure complete moisture dissemination" (AIA 1993).

In some cases, for example, discrepancies in the output capacity of the humidifier are observed. A humidifier capacity that is based on 2-lb/in² gauge steam input will be installed in an HVAC system with no pressure-reducing valve between the humidifiers and the 8- to 10-psig steam supplied by the building's boilers. This may result in a humidifier with more than twice the capacity desired. This can cause a condensation problem because of longer vapor trail length as well as problems that arise because the controls will tend to "hunt" excessively for a control position.

To humidify buildings in cold winter climates, the insulating details of the building's exterior envelope must be considered to avoid problems with condensation and possible freezing within the envelope. For humidified buildings in northern climates, a vapor barrier directly on the exterior side of the wallboard helps prevent moisture migration and reaching dew point where building materials can be wetted. Generally before installing a humidification system in a building in a cold climate, a thorough evaluation of the building envelope should be performed to ensure that moisture condensation in the building envelope does not become a problem. Generally, the thermal characteristics of windows and their framing will be the first element of the building envelope to experience condensation. Generally, it has been found that most new buildings in the Boston area can accommodate 25 to 30 percent RH (relative humidity) with proper care to ensure the integrity of the building envelope.

8.4 DRYERS

A common problem for a building's HVAC system is to dehumidify or dry air. For most commercial buildings in the United States, dehumidification is accomplished by chilling the HVAC system's supply air below its dew-point temperature. This scheme generally is the most cost-effective approach as long as drying the supply air to a dew point in the 53 to 55°F range is adequate for the application. For commercial office buildings, supply air is generally cooled to a 55°F saturated condition (i.e., 100 percent RH in the supply air, which corresponds to a 55°F dew-point temperature) to be supplied to the occupied space through a supply-air diffuser. At a space temperature of 72°F, this dew-point temperature, when combined with typical internal moisture sources, results in a relative humidity of 55 to 60

percent, which is within the ASHRAE “thermal comfort envelope” for office occupants (ASHRAE 55-1992).

For applications that require a dew point much lower than approximately 50°F or very precise control of both temperature and dew point, desiccant-based dehumidification techniques become economically viable. Desiccant-based systems rely on either solid or liquid absorbent materials to remove moisture from the conditioned airstream. The moisture absorbed by the desiccant is then transferred to outside of the building envelope by a regeneration process. The sorbent material’s moisture-retaining properties are regenerated by heating the material, to drive off the absorbed moisture. Figures 8.27 and 8.28 illustrate schematically the operation of liquid and solid desiccant-based drying systems, respectively.

In the water absorption part of the drying cycles, the desiccant temperature rises. If some method of cooling is not applied to the system, the temperature of air contacting the desiccant will also rise. This condition is often desirable in conditions when the system is operating under a load that is some fraction of the system’s design condition. In these conditions the desiccant system minimizes the energy that might otherwise be required to maintain low dew-point temperature and maintain the required temperature by minimizing the reheat energy that would be required to attain this same control when using a conventional cooling-coil approach.

Generally, a conventional cooling coil or a provision to cool the liquid desiccant solution is required to provide precise control over both the air discharge temperature and moisture content for a system that operates over a wide range of operating conditions.

8.5 COOLING TOWERS

Cooling towers are commonly utilized in buildings as a heat exchanger to transfer the heat being rejected by the building's air-conditioning system into the ambient environment. Cooling towers provide the means of accomplishing this objective by utilizing the latent heat of evaporation of a small fraction of the water circulated to the tower to cool the remaining cooling-tower water. The evaporation process, and therefore the cooling capacity of a tower, is typically enhanced by air movement through the tower, which is generally provided by propeller-type fans. The ambient-air parameter that best governs cooling-tower performance is wet-bulb temperature. Figure 8.29 illustrates the components of a typical cooling tower.

In commercial buildings, cooling towers are typically sized to cool the condenser water from the building's chiller plant by approximately 10°F. Therefore, the size of the cooling tower is determined by the amount of heat to be rejected by the tower, the design wet-bulb temperature for the building, the design inlet temperature of the tower, and the desired exit water temperature.

Figure 8.30 illustrates the psychrometric process that occurs in a typical cooling tower on a design day. Vector AB in Fig. 8.30 may be separated into vectors AC , which represents sensible-air heating (and sensible-water cooling), and component CB , which represents latent air heating (latent water cooling). If the entering air condition is changed to point D at the same wet-bulb temperature but at a different dry-bulb temperature, the total heat transfer remains the same, but the sensible and latent components have changed. In case AB , heat was transferred from the cooling-tower water to ambient air by sensible and latent heating of the incoming air. In case DB , heat is transferred from the water to the air again by sensible cooling of the water by evaporation, resulting in sensible cooling, and latent heating of the incoming air.

Typically the cooling tower in a commercial building is designed to operate with an inflowing water temperature of 95 to 100°F and an exiting water temperature of 80 to 90°F. With this range of temperatures, the cooling tower provides an excellent incubator for

FIGURE 8.29 Cross-section view of a cooling tower typically found in commercial buildings. (Reprinted by permission from 2000 ASHRAE Handbook: Equipment, ASHRAE, Atlanta, GA, p. 36.6.)

growing and proliferating *Legionella pneumophila* bacteria. Cooling towers have been implicated in numerous cases of *Legionella* outbreaks. However, *Legionella* in cooling towers can be controlled by careful water treatment and monitoring for the presence and proliferation of the organism.

In some climates, cooling towers can be used during part of the year to provide cooling for the building's cooling-water loops without the use of the chiller. Operation of the cooling tower and cooling loop in this manner is commonly referred to as an *economizer cycle*. In most instances the cooling tower would interface with the chilled water piping loop through a water-to-water heat exchanger. Typically this heat exchanger is of a "plate and frame" design. Figure 8.31 provides a typical schematic of a cooling tower piped to work on an economizer cycle.

Cooling towers, in addition to requiring the normal maintenance of their mechanical components, require a chemical program to maintain the cleanliness of the cooling tower-condenser water loop. The cleanliness of this system can directly affect the heat

FIGURE 8.30 Psychrometric analysis of air passing through a cooling tower. (Reprinted by permission from 2000 ASHRAE Handbook: Equipment, ASHRAE, Atlanta, GA, p. 36.2.)

FIGURE 8.31 Typical piping for a water-side economizer cycle. (Reprinted by permission from 2000 ASHRAE Handbook: Equipment, ASHRAE, Atlanta, GA, p. 36.9.)

transfer and therefore the capacity and efficiency of the entire chilled-water cooling system. The chemical treatment program should be designed to minimize the accumulation of scale, slime, and algae on heat-transfer surfaces. Typically this chemical treatment program is tailored for each site according to the properties of the makeup water, as well as the materials used in the system. The compatibility of treatment chemicals and their corrosive action on system materials is a constraint that requires careful consideration in the design of any treatment program.

8.6 SUMMARY

Reviewing the characteristics of some of the more important subcomponents of HVAC systems demonstrates the careful design that is required to appropriate functioning. Many of the subsystems rely on subtle yet important physical properties to help provide operation that is economical, effective, and safe. Furthermore, the interrelationship between these components and the building's physical structure and ambient environment must be clearly understood and taken into account before completing designs.

CHAPTER 9

AIR CLEANING—PARTICLES

Bruce McDonald
Ming Ouyang, Ph.D.
Donaldson Company, Inc.
Minneapolis, Minnesota

9.1 INTRODUCTION

This section covers cleaning airborne particles from both ventilation air and recirculated air. The cleaning of gases and vapors is addressed in Chap. 10.

Airborne particles can cause various indoor air quality (IAQ) problems, some of which include

- Health problems for occupants of a space (see Chaps. 21 to 28).
- Discoloration and visible dusting of surfaces
- Equipment malfunction
- Increased probability of fire hazards when lint and other materials accumulate in ductwork
- Higher probability of postoperative infection when airborne bacteria are present in operating-room air

Therefore, air cleaning should play an important role in mitigation and prevention of IAQ problems. Particles are always present in indoor air, either coming from interior sources or brought in with infiltrating air. Air-cleaning devices remove many of the particles in the air passing through them, thus effectively reducing the total number of particles present. Air cleaning extends from the simple task of preventing lint and other debris from plugging heating and cooling coils to removing particles as small as a few tenths of a micrometer, which could potentially cause a short circuit on a microchip.

9.2 BRIEF DESCRIPTION OF AEROSOLS

A suspension of solid or liquid particles in the air is called an *aerosol*. This includes particles in the size range from about 0.001 to 10 μm that remain in air for long periods of time. It also includes larger particles up to 100 μm , which settle out of calm air in a matter of minutes. Detailed information on particles and environmental tobacco smoke can be found in Chap. 30.

Aerosols include mist, smoke, dust, fibers, and bioaerosols such as viruses, bacteria, fungi, algae, and pollen. Despite their difference in chemical composition or biological properties, airborne particles are usually removed by physical means such as using inertial apparatus, filters, or electrostatic precipitators. Thus, only their physical properties, which affect how they are removed, are of importance in this section of the handbook.

Particle size is the most important physical parameter for characterizing the behavior of aerosols. Table 9.1 lists size ranges for commonly found particles. It is largely the particle size that determines if a particle can be removed by a specific method. Most aerosols cover a wide range of sizes. A hundredfold range between the smallest and largest particles of an aerosol is not uncommon. The size distribution of aerosols reflects the nature of the nearby aerosol sources and the process of growth, transport, and removal.

The particle size mentioned above is aerodynamic particle size. It is the interaction of the particle with the suspending air that determines its behavior until it's removed. If a particle were to behave in an aerodynamic sense like a 1- μm sphere with a specific gravity of one, regardless of its shape, density, or physical size, one would say that the particle has an aerodynamic diameter of 1 μm . Unless otherwise stated, *particle size* referred to in this chapter should be understood as aerodynamic size. It should be noted that any elongated particle such as an asbestos fiber may have different aerodynamic particle sizes depending on its orientation when settling out in the room or its alignment with flow stream in inspired air.

Ambient aerosols except in the immediate vicinity of combustion sources, typically are bimodal in distribution, with a saddle point in the 1- to 3- μm range. Particles smaller than approximately 2.5 μm are referred to as *fine mode*, and that larger than approximately 2.5 μm as *coarse mode* (Fig. 9.1). The coarse particles are mainly mechanically generated with lifetimes in the atmosphere of a few hours to many hours. The fine particles are produced by photochemical atmospheric reactions and the coagulation of combustion products from automobiles and stationary sources, with lifetimes of several days or more. As will be shown, particles greater than 1 μm are generally easier to remove than are those between 0.1 and 1 μm . Depending on the situation, fine particles under 1 μm may be as or more harmful than those over 1 μm , and need to be removed at least as efficiently as coarse particles. Figure 9.2 shows the bimodal nature of typical ambient aerosol and relates it to the standard sampling methods.

TABLE 9.1 Ranges of Common Indoor Particles

Particle	Diameter, μm	Particle	Diameter, μm
Skin flakes	1–40	Asbestos	0.25–1
Visible dust and lint	>25	Resuspended dust	5–25
Dust mite	50	Tobacco smoke	0.1–0.8
Mite allergen	5–10	Diesel soot	0.01–1
Mold and pollen spores	2–200	Outdoor fine particles (sulfates, metals)	0.1–2.5
Cat dander	1–3		
Bacteria*	0.05–0.7	Fresh combustion particles	< 0.1
Viruses*	<0.01–0.05	Metal fumes	<0.1
Amoeba	8–20	Ozone- and terpene-formed aerosols	<0.1
Mineral fibers	3–10		

*Occur in larger droplet nuclei.

FIGURE 9.2 Indoor sampling fraction related to a typical ambient particulate mass distribution.

9.3 PARTICLE REMOVAL BY FILTERS, ELECTRONIC AIR CLEANERS, CYCLONES, AND SCRUBBERS

Two of the most important performance parameters for particle removal devices are energy cost and particle collection efficiency. While pressure drop reflects the mechanical energy cost to drive airflow through a device, particle collection efficiency shows the effectiveness of the device. Both parameters depend on types of removal devices, their detailed structure, and operating conditions such as flow rate. In addition, particle collection efficiency also depends on the characteristics of the particles.

Filters

In this section, fibrous filters will be discussed. It should be noted that the same mechanisms and performance characteristics apply to other types of air filters such as those made of foam or membrane.

Fibrous filters are used extensively for air-cleaning purposes. The fibers are much longer than the filter media layer is thick and tend to lie in or close to the plane of the filter media. The filter media may be used flat, or folded in various ways to yield a more compact filter. In either case, the fibrous filter can be viewed as an assembly of fibers randomly in planes perpendicular to the direction of flow. Fibrous filters may contain fibers with sizes from as large as dozens of micrometers to as small as about $0.1\text{ }\mu\text{m}$. Solidity of filter media is the fraction of the total volume of the sheet that is solid. The solidity of a typical filter media ranges from about 30 percent to as low as 1 percent. The common types of fibers are cellulose fibers (wood fibers), glass fibers, and synthetic fibers.

A common misconception is that a filter works like a sieve, that particles suspended in air are removed only when they are larger than the interfiber spaces. On the contrary, air filtration is very different from the use of screens on air intakes to keep out leaves, birds, and other items. Because of their microscopic nature, particles are removed by their collision to fibers. Figure 9.3 shows a scanning electron micrograph of particle collection by fibrous filters. Once they make contact with the fiber surface, particles generally remain attached because of strong molecular force between particles and fibers. Sieving is not a primary mechanism in air filtration, as particles with such size could be easily collected because of other mechanisms. Common filtration mechanisms are listed as follows:

Diffusion. Particles suspended in the air are constantly bombarded by the molecules around them. Thus, they have a random motion around their basic path along the air streamlines, which increases the probability of the particles contacting fibers and being collected. At atmospheric pressure, particles smaller than about $0.2\text{ }\mu\text{m}$ have significant deviations from their streamlines, making diffusion an effective filtration mechanism. Diffusion is a sensitive function of velocity. Lower velocity means more time for particles to move away from their streamlines, and thus an increased probability for the particles to be captured.

Interception. Even if particles follow the airstream exactly, they could make contact with the fibers because of their finite physical sizes. This process has little dependence on velocity, and is effective for particles larger than about $0.5\text{ }\mu\text{m}$.

Inertial impaction. Particles in air that either are heavy or are at high velocity have significant inertia. In this case, they have difficulty following the airstream bending around fibers, and thus make contact with the fibers and are collected. Inertial impaction is generally effective for particles larger than about $0.5\text{ }\mu\text{m}$, depending on air velocity and fiber size.

FIGURE 9.3 Particle collection by fibrous filter, scanning electron microscopic picture.

Capture by electrostatic force. Under some circumstances, particles or filter media may be intentionally or unintentionally charged; thus electrostatic force may play a role in particle collection. Charged particles will be attracted to fibers with opposite charges by coulombic force. If either particles or fibers are charged, particles will be attracted toward the fiber at close range by image forces, which are weaker than coulombic forces. External electrical fields may be applied; thus, charged particles will acquire additional cross-flow motion that leads to higher filter efficiency. Similar to diffusion, low velocity enhances collection by electrostatic force.

Diffusion is very strong for particles smaller than a few tenths of a micrometer; interception and inertial impaction are very effective for particles larger than about $0.5\ \mu\text{m}$. Because of these opposing trends, there is a minimum efficiency for filter media at a particle size between 0.1 and $0.4\ \mu\text{m}$, depending on fiber diameter and air velocity. Initial efficiency and its contribution from various mechanisms are shown in Fig. 9.4. Filters, depending on fiber diameter, media thickness, and packing density, could have a minimum efficiency ranging from a few percent for low-efficiency filters to 99.97 percent for high-efficiency particulate air (HEPA) filters or considerably higher.

Although particles generally stick to fibers after making contact, there are exceptions. When a heavy particle traveling at high velocity hits a fiber, it may bounce off. Particle bounce depends on the particle's mass, velocity, direction relative to fiber, and fiber size. In addition, bounce is a very sensitive function of hardness and elasticity of fiber and particle. Bounce for particles smaller than a few micrometers at velocities lower than $20\ \text{cm/s}$ is usually negligible. For applications where particle bounce may be an issue, fibers can be coated with a liquid or adhesive that tends to reduce particle bounce dramatically.

FIGURE 9.4 Filter efficiency curve.

Filter Types by Collection Mechanisms and Effect of Filter Loading

Mechanical filters. Filters that collect particles through mechanical mechanisms (diffusion, interception, and inertial impaction) without the influence of electrostatic forces are called *mechanical filters*. As particles are captured by filters, they become part of filter structure. Collected particles increase the pressure drop as they provide resistance to airflow, and contribute to filter efficiency as they become particle collectors as well. The loading process of fibrous filters is typically classified as two stages: depth loading and surface loading. Initial deposition of particles generally occurs in the depth of filter media. As more particles are collected in the filter medium, the top layer of the filter medium becomes very efficient and particles start to bridge across the medium surface. Eventually, particles will deposit on the filter medium surface in a cake form (see Fig. 9.5 for mechanical filter loading curve).

Electrically charged fibrous filters (electrets). The advantage of materials of this type is that the charge on the fibers considerably augments the filtration efficiency without contributing to the airflow resistance. Particle collection efficiency by electrically charged filters is altered by a combination of two causes. One is the same as that for mechanical filters, efficiency changes due to mechanical means increases. The other is that the deposited material, interacting with the electric charge on the filter, reduces efficiency due to electrical means. The combined effect is complicated as the two processes occur at the same time. The total effect may depend critically on the structure of filter, material properties of particles and fibers, operating condition, as well as amount of dust loaded. For filters with a large portion of the efficiency due to electrostatic forces, filtration efficiency will decrease initially as the electrostatic collection mechanisms are reduced. Eventually, as enough particles are collected, the efficiency will increase but at the expense of pressure drop. See Fig. 9.6 for the loading curve of an electrically charged filter.

At times, when filters are heavily loaded, subject to unstable operating conditions or external force, chunks of particles already collected could become loose and penetrate through the filter. Particle shedding occurs less frequently when an adhesive coating is used on fibers.

FIGURE 9.5 Loading curve, mechanical filter (loaded with submicrometer solid aerosol).

FIGURE 9.6 Loading curve, electrically charged filter (loaded with submicrometer solid aerosol).

Electronic Air Cleaners

An *electronic air cleaner* is a device that collects particles suspended in a gas stream as a result of electrical precipitation (Fig. 9.7). Electronic air cleaners are also referred to as *electrostatic precipitators* (ESPs). Common electronic air cleaners consist of ionizing and collecting parts arranged sequentially or combined in a single stage. The air passes between parallel plates. Between these plates, equally spaced wires serve as high-voltage electrodes. When air passes through the interelectrode space, the ions produced by corona discharge

FIGURE 9.7 Electronic air cleaner. (Photograph courtesy of Honeywell Inc.)

charges the particles. Then the electric field drives the particles either to the grounded plates or to specially designed collecting plates.

When the collector plates are loaded with dust, the efficiency of the electronic cleaner is reduced, sometimes dramatically, which is frequently indicated by arcing between oppositely charged plates. The collector plates can be cleaned in place automatically or manually or can be cleaned after removal by washing, or “rapping.” Because of the decreased efficiency during its operation, initial efficiency may not be a good indicator as to how the electronic air cleaner performs. Instead, frequency of cleaning or maintenance may be more important. Unlike cyclones and filters, the major energy consumption of an electronic air cleaner comes from the electric energy used to ionize the air rather than the pressure drop across its structure.

Inertial Separators, Cyclones, and Louvers

Inertial separators turn the airflow and use the inertia of the particles to separate them from the airstream. See Fig. 9.8 for cyclone and louver pictures.

Inertial devices remove only coarse particles. Their value is mainly for the removal of coarse dust, raindrops, and other material from large volumes of air where a small residue is unimportant, or as a preseparator before passing through more efficient filters.

Louvers are used extensively in air intakes and may be used in other applications such as removing grease from kitchen exhaust. Cyclones are used primarily in industrial air cleaning where there is high concentration of aerosol.

FIGURE 9.8 (a) Cyclone picture. (Photograph courtesy of Donaldson Company, Inc.) (b) Louver picture. (Photograph courtesy of AAF International, Inc.)

Scrubbers

Scrubbers collect particles on liquid droplets that are sprayed into the airstream and then remove them. Scrubbers are used primarily in specialized industrial air cleaning such as paint booths and cleaning of power plant exhaust.

9.4 FILTER TYPES BY FILTER MEDIA AND CONSTRUCTION

There are four basic types:

Flat-panel filters (Fig. 9.9). *Flat-panel filters* are air filters in which all filter media is in the same plane; thus the face velocity and media velocity are the same. *Face velocity* is the velocity of the air approaching the filter; the *media velocity* is the air velocity approaching the medium.

Pleated-panel filters (Fig. 9.10). Pleated filters use an extended filter media area to make the media velocity much lower than face velocity; thus they typically have a much higher filter efficiency at acceptable pressure drop. Typical pleat depths range from 1 to 12 in.

Bag or pocket filters (Fig. 9.11). The nonsupported mat filter is one of the most popular designs for high-efficiency air filters used today. When air flows through bag filters, the filters expand, exposing all the media to the airstream.

FIGURE 9.9 Flat-panel filters. (Photograph courtesy of AAF International, Inc.)

FIGURE 9.10 (a) Pleated-panel filters. (Photograph courtesy of AAF International, Inc.) (b) High-efficiency pleated-panel filters. (Photograph courtesy of Donaldson Company, Inc.)

FIGURE 9.11 Bag or pocket filters. (Photograph courtesy of AAF International, Inc.)

Moving-curtain/renewable media filters (Fig. 9.12). *Renewable filters* are devices in which clean filter media are unrolled at one end, exposed to a dirty airstream. It is advanced at intervals to keep the pressure drop through the exposed airstream within a desired operating range. Dirty media are rolled onto a takeup reel at the other end of the filter.

9.5 RATING FILTER AND ESP PERFORMANCE: TEST METHODS AND STANDARDS

The true measure of air filter performance is the filter efficiency, pressure drop, and life in an application. Obviously, it is not practical to test every filter against every potential application. Therefore, to compare filters, manufacturers and users must turn to standardized laboratory tests.

Test Dusts

Such tests must use a standardized, synthetic contaminant to challenge the filters. The choice of contaminants is difficult. It is not easy to find a material that can be easily used in the lab and is a realistic analog of the application aerosol. Moreover, there are infinite

FIGURE 9.12 Moving-curtain/renewable media filter. (Photograph courtesy of AAF International, Inc.)

varieties of aerosols in actual applications. As discussed earlier in this section, typical ambient aerosol contains both a submicrometer fine mode and a supermicrometer coarse mode. The two modes affect air filters differently, so a realistic test aerosol should contain both modes. The development of a realistic test aerosol is further complicated by a wide range of materials present in ambient aerosols including both solids and liquids.

One common standardized material is Arizona dust that was standardized by the Society of Automotive Engineers (SAE 1993). It has now become an ISO standard material in ISO 12103 Part 1 (ISO 1997). There are four grades that differ in fineness. The maximum and minimum dimensions of the particles are nearly the same. The primary constituent of these irregularly shaped particles is SiO_2 . The A2 fine dust is commonly used for air filter testing. Although A2 is called “fine test dust,” it is actually similar in size to the coarse mode of atmospheric particles.

A2 fine test dust does not adequately represent the submicrometer mode in the atmosphere, which comes primarily from combustion sources. Nor does it include the fibrous sort of material that might commonly be found indoors that come from clothing, carpeting, and other furnishings. The synthetic test dust in ASHRAE 52.1 (ASHRAE 1992) is designed to be more realistic by adding fine particles and fibers to ISO A2 fine test dust. ASHRAE test dust contains 72% ISO A2 fine test dust, 23% powdered carbon, and 5% cotton linters. While ASHRAE test dust is more realistic and a more severe challenge than ISO A2 test dust alone, it is still coarser than typical atmospheric aerosols. It does not adequately model the effects of many real-world aerosols such as diesel soot.

Examples of the shortcomings of the test aerosols used in the current standards are

- Two filters have the same life (dust-holding capacity) when tested in the lab, but their life in a real application, which is dominated by submicrometer aerosol, is different by a factor of 3.

- Electret filters may show little or no drop in efficiency when tested with laboratory test dust. In applications with certain aerosols such as diesel exhaust or cigarette smoke, they may show a very significant drop in efficiency during the initial loading stages.
- After loading with standard laboratory test dust, many filters shed particles. But filters tested after use in a variety of applications do not.
- The carbon in the ASHRAE test dust may cause electrical short circuits in electrostatic precipitators to a greater extent than is experienced in application.

The committees in SAE and ASHRAE that are responsible for air filter test codes recognize the problem and are looking for better test aerosols. These difficulties notwithstanding, the standard test dusts do provide ways to compare filter performance in a controlled, repeatable way and may represent some applications.

Testing Filters (Fibrous Media Type)

Current Standard: ASHRAE 52.1. The primary filter test methods for filters used in HVAC applications for IAQ are presented in ASHRAE 52.1. That standard contains three basic tests; two measure filter efficiency, and one measures dust-holding capacity.

Arrestance. *Arrestance* is the mass efficiency when the filter is challenged with ASHRAE test dust. ASHRAE test dust is fed to the filter under test with a high-efficiency filter downstream. The arrestance is determined from the mass of dust fed and the mass of dust collected on the high-efficiency filter. The arrestance test is useful primarily for relatively low-efficiency filters. Using the term *arrestance* helps differentiate this measure of efficiency from other measures such as the dust spot efficiency.

Dust Spot Efficiency. The *dust spot efficiency* test is designed to measure an air filter's capability to reduce soiling. The dust spot efficiency test uses white, high-efficiency (HEPA) filter paper to sample the air from upstream and downstream of the filter under test while drawing ambient air through the filter. Particles collected on HEPA sample media discolor the media. By comparing the light transmission capability of upstream and downstream sample media, the filter dust spot efficiency is measured. Because the test relies on sooty particles in the ambient air to discolor the sample media, the test duration depends on the ambient aerosol concentration. However, the efficiency measurement is relatively independent of the ambient aerosol.

Dust-Holding Capacity. The pressure drop of the filter is measured as test dust is fed to the filter. During the test, arrestance is measured at least 4 times. The test is terminated when a maximum pressure drop is reached or the arrestance decreases by a specified amount.

The *dust-holding capacity* is the total dust held by the filter up to termination of the test. The test standard also provides a method for feeding dust to moving-curtain/self-renewable filters to measure their performance.

ASHRAE 52.2. A new test method known as ASHRAE Standard 52.2, *Method of Testing General Ventilation Air Cleaning Devices for Removal Efficiency by Particle Size* (ASHRAE 1999a), was developed. Standard 52.2 does not replace 52.1.

Particle Size Removal Efficiency. The standard provides a method to measure filter efficiency for particles from 0.3 to 10 μm in 12 size ranges. The aerosol concentration upstream and downstream of the filter is measured with a particle counting-sizing instrument, an optical particle counter or aerodynamic particle counter. The efficiency in each size range is calculated. Recognizing that filter efficiency varies with the amount of aerosol collected, the test method includes the measurement of an initial efficiency with a clean filter

and five more measurements of particle size efficiency after five increments of dust loading. The six particle size efficiency curves are compared, and the lowest efficiency measurement in each size range is selected to create a composite minimum-efficiency curve. Figure 9.13 shows an example of particle size efficiency curves.

Minimum-Efficiency Reporting Value. In an effort to provide a simplified index of filter efficiency, a single number to characterize the filter efficiency, the standard contains a method to assign a minimum-efficiency reporting value (MERV) based on the minimum-efficiency curve. Because air filter performance is a strong function of flow rate, MERV includes the test flow rate. MERV is also dependent on the amount of test dust fed to the filter under test. The procedure for determining a filter MERV includes a minimum final pressure drop requirement. While the filter is loaded during the test, filter life or capacity is not determined by this test procedure.

High-Efficiency Filters

95 Percent DOP Filters, Also Known as “Hospital”-Grade Filters, MERV 16. These filters are beyond the range of ASHRAE 52.1 efficiency test method. Historically, they have been tested with the same methods as HEPA filters (see next section), with two exceptions. The 95 percent DOP filters are not scanned for leaks, and the 95 percent DOP filters are typically lot-tested while HEPA filters are normally 100 percent tested. These filters are in the highest efficiency group of filters possible to test with the methods in ASHRAE 52.2.

High-Efficiency Particulate Air (HEPA) and Ultra-Low-Penetration Air (ULPA) Filters. Several tests are referred to as *dioctylphthalate (DOP) oil-like material* tests. The “hot DOP” test is used to measure overall efficiency of filters. “Cold DOP” tests refer to a scan or probe test where the exit plane of the filter is scanned with a probe to find leaks.

The hot DOP efficiency test for HEPA filters [IEST types A, B, C, and E (IEST 1993a), MERV 17 and 18]] is described in MIL-STD-282 (MIL-STD-282 1995). The same basic test is described in other standards (ASTM 1995). HEPA filter efficiency is clearly defined

FIGURE 9.13 Example of particle-size efficiency curves. [From ASHRAE (1999a).]

in several standards (MIL-STD-282 1995, MIL-F-51068 1988, DOE 1997) as having a minimum efficiency of 99.97 percent on 0.3- μm particles. Unfortunately, the term is abused. It is improperly applied to lower-efficiency filters or used in phrases such as “HEPA-like filters” when the filters do not meet the minimum 99.97 percent efficiency requirement.

A nearly monodispersed oil aerosol is generated by evaporating and recondensing the oil. The size range is relatively narrow, and the size can be controlled with the temperatures and flow rates in the generator. The aerosol is detected with an aerosol photometer that senses the light scattered from many particles.

DOP has been listed as a suspected carcinogen. To a large extent it has been replaced with a poly (α -olefin) (PAO) synthetic oil, which has essentially the same physical characteristics. However, many people still refer to the tests as DOP tests.

HEPA filters are also tested using particle counting methods such as those that are used for ULPA filters. There is currently no U.S. standard for testing HEPA filters with particle counting methods. The correlation between the counting method and the hot-DOP method will depend on factors such as the test aerosol size distribution, the width of the particle counter size bins, and the filter efficiency as a function of particle size.

IEST Recommended Practice RP-CC-007 (IEST 1993b) provides a test method for ULPA filters (IEST type F, MERV 20) that utilizes optical particle counters. The RP covers testing of filters that have 0.001 to 0.0001 percent penetration (99.999 to 99.9999 percent efficiency) in the 0.1- to 0.2- μm size range.

In addition to tests of overall efficiency, most HEPA and all ULPA filters are tested for leaks (IEST 1993a, 1998).

Aerosol Photometer Filter Scan Test Method (Cold DOP Test). An oil aerosol is generated upstream of the filter using a Laskin nozzle atomizer. An aerosol photometer is used to scan the entire exit plane of the filter. For HEPA (MERV 18) filters, readings greater than 0.01 percent of the upstream value are considered leaks that must be repaired.

Discrete-Particle Counter Filter Scan Test Method. Using a particle counter rather than a photometer allows the use of much lower aerosol concentrations and makes it possible to find smaller leaks. Use of particle counters allows the use of polystyrene of latex spheres, solid particles that are acceptable for use in filters for demanding cleanroom applications.

Room Air Cleaners, AHAM. Portable room air-cleaning performance is dependent on both the airflow and the filter efficiency. The combination is measured as the clean-air delivery rate with test procedures in ANSI/AHAM AC-1 (ANSI/AHAM 1988). The *clean-air delivery rate* (CADR) is the amount of clean air that an air cleaner delivers to a room. (Essentially, an air cleaner with a flow rate of 100 cfm and an efficiency of 80 percent has a CADR of 80 cfm.) CADR is determined from measurements of the decay rate of aerosol concentration when the unit is operated in a defined chamber. Three types of contaminant are used: A2 fine test dust, tobacco smoke, and pollen. AHAM administers a performance certification program for the benefit of manufacturers, retailers, and consumers.

Safety and Flammability, UL. Often the characteristic of interest is the possibility of smoke generation that may be carried downstream. UL900 (UL 1994) provides two classes: *class 1 filters*, which “do not contribute fuel when attacked by flame and emit only negligible amounts of smoke”; and *class 2 filters*, which “burn moderately when attacked by flame or emit moderate amounts of smoke or both.”

Filters for critical high-efficiency applications such as in nuclear power and containment of biohazards are often tested to UL586 (UL 1990) or MIL-STD-F-51068 (MIL-F-51068 1988). Those standards include test of the filter’s ability to retain efficiency after exposure to high temperature, higher than normal pressure drop, and other conditions.

European. EN779-1993 (CEN 1993) is similar to ASHRAE 52.1. EN779 is being revised. The dust spot efficiency test will be replaced with a fractional efficiency test standard. The new fractional efficiency test is noticeably different for ASHRAE 52.2; for example, it covers a different particle size range (0.2 to 3.0 μm).

A later (1995) European standard for HEPA and ULPA filters was EN1822 (CEN 1998). It applies up-to-date particle counting and sizing technology to measure the efficiency at the most penetrating particle size. It includes a rational classification system that covers more than seven orders of magnitude. However, the standard weakens the meaning of HEPA by applying it to filters with efficiencies as low as 85 percent on the most penetrating particle sizes.

Testing Electrostatic Precipitators (ESPs)

To some extent, the same test methods can be used for ESPs. However, unique challenges arise when trying to apply the methods to ESPs:

1. The life cannot be defined in terms of increase in the pressure drop because it doesn't increase. Rather, it would make more sense to define the end of life on the basis of minimum efficiency before the ESP is cleaned or on an amount of test dust fed to the ESP. At this time, there is no standard definition for the life of ESPs. Frequently methods adapted from the methods described above are used to measure just the initial efficiency of the ESP.
2. Because of the high voltages involved, additional tests for safety of the high-voltage supply are important (UL 1997).
3. Because of the potential for generating ozone, tests of ozone production are performed (ARI 1993a, 1993b).

9.6 APPLICATIONS

Filter Types by Efficiency

Filter applications are driven largely by particle removal efficiency requirements. The selection process involves compromises between efficiency and cost. Hence it is appropriate to classify filters by efficiency. Table 9.2 is adapted from the ASHRAE proposed filter test method 52.2, Table 2 in Chap. 24 of the *ASHRAE Systems and Equipment Handbook* (ASHRAE 1996), and other sources. It provides a convenient framework for comparison of filters of different efficiencies along with some application guidelines.

Costs

Costs include initial cost of the filters, the required mounting, the blower capacity requirements, and the operating cost. Operating cost includes replacement cost, both parts and labor, and the power used to move the air through the filters. Although it is relatively easy to calculate the costs associated with installing and maintaining the filtration system, it is not as easy to calculate the indirect costs and savings. Those savings and benefits should be balanced against the costs of installing and maintaining the filtration system. The benefits and savings of higher filtration efficiency include effect of improved IAQ on worker health and productivity, reduced cleaning costs, protection of equipment, and maintaining high efficiency of heat exchangers. See Chap. 56 for further discussion of the cost of poor IAQ.

TABLE 9.2 The Spectrum of Air Filter Efficiencies and Applications

Minimum-efficiency reporting value (MERV)*	Approximate equivalent efficiency, other standards†		Application guidelines‡	
	IEST RP-007 0.1–0.2 µm	MIL-STD-282 0.3 µm	Typical contaminant controlled, smallest particles of interest	Typical applications and limitations
>MERV 20	>99.9999%	N/A	Very high efficiency on all size particles (efficiency rating at or near most penetrating particle size; higher efficiency for larger and smaller particles)	Cleanrooms such as for semiconductor manufacturing
MERV 20	99.999–99.9999%	N/A	Very high efficiency on all size particles (efficiency rating at or near most penetrating particle size; higher efficiency for larger and smaller particles)	Sterile environments for pharmaceutical manufacturing, orthopedic surgery, TB and immune-compromised patients’ facilities

MERV 3	<20%	70–75%	Dust mites Sanding dust	Residential Window air conditioners
MERV 2	<20%	65–70%	Spray paint dust Textile and carpet fibers	Protect heat exchanger surfaces from dust and lint
MERV 1	<20%	<65%	>10- μ m particles	Prefilters for MERV 8–12
				Throwaway: disposable fiberglass or synthetic panel filters Washable: aluminum mesh, latex-coated animal hair, or open-cell foam panel filters; woven polycarbonate panel filters —§

*Strictly speaking, MERVs include a test airflow rate. This table compares only the efficiency characteristics of the filter; hence the airflow rate is not included.

†Note that the other standards referenced are different at different efficiency levels. The MERV chart covers an extremely wide range of filter efficiencies; different measurement methods are required for different ranges of efficiency.

‡This is only a very rough guide to filter application. Individual applications must consider the factors discussed in the accompanying text, other references, and the advice of the filter supplier.

§Strictly speaking, the minimum efficiency reporting value does not apply to electronic air cleaners. Hence, it is not appropriate to place them in this table. Refer to discussion concerning testing of efficiency and life of electronic air cleaners. Nonetheless, it should be noted that electronic air cleaners might be used for many applications from MERV 1 up to approximately MERV 16.

¶For high-efficiency filters, the types are denoted by classes defined in Institute of Environmental Sciences and Technology Recommended Practice RP-CC-001. RP-CC-001 is in revision as of this writing, and publication of the revision is expected by the end of 2000. Class G is a new class being introduced in the revision.

Source: This table is adapted from ASHRAE 52.2P (ASHRAE 1999a) with additional information.

Filter Applications and Design Considerations

In any filter application, numerous things need to be considered. The following list of questions is provided as a starting point. Several specific aspects are discussed in more detail following the list.

- What is the need? Is it, for instance, to protect HVAC equipment, prevent soiling, remove specific contaminants, provide air of specified cleanliness for people or processes, prevent the spread of disease, or provide acceptable fresh air when the outside air is not acceptable?
- What are the sources of the particles? What materials are the particles? Are there toxic or hazardous materials involved? What is the generation rate or the concentration? Both internal sources and particles in the ventilation air need to be considered.
- Are there other methods of control available? In particular, can the source of the particles be reduced or eliminated?
- Given the needs defined in the first step, how clean does the air need to be?
- Is it necessary to achieve that level of cleanliness in one pass through the filter, or is it acceptable to depend on multiple passes through the filter in a recirculating system?
- What is the operating cycle of the system? Is there airflow only when there is need for heating or cooling, is the volume of flow dependent on the need for heating or cooling [variable-air volume (VAV) system], is it on a timer, or is it constant?
- Given the source and the efficiency, how much material will the filters accumulate?
- How much airflow is needed? Other considerations such as heating and cooling will dictate airflow. Is that enough to deal with the particulate removal needs?
- What pressure drop is available?
- How much space is available? What other equipment is near the filter that may affect filter performance?
- What are the applicable codes and safety requirements?
- What will the initial investment be?
- What will be the cost of maintaining the system and replacing the filters? What are the indirect costs and benefits?
- How will the filters be handled and disposed of? Is there a need to protect the maintenance personnel? Is there a need to protect the environment?

While these application questions are aimed at the choice of particulate filtration equipment, they also impact the design of the rest of the system, including the amount of airflow, the pressure capability of the blower, the amount of makeup and exhaust flow, the flow patterns, pressurization of the space, and how well the space needs to be sealed.

Space and Size. Space must be available not just for the filters and ducts but also for servicing the filters. Filters that are easy to access are more likely to be maintained properly. There must be sufficient distance between the filters and equipment in the ducts upstream and downstream of the filters to avoid interference effects. Air filters perform best with uniform approaching airflow, which should be considered when designing applications. In the case of moving-curtain/renewable media filters, the filter may cause nonuniform flow as fresh media is advanced into the duct. That may affect the performance of equipment downstream of the filter such as electrostatic precipitators or heat exchangers.

Undersized filters mean higher pressure drop, which in turn means larger, more costly blowers, higher energy costs, and more noise. Undersizing the filters also means shorter life and higher replacement costs.

Increasing filter size can increase the capacity significantly. Not only is there increased area to hold the dust but also that medium is operating at a lower velocity and lower initial pressure drop across it.

Keeping Filters Dry. When designing an air filter application, one of the most important considerations for maintaining good IAQ is to ensure that the filters stay dry. As discussed in Chap. 5, there is a possibility of fungal or bacterial growth in HVAC systems when conditions are favorable. It has been demonstrated that little or no growth is likely to occur if the filters are kept dry and the relative humidity is lower than some threshold (Kemp et al. 1995). Hence, one should be very careful to ensure that moisture from humidifiers and cooling coils cannot wet downstream filters. That may require additional space between the moisture source and the filter. In some cases, it is advantageous or necessary to install mist eliminators downstream of humidifying equipment, cooling coils, or other components. Consult the manufacturers of the equipment for recommendations. Mist eliminators are just particulate filters. The difference is that they are rather low efficiency except for rather large droplets and they are designed so that water can drain easily. Presumably when they are collecting water, the water drains freely and when they are not collecting water, they dry rapidly and thoroughly. Mist eliminators should be serviced regularly to ensure that they function correctly and do not become sites for growth of fungi or bacteria. Filters in an airstream that includes outside air need to be protected from rain, mist, fog, snow, condensation, and other conditions. (See also Chaps. 5, 7, and 60.)

Sealing for High Efficiency. To obtain high efficiency, the filter mounting and ducts need to be carefully sealed. That is extremely important when trying to obtain HEPA filter performance. For example, a leak of 1 cfm out of 1000 will reduce the efficiency of the installed filter from greater than 99.97 to less than 99.9 percent. A 1-cfm leak bypassing a HEPA filter can increase the amount of 0.3- μm particles downstream by a factor of nearly 10. The same leak can increase the number of larger particles downstream by several orders of magnitude. HEPA leak tests are designed to detect leaks of 0.0001 cfm.

Safety Issues: Flammability and Handling of Contaminated Filters

This section addresses acute issues, not chronic or IAQ issues.

Many applications will require some level of control of the flammability of the clean filter. Check with applicable building codes. Note that the UL flammability tests apply to clean filters. Accumulated dust may contribute significantly to the flammability or smoke generation potential. The HVAC system as a whole contributes to fire and smoke safety. (See Chap. 14.)

ESPs should meet appropriate safety standards to minimize the possibility of shocks from the high voltage.

Appropriate safety precautions such as facemasks, gloves, and bagging the dirty filters are necessary when handling and disposing of used filters. The deposits on the filters are a concentration of whatever particulate has been removed from the air. If toxic or hazardous material is to be collected, bag-in/bag-out housings should be considered. If the filters have become wet or the humidity is high, there may be active growth with the potential for shedding large quantities of fungal spores or bacteria.

Biological Particles: Collection, Possibility of Growth, and Use of Antimicrobials

In IAQ applications of air filters, the filters will collect biological material with the potential for growth and nutrients that will support that growth.

Biological particles are collected with the same efficiency as inert particles of the same aerodynamic size (Brosseau 1994). Many virus and bacteria are associated with other particles that are larger than the fundamental size of the organism. Therefore, while individual virus and bacteria are near the most penetrating particle size, they are collected with higher efficiency.

1. Will there be growth? If soiled filters are wet or under high humidity conditions, growth is likely.

2. Will the growth be harmful; will it get into the airstream? If there is growth, it may cause additional organisms or spores to be shed into the airstream. Even if there is not direct shedding of active biological material, the growing organisms may contribute undesirable odors (Bearn 1993). Growing organisms may damage the air filter or the filtration system, for example, by creating corrosive conditions that attack the hardware.

3. Does putting antimicrobial or biocidal treatment on the filter medium affect the growth? This is a controversial topic. Vendors selling the antimicrobial chemicals and filter manufacturers that sell treated filters claim or imply that treated filters can keep the filters from becoming sources of contamination and can improve IAQ. Claims are made that the treatment is nonmigrating and not offgassing. Others express skepticism about the need and effectiveness of the treatments pointing to the lack of growth except under extreme conditions of high relative humidity or presence of liquid water with nutrient material on the filter. There is also concern about introducing the antimicrobial material into the airstream.

An ASHRAE research project (ASHRAE 1999b) provides a good background on the effect of antimicrobial treatment of air filters.

The USEPA has approved a number of antimicrobial materials for use in air filters. The approval is for use as a preservative. That does not mean that claims can be made for aesthetic or health benefits. The EPA has indicated concern about claims made concerning the current usage of the approved products.

In the collection and growth of biological organisms on air filters, it is critically important to keep the filters dry and keep the RH low (see Chap. 45). Also, the filters should be serviced regularly.

Upgrading Filtration in Existing Applications

Changes to the HVAC system may be considered as part of a remediation program to improve IAQ. Such changes might include increasing airflow, increasing filter efficiency, increasing filter capacity, changing the maintenance schedule or procedures, changing the amount of outside air, using continuous fan operation, and rebalancing the airflow distribution.

Increasing Airflow. If system airflow is increased and no changes are made to the filtration, the filter pressure drop will increase and the life will decrease (NAFA 1997). The filtration efficiency of fibrous filters may also change as a result of the velocity increase, although the effect will be slight for flow rate increases that are practical within existing

HVAC systems. The efficiency on particles smaller than about $0.5\ \mu\text{m}$ will decrease and the efficiency for larger particles will increase. An exception is that for low-efficiency filters, “bounce” of large particles (over $\sim 5\ \mu\text{m}$) will reduce efficiency.

In some cases, it may be possible to avoid the increase in pressure drop and loss of life by installing filters with higher flow capacity and the same efficiency into the existing housing. For example, with pocket-type filters or pleated-cartridge-type filters, increasing the number of pockets or pleats may be an option. If there is space available in the duct, longer pockets are another option. Deeper pleated filters generally require changing the filter mounting.

ESPs lose efficiency as flow rate is increased. The increase in pressure drop of ESPs is likely to be negligible for flow rate increases that are practical within existing HVAC systems.

Increasing the flow rate will increase power consumption and operating costs. It will also increase the noise generated by the HVAC system. (See also Chaps. 18 and 19.)

Increasing Efficiency. If the higher-efficiency filter is the same size, the same construction, and has the same type of filter medium, the pressure drop will be higher and the life will be shorter. The airflow will be lower unless compensating change can be made in the blower such as increasing the speed. Lower airflow may adversely affect the ability to clean the air as the CADR may be reduced. Also, lower flow may adversely affect the performance of the other components of the HVAC system.

It may be possible to increase the amount of media area as described above such that the pressure drop is the same as with the original, lower-efficiency filters. It is possible to increase efficiency without affecting the pressure drop by using a different type of filter medium such as an electret medium or a medium with finer fibers. The use of electret media must be approached with caution since the efficiency of the electret media may decrease with loading. For example, replacing the traditional 49¢ panel filter in a residential HVAC system with a pleated electret can yield dramatic improvements in initial efficiency.

Maintenance and Cleaning

To facilitate and encourage proper maintenance, filters other than electrostatic precipitators should have permanently installed indicators of pressure drop or in the case of automatic self-renewing filters, indicators that the media supply is exhausted. ESPs should have status indicators.

As mechanical filters are loaded with contaminants, the filter pressure drop and efficiency increase, the airflow decreases, and the HVAC system efficiency decreases. When using mechanical filters (nonelectret), more frequent filter replacement will mean that the average efficiency is reduced. An exception to this is with low-efficiency, high-velocity cases where shedding may be a problem and where adhesive-coated filters become covered with dust, so additional dust does not stick. Another exception is electret-type filters. Efficiency may decrease as the filter is loaded. With variable volume systems, one must be careful to measure pressure drop at the same operating condition (flow rate) each time.

For electrostatic precipitators, the pressure drop does not increase but the efficiency decreases. Hence, the maintenance schedule involves a compromise between the cost of frequent cleaning and the higher average efficiency when the device is cleaned frequently. In systems with prefilters, the prefilters are typically changed several times before the final filters are changed.

Filter maintenance schedules should consider not only pressure drop and efficiency but also possible odor from dirty filters (see also Chap. 21). The need for replacement depends not only on the amount of dust collected but also the type of material that is collected. An

obvious example is filters that have collected cigarette smoke. Metabolic products of organisms growing on a filter may cause odor. With frequent filter replacement it is possible to trade increased maintenance cost for reduced pressure drop and reduced likelihood of problems with odor or biological growth.

Filters should not be changed when the HVAC system is running. To do so increases the possibility of contaminating the system and makes the working conditions more difficult for the personnel.

If filters have become wet and have growth on them, it may be advantageous to remove them before they dry. Lack of moisture will exacerbate the release of spores (Foard et al. 1997).

Changing air filters is not the only maintenance of a filtration system that is important for maintaining good IAQ. A complete maintenance program includes making sure that condensate drains are clear, ducts are clean, and mist eliminators are clean and functioning properly (see Chap. 64).

9.7 ADDITIONAL CONSIDERATIONS

Clean-Air Delivery Rate (CADR) and Capability of Portable Room Air Cleaners

Portable air-cleaning devices containing a filter or electrostatic precipitator, and a fan are sold to clean the air in a room or small area. They may also contain other devices such as activated carbon, or UV light. Such devices may be effective in improving IAQ in the local space, but several cautions must temper expectations. The ability of room air cleaners to significantly affect the IAQ of a space is dependent on several factors. The primary factor is the CADR as described in the section on the AHAM test for portable room air cleaners. Other factors include the volume of the space, the air exchange rate in and out of the space, the quality of the air entering the space, sources of contamination in the space, the type of contaminants, other mechanisms for removing the contaminants, the airflow patterns in the space generated by the building ventilation system, opening and closing doors and windows, and the room air cleaner itself. These factors affect both the rate at which the room air cleaner can clean the space and the ultimate level of cleanliness that can be obtained. The filter efficiency and airflow rate are reflected in the CADR; the other factors are application-specific. It is easily possible to overwhelm portable air cleaners with infiltration of contaminated air and not to appreciably reduce the contaminants in the room air. Small tabletop units with low CADRs may be quite ineffective (ALA 1997).

CADR and HVAC Systems. Although CADR is normally applied to portable air cleaners, the same concept applies to central HVAC systems. The same factors, such as the volume of the space and the air exchange rate, help determine how quickly the HVAC system can clean up the space and the ultimate level of cleanliness.

Intermittent and Variable Airflow Operation

When evaluating the effect of filter applications on the IAQ, one must consider the operation of the system. Filters in HVAC systems are only effective when there is flow through the system. An air filter in an HVAC system cannot clean the outdoor air that enters in an uncontrolled manner through infiltration until the air is recirculated. Typical residential HVAC systems have flow only when heating or cooling is required and have uncontrolled

infiltration. In this case, portable room air cleaners may be more effective at cleaning the air (ALA 1997).

Some commercial HVAC systems operate in a VAV mode. The airflow rate varies depending on the heating or cooling requirements. This may affect the air exchange rate (Bearg 1993). It also may affect the effectiveness of filtration in the system.

Some authors [e.g., Krzyzanowski and Reagor (1990)] have advocated continuous fan operation for buildings containing dust-sensitive materials. Cleanrooms normally operate with continuous flow to maintain the required cleanliness.

Ion Generators and Soiling Walls and Furnishings

Some vendors sell ion generators as air-cleaning devices. To the extent that these devices are effective at removing particles from the air, the particles are deposited on the walls and furnishings in the area where the device is used. Ion generators may also generate ozone.

In addition to the issue of soiling surfaces, it should be noted that excess air ions might affect people positively or negatively. Those effects may contribute to the perceived IAQ.

Ozone Generation

ESPs can generate ozone and oxides of nitrogen. As discussed in Chap. 10, ozone and oxides of nitrogen are indoor air pollutants that contribute to reduced IAQ. It is important to ensure that such production does not adversely affect the IAQ of the space that the ESPs are used to clean. Properly designed, installed, and maintained ESPs produce ozone levels that are relatively low compared to levels acceptable for human exposure, although these might be detectable by many people. A malfunctioning unit may produce more. Most commercial units have a cutoff switch coupled to the blower or an airflow sensor.

Self-Charging Filters

Occasionally one sees claims that air flowing through an air filter will charge the filter with the implication that electrostatic forces will contribute to the efficiency of the filter. The airflow cannot directly charge the fibers as the energy available in the air molecules striking the fiber is not adequate to create the required separation of charges (Brown 1993). The filter may have some charge since many materials have an intrinsic charge. However, it is not of the same order of magnitude as the charges in electret filters.

CHAPTER 10

REMOVAL OF GASES AND VAPORS

Dwight Underhill, Sc.D., C.I.H.
*School of Public Health
University of South Carolina
Columbia, South Carolina*

10.1 INTRODUCTION

Why spend money to clean the air we breathe when outdoor air is free and (we hope) uncontaminated? One reason is that air that appears clean even to the EPA may still be too polluted to use, for example, in museums and libraries, where even trace levels of contaminants can do irreparable harm. Zoos, restaurants, and funeral homes, to give another set of examples, may produce their own air pollutants in unacceptable concentrations. And finally, we produce our own pollution—we release odors into the ambient air, and it may be more economical to cleanse the indoor air and recycle a certain fraction of it than heating (or cooling), and possibly humidifying or dehumidifying the fresh air from the outside.

Unwanted vapors can be removed by many different procedures, but only adsorption has found widespread use. Other procedures—including absorption by liquid sprays, condensation, catalytic combustion, photocatalysis, plasma-induced reactions, and pressure swing adsorption, may be used for specialized purposes, such as by the military, where the outside air could be highly contaminated and exceptional treatment is needed. Additionally, the development of low-temperature catalyses may lead to their particular uses, including treating air *brought into* the passenger space of automobiles. Also, at high altitudes (e.g., 60,000 ft), ozone can enter the troposphere from the stratosphere through a process of tropopause folding. For this reason catalytic procedures are commonly used to remove ozone from the ventilation air of high-flying aircraft. This chapter reviews current developments in these areas, with emphasis on the most common procedure: adsorption.

10.2 ADSORPTION

Adsorption is in one respect a very simple process; to remove gases and vapors by adsorption, the air is passed through an adsorption bed such as shown in Fig. 10.1. This procedure is used, for example, in commercial buildings (office buildings, beauty salons, print shops, restaurants, retail stores), fitness centers, health care facilities (including hospitals, convalescent homes, extended-care facilities, physicians' offices, laboratories), airports, schools and libraries, industrial plants, social halls, and residences (odors from pets, entertainment, painting, hobbies). Adsorption on activated carbon is especially useful in removing diesel fumes, hydrocarbons, tobacco smoke, body odor, cooking odors, and volatile organic compounds. Impregnated adsorbents are used to remove low-molecular-weight compounds, such as ammonia, hydrogen sulfide, and formaldehyde, which are poorly adsorbed on the unimpregnated adsorbent. The primary disadvantage in this process is that the adsorption beds eventually become saturated with contaminant and must be replaced. As a rough approximation, the time between replacement depends inversely on the concentration of the contaminant passing into the adsorption bed. Thus the lower the concentration of contaminant, the less expensive the cleansing procedure, making this process well suited for use at the low concentration of contaminants usually found in indoor air.

But the use of activated carbon can also be quite complex. Some have called its application "black magic." The purpose of this section is to take away as much as possible of the mystery in its use.

A brief description of the manufacture of activated carbon is a good starting point in gaining an understanding of this unique material (Ecob, undated). In one manufacturing

FIGURE 10.1 V-configuration adsorption bed. [Figure taken from a diagram in commercial literature by Barnebey & Sutcliffe Corp. (ca. 1970).]

process, a vegetable material rich in cellulose (e.g., coconut shell) is charred in the absence of air to convert the cellulose to carbon. The chemical reaction giving the carbon base is

In a second step the carbon base is slowly oxidized in the presence of steam, and through this chemical reaction, some carbon is removed:

This second step creates the micropores in the carbon, giving the very high surface area necessary for a good adsorbent. The product is activated carbon. Although this process involves chemical reactions, it is known as *physical* activation. Some important facts about activated carbon are

- Activated carbon's structure is like a natural sponge, having a network of pores extending throughout the bulk of the material. As in a natural sponge, there are a wide variety of pore diameters, with the pores smaller than 2 nm termed *micropores*, the pores between 2 and 50 nm termed *mesopores*, and those greater than 50 nm termed *macropores*. Virtually all pores are invisible without a microscope. Pores with diameters less than 5 nm account for most of the adsorptive capacity.
- Internal surface areas of good quality activated carbons are in the range of 1100 to 1200 m²/g. With this degree of activation, approximately *half* the carbon atoms in the adsorbent are on the internal surface of the pores and available to adsorb contaminants.

Activated carbon can be made from a variety of carbonaceous materials, including coconut shell, wood, peat, and coal—all of plant origin. Most gas-phase filter applications use coconut shell- or coal-based carbon. There is a shift to larger pores as one passes from coconut shell to coal to peat to wood. Activated carbons having small-diameter micropores (microporous carbons) are better adsorbers of small molecules, and are also the most retentive. High-grade coconut-base charcoal removes most volatile organic compounds at a capacity of 33 percent by weight, and is hard enough not to readily dust while in service. However, shell-based carbons are not best for all applications. For example, at relative humidities greater than RH 95%, a coal-based carbon may perform better than a shell-based carbon.

A relatively new material, activated-carbon fibers, is under development, and may supplant granular activated carbon in some of the latter's traditional uses. [See, for example, Mori et al. (1997) and Li et al. (1997).]

Once the activated carbon has been manufactured, how is it best used to purify room air? Some basic problems that face a user of activated carbon include those described in the following subsections.

Selecting the Appropriate Commercial Grade of Carbon

There are many commercial grades of carbon available, and without guidance, one might (quite literally) select an activated carbon more appropriate for barbecuing than for air purification.

The American Society for Testing and Materials (ASTM) has developed basic standards for determining the quality of activated carbon. The first step in working intelligently with activated carbon is to become familiar with these standards, which include the following:

D2652. Standard Terminology Relating to Activated Carbons. This standard gives the basic definitions required to apply the test procedures that follow. These definitions are particularly important to vendors and consumers of activated carbon, for they define the basic terminology used in contracts to buy and sell activated carbon.

D2854. Apparent Density of Activated Carbon. Without knowledge of the bulk density of the activated carbon, one would not know the *weight* of activated carbon needed to fill an adsorption bed of a given size. The weight of activated carbon present is key to longevity in a given application. In this test the bulk density is determined by dropping the activated carbon at a known rate and distance into a graduated cylinder and weighing the charcoal that is in the cylinder after it is filled.

D2862. Particle Size Distribution of Granular Activated Carbon. In practice, the charcoal granules can be either too large or too small for the adsorbent to be most effective. If the granules are too small, the pressure drop across a bed will be too high; conversely, if the granules are too large, there is reduced contact between the adsorbent and the air passing through it, and removal efficiency is poor. This test places the adsorbent over a set of wire cloth sieves, with the largest mesh sieve placed at the top, and the subsequent sieves placed, going from top to bottom, in order of decreasing mesh size. These sieves are then vibrated for a fixed period of time at a predetermined intensity, and the amount of activated carbon on each screen is determined by weighing. The finer the granules, the greater the percent of the activated carbon that will be found on the lower sieves. Typically a coarse activated carbon may have a mesh size of 4×8 ; and a finer-mesh-activated carbon a mesh distribution of 16×30 . The numbers given here refer to the U.S. sieve series, with the *smaller* numbers referring to the larger mesh sieves.

D2866. Total Ash Content of Activated Carbon. Activated carbon should contain a minimum of inorganic contaminants. To determine the quantity of inorganic material present, a sample of the adsorbent is autoclaved at 650°C , oxidizing away the carboniferous component, and the resultant ash is weighed.

D2867. Moisture in Activated Carbon. Activated carbon readily picks up environmental moisture. Activated carbon should be purchased on the basis of *dry* weight; otherwise one is purchasing water at a very high cost. To determine the percent of moisture, a sample is weighed, then dried for 4 h at 150°C , and reweighed. The percent loss of weight is taken to represent the water content.

D3467. Carbon Tetrachloride Activity of Activated Carbon. Without a large micropore volume, the adsorbent will rapidly saturate with adsorbed material. The uptake of CCl_4 from a nearly saturated stream of CCl_4 is proportional to the available micropore volume. This test describes a standard procedure for such a test, including the quantity of carbon to use, the flow rate of the CCl_4 , and the times at which the adsorbent is weighed. Although not mentioned in the standard, the volume of micropore space, in terms of milliliters per hundred grams of adsorbent, is approximately the measured carbon tetrachloride activity divided by the specific gravity of liquid carbon tetrachloride (1.594 at 25°C). Activities for good-quality activated carbons range from 55 to 90 percent, although for some specific uses, such as the control of radioactive gases, a lower activity may be preferable.

D3802. Ball Pan Hardness of Activated Carbon. The activated carbon in an adsorption bed is subject to attrition from the vibrations induced, among other factors, by the air passing through it. As this occurs, the adsorbent is reduced to a powder; and if this occurs rapidly, the activated carbon will settle (causing air to bypass the adsorbent), and the loose carbon will soil the surroundings of the adsorption unit. Here the hardness is determined by shaking a sample of the adsorbent, under carefully controlled conditions, with stainless-steel balls, and the amount of dust that is formed in this process is

weighed. The percent of the adsorbent *that is not* reduced to powder is reported as the “hardness” of the sample. In actuality this is a test for resistance to attrition. A good quality activated carbon may have a hardness of 98 percent.

Determining the Capacity of the Adsorbent for the Contaminant

An adsorption isotherm gives the relationship between the concentration of contaminant and the amount of that contaminant—at a given temperature—that will be adsorbed at equilibrium on the adsorbent. Figure 10.2 shows two typical adsorption isotherms. In this figure, the vertical axis gives the concentration of contaminant in the air and the horizontal axis, the uptake of contaminant on the adsorbent. This information is crucial; unless it is known, for example, that so many pounds of activated carbon will remove some quantity of material, the effectiveness of the adsorbent really is not known. The chemical literature contains literally hundreds of isotherms, and there are excellent reference books describing their use (Smisek and Cerny 1970, Flood 1967). Some isotherms, like the Langmuir isotherm, are appropriate for some uses, but rarely to the user of activated carbon. The two isotherms that a user of activated carbon should be aware of are the BET and the Dubinin–Radushkevich isotherms.

The Brunauer–Emmett–Teller (BET) Isotherm. The BET isotherm is very useful in describing the absorption of light gases, especially at low temperatures, such as at the temperature of liquid nitrogen. This isotherm is

$$\frac{x}{V(1-x)} = \frac{(C-1)x}{V_m C} + \frac{1}{V_m C} \quad (10.1)$$

FIGURE 10.2 The BET and the Dubinin–Radushkevich isotherms.

where C = constant

V_m = volume of adsorbed gas required to cover the surface of adsorbent with a single layer of molecules (a monolayer)

V = volume of adsorbed gas

x = ratio of vapor pressure of adsorbate to vapor pressure of solid or liquid adsorbate at the test temperature (e.g., if the vapor pressure of the compound in the air were 10 mmHg, and the vapor pressure of the pure compound were 100 mmHg, then $x = 0.10$)

The BET isotherm is also important because it allows the surface area of an adsorbent to be determined. If the function of V and x on the left-hand side of Eq. (10.1) is plotted against x , a straight line would be obtained with a slope of $(C - 1)/V_m C$ and an intercept of $1/V_m C$. Thus, from the slope and y intercept of this line, V_m can be determined, and finally, if the surface covered by an individual molecule is known, the surface area of the adsorbent can be calculated from V_m . In these measurements, nitrogen is commonly used as the adsorbate and the area covered by a nitrogen molecule (depending slightly on the temperature) is $16.2 \text{ \AA}^2$. The surface area of an adsorbent is an important measure of the quality of the adsorbent. One important fact in using the results of this procedure is that it has an inherent error of about ± 10 percent. In purchasing an activated carbon, the buyer should be aware that differences between surface areas less than 10 percent may be meaningless.

The Dubinin–Radushkevich Equation. Our interest is generally in the adsorption of larger molecules, however, such as volatile organic compounds. For these substances, the Dubinin–Radushkevich equation has been found to give better results. The basis of this equation is the assumption that the activated carbon contains micropores in which the adsorbed organic vapors can condense out in the form of a liquid (Astakhov et al. 1969, Dubinin and Astakhov 1971). This equation is

$$M = V_0 \rho \exp [-k (RT \ln x)^b] \quad (10.2)$$

where M = weight of adsorbed material, mL/kg

V_0 = micropore volume of the adsorbent, cm^3/kg

ρ = density of the liquid contaminant, g/cm^3

k = the first structural constant, $\text{mol}^b \cdot \text{cal}^{-b}$

b = the second structural constant, dimensionless

R = ideal-gas constant, $1.9872 \text{ cal}/(\text{mol} \cdot \text{K})$

T = absolute temperature, K

x = as defined in Eq. (10.1)

For the basic assumption of the Dubinin–Radushkevich equation—that the adsorbate is held as a liquid in the micropores of the charcoal—to be valid, the adsorbate must be at or below its critical temperature T_c , or else the liquid phase cannot form. Thus at room temperature the Dubinin–Radushkevich would be appropriate for the adsorption of n -butane ($T_c = 152^\circ\text{C}$), but not for methane ($T_c = -82.1^\circ\text{C}$), on activated carbon.

One strong point of Eq. (10.2) is that the factors in it can be correlated with physical properties of either the adsorbent or the adsorbate. The factors V_0 , ρ , P , and P_0 are associated with the adsorbate; whereas the structural constants (k and b) are characteristic of the adsorbent. One reason for using a highly activated charcoal is that the pore volume (V_0) increases as the activation of the carbon is increased.

The structural constants describe the distribution of pore sizes in the activated carbon. In earlier studies it was commonly assumed that the value of b was equal to 2; but values

of b differing from $b = 2$ have been found for many commercial activated carbons (Richter and Schütz 1991). Note that $b = 2$ gives the most commonly used version of the Dubinin–Radushkevich equation and that $b = 1$ gives the Freundlich isotherm. In practice, b usually lies between 1 and 2. The other structural constant k may change slightly as the adsorbate is changed. Sansone and Jonas (1981) give a procedure using the index of refraction to determine the factor k for one adsorbate if the factor k is known for another adsorbate on the same activated carbon.

Determining the Efficiency of the Bed

After the adsorption capacity for the air contaminant is known, for example, in pounds of contaminant per pound of adsorbent, what will be the practical efficiency of the adsorption bed?

As a stream of polluted air passes through an initially clean adsorption bed (Fig. 10.3), there is a band of partially saturated adsorbent between the clean adsorbent and the saturated adsorbent. Only when this band reached the exit of the adsorption bed does contaminant pass through the adsorption bed (see line 1 in Fig. 10.4). A goal of good bed design is to keep this band as narrow as possible so that the entire adsorption bed will be near saturation before breakthrough occurs. Should the band be wide, then the breakthrough curve will resemble line 2 of Fig. 10.4. This line shows an appreciable contamination of the air passing through the adsorber before the capacity of the adsorber was spent.

FIGURE 10.3 The adsorption wave in an adsorption bed.

FIGURE 10.4 Two typical breakthrough curves.

Very often a mathematical curve called the J function is fitted to the breakthrough data (Perry 1984), and the parameters that describe this function are then used to characterize the breakthrough curve. The J function has the form

$$J(N, Nt') = 1 - \int_0^N \exp(-Nt' - z) I_0(2\sqrt{Nt'z}) dz \quad (10.3)$$

where I_0 = modified Bessel function of the first kind
 N = number of theoretical plates, dimensionless
 t = time from beginning of test challenge, h
 t_h = ideal holdup time, h
 $t' = t/t_h$

The factors in Eq. (10.3) are easily defined. The ideal holdup time t_h is the time required to saturate the adsorbent bed if the bed took up all the contaminant that passed into it. The number of theoretical plates N describes the steepness of the breakthrough curve. The higher the number of theoretical plates, the closer the breakthrough curve approaches the highly efficient breakthrough curve (line 1 in Fig. 10.4). It has been a common procedure for engineers to study the effect of bed design, temperature, airflow velocity, contaminate concentration, relative humidity—in fact all the variables that might affect the performance of an adsorption bed—and determine how these factors change the mean holdup time and the number of theoretical plates. If the adsorption bed has too few theoretical plates (say, below 10), its performance will be poor.

Fitting the J function to data was once commonly done using a nomograph, but today it can be quickly done by microcomputer (Forbes and Underhill 1986). There are many other possible equations which can be fitted to experimental data, but the J function is not only one of the simplest functions for analyzing the dynamic performance of adsorption beds but also the most commonly used—therefore the results obtained using this function are understandable by engineers working on similar problems.

The semiempirical Wheeler equation (Jonas and Rehmann 1974),

$$t_b = \frac{v_e}{C_{in}Q} \left\{ M_c - \left[\frac{\rho_c Q}{k_v} \ln \left(\frac{C_{in}}{C_{out}} \right) \right] \right\} \quad (10.4)$$

where t_b = breakthrough time, min
 v_e = equilibrium mass adsorbed, g/g activated carbon
 $C_{in,out}$ = inlet and outlet concentrations, g/cm³
 Q = volumetric flowrate through bed, cm³/min
 M_c = mass of carbon in bed, g
 ρ_c = density of bulk carbon, g/cm³
 k_v = adsorption rate constant, min⁻¹ ($= 14.41 U^{0.5} d_p^{1.5}$)
 U = superficial air velocity, cm/min
 d_p = carbon granule diameter, cm

proved useful in the study of the performance of thin adsorption beds, such as respirator cartridges. It is not as versatile as the J equation, but it is easier to use in calculations.

Ensuring Removal of Contaminant by Absorbent in Presence of Water Vapor

Water vapor is always present at far higher concentrations than is any contaminant. For example, at 25°C air saturated with water contains 25,000 ppm of water vapor. How can

one be certain that the adsorbent will remove the contaminants present in concentrations of a few parts per million in the presence of these much higher concentrations of water vapor?

Charcoal can adsorb most organic vapors in the presence of very high concentrations of water vapor for one basic reason—most organic molecules are larger than molecules of water and are more strongly attracted to the activated carbon than is water vapor. It would be very helpful if we knew how relative humidity affects the adsorption of complex mixtures, such as the complex mixture that makes up polluted air. But at this time the best experimental data that are available are for the effect of relative humidity on the adsorption of a single organic component from air. Different results have been seen for the effect of relative humidity on the adsorption of water-soluble organic compounds and on water-immiscible compounds (Underhill 1987, Kavar and Underhill (1999). Figure 10.5 demonstrates the effect of relative humidity on different concentrations of trichloroethylene (Werner 1985). The strong reduction in the adsorption at high relative humidities is apparent; what is not yet well understood is how water vapor interferes with the adsorption of the complex mixture that comprises indoor air contaminants at the low concentrations in which they are found in the ambient air. At this time we can state with confidence that the relative humidity, especially if it is over 55%, is detrimental.

Adsorption of Mixtures

In most cases, indoor air pollutants are a complex mixture of very low, often highly variable (e.g., with occupancy), concentration of compounds, many of which may be unknown at the time that the adsorption unit is selected. The hundreds of volatile compounds present in cigarette smoke illustrate this, and cigarette smoke may be only one of the components present in contaminated indoor air. This is in contrast with what is found in industry, where adsorption is often applied to constant concentrations of one (or at most a few) known components. The unfortunate fact is that the adsorption of complex mixtures at low concentrations is not

FIGURE 10.5 Effect of relative humidity on the adsorption of trichloroethylene. [Information taken from Werner (1985). Figure redrawn by Dwight Underhill.]

well understood. As an illustration, the EPA published test results in which a mixture of the vapors of three components (2-ethoxyethyl acetate, toluene, and propanone) was passed through an adsorption bed. Figure 10.6 shows the result. The lightest component, propanone, passed the most rapidly through the bed. There was also displacement of lighter components by heavier components. The real world is far more complex. Cigarette smoke alone contains hundreds of compounds, and the interactions of these compounds in an adsorption bed is largely unknown. What is known is that activated carbon can adsorb large quantities of indoor air pollutants, even at the low concentrations of these substances found in indoor air. As an example, it is not uncommon for activated carbon to adsorb as much as 20 to 30 percent of its weight in contaminants on exposure to indoor air pollutants before losing its ability to adsorb additional contaminant. One reason for this high adsorption capacity is that many chemical reactions take place between the reactive materials that are adsorbed (aldehydes, organic acids, ketones, sulfides, amines, etc.), and the resultant high-molecular-weight compounds that are formed are relatively nonvolatile. These compounds become so tightly bound to the carbon that the only way to remove them is to reactivate the carbon. But the rate of these reactions, as well as the extent with which they can go forward, is still not well understood. The rate of these reactions is probably far higher at high relative humidities; this is another area where more needs to be learned.

The Basic Design Parameters in an Adsorption Bed

1. *Contact time:* The air must be in contact with the activated carbon for a time—generally at least 0.1 to 0.2 s—for the adsorption to near completion. This contact time t_c is

FIGURE 10.6 The adsorption of a three-component mixture. [Figure taken from MSA Research Corp. (1973).]

$$t_c = \frac{V_b}{Q} \quad (10.5)$$

where V_b = volume of activated carbon, m^3

Q = airflow, m^3/s

t_c = contact time, s

2. *Pressure drop across the unit:* Knowing the pressure drop is important—after all, it is a part of the ventilation system. The first point about the pressure drop is that it is (roughly) directly proportional to the airflow velocity, and generally can be estimated from graphs supplied by the vendor.

The second point is that there are two conflicting factors in bed design that involve the pressure drop; we want to use a large volume of adsorbent, yet to pass the air through a thick bed (Fig. 10.7a) containing this carbon may give an unacceptably high loss of pressure. To get the desired low-pressure drop, either partial bypass (Fig. 10.7b) or extended surfaces are used (Fig. 10.7c–f). The adsorption bed shown in Fig. 10.1 uses a number of V sections placed in parallel. In commercial V banks, there may be 30 to 40 lb of carbon per 1000 cfm of air. Also commercial adsorption beds are available in sizes that match standard ductwork, such as 2×2 or 1×2 ft. Additional details on commercial designs are available in the literature (ASHRAE 1983, Godish 1989), but this information is subject to change from competition in the marketplace. The most important fact to remember is that in buying an adsorption bed one is purchasing both adsorbent carbon and a unit to hold this adsorbent and place it in close contact with the air passing through the unit. The more adsorbent and the lower the pressure drop across the unit, the better the performance will be over time. It costs less to build a unit that has either a higher pressure drop or contains less carbon, so the buyer must not base a purchase solely on the criterion of the lowest possible cost.

Factors to Consider in Installation of an Adsorption Bed

At the time of installation, important factors to consider are:

1. Is there sufficient vacuum (or pressure) to maintain the desired flow? Often backfitting of existing facilities is requested. A common example is for a hospital in which a heliport has been installed (or in which the weekly testing of emergency power generators) creates unacceptable diesel fumes. If this installation is an upgrade, is there sufficient space and carrying capacity to support the added volume and weight of the unit? Can the adsorption bed be placed in an area permitting easy access to change the adsorber, or to check for leaks? Even small leaks can compromise the effectiveness of a large unit. A rapid, and often effective, procedure for locating leaks in a large installation is to place a floodlight inside the unit at night, and look for light leaking either outside the unit or across the adsorption bed.
2. Can the unit be placed far enough away from fans or other mechanical devices so that vibration will not cause settling and/or attrition of the activated carbon?
3. Should the unit include either a prefilter or an afterfilter? This depends on the dustiness of the inflowing air, and the degree with which attrition of the carbon can be tolerated.
4. Is the influent air either too humid or too warm for satisfactory performance? If so, can the air be conditioned, perhaps by mixing with outdoor air? If the excess humidity (or even water droplets) is from an air-conditioning unit, can the adsorber (or the air conditioner) be relocated?

FIGURE 10.7 Adsorption bed configurations. (a) Thick bed tray; (b) partial bypass; (c) trays in V configuration; (d) serpentine configuration; (e) intermediate bed depth V module; (f) thick bed extended surface area module. [Modified from ASHRAE (1983).]

5. The unit must be transported to the installation site carefully—If horizontal trays are to be used (and a horizontal orientation is generally preferred to reduce bypassing through settling), then they should be transported horizontally to prevent settling that will leave airgaps in the adsorber. In a new installation the adsorber should not be operated until it is needed, otherwise contaminants from degassing (from paints, resins, furniture, plastics, etc.) will cause the unit to lose capacity before it is used.

How Long the Adsorbent Can Be Used Before Replacement

It is difficult to tell, other than by loss of performance, when the adsorbent has lost its ability to adsorb additional contaminant. Unlike the pressure drop in filters for particulate matter, the pressure drop across an adsorbent bed does not change as the carbon collects adsorbate (contaminant). There is no way of ensuring continued satisfactory performance other than taking out a sample of adsorbent and testing it, or by replacing the adsorbent before its *predicted* lifetime has been reached. A standard of 4.5 lb/1000 ft³ per year has been a design guideline for many years, but it may overstate the amount of carbon needed. The time that a unit can remain in service depends on the rate at which organic vapors are generated in the space being deodorized.

Another old guide to estimate the effective use time is the *Odor Index* developed by Barnebey-Cheney Co. From this odor index (see Table 10.1) in typical usage, one pound of charcoal will purify the following cubic feet of space for one year: type A, 2000 ft³; type B, 800 ft³; type C, 300 ft³; type D, 100 ft³. The difficulty remains that the accuracy of these estimates depends on the release of consistent amounts of adsorbable vapors from similar sources, and, to cite examples, whether we can assume that all funeral homes (or bars) are similar. The idea of ranking areas to estimate their probable need for replacement carbon has merit, and it would greatly advance the field if vendors could find a way to pool their data so that the *Odor Index* could be updated and expanded.

Few industrial test data are appropriate to the indoor environment. For example, tests of the effectiveness of an adsorption bed, challenged with high concentrations of toluene (a stable chemical that generally does not react while adsorbed), may give very different results from the simultaneous adsorption of low concentrations of many reactive compounds. Given the variability in the concentration of contaminants, it will always be challenging to estimate the service life of an adsorption bed in a given situation. But such selection could be facilitated if there were a consistent set of performance standards in which the performance of adsorption beds could be compared under care-

fully controlled conditions of flow velocity, temperature, relative humidity, challenge gas composition and concentration, among other factors. An example of a performance standard is the German National Standard, DIN 71460, which permits adsorptive filters for automobile cabins to be tested under standard conditions for their effectiveness in removing four very different challenge agents (toluene, butane, sulfur dioxide, and nitrogen dioxide).

10.3 CHEMISORPTION

Chemisorption on Impregnated Activated Carbon

Activated carbon is not effective in removing sulfur dioxide, low-molecular-weight aldehydes and organic acids (especially formaldehyde and formic acid), nitric oxide, and hydrogen sulfide, but it can be impregnated with chemicals (impregnants) that do react with these contaminants. In this case the activated carbon serves as a carrier of the impregnants, enhancing the reaction rate by providing a large surface on which the chemical reaction(s) can transpire. An example of a chemisorbent is as follows. Activated carbon is immersed in a solution of sulfur dissolved in carbon disulfide; the carbon is then dried, leaving the elemental sulfur coating the surface of the carbon. The treated carbon is especially effective in removing mercury vapors from an airstream because the sulfur reacts with mercury vapor to form mercuric sulfide.

Other impregnated carbons have uses as diverse as the removal of hydrogen sulfide, formaldehyde, acid gases, radioactive iodine, ammonia, chlorine, war gases, arsine, phosphine, chlorine, nitrogen dioxide, and sulfur dioxide (Anonymous 1994). The patent literature is an excellent guide to the compounds that have been found to be useful as impregnants. In general, there is no difference between the sorption beds used to contain impregnated versus unimpregnated carbons. However, because a chemical reaction is involved, the contact time must be sufficiently long to allow the chemical reaction to near completion—a time that in practice can vary greatly (e.g., from 0.01 to 0.4 s). Another difference is that increased relative humidity and increased temperature can speed up the rate of the chemical reaction, whereas for physical adsorption these factors are always detrimental.

Many chemical defense systems are based on the use of Whetlerite, an activated carbon impregnated by an ammoniacal solution of copper(II) and chromium(VI) salts. Disadvantages of this chemisorbant are (1) its short lifespan—it may lose 75 percent of its effectiveness in a year; (2) release of the impregnating compounds, ammonia, which causes breathing discomfort, and chromium(VI), known to be carcinogenic; and (3) the need for replacement of the adsorbent immediately after any challenge.

Chemisorption on Permanganate-Impregnated Alumina

Many reactive compounds can be removed from air by chemisorption on potassium permanganate-impregnated alumina (Purafil undated, 1993). Table 10.2 gives comparisons between the adsorption capacities of activated carbon and potassium permanganate-impregnated aluminum oxide for some important air contaminants. In Table 10.2, the adsorptive capacities are percent uptake by weight observed at the point of 95 percent breakthrough of contaminant through the adsorption bed.

From Table 10.2, the potassium permanganate-impregnated aluminum oxide was superior in the removal of most highly reactive compounds (nitric oxide, sulfur dioxide

TABLE 10.2 Comparison of the Capacity (in Weight Percent) of a Chemisorbent and Unimpregnated Activated Carbon Material

Capacity, weight %	Nitrogen dioxide	Nitric oxide	Sulfur dioxide	Formaldehyde	Hydrogen sulfide	Toluene
$K_2MnO_4 +$ Al_2O_3	1.56	2.85	8.07	4.12	11.1	1.27
Activated carbon	9.15	0.71	5.35	1.55	2.59	20.96

Source: Taken from Muller and England (1995).

formaldehyde, and hydrogen sulfide). It was *not* as good as the activated carbon for removing nitrogen dioxide, which is to be expected, as potassium permanganate is a strong oxidizing agent, and nitrogen dioxide is in such a highly oxidized state that it cannot be oxidized further. In the same context, the chemisorbent was very effective in the removal of hydrogen sulfide, an easily oxidized compound. And as would be expected, the chemisorbent had poor capacity for the removal of toluene, an organic compound that is resistant toward oxidation.

In estimating the use time from data such as in Table 10.2, one must remember that the bulk density of permanganate-impregnated alumina is about 50 lb/ft³, whereas that for granular activated carbon ranges between 30 and 32 lb/ft³ in most applications. Therefore, nearly twice as much (by weight) of permanganate-impregnated alumina can be placed in the same volume as granular activated carbon. An uptake of 10 percent by weight of contaminant on a system containing permanganate-impregnated alumina may give the same capacity as a 16% uptake on granular activated carbon.

Permanganate-impregnated alumina may initially contain 4 to 8% potassium permanganate by weight. Higher loadings may not give an effective use of the oxidant because of the tendency of potassium permanganate to form crystals at higher loadings. Once the permanganate-impregnated alumina has been put into use, it will gradually lose this initial activity, and the question rises concerning the residual activity of the potassium permanganate. This assay is usually carried out by wet chemistry, in which the steps are (1) eluting the potassium permanganate from the adsorbent, (2) adding an excess of dissolved iodine to the extract, and (3) backtitration with sodium thiosulfate. Results can be obtained far more quickly—and possibly as reliably—by a colorimetric analysis of the purple extract, in which the extract is compared to standardized solutions of potassium permanganate.

Standardized tests for permanganate-impregnated alumina are not available from ASTM, and as a rule, the ASTM test procedures for granular activated carbon are not useful for permanganate-impregnated alumina.

Aluminum oxide is naturally hydrophilic, and on normal contact with the atmosphere will pick up 15 to 25% by weight moisture. This moisture is sufficient to maintain a high fraction of the potassium permanganate impregnate in an aqueous solution covering the internal surface of the adsorbent. In this form, the potassium permanganate is highly reactive. If, however, the relative humidity is reduced, say, to <30% for long periods of time, or <5% for short periods of time, then the water film will begin to evaporate, and the potassium permanganate will form small crystals, which are far less reactive. If permanganate-impregnated alumina is to be used in a dry atmosphere, it is advised that pilot tests first be run to determine whether the chemisorbent can be effective. On the other hand, one should avoid conditions where high relative humidity will leach out the impregnant.

Even though chemisorption and physical adsorption—the removal processes on permanganate-impregnated alumina and granular activated carbon, respectively—are quite different, the design of adsorption beds using these materials is essentially the same. The underlying reason is the desire for a short contact time with a low pressure drop. A typical contact time in a permanganate-impregnated alumina bed is 0.01 s, corresponding to 500 fpm passing through a 1-in.-deep bed. A typical removal efficiency of such a bed for reactive contaminants is 85 percent. Such beds operating in series may give adsorption efficiencies of >98 percent.

As Table 10.2 shows, there are airborne species for which the permanganate-impregnated alumina outperforms granular activated carbon and other airborne species for which permanganate-impregnated alumina outperforms granular activated carbon. To try to get the optimal adsorption where both species are present, it is a common practice to use mixtures with granular activated carbon, usually in a 50/50 mixture by volume. One observation with such mixtures has been that the granular activated carbon often outlasted the permanganate-impregnated alumina, sometimes by factors as great as 3 or 4. The use of heavily impregnated alumina (e.g., containing 8% potassium permanganate by weight) has helped narrow this performance gap.

Applications include airports, commercial office buildings, health care facilities, hotels, industry (including pharmaceutical and microchip manufacturing), museums, restaurants, restaurant cooking grills, university facilities, and zoos.

The time for which permanganate-impregnated alumina may be used before losing its activity is highly variable. In treating outdoor air, a 1-in.-thick bed permanganate-impregnated alumina having a 500 fpm face velocity may last for a year, giving a removal efficiency of 85 percent averaged over this period. But this projected use time varies enormously with respect to the concentration of pollutants, and this, in turn, varies not only from city to city, but also with the location in the city. Small changes, such as taking air in from a high floor rather than at street level, can make a substantial difference in use time.

10.4 OTHER PROCESSES

Catalysts

Ozone is a hazard to flight personnel and passengers in commercial aircraft flown at high altitudes. At 60,000-ft altitude, the mean ozone concentration in the winter months can be 3 ppm, 30 times the FAA (Federal Aviation Administration) exposure limit of 0.1 ppm in the airplane cabin zone. Abatement of this ozone is technically feasible through a number of procedures, but thermal catalytic decomposition using palladium on an alumina substrate is particularly effective (Heck and Farrauto 1995). Catalytic beds for ozone removal are also in common use in xerographic copiers. These catalytic beds have a finite use time, and after they fail, the odor of ozone near the copy machine can become quite intense.

The current patent literature reveals that there is intensive development of new catalytic materials that remove several important air contaminants at or near room temperature. Especially interesting are catalysts that remove carbon monoxide and nitric oxide, as these are key components of automobile exhaust, and thus major pollutants in garages, tunnels, automobile passenger cabins, and other areas. The obvious advantage of room-temperature catalysts over adsorbents is that the former do not become saturated with contaminants.

Pressure-Swing Adsorption

In pressure-swing adsorption, two adsorption beds are operated in parallel (Skarstrom 1972). While the first bed is purifying a stream of compressed air, the second bed uses a fraction of the clean air output from the first bed to backflush from it, at atmospheric pressure, any adsorbed contaminants. Eventually the first bed nears saturation with contaminant and the second bed is cleansed of contaminants. Then the roles of the beds are reversed; the compressed air to be cleansed is passed through the second bed, and a fraction of the effluent air from the second bed is then used to backflush the first bed. The air passing through the bed under compression *not used to backflush* the other bed is the cleansed air that is the product of this process. To give an example of this process, assume that 1 L of air can be passed through the first bed at 10 atm pressure before breakthrough occurs. This 1 L can be decompressed to give 10 L of air at atmospheric pressure. If only 5 L of air is needed to backflush the bed at atmospheric pressure, then the remaining 5 L of purified air are available for other purposes, including air supply to personnel. The cycling time in these systems can be very short, permitting a high flow of purified air. Attractive features of this process include (1) the adsorbent is constantly renewed, and (2) very high purification factors are readily attainable. Pressure-swing adsorption seems especially attractive for supplying air to military personnel in confined spaces such as tanks, where the power required for the pressure cycle is readily available and a high decontamination factor is required.

Plasma Destruction and Photocatalytic Destruction

Plasma treatment of contaminated air has the potential to treat large flows of air with exceptionally high decontamination factors for a wide variety of toxic materials, especially at low concentrations, such as may be released from paint shops, on-site remediation, and pharmaceutical manufacture (Nunez et al. 1993). But the corona discharge can produce by-product nitrogen oxides in sufficient concentrations to make the treated air unbreathable, and thus a second system, perhaps a catalytic converter, may be needed to make the air breathable. There is also the question of cost. Plasma treatment may be too expensive for the routine treatment of low concentrations. One cost estimate is that to remove 5 ppm of CH_2O in 5 h requires a discharge power of ≈ 5 to 20 W/m^3 of occupied space (Storen and Kushner 1993). There are many variations on the plasma model; some systems use the plasma in conjunction with a solid adsorbent on which the decomposition occurs.

A newer approach is the use of ultraviolet (UV) light in conjunction with a titanium dioxide adsorbent (Hisanaga and Tanaka 1995, Raupp and Junio 1993, Peral and Ollis 1997). There is considerable variation between compounds in the degree with which the adsorbent and the UV light interact to cause decomposition of the airborne compounds. Also it is known that some compounds, such as oxygenated compounds can be decomposed by near-UV radiation. A basic difficulty with this new process appears to be obtaining the required minute volume through the air cleaner.

Ozone

Ozone is a very reactive compound easily generated in highly toxic concentrations in air passing through an electrostatic field. A recent review should put to rest the 100-year-old (1900–1999) controversy regarding the use of ozone as an air purifier (Boeniger 1995). There it was reported that ozone, through its own odor, might mask some odors, but this effect is small. Ozone also may react with odiferous organic compounds, but the rate of

reaction is generally very low; for instance, it would take more than 880 years to reduce the concentration of toluene by 50 percent on exposure to 100-ppb ozone. Furthermore, the reaction products formed are often less desirable than the unreacted compounds—for example, the reaction products of ozone with toluene include aldehydes that have a far more unpleasant odor (and are far more toxic) than the parent toluene. Even less desirable is the presence of the unreacted ozone, which at the relatively low concentration of ≈ 120 ppb can cause eye irritation, visual disturbances, headaches, dizziness, dry mouth and throat, chest tightness, insomnia, and coughing (Sittig 1991). The danger to the general public from ozone generators increased by their use in public areas (such as hotels) without warning to those so exposed. Some vendors try to disguise the fact that their so-called “air-purifying device” generates ozone, so that the person using it will not be aware of the health risks involved. Also, as there are no standards for commercial ozone generators, there is the danger that a particular generator may give a far greater output of ozone than was originally intended. The writer of this chapter once used an ozone generator designed for indoor use to expose laboratory guinea pigs to *lethal* concentrations of ozone. The important point is that despite some misconceptions to the contrary, ozone is a very toxic compound. The harmful effects of human exposure to ozone are of current concern to the American Lung Association, the Environmental Protection Agency, and the Federal Trade Commission.

10.5 RESOURCES FOR FURTHER READING

Essentially all information available in the scientific literature regarding cleansing of indoor air published since 1992 can be found in *Chemical Abstracts* in the general subject index under the recently added heading of *Air Purification*. Under this heading in the 13th collective general subject abstract are approximately 2000 references, including many patents. An older, but still very useful review of the removal of organic vapors from the indoor environment, is *Indoor Air Pollution* (Godish 1989). The basic reference for engineers interested in the removal of either gases or particulates remains *The Chemical Engineers' Handbook*, which is updated periodically. Finally, a comprehensive—yet very readable—review of current adsorption theory has been presented by Manes (1998), who pioneered many developments in this area.

CHAPTER 11

DISINFECTING AIR

Edward A. Nardell, M.D.,

Associate Professor of Medicine

Harvard Medical School, The Cambridge Hospital

Cambridge, Massachusetts

11.1 INTRODUCTION AND HISTORICAL BACKGROUND

Current understanding of both airborne infection and air disinfection began in the 1930s with observations and experiments by William Firth Wells, a Harvard sanitary engineer (Wells 1934). Wells had been engaged by the Massachusetts Department of Public Health to investigate the potential for respiratory infections from aerosols of stagnant water used to keep down dust in New England textile mills (Wells and Riley 1937). Employing an air centrifuge he had developed earlier, Wells sampled air in the mills and recovered bacteria. Together with Richard Riley, a medical student working on the project, Wells made two brilliant intellectual leaps from that observation: (1) airborne particles carrying microorganisms are the dried residua (i.e., droplet nuclei) of larger respiratory droplets which evaporate almost instantaneously, and (2) droplet nuclei are also the mechanism of person to person transmission of airborne respiratory infections, such as measles and tuberculosis. Having proved that air could be the vehicle of infection, the subject of longstanding scientific debate, Wells and Riley proceeded to investigate methods of air disinfection. The decades of laboratory and field experiments that followed resulted in a firm scientific foundation for what are now the disciplines of aerobiology and air disinfection (Riley and O'Grady 1961, Wells 1955). Unfortunately, relatively little research has followed those important early experiments.

Tuberculosis had been an important stimulus for the early investigations of airborne infection, but its incidence was already declining, and it was widely believed that transmission

would no longer be an important problem following the 1946 discovery of streptomycin, the first highly effective treatment. Likewise, it was believed immunization would eradicate or control the important airborne viral infections, such as measles, smallpox, and influenza. Except for smallpox, these predictions of victory over both tuberculosis and viruses have proved premature. Despite the persistent importance of these diseases, research on airborne infection and air disinfection has received little attention, except for work on surrogate organisms done in laboratories associated with military defense (Cox 1987). The recent resurgence of tuberculosis in industrialized countries, however, with institutional outbreaks of multidrug-resistant strains, has been a stimulus to reexamine the results of earlier research, and the more recent aerobiology information on surrogate organisms, and to initiate new investigations.

Moreover, the combination of HIV infection and tuberculosis in sub-Saharan Africa, Asia, and eastern Europe has led to global concerns over the spread of drug-resistant tuberculosis in institutions and other indoor environments, such as aircraft (Miller et al. 1996, Pablos-Mendes et al. 1998). The absence of resources for adequate disease treatment in low-income countries presents a challenge for those interested in cost-effective infection control. Further discussion on tuberculosis is found in Chap. 47.

11.2 AIR DISINFECTION STRATEGIES

Before discussing the technological approaches to air disinfection currently in use, it is necessary to emphasize two assumptions inherent in this approach to infection control.

1. Air disinfection assumes that the airborne route is the predominant route of transmission for the infection of concern. This may seem obvious, but for some infections, rhinovirus and *Legionella*, for example, considerable controversy has existed over the relative importance of airborne transmission versus transmission by large droplets (direct contact) in the case of rhinovirus, and potable water with subsequent aspiration into the lungs in the case of *Legionella*. Clearly, air disinfection will not be effective against infections that are not spread by particles that are truly airborne.
2. Air disinfection in specific locations also assumes that those locations are the principal sites of transmission. For example, measles is known to be an airborne infection, and air disinfection in schools was postulated to be a logical approach to control in the prevaccination era. However, a successful trial of upper-room ultraviolet germicidal irradiation (UVGI) to control measles transmission in schools in suburban Philadelphia was followed by two failed field trials in other locations where students either rode together on school buses, or returned home to crowded urban tenements. Although transmission may have been averted in school by UVGI, it apparently occurred in other congregate settings where air disinfection could not be applied, and the impact of the intervention was not significant (MRC 1954, Perkins et al. 1947, Wells et al. 1942). To be effective, air disinfection must be targeted to true airborne infections and only when the most important sites of transmission are included.

11.3 DROPLET NUCLEI TRANSMISSION

Secretions in the lower respiratory tract are normally sterile. However, in persons with respiratory infections, mucociliary secretions carry organisms up to the trachea and pharynx where they are expectorated or swallowed. Coughing, sneezing, and other expiratory maneuvers generate high-velocity airflow over the wet mucosal layer, sheering off droplets

containing infectious organisms. Factors that influence the rate at which infectious aerosols are released into the air are not well defined, but the numbers of organisms present, the force of coughing and sneezing, and the physical properties of secretions are believed to be important. Particle size of aerosols is related to air velocity. In sneezing and coughing, peak airflow in the bronchi approaches 300 m/s, resulting in particles averaging approximately 10 μm in diameter in exhaled air (Riley and O'Grady 1961). Infectious particles consist of respiratory fluid of variable consistency, one or more organisms, and possibly mucus and other debris present in the respiratory tract. Once ejected into the air, large particles settle rapidly onto surfaces, where they dry and become part of household dust. Although some organisms remain viable in dust, and dust can be resuspended into the air, the large average size of dust particles assures that they will again settle quickly. If inhaled, dust particles impact in the upper respiratory tract, which may or may not be vulnerable to the particular infectious organisms it contains. In the case of tuberculosis, infectious particles must reach the vulnerable peripheral (alveolar) region of the lung to initiate infection. Therefore, dust has not been associated with tuberculosis transmission. Smaller droplets containing viable organisms settle more slowly, and evaporate quickly, depending on their solute composition and on ambient temperature and humidity. As they evaporate and lose mass, they settle more slowly, ultimately settling so slowly (average 0.04 ft/s) that ordinary room air currents are sufficient to keep them airborne indefinitely. Wells called these dried residua of respiratory droplets, "droplet nuclei." Note that the size and shape of the naked microorganisms do not necessarily define the dimensions of infectious droplet nuclei. Most viruses are far smaller than tubercle bacilli, but in both cases droplet nuclei are believed to average 1 to 3 μm in diameter. The complex process of aerosolization and dehydration, the presence of additional solids and solutes, and the vulnerability of various sites in the respiratory tract all determine the size of airborne infectious particles.

11.4 PRINCIPLES OF AIR DISINFECTION

Infectious droplet nuclei behave like any other airborne particulate of similar size and mass. Epidemiologic investigations have shown that they follow airflow patterns in buildings, sometimes causing infection in areas of the building remote from their source (Hutton et al. 1990). However, infection is most likely to spread between people within contiguous indoor airspace, where the concentration of droplet nuclei is highest. Infection requires the inhalation of one or more infectious droplet nuclei (the infectious dose), depending on the virulence of the infectious agent and the resistance of the host. Since the number of infectious droplet nuclei needed to cause infection is seldom known, it is convenient to use the term *infectious dose* to mean, however, that many droplet nuclei are needed. Wells used the term *quanta* for this unknown number, symbolized by q . Airborne infections vary greatly in contagiousness (Wells 1955). Measles, for example, is considered among the most contagious of airborne infections, whereas tuberculosis generally requires prolonged exposure between a source case and susceptible hosts. In both cases, however, the risk of infection is proportional to the concentration of infectious particles in the air. The goal of air disinfection is to reduce the concentration of infectious particles by dilution, removal, or inactivation.

11.5 CURRENT METHODS OF AIR DISINFECTION

Two of the three available methods of air disinfection, ventilation and filtration, are familiar, commonly used to remove noninfectious airborne particulates. Because these modalities are

discussed throughout this handbook, only those aspects peculiar to the control of airborne infection are mentioned here. A third method unique to infectious particles, germicidal ultra-violet irradiation (UVGI), will be discussed here in greater detail.

11.6 VENTILATION FOR CONTROL OF AIRBORNE INFECTION

The earliest ventilation standards were set, in part, to reduce person to person spread of airborne infections such as tuberculosis (Fig. 11.1). Eventually, largely due to the work of Yaglou, a contemporary of Wells at Harvard, comfort became the primary determinant of ventilation rates in buildings. It has been assumed, but never proved, that ventilation rates sufficient to assure comfort for most room occupants would also control other airborne pollutants, including infectious agents. Indeed, while there are examples of extensive airborne transmission under conditions of poor ventilation, substantial transmission also occurs where comfort criteria are satisfied (Calder et al. 1991, Nardell et al. 1991). Although it has been possible to establish threshold levels of outside air ventilation to control odor, based on the comfort of a majority of room occupants, it has not been possible to define levels of ventilation that would protect most occupants from most airborne infections. The variables (source strength, virulence, duration of exposure, and susceptibility) are simply too great. Moreover, there are potential conflicts between the comfort and health paradigms. For example, occupants of a movie theater who are being entertained for 2 h or less might well tolerate half the outside air ventilation recommended for office buildings as long as temperature and humidity are satisfactory. Less outside air ventilation could save theater operators significant heating and cooling costs, and generate less air pollution. However, if even one member of the audience has influenza in an infectious stage, mathematical modeling would suggest that the intensity of exposure will be approximately double (under well-mixed conditions), and that twice as many occupants are likely to be infected at the lower ventilation rate. Although less ventilation increases the risk and more ventilation reduces it, any level of ventilation recommendation chosen to prevent infection is inherently a compromise, heavily dependent on the conditions of exposure and the level of risk society is willing to accept for a given cost. Cost considerations aside, there are theoretical and practical limitations to the efficacy of environmental controls for airborne infections in most congregate settings (Nardell et al.

FIGURE 11.1 Changing ventilation standards: history and philosophy.
[From Nardell (1998).]

1991). Despite these limitations, health is again being considered as a criterion for revised ventilation standards.

Insights into the role of ventilation in reducing the risk of airborne infection (and other airborne particle) have been gained through the use of mass balance equations. Although these probabilistic models depend on several assumptions that are unlikely to be strictly valid under the actual conditions of transmission, they have proved useful in estimating, for example, the effect on risk of changing ventilation when other parameters remain constant. Assuming steady-state conditions, uniform host susceptibility to infection, uniform virulence of pathogens, and complete air mixing, Eq. (11.1) has been applied to the transmission of tuberculosis and measles. The derivation and use of this and other models have been reviewed (Gammaitoni and Nucci 1997, Nicas and Seto 1997, Riley and Nardell 1989). In essence, the equation as used by Wells and Riley states that the probability of inhaling an infectious dose is proportional to the concentration of infectious droplet nuclei (a function of their generation rate and removal rate), and to the duration of exposure.

$$C = S(1 - e^{-Iqt/Q}) \quad (11.1)$$

where C = number of new cases

S = number of susceptibles exposed

e = natural logarithm

I = number of infectious sources

q = number of infectious doses generated per minute

p = human ventilation rate, L/min

t = exposure duration

Q = infection-free ventilation, L/min

Several infectious disease outbreaks have been investigated where many of the transmission factors listed above were known or estimable. Two tuberculosis exposures provide insights into the role of ventilation in air disinfection and are described in detail here.

An office worker was ill on returning home from a month-long holiday, but reported for work daily for a month before she was diagnosed with pulmonary tuberculosis. Tuberculin skin testing of 67 coworkers initially skin test negative revealed that 27 (40 percent) became infected as a result of this exposure (Nardell et al. 1991). Ultimately, one of those infected, who had declined treatment for latent infection, progressed to active TB, and was successfully treated. The building had long been the source of air quality complaints and had been investigated twice before and once after the TB exposure. On the basis of CO₂ measurements, it was estimated that outdoor air ventilation averaged approximately 15 cfm (ft³/m) per occupant. Knowing the duration of exposure, and the number of exposed occupants, it was possible to estimate q , the number of infectious doses generated per hour, as 13. For comparison, newly diagnosed tuberculosis patients on therapy on an experimental ward in Baltimore had produced an estimated 1.25 infectious doses per hour, but one highly infectious case produced 60. Assuming that 13 infectious doses were generated per hour in the office building, it was then possible to postulate levels of ventilation higher and lower than what actually existed in the building at the time of the exposure, and calculate the effect of those theoretical conditions on the infection rate during a month-long exposure. Had outdoor air ventilation been only half what was actually found (7.5 cfm/person), roughly twice as many susceptibles would have been infected (52 in 67, or 78 percent). Had outdoor air ventilation been twice the actual figure (30 cfm/person), roughly half as many susceptibles would have been infected (13 in 67, or 19 percent). These first-order kinetics are characteristic of many processes where the effect, in this case the removal of infectious organisms, is dependent on their concentration. One well-mixed air change removes 63 percent of existing air contaminants, leaving 37 percent behind. A second well-mixed air change removes

63 percent of the remaining 37 percent, leaving 14 percent (0.37×0.37) of the original concentration behind, and so on. As airborne concentrations of organisms fall, ventilation becomes increasingly inefficient in reducing their concentration further (Fig. 11.2).

Although outside air ventilation is essential for maintaining indoor air quality, controlling the concentration of odors and a variety of potentially noxious contaminants, it is difficult to control airborne infections where the dose required is low and exposure duration potentially long. The protection achievable is inversely related to source strength, which is discussed next.

11.7 SOURCE STRENGTH AND THE CONCENTRATION OF DROPLET NUCLEI

In another outbreak situation where the mass balance equation was used, 10 of 13 (80 percent) susceptible exposed workers were infected during a 150-min procedure in an intensive care unit (Catanzaro 1981). The source case produced 240 infectious doses per hour, but even that remarkable TB case generated only a fraction of the contagion of the index case of a measles epidemic in a school in upstate New York where more than 5000 infectious doses per hour were produced (Riley et al. 1978). The large numbers of infectious particles generated and lack of host resistance (in the absence of immunization) may explain why measles and chicken pox appear to be much more contagious than tuberculosis. Whereas large numbers of contacts are often infected after only brief exposure to these and other childhood respiratory viruses, infection with tuberculosis usually requires prolonged contact, such as living or working with the source case.

Equation (11.1) has also been used to calculate the approximate concentration of airborne doses of infection. Whereas the air on the intensive care unit (cited above) had approximately 1 infectious dose in just 70 ft^3 of air, the air exhausted from Riley's experimental TB

FIGURE 11.2 The effect of ventilation on the probability of infection. These curves are the result of modeling actual TB exposures, using the Wells-Riley mass-balance equation (see text for details). In the intensive care unit, baseline ventilation was poor, and modest increases would result in marked reductions in transmission. In the office building, baseline ventilation was much better, and major increases would still leave many occupants unprotected. [From Nardell (1998).]

ward had 1 dose in more than 11,000 ft³ (Riley et al. 1962). But even the latter comparatively low level of air contamination presents a health risk for occupants sharing that air for prolonged time periods, especially for infections such as tuberculosis, where the infectious dose is a little as one inhaled droplet nucleus. Riley calculated that the concentration estimated on his tuberculosis ward explained, approximately, the rate of infection of student nurses in the prechemotherapy era (Riley 1957). It took about a year, on average, to become infected.

11.8 AIR SAMPLING FOR TUBERCULOSIS

Measuring the concentration of infectious droplet nuclei in air would be extremely useful in the control of airborne infections. Unfortunately, with the exception of Riley's use of large numbers of guinea pigs as living air samplers for tuberculosis, quantitative air sampling for infectious organisms has proved fruitless. Unless the infectious organisms of interest are artificially aerosolized in large numbers, they compete unsuccessfully in culture against more numerous, faster growing environmental organisms. Micropore membrane air sampling and polymerase chain reaction (PCR) technology has been applied to the detection of tubercle bacilli in hospital isolation rooms (Mastorides et al. 1999). Air sampling for 6 h at a rate of 2 L/min (25-ft³ sample) successfully detected tubercle bacilli near the head of the beds of six of seven hospitalized patients with culture-proved pulmonary tuberculosis. However, PCR detects with exquisite sensitivity and specificity the DNA of both living and dead organisms. From artificial aerosolization experiments, it has been estimated that as few as 12 percent of organisms survive the stressful process of droplet formation and rapid dehydration (Loudon et al. 1969). In room air, moreover, organisms are subjected to numerous other stresses including temperature, humidity, natural radiation, oxidants, and toxic air pollutants (Cox 1987). Unless PCR detection can be refined to correlate quantitatively with culturable organisms, and ideally, with organisms infectious for a highly susceptible host such as humans or guinea pigs, the results of such sampling will be impossible to interpret, and potentially misleading.

11.9 AIR FILTRATION FOR CONTROL OF AIRBORNE INFECTION

Because an increased level of ventilation may exceed the capacity of existing HVAC systems, and is costly in terms of energy utilization, air filtration has been suggested as an alternative way to achieve the equivalent of extra air changes for the purpose of reducing airborne infectious particles. High-efficiency particulate air (HEPA) filters have been used in central ventilation ducts to interrupt the recirculation of droplet nuclei. More commonly, room units, often incorporating both HEPA filtration and UVGI, have been used as an alternative to additional ventilation in isolation rooms, waiting rooms, and other high-risk settings. Several studies have shown that such devices can effectively reduce the concentration of inert test particles from rooms (Miller-Leiden et al. 1996, Rutala et al. 1995). Because 1- to 3- μ m infectious droplet nuclei are far less penetrating than the 0.3- μ m particles HEPA filters are designed to trap, these and even somewhat less efficient filters should be highly effective for reducing airborne infectious particles. However, room filtration machines face challenges similar to room ventilation, but often at a disadvantage. As noted above, each doubling of effective, well-mixed ventilation reduces by approximately half the risk of infection. Depending on baseline conditions, it may or may not be possible to double or quadruple equivalent room ventilation through such a device, and risk reductions of half to a quarter may not be considered satisfactory protection.

Flow rates through HEPA filters are limited by airflow resistance, noise, and drafts in rooms. Like room ventilation, but more so for room filtration machines, it is possible for infection-free air to find its way from the machine air discharge back to the air intake without mixing well with room air, and therefore, not contributing much to air disinfection. This “short circuiting” is minimized by separating the air discharge and intake locations, and by directional airflow, but it is difficult to eliminate entirely, especially in freestanding filtration devices. As a general rule, the smaller the room and the closer to the source the location of the filter, the more efficient air filtration will be for infection control purposes. For example, HEPA filtration is ideal to filter exhaust air from small booths used for sputum induction and other cough-generating procedures.

The use of both HEPA filters and UVGI in the same room air disinfection unit is redundant. HEPA-filtered air is essentially sterile and need not be irradiated, and properly UV-disinfected air need not be HEPA-filtered. There has been some concern expressed about the safety of handling or changing HEPA filters that had been used for air disinfection purposes. This concern is not founded in theory or in experience. There have been no reports of transmission of tuberculosis or other airborne infections from filters or other fomites. To be inhaled deep into the lungs, viable infectious organisms must be associated with particles the size of droplet nuclei. Once on surfaces, such as HEPA filters, however, droplet nuclei become associated with dust, and if somehow resuspended, quickly settle out, and if inhaled, are unlikely to reach the vulnerable alveolar level. Studies of HEPA filters intentionally contaminated with mycobacteria indicate a high mortality rate within hours (Ko et al. 1998). Used HEPA filters should be handled with care, but special infection control procedures are not needed. Although UVGI is highly effective in killing airborne mycobacteria, killing on surfaces is much less efficient. Irradiating the surfaces of HEPA filters in room air disinfection devices is not necessary and is unlikely to be helpful.

11.10 ULTRAVIOLET GERMICIDAL IRRADIATION

UVGI was extensively studied by Wells (1955), Luckiesch (1946), and other investigators in the 1930s and 1940s, and widely deployed in health care facilities to control transmission of tuberculosis, measles and other viruses before the introduction of tuberculosis chemotherapy and vaccinations. UVGI never became fully established, however, falling between the disciplines of lighting and HVAC engineering. Detailed guidelines have only recently been published (First et al. 1999a, b), efficacy in field trials has never been convincing, and the design of lamps and fixtures did not progress until the late 1990s. On the other hand, there is no doubt that short-wavelength (254 nm) UV (UV-C) radiation is highly germicidal for most airborne pathogens. While UVGI can be deployed within ventilation ducts or room air disinfection devices, similar to HEPA filters, it suffers from some of the same limitations of air filtration and ventilation when applied in that manner. Air must still be moved through the device at a rate sufficient to double or quadruple the existing ventilation rate just to reduce risk by a half or three-quarters. Noise and drafts from high rates of air movement become objectionable to room occupants. Compared to HEPA filters, UVGI in ducts offers much less airflow resistance, and is useful in some applications. A unique advantage of UVGI over other means of air disinfection is its application in the upper room. Fixtures irradiate and disinfect the air in a large portion of air in the upper room, above the heads of occupants. Air slowly rises from the lower room into the irradiated zone, driven by body heat and other heat sources, body motion, drafts, and forced air from HVAC systems. Disinfected air from the upper room descends and dilutes infectious particles in the lower room. The process is silent, draftless, and energy efficient. Moreover, upper-room UVGI air disinfection is well suited to retrofitting older buildings with or with-

out HVAC systems. It is particularly useful in large spaces such as lobbies and waiting rooms, areas that are difficult to adequately treat with high rates of ventilation or filtration. Shelters for the homeless in this country and hospitals and prisons in developing countries are examples of areas where upper-room UVGI may be useful. The theory and application of upper-room UVGI are the subject of a recent two-part review (First et al. in press a, in press b). Included are examples of design layouts and cost comparisons with equivalent air disinfection using ventilation in the hospital setting.

However desirable in theory, to be accepted and effectively applied, upper-room UVGI must be supported by sound scientific data on efficacy and safety, and solid engineering guidelines. The following sections briefly review the current state of our understanding of upper-room UVGI, and outlines research that is either needed or under way.

Efficacy of Upper-Room UVGI: Historical Data

As already noted, UVGI was first tested against airborne mycobacteria by William Firth Wells at Harvard University in the late 1930s, soon after he described the droplet nuclei theory of airborne transmission (Wells 1955). In 1946, Luckiesch, working at the General Electric Laboratories at Nela Park, Ohio, published a monograph on the application of germicidal irradiation, detailing extensive experimental work on the interaction of room ventilation and upper-room UV air disinfection (Luckiesch 1946). As mentioned earlier, although Wells published a field trial demonstrating the efficacy of upper-room germicidal irradiation in halting measles transmission in suburban schools outside Philadelphia, attempts to replicate that success were stymied in sites where the schools selected were not the only important sites of transmission (Wells et al. 1942). In one study, transmission occurred on school buses, and in the other, in crowded urban tenements where children played together (MRC 1954, Perkins et al. 1947). Wells' work on germicidal UV was continued through the 1970s by Riley and colleagues working at Johns Hopkins University, and at just a few other research centers since that time (Riley and Permutt 1971; Riley et al. 1971a, 1971b). As important as efficacy studies in the community were, the germicidal effects of UVGI were better defined by experiments conducted under carefully controlled conditions. Using a bench-scale exposure chamber, Riley demonstrated the relative susceptibility of various microorganisms, including virulent and avirulent tubercle bacilli (Riley et al. 1976). For reasons that were unclear at the time, at humidities over 70 percent the germicidal effect for the test organisms *Shigella marcesans* and *Escherichia coli* was greatly reduced (Riley and Kaufman 1972). This is highly relevant to the application of UVGI in humid climates around the world. High humidity experiments have only recently been performed using mycobacteria (Ko et al. 2000). The results also show decreased killing at high humidity, but a smaller decrease than noted for nonmycobacteria. Although the mechanism of how humidity protects airborne organisms from germicidal UV is uncertain, the increased water content of larger particles may play a role. It is anticipated that decreased susceptibility at high humidity can be overcome by increased UV dose (intensity or duration of exposure).

Understanding that controlled exposure conditions (i.e., bench-scale experiments) were unlikely to predict air disinfection in rooms, Riley and Middlebrook performed room experiments in which test mycobacteria of known UV susceptibility were aerosolized into a sealed, unventilated 19-m² room, the air mixed well with a fan, and their disappearance rate measured by quantitative air sampling with and without upper-room UV (Riley et al. 1976). Air mixing in the room was primarily by convection currents generated by a single radiator and whatever air infiltrated windows and walls. In one set of experiments, a single 17-W UV fixture suspended 0.6 m from the ceiling resulted in disappearance rates for mycobacteria

equivalent to adding 10 ACH (air changes per hour) to the existing 2 ACH. This experiment of the late 1970s remains the basis for the current UV dosing guideline of approximately one 30-W suspended fixture, or two 30-W wall fixture, for each 19 m² of floor area. Dosing is also guided by the need to maintain safe UV levels for occupants in the lower room. The safety of germicidal UV is briefly discussed below.

New Research on UVGI

After decades of relative inactivity, new research is under way that will test the efficacy of upper-room UV to prevent TB in homeless shelters in six U.S. cities. Like Wells' UV field trial in schools over 50 years earlier (at the time of writing), this epidemiologic study actually tests two intertwined hypothesis at once: whether air disinfection (of any kind) in shelters can protect workers and homeless people, and whether upper-room UV is effective under the conditions of the study. If UV is proved effective, a secondary goal of this project is to develop engineering guidelines for wider, more effective UVGI application. Toward developing better engineering standards, new basic research is also under way at several universities. Several centers are applying computational fluid dynamics (CFD) to UV air disinfection in rooms. The goal of the CFD analysis is to predict air disinfection in the breathing zone resulting from the interaction of upper-room UV and airborne mycobacteria distributed in the irradiated zone by room air currents. This work has required that Riley's data on UV susceptibility of mycobacteria and other airborne test organisms be confirmed in a bench-scale exposure chamber, and extended to high-humidity conditions, as noted above. It is anticipated that CFD will greatly aid in fixture design, fixture placement in rooms, and the optimal interaction of upper UV systems and room ventilation. However, it will first be necessary to validate the CFD predictions, and plans are under way for full-scale room experiments where test mycobacteria will be aerosolized and their inactivation by UV determined by air sampling. Finally, it would be highly desirable to repeat Riley's experimental TB ward experiments in a high-prevalence country like South Africa, using guinea pig air sampling for human-source tubercle bacilli, with modifications which would permit the rapid assessment of a variety of air disinfection strategies for use under high-prevalence conditions.

The Safety of UVGI

UV energy inactivates microorganisms by damaging their nucleic acids and vital proteins. Germicidal technology benefits from several fortuitous properties of UV and of droplet nuclei: (1) the optimal UV wavelength for the damaging biological effects is close to 254 nm, a narrow UV band generated by inexpensive mercury arc lamps; (2) short-wavelength UV (UVGI, UV-C), although inherently more biologically active than longer UV wavelengths (UV-A and UV-B), is much less penetrating into matter; and (3) the minute size of airborne particles renders them highly vulnerable to UV-C despite its limited penetrating capacity. All UV-C in sunlight is absorbed in the atmosphere whereas UV-A and UV-B increasingly penetrate the earth's thinning ozone layer, and also penetrate human tissues to contribute to skin cancer and cataracts. Whereas as much as 50 percent of longer wavelength UV penetrates the outer, dead layer of skin, only 5 percent of UV-C reaches the top living layer of skin cells, and little or none reaches the lens within the eye (Bruls 1984). The National Institute for Occupational Safety and Health has set the 8-h exposure limit for UV-C at 60 mJ/cm² based on the avoidance of superficial, transient, corneal eye irritation (photokeratitis). Just 4 h of sunbathing between 10 A.M. and 2 P.M. delivers as much as 740 mJ/cm² to the skin surface (Sternborg 1988). By comparison to outdoor exposure to the more penetrating UV A and B of sunlight, the added

health hazard of less penetrating, low-intensity, indirect UV-C exposure reflected from the upper room is minimal. Most UV-C overexposure incidents entail accidental direct exposures to germicidal lamps in the upper room of workers where fixtures were not turned off, or where installations or fixture designs were unsafe. Many current UV fixtures use closely spaced, deep louvers to produce a narrow beam of UV in the upper room with minimal reflection into the lower room (Fig. 11.3). Before UV installations are commissioned for use, careful measurements in both the upper- and lower-room areas are required to be certain that the irradiation produced is both safe and effective.

11.11 NOVEL APPROACHES TO AIR DISINFECTION: DISPLACEMENT VENTILATION

All three methods of air disinfection discussed here depend on room air mixing to remove or inactivate infectious droplet nuclei throughout the room. However, a relatively new strategy, displacement ventilation, discussed elsewhere in this handbook, avoids mixing and works on an entirely different principle. Droplet nuclei are moved up out of the breathing zone by warm air introduced in the lower room. This has the theoretical advantage of reducing potential exposure time in the lower room. While this may be applicable for newly built specialized rooms, such as isolation and procedure rooms, it is probably not going to be applicable in the large variety of rooms and buildings associated with TB transmission, some of which have older mechanical systems, or lack them altogether. Like other modes of ventilation, filtration, and upper-room UVGI, there are no published field trials demonstrating the efficacy of displacement ventilation in controlling airborne infection.

FIGURE 11.3 Upper-room germicidal irradiation fixtures. Three styles of fixtures are shown: center wall, corner, and pendant. Various styles are needed to accommodate existing spaces.

12.1 INTRODUCTION

This chapter describes those controlled building functions that affect or are affected by the indoor environment. The emphasis is on heating, ventilating, and air-conditioning (HVAC) systems because they have a significant impact on indoor air quality. The discussion of HVAC systems is limited to what is commonly referred to as “air side” systems because the water and steam loops, refrigeration cycles, and cooling towers have little or no direct impact on indoor air quality. Other controlled building functions, such as lighting and fire suppression, are also described.

12.2 HVAC COMPONENTS

Air-handling systems in buildings contain a number of discrete components that each have an impact on the overall system performance. The components that affect the control of air-side functions of the HVAC process are described next.

Actuators

Actuators are used to modulate or position dampers and valves to control the flow of air and other fluids. Common types of actuators are electric motors and pneumatic pistons. The most commonly used electric motors are synchronous alternating current motors, which may be controlled as stepper motors, and direct current motors. It is common practice to use gear drives with large gear ratios so that large torques or forces may be applied with relatively small, inexpensive motors. Gear failure (e.g., a broken gear tooth) is a common failure mode of electric actuators.

Pneumatic actuators for HVAC systems are usually spring-loaded pistons with just one pressurized chamber. Air pressure in the cylinder pushes against the spring and any other forces acting on the piston such as friction or aerodynamic forces from a damper. The spring returns the piston to the “normal” position on a loss of pressure. In North American buildings, the pressure main that supplies air to the piston is usually pressurized to 20 lb/in². Solenoid valves, electric-to-pneumatic transducers, and pilot positioners are commonly used to throttle the air coming from the main.

Dampers

Using the assumptions that are commonly applied to flow through orifices and nozzles, the volume flow rate of air through a damper can be expressed as follows:

$$Q = fCA \sqrt{\Delta p / \rho} \quad (12.1)$$

where Q = volume flow rate

f = nondimensional flow characteristic

C = nondimensional flow coefficient

A = area of the damper

Δp = pressure drop across damper

ρ = density of the air

When the pressure drop and density are constant, the flow characteristic is, in theory, solely a function of the position of the damper. Under these conditions, the flow characteristic is referred to as the *inherent characteristic*. The inherent characteristic is dependent on features of the construction of the damper, including the construction of the seal between the damper blades and the housing, and the arrangement of the damper blades (i.e., parallel or opposed rotation).

For a damper installed in a duct, the pressure drop across the damper will vary with the damper position. This variation causes the installed characteristic to differ from the inherent characteristic. For a single duct or a branch in a larger system, the distortion of the inherent characteristic is modeled with a parameter called the “authority,” which is the ratio of the pressure loss across the damper to the pressure loss across the branch. Dampers with very low authority are difficult to control because a small change in position will cause a large change in the flow rate. Low authority may be caused by oversizing dampers. Dampers with high authority produce higher pressure losses and therefore waste energy.

Flow characteristics of dampers can be found in the *ASHRAE Applications Handbook* (ASHRAE 1995). However, the characteristics of some dampers may be significantly different from those shown in that handbook. Variations in the inherent characteristics are caused by the design of the seal and the geometry of the dampers near closure, among other things.

Fans

For fans (and pumps) the steady-state relations between speed, pressure, flow, and power are nonlinear. Idealized similarity relations between these variables can be found in any introductory text on fluid mechanics [e.g., White (1979)]. The relation between speed and power is cubic, which implies that modulating the capacity by modulating the speed is more efficient than doing so by throttling. The relation between pressure and power is quadratic, which implies that the gain of pressurization loops will generally be higher at high pressure than at low pressure.

Heat Exchangers

The heat-transfer rate through fluid-to-fluid (e.g., water-to-air) heat exchangers is usually controlled by modulating the flow rate of one or both of the fluids. In air-handling units, the heat-transfer rate is controlled by modulating the water flow rate.

The steady-state characteristic of heat exchangers is an important feature because it affects the performance of the controls that involve the heat exchanger. Engineers usually characterize heat exchangers with an effectiveness parameter denoted as ϵ . The effectiveness is usually described as a function of the heat-transfer capacity of the heat exchanger, which is denoted as the number of transfer units (NTU). The ϵ -NTU relation can be transformed into a relation that is more useful from a control perspective. It is the relation between the fraction of the full heat transfer and the fraction of the full flow of the controlling fluid (e.g., chilled water). This relation is the heat-transfer characteristic of the heat exchanger. Like the ϵ -NTU relation, the heat-transfer characteristic is nonlinear. Generally, the slope of the heat-transfer characteristic is higher at low flow rates than at high flow rates.

Sensors and Measurements

Temperature Sensors. Thermocouples sense temperature using the Seebeck effect. When dissimilar metals are placed in contact at two junctions so that a conducting loop is formed, then an electrical current flows through the loop if the junctions are at different temperatures. If the loop is opened, then an electrical potential will form. For the temperature differences encountered in building control systems, this potential is small, so high-gain amplifiers are needed when using thermocouples for building controls.

Resistance temperature device elements use the fact that the electrical resistance of metals such as nickel varies linearly with temperature over a wide temperature range. The percent variation in the resistance is small for the temperature ranges encountered in building controls, so amplification may be required.

Thermistors are temperature-sensing elements made from semiconducting material that exhibits a large change in resistance for a small change in temperature. The relation between temperature and resistance is nonlinear for thermistors, and for most thermistors the resistance will be lower when the temperature is higher.

Humidity Sensors. There are numerous methods used to measure humidity. One common method is to apply the fact that the capacitance of some materials is affected by the humidity. Another method involves cooling a reflective surface to the temperature at which condensation forms. Condensation is detected with an optical sensor. Humidity switches often are based on the fact that materials will expand and contract as the humidity rises and falls. Human hair is still used as a material in some humidity switches.

Flow Sensors. Flow rates for HVAC systems are often specified in volumetric units. However, heat-transfer rates and contaminant concentrations are affected by mass flow rates rather than volume flow rates. Conversion between the two requires that the density be known or measured.

The *volumetric flow rate* is the product of the area of the duct and the average velocity. The *mass flow rate* is the product of the volumetric flow rate and the density. Assuming that air is an ideal gas, the density can be expressed as

$$\rho = \frac{P}{RT} \quad (12.2)$$

where P = absolute pressure

R = gas constant

T = absolute temperature

Below an altitude of 10,769 m (35,332 ft) above sea level, the pressure of the standard atmosphere is given by the following equation (List 1971):

$$P = P_0 \left(1 - \frac{a}{T_0} Z \right)^{g/aR_a} \quad (12.3)$$

where P_0 = standard atmospheric pressure at sea level (101.3 kPa)

a = standard temperature lapse rate (0.0065°C/m)

T_0 = standard absolute temperature at sea level (288 K)

g = gravitational constant (9.80665 m/s²)

R_a = gas constant for dry air [287.055 J/(kg·K)]

The gas constant of moist air is a function of the humidity of the air as follows:

$$R = \frac{R_a + WR_w}{1 + W} \quad (12.4)$$

where R_w is the gas constant of water vapor and W is the humidity ratio, which is defined as the ratio of the mass of water vapor to the mass of dry air.

The most common methods of measuring flow rate both involve measuring the velocity at one or more points. The biggest problem with accurate flow measurement is that the velocity distribution may be irregular unless there is a long run of straight, unobstructed duct upstream and downstream of the measurement point. Near bends and obstructions, the velocity distribution may vary by more than 100 percent of the mean velocity, and the flow direction may change sign (Idelchik 1994).

The two most common methods of measuring velocity are described below.

Pitot Tube. The *pitot tube* is one of the most commonly used devices for measuring velocity in ducts. It consists of a tube with one end facing upstream and the other facing orthogonally to the flow direction. The end facing upstream is exposed to the total pressure. The other end is exposed to the static pressure. Traditionally, the tube is looped vertically, and a fluid is placed in the tube. The height difference is proportional to the velocity pressure. In digital control systems, the fluid is replaced with a differential pressure sensor.

Assuming that a Bernoulli equation can be used to model the flow, the relation between the velocity pressure and the velocity is as follows:

$$V = \sqrt{2\Delta p/\rho} \quad (12.5)$$

It is common to replace the static pressure tap with one that is facing downstream so that the pressure signal is larger. Doing so amplifies the pressure signal and changes Eq. (12.5) to

$$V = \sqrt{2\Delta p / \rho K} \quad (12.6)$$

where K is the amplification factor. It is usually assumed that K is constant, even though it is not. A typical value of K is 2.25.

Many pitot tubes average the velocity and static pressures at more than one point each by replacing the conventional pitot tube with a manifold having orifices facing upstream and downstream. This leads to a velocity error because of the nonlinear relation between pressure and velocity. The orifices are typically small, so they can be prone to clogging.

Heated Resistors. Hot wire anemometers use the fact that the heat transfer from a heated body placed in a moving fluid is affected by the fluid velocity. The relation between the heat transfer and the velocity is sometimes referred to as *King's law* (Ower and Pankhurst 1977), which is a relation between the heat-transfer rate from a spherical object and the temperature and velocity of the fluid. It is expressed as follows:

$$H = kT + \sqrt{2\pi k c_v \rho d} V^{1/2} T \quad (12.7)$$

where H = heat-transfer rate from sphere

k = thermal conductivity of the fluid (e.g., air)

c_v = specific heat of fluid at constant volume

ρ = density of fluid

d = diameter of sphere

V = velocity of fluid

T = temperature difference between the sphere and the surrounding fluid

In practice, an electrical resistor (e.g., a thermistor) is held at a constant temperature, and the electrical power required to hold it at that temperature is measured. Note that it is necessary to measure the ambient temperature of the fluid in order to use King's law.

Hot-wire anemometers are generally more accurate than pitot tubes at low velocities. Hot-wire anemometers generally cannot operate accurately over as large a temperature range as pitot tubes. Fouling can cause hot-wire anemometers to become less accurate with time.

Pressure Sensors. One of the most common kinds of pressure sensors used for control purposes is that which is based on the changing capacitance of a deflecting membrane. The pressure causes one of the plates of a parallel-plate capacitor to deflect, thus changing the capacitance. Capacitive sensors require temperature compensation.

Another technique for measuring pressure involves the use of piezoresistive films. The electrical resistance of a piezoresistive material will change as mechanical pressure is applied to it. Sensors of this type also require temperature compensation.

Occupancy. The most common kind of occupancy sensor is the motion detector. Typically, a pyroelectric sensor is placed behind a fresnel lens. Pyroelectric materials develop an electrical charge when heated. The lens focuses the infrared energy from nonoverlapping regions onto the sensor; as an object moves through the field of view, the intensity of the infrared energy on the sensor changes. The corresponding changes in electric charge are detected as motion.

Fire and Smoke. The two most common sensing methods for fire and smoke are photoelectric sensors and ionization sensors. Photoelectric sensors detect the presence of smoke by sensing the attenuation of intensity of a light source by smoke particles. Ionization sensors detect the presence of ionized particles that are emitted by a fire. In theory, ionization sensors are more sensitive to smoldering fires than photoelectric sensors.

Gas sensors may also be used to detect fires. Carbon monoxide sensors can be used to detect the presence of a fire by sending an alarm when the concentration exceeds a threshold.

Federspiel (1997) has proposed that the response of such an alarm can be improved with signal processing that eliminates the accumulation dynamics of the room or space containing the fire. Milke and McAvoy (1997) have shown that the use of multiple sensors and signature analysis can be used to improve the speed of detection and also enable a fire detection system to determine the kind of fire.

Control Issues for Sensors

Accuracy and Precision. *Accuracy* refers to persistent or constant errors such as a bias or very low frequency errors such as a drift. *Precision* refers to higher frequency errors. Obviously, sensors that are inaccurate degrade the performance of a control system. Sometimes digital control systems can compensate for inaccurate sensors with self-calibration routines, but inaccurate sensing generally leads to inaccurate control. Imprecise sensors also cause control problems. Fluctuating measurements can cause too much control activity which may lead to excessive wear and premature failure of actuators, dampers, and valves. Control systems can be designed so that they are less sensitive to imprecise sensors, but this type of robustness generally comes at a cost of reduced-control performance.

Dynamic Response. The phase lag associated with sensing elements (e.g., the time required to respond to a step change) will slow the open-loop response of the system. However, adding lag to a sensing element will usually make an oscillatory control loop more oscillatory, not less. For some noisy process control loops such as pressure control loops and flow control loops, it may be necessary to filter the output of the sensor (i.e., add lag) in order to reduce actuator motion. With digital control systems, this can be done easily with software. If filtering is added, the controller should be retuned to account for the additional phase lag.

Location. Sensor location is an important feature of every building control system.

Space temperature sensors should be located away from heat sources yet as close to occupants as possible. They should also be located away from the plume from equipment and the throw of diffusers.

Outdoor air temperature sensors should be shielded from solar radiation. They will be more accurate if air is continually moving over the sensing element. If the sensor is installed inside the outdoor air intake, it will not accurately measure the outdoor air temperature when the outdoor air dampers are closed.

Averaging temperature sensors used to measure mixed-air temperature should extend close to the bottom of the duct so that when the outdoor air is cold, the sensor accurately measures the temperature of the stratified air.

For good accuracy, there should be several straight duct diameters upstream and downstream of air velocity sensing elements such as pitot tubes and hot-wire anemometers. This fact makes accurate, direct measurement of outdoor airflow rates difficult because it is common to have no outdoor air duct whatsoever.

Motion detectors will be less likely to become obstructed when installed near the ceiling.

12.3 HVAC CONTROL FUNCTIONS

Terminology

control error The setpoint minus the controlled variable.

DDC Direct digital control.

derivative control Control effort or action which is equal to the time rate of change of the control error.

feedback Process output information used to determine process inputs in real time.

integral control Control effort or action which is equal to the continuous sum of all previous control errors.

PID Proportional plus integral plus derivative control.

proportional control Control effort or action which is a linear function of the deviation of the controlled variable from the setpoint.

setpoint The desired or reference level of a controlled variable such as temperature.

Temperature Control

Temperature control is one of the basic functions of an HVAC system. The temperature in spaces supplied by centralized air-handling units is usually controlled with pneumatic controls, although digital controls are becoming more common in new construction. Most pneumatic controls are *proportional-only devices*, which means that as the load increases, the deviation from the setpoint increases. Better control performance can be achieved if integral control action is added. This usually requires the use of DDC technology, which is more expensive. Federspiel (1998) developed a mathematical model that relates the temperature control performance to the complaint rate, and hence the operational cost. This model can be used to evaluate the cost-benefit analysis of technology that can deliver improved control performance.

In large buildings, two kinds of air-handling systems serve multiple zones: constant air volume (CAV) and variable-air volume (VAV). Some systems are hybrids. *Constant-air-volume* systems heat or cool the supply air to approximately 55°F and then reheat the supply air to each zone or heat and cool a fraction of the supply air and vary the mixture temperature to control the space temperature. These systems are inefficient, and have been outlawed by some energy codes. *Variable-air-volume* systems heat or cool the supply air to approximately 55°F but supply it at a different flow rate to each space. In spaces that require heating, such as perimeter spaces, reheat is used even with VAV systems. The supply air temperature is typically controlled to 55°F.

In smaller buildings, packaged rooftop air-handling systems are used to control the temperature. These units most commonly control the temperature in just one location. Rather than modulating controls, the units typically have staged heating and cooling. A common configuration is two stages of cooling and two stages of heating. The cooling stages will often be direct-expansion refrigeration cycles, which means that the cooling fluid is a refrigerant rather than chilled water. It is common for each cooling stage to be a completely separate refrigeration cycle with its own compressor. The supply temperature is rarely controlled in single-zone units. The stages are engaged by switches in a thermostat located in the occupied space. The thermostat control logic may be as simple as engaging a stage as the temperature crosses a level associated with that stage, similar to an ON/OFF thermostat in a residence. Digital controls may contain more complicated logic and calculations designed to keep the temperature closer to the setpoint or cycle the equipment less frequently.

Most built-up, centralized air-handling systems and many packaged systems have an *economizer*, which enables the air-handling system to provide cooling by bringing cool outside air into the building. When the outdoor temperature is below 55°F, the dampers modulate to control the mixed air temperature to 55°F. Usually the three sets of dampers are interlocked, either mechanically or by control logic. It is shown in a later section that interlocking the dampers may cause problems under some conditions. When the outdoor air

becomes sufficiently hot, the outdoor air dampers are returned to a minimum position or the outdoor airflow rate is controlled to a minimum flow rate. There are several different criteria that are used to switch to minimum ventilation. The most common criterion is based on the dry-bulb outdoor air temperature. A typical switch point is 68°F.

Humidity Control

Humidification is usually provided with steam sprays or water atomizers. Dehumidification may be achieved with desiccants which are recharged by heating, or by passing air first through a cooling coil and then reheating it. Humidity controls are commonly found in applications such as archives and food storage where the contents in the space may be adversely affected by high or low humidity. It is less common to find humidity control in office buildings even though outdoor weather conditions in cold climates can result in indoor humidity that is below the limits prescribed by ASHRAE.

Pressure Control

Pressure controls are used to control the static pressure in the ducts of VAV systems so that fan power will be conserved when the demand for air is low. When there is a single main, the pressure sensing location is typically two-thirds of the way to the end of the main. When there are multiple mains, sensors may be placed in each main. The highest pressure is controlled to a setpoint.

Setpoint resetting may be used to reduce the fan power of VAV systems. The objective of setpoint resetting is to continually or periodically adjust the pressure setpoint so that the air dampers are maintained as wide open as possible. Lorenzetti and Norford (1994) have shown that setpoint resetting reduces fan energy by 19 to 42 percent.

Space pressure is often controlled in laboratories, containment spaces in hospitals, and cleanrooms. In laboratories and containment spaces in hospitals, the objective is generally to have the space pressure lower than that of the surrounding or adjoining spaces so that harmful chemical and biological contaminants do not enter those spaces. The pressure in cleanrooms is generally controlled to a level higher than that in the surrounding or adjoining spaces so that particulates and other contaminants do not enter the cleanroom.

There are two methods of controlling space pressure:

1. *Directly:* With this method, the difference between the space pressure and the pressure in an adjoining space is measured with a differential pressure sensor. The differential pressure is maintained at a constant level by a feedback controller. One problem with this method is that the pressure sensor must possess very good resolution because the typical differential pressures for space pressurization are very small (e.g., 0.05 in. in water column). Another problem is that the opening and closing of doors causes such large changes in the resistance between the two spaces that the controls often saturate, especially if the doors are left open.
2. *Controlling the flow supplied to the space and the flow exhausted from the space in such a way that there is a difference between the two:* If the space is to be negatively pressurized, then the supply should be less than the exhaust, and the converse if positively pressurized. One problem with this method is that it requires accurate measurement of the supply and exhaust flow rates because the desired difference may be a small fraction of either the supply or exhaust flow rate.

Flow Control

Flow control loops are found in VAV air-handling systems that are “pressure independent.” In this application, the flow control loop is embedded in the temperature control loop in a cascaded configuration. This means that the temperature controller determines the setpoint for the flow controller. This feature decouples the temperature controls. Without the flow loops, changes in a damper setting in one zone would change the flow rates to other zones.

Noisy measurements from turbulence and other sources, nonlinear characteristics of dampers, and changing control performance requirements complicate the control of airflow in VAV systems. Wolochuk et al. (1995) documented that the turbulence intensity of airflow just downstream of a bend in a duct could be as high as 47 percent, and that it could be 6.7 to 10.2 percent in a straight duct. The gain of dampers can change by an order of magnitude from one operating point to another. When the VAV terminal unit is controlling the space temperature, the flow controller should reject the process noise in order to maximize the life of the actuator. A fast response is less critical in this mode because the response of the space temperature to a change in the flow rate is slow. However, when manually operated during commissioning or troubleshooting, the flow control loop should respond quickly so that the operator’s time is not wasted. Sensitivity to noise is less critical because the fraction of time spent in this mode is small. Federspiel (1997) has developed a control strategy that meets these control objectives by modulating the magnitude of a deadzone in response to an adaptive estimate of the magnitude of the measurement noise, the magnitude of setpoint changes, and the mode of operation.

Ventilation Control

Ventilation is not actively controlled in most buildings. Instead, it is provided through the operation of the temperature controls. Minimum damper settings are used to ensure that minimum ventilation levels specified by codes and standards are provided.

Measuring Outdoor Airflow Rate. The outdoor airflow rate is one of the most important parameters of a ventilation system. It is also one of the most difficult parameters to measure accurately.

One of the primary problems of measuring outdoor airflow rate in mechanically ventilated buildings is that there is no outdoor air duct in which to place a velocity measuring device. In air-handling systems mounted on roofs, the outdoor air dampers are mounted on the sheet-metal housing, and outdoor air is drawn directly into the mixed-air chamber. When an outdoor air duct exists, it usually contains a contraction, obstructions, and bends that significantly disturb the air velocity distribution in the duct. Wolochuk et al. (1995) documented that the standard deviation of the air velocity distribution just downstream of a bend in a duct was 30 percent of the mean velocity, with the peak-to-peak variation approximately equal to the mean velocity. The standard deviation in a straight duct was 4.7 percent of the mean.

Drees et al. (1992) describe a method of measuring outdoor airflow rate that uses a supply airflow measurement, a carbon dioxide sensor, and a multiplexer to determine the outdoor airflow rate indirectly. The carbon dioxide concentration of the outdoor air, the return air, and the supply air are measured to determine the fraction of the outdoor air in the supply air. The product of the outdoor air fraction and the supply airflow rate is the outdoor airflow rate. The multiplexer is used to eliminate calibration errors of the carbon dioxide sensor. This technique does not require the presence of an outdoor air duct.

Reverse Airflow. Architects and HVAC engineers usually assume outdoor air does not enter buildings through the exhaust-air outlet. Consequently, buildings can have exhaust-air outlets located near pollution sources. Janu et al. (1995), Elovitz (1995), and Seem et al. (1998) have observed air entering air-handling units (AHUs) through the exhaust-air outlets. Air entering an AHU through the exhaust-air outlet will negatively impact IAQ when the exhaust-air outlet is located near a pollution source. Furthermore, outdoor air entering through exhaust openings will bypass any prefilters or preheat coils which may be placed in the outdoor air duct.

Traditional AHU control systems link the positions of the exhaust-air damper, recirculation-air damper, and outdoor-air damper. The exhaust- and outdoor-air dampers are normally closed, and the recirculation-air damper is normally open. The dampers are sequenced such that as the exhaust- and outdoor-air dampers begin to open, the recirculation-air damper begins to close. Either mechanical linkage or the control system is used to maintain the following position relationship between the three dampers:

$$\theta_{\text{out}} = \theta_{\text{ex}} \quad (12.8)$$

$$\theta_{\text{re}} = 1 - \theta_{\text{ex}} \quad (12.9)$$

where θ_{out} is the fraction of fully open position of the outdoor-air damper, θ_{ex} is the fraction of fully open position of the exhaust-air damper, and θ_{re} is the fraction of fully open position of the recirculation-air damper.

Seem et al. (1998) describe a new AHU control system for a VAV system that uses volume matching to control the return fan. With volume matching control, the supply-airflow rate is greater than the return-airflow rate by a constant amount. The New control system links the position of only the exhaust-air damper and the recirculation-air damper using the relationship in Eq. (12.9). During occupied times, the outdoor-air damper remains 100 percent open: $\theta_{\text{out}} = 1$. If the minimum ventilation airflow requirement is the same as the volume matching differential, the exhaust-air damper should be fully closed ($\theta_{\text{ex}} = 0$) and the recirculation-air damper should be fully open ($\theta_{\text{re}} = 1$) when minimum ventilation is desired.

Simulations were performed to compare the traditional and new control systems for an AHU with the following characteristics: supply airflow rate is 5 m³/s, return-airflow rate is 4 m³/s, area of outdoor air damper is 2.5 m², and areas of exhaust- and return-air dampers are 2 m². The system of equations is based on the principles of conservation of mass and energy (Seem and House 1996).

Figure 12.1 shows the flow rate of air through the exhaust-air outlet as a function of the exhaust-air damper position for both the traditional and new control systems. Negative values of the exhaust-airflow rate indicate that air is entering the AHU through the exhaust-air outlet. For the traditional control system, outdoor air enters the AHU through the exhaust-air outlet when it is less than 30 percent open. Also, the problem occurs more often at low-load conditions. For the new control system, outside air does not enter the AHU through the exhaust-air outlet.

Other simulations showed reverse airflow with the new control system for an AHU with oversized dampers and a supply airflow rate 3 times greater than the return-airflow rate. These are the extreme conditions alluded to previously. For this system, the reverse-airflow problem can be prevented by increasing the flow resistance through the recirculation air damper. The flow resistance of a damper can be increased by disabling and closing a damper blade, or by limiting the maximum open position of the damper.

Field tests were performed for both the traditional and new control systems for an AHU at the Iowa Energy Center Energy Resource Station located near Des Moines, Iowa. The AHU has opposed blade dampers, each with a separate actuator. During the field tests, the supply airflow rate varied from approximately 1.32 to 1.56 m³/s. The return fan was con-

FIGURE 12.1 Simulation exhaust-airflow rates for the traditional and new control systems.

trolled to maintain the flow difference between the supply and return air ducts at $0.28 \text{ m}^3/\text{s}$. The measured flow difference varied from approximately 0.21 to $0.35 \text{ m}^3/\text{s}$.

Figure 12.2 shows the exhaust-airflow rates for the traditional and new control systems as a function of the control signal to the exhaust damper. Note that the curves in Figure 12.2 are similar to the curves in Figure 12.1 for the simulation results. From Figure 12.2 it appears that the traditional control system allows reverse airflow and that the new control system prevents reverse airflow. A custom-built flow direction indicator confirmed that when the exhaust-air damper is less than 30 percent open, air is drawn into the AHU with the traditional control system. Also, no reverse airflow was observed with the new control system.

Demand-Controlled Ventilation. Demand-controlled ventilation (DCV) is an energy-efficiency technology. The amount of ventilation air provided to a building is dynamically adjusted so that it is no more but no less than the requirements specified in codes or standards such as ASHRAE Standard 62 (ASHRAE 1989). The effect of demand-controlled ventilation is to reduce the amount of ventilation air that must be conditioned to cool a building, and therefore to reduce the energy cost of air conditioning.

Energy cost-savings benefits of demand-controlled ventilation have been documented in a number of studies. Emmerich and Persily (1997) reviewed the literature on carbon dioxide-based demand-controlled ventilation. The mean and median energy cost reductions attributed to demand-controlled ventilation in field tests were 28 and 16 percent, respectively. The amount of cost savings varied and was dependent on the system type and weather conditions.

A number of indicators of demand are used in DCV strategies. When large sources of harmful contaminants are present, contaminant concentration is used. Since sources of harmful contaminants are seldom large in commercial buildings, ASHRAE Standard 62 (ASHRAE 1989) contains prescriptive ventilation requirements that are based on the number of occupants in a building. Given two buildings of the same size, the one with more occupants must be provided more ventilation air. Since the number of occupants varies in most buildings, there is an opportunity to reduce the ventilation rate during some parts of the day relative to that time when the building contains the maximum number of occupants.

Since occupants persistently produce carbon dioxide, carbon dioxide is used as an indicator of occupancy. It is also used as a surrogate for odor-producing bioeffluents. As an

FIGURE 12.2 Field results for the exhaust-airflow rates for the traditional and new control systems.

indicator of occupancy, carbon dioxide concentration is a lagging indicator. The building volume functions as an accumulator and induces a time lag that is proportional to the volume of the building and inversely proportional to the outdoor airflow rate.

Demand-controlled ventilation is often implemented so that the ventilation rate is increased proportionally to the carbon dioxide concentration. This method is referred to as *proportional demand-controlled ventilation*. As the concentration increases, so does the amount of outdoor air provided to the building, and as the concentration decreases, so does the outdoor airflow rate. Proportional demand-controlled ventilation is often configured so that no ventilation is provided until the carbon dioxide concentration exceeds a level that is significantly greater than the outdoor concentration. This level is sometimes called the *setpoint*.

A problem with proportional demand-controlled ventilation is that the time lag associated with the carbon dioxide accumulation process causes the ventilation rate to be too low when the number of occupants is rising and too high when the number is falling. Depending on the setpoint and the maximum number of occupants, it is possible that proportional demand-controlled ventilation will not ventilate at all. When proportional demand-controlled ventilation underventilates, it is possible for the accumulation of contaminants not related to human occupancy such as volatile organic compounds (VOCs) from carpets or wall coverings to accumulate to significant levels. Therefore, it is likely that proportional demand-controlled ventilation will produce poor indoor air quality during some period of each day. For example, in an office building occupied between 7 A.M. and 5 P.M., proportional demand-controlled ventilation may lead to poor indoor air quality in the morning.

These problems with time lag and the potential for poor indoor air quality have been identified by Federspiel (1995, 1996), and a mitigating technology called *on-demand ventilation control* (ODVC) has been proposed which retains the energy-conserving benefit. The principle of ODVC is to measure concentrations and flow rate, and use this information along with a mathematical model of the carbon dioxide accumulation dynamics to estimate the current intensity of the carbon dioxide source. Ventilation is then provided proportional to the estimated source intensity. Since the source intensity is a nonlagging indicator of occupancy, the problems with lag are eliminated.

There has been some investigation into the effect that demand-controlled ventilation has on indoor air quality. Woods et al. (1982) showed that with CO₂-based DCV, occupants did not perceive any change in the air quality relative to the base control strategy, but that they

did perceive the space to be warmer even though the temperature was the same for both control strategies. In a field experiment, Zamboni et al. (1991) found that odor intensity ratings of occupants were greater with DCV than without it. In a simulation study, Emmerich et al. (1994) showed that the concentration of contaminants not generated by occupants could exceed short-term and long-term limits with DCV depending on how the strategy was implemented. Carpenter (1996) conducted computer simulations which showed that the average formaldehyde concentration would be higher with a carbon dioxide-controlled ventilation system, and that the higher average concentration was due to the time lag and setpoint of the proportional demand-controlled ventilation system. Although the source emission model for this contaminant was not accurate, the study still indicates that proportional DCV may lead to elevated levels of other kinds of contaminants not produced by humans. There has been no work on the effect that DCV has on worker productivity.

12.4 INDIVIDUAL CONTROL

In some commercial buildings, occupants are able to control some aspects of their environment. One form of individual control is adjustment of a temperature setpoint. In small commercial buildings that do not have an on-site maintenance staff, and in areas of larger commercial buildings where occupants have individual offices, it is common for the occupants to have control of the temperature setpoint. A problem that often arises when occupants can control setpoints in buildings heated and cooled with centralized HVAC equipment is that the occupants are neither educated about how central HVAC systems operate, nor are they provided with information about the current state of operation. This leads to a mismatch between the occupants' expectations and the systems' capabilities. For example, during winter, the mechanical cooling system may be disabled. On an unusually warm spring day before the mechanical cooling is enabled, occupants may become too warm. If they do not know that the mechanical cooling is disabled (which is normally the case), they will often keep lowering the space temperature setpoint until it is at its lowest setting (e.g., 55°F). When the mechanical cooling is enabled later, they may arrive at work and find that it is 55°F in the office. This problem could be avoided if the occupants were educated and provided with information about the current state of operation of the system.

Depending on the geographic location and work environment, other individual controls that are in common practice include task lighting and operable windows. Occupants will often use desk fans for individualized thermal control.

In an effort to increase occupant satisfaction with the indoor environment, reduce operating costs, and improve worker productivity, systems designed to provide individual control of thermal conditions and lighting at workstations in open-plan office buildings have been proposed. These systems are sometimes referred to as *task/ambient conditioning systems*. Depending on the design, they may allow individual users to control the direction, speed, and sometimes the temperature of air supplied to the work area. They also may contain individual control of radiant heating, lighting, and other functions that allow the user to customize their local environment, and occupancy sensing so that the system can revert to an energy-conserving mode when the work area is not occupied.

A number of benefits of task/ambient control systems have been studied. Bauman et al. (1998) showed that a system which delivers air to the desktop yielded significantly higher occupant satisfaction ratings. They also showed that occupants who used the task/ambient control systems were less sensitive to variations in the ambient temperature than those who did not.

Fisk et al. (1991) and Faulkner et al. (1993a, 1993b) showed that the local ventilation effectiveness of task/ambient systems that deliver air to the desktop or to the floor near an

occupant could be 15 to 30 percent higher than a conventional system with ceiling supply and return under some conditions. Typically, the air must be directed at the individual to effect this improvement.

Seem and Braun (1992) used computer simulations to show that the energy use of a building with individual control systems that deliver cooled air to the desktop may range from 7 percent less than a conventional VAV system to 15 percent more than a conventional VAV system. The largest savings came from situations in which the occupants were frequently away from their desks because the system contained an occupancy sensor that shut off task lights and fans when occupants were away. Extra energy usage was attributed to the use of radiant panels and the need for fans in the units. Borgers and Bauman (1994) also used computer simulations to study the energy use of task/ambient conditioning systems. One system delivered air through the floor near the occupants, and one delivered air to the desktop. The desktop system was the same as the system studied by Seem and Braun (1992). It was found that the energy usage of the floor delivery system was 2.5 percent less than that of a conventional VAV system, and it was found that the energy usage of the desktop system was 5.7 percent lower than a conventional VAV system. These simulations did not include radiant heating.

Kroner et al. (1992) showed that disabling some features of the individual control systems in an office building reduced the productivity of the workers by 2.8 percent.

12.5 LIGHTING CONTROLS

One of the most common types of automated controls for lighting are programmable timers. These controls allow the facility manager to program the lights to turn on and off on schedule, and also allow for occupants to override the normal schedule, usually through a telephone-based interface, so that lights can be operated during off hours.

Another common kind of automated lighting control is an occupancy sensor. These are usually pyroelectric motion sensors. Often these sensors are integrated into a light switch. The use of motion sensors for lighting control has three problems. The first is that line of sight is necessary. If the sensor is obstructed (e.g., by a filing cabinet) or if the occupant is working behind an obstruction such as an office partition, the sensor cannot “see” the occupant, so it will shut the lights off. Another problem is that the sensors detect motion only. Lack of motion is determined by a timer. The final problem with the use of motion detectors for lighting control is that spaces can be occupied by occupants who are not moving, or are not moving sufficiently to trigger detection. This fact can cause motion detectors to shut lights off when occupants are present even if there is no obstruction.

Federspiel (1997) has shown that carbon dioxide sensors, combined with signal processing which cancels the accumulation dynamics of a space, can be used to detect the presence of occupants. This technology is not fast enough to turn lights on (the fastest detection time is about 20 s), but it is highly effective at turning lights off without doing so when the space is still occupied because it can detect obstructed or nonmoving occupants.

Another less common kind of automated lighting control involves the use of a light intensity sensor, a dimmable ballast, and a feedback controller. The ballast is modulated by the controller to keep the lumen level indicated by the sensor at a nearly constant level. These systems are sometimes referred to as *demand-controlled lighting systems*. They can reduce the energy required for lighting by using daylight as a lighting source. As with many building control systems, the location of the sensor strongly affects the performance of the system.

Eley et al. (1992) provide a thorough discussion of lighting control technology.

12.6 SMOKE AND FIRE CONTROL

Fires typically go through three phases: the incipient phase, the steady-state phase, and the hot smoldering phase. The *incipient phase* is the earliest phase where the fire is limited to the original combustion site. The sensing techniques described in Sec. 12.2 (under “Fire and Smoke”) are able to detect the fire at this point. The incipient phase ends when the unburned combustible gases accumulated at the ceiling begin to ignite (commonly called *rollover*). At this point the fire is still localized and can be extinguished safely by firefighters or a sprinkler system. By the middle of the incipient phase the room is filling with thick dark smoke, thus greatly limiting visibility and causing respiratory hazards due to oxygen deficiency, elevated temperatures, particulates, and toxic compounds. As a result, most fire-related deaths are caused by smoke inhalation. If unabated, the fire will progress to the *steady-state phase*. In this phase the initial fire area will flash over (i.e., flames will cover the entire room) and the fire will rapidly spread to other areas. If the area of confinement is sufficiently airtight, the fire intensity will eventually decrease as the available oxygen decreases. This is called the *hot smoldering phase*.

It is critical that the smoke and fire control systems be able to detect fires in the incipient phase so that the structure can be safely evacuated and fire suppression efforts started. Many buildings utilize pressurization strategies in an effort to control smoke intensity and migration to enable people to more easily exit the building. Because elevators are normally placed out of service during a fire, the stairwells in multistory buildings are often pressurized to keep smoke from entering them. The pressure in the stairwells must be maintained within certain limits. If the pressure is too low, smoke enters the stairwell; if it is too high, it becomes very difficult to open the doors into the stairwell. In some buildings pressurization schemes are also employed to keep the smoke contained in one area and prevent its migration to other areas. This is accomplished by closing off the supply air and maximizing the exhaust air at the original combustion site and maximizing the supply-airflow rates in the zones surrounding the combustion site.

In structural fires, the primary method of extinguishment is temperature reduction by water cooling. Water can be supplied by firefighters or sprinkler systems. Sprinkler systems are an effective means to improve life safety because they activate quickly before a fire grows large. They also minimize property damage because they place the water only on and around the fire. In most systems, the sprinkler heads contain a temperature-sensitive material (fusible link, liquid-filled glass bulb, chemical pellet), which causes the head to open once a predetermined temperature [ordinarily 135 to 170°F (57–77°C)] is reached. These temperatures are attained while the fire is still in its incipient phase. Data compiled by Factory Mutual Research Corporation indicate that about 70 percent of all fires are controlled by the activation of five or fewer sprinklers.

There are several types of sprinkler systems, but two are most commonly used: wet-pipe and dry-pipe systems. In *wet-pipe systems* the distribution piping located through the structure is filled with pressurized water. Thus, when a sprinkler head opens, water immediately flows into the fire. Wet-pipe systems cannot be used in areas subject to freezing such as a parking garage. In *dry-pipe systems*, which can be used in areas subject to freezing, compressed air replaces the water in the distribution piping. If a sprinkler head opens, the air pressure in the distribution piping drops. This allows a clapper valve to open, which, in turn, fills the pipe with pressurized water. At this point the dry- and wet-pipe systems work in an identical manner to suppress or extinguish the fire.

CHAPTER 13

VENTILATION STRATEGIES

Martin Liddament, B.A., Ph.D., MASHRAE

Oscar Faber Group Ltd., Albans, Hertfordshire, United Kingdom

13.1 SUMMARY AND INTRODUCTION

A wide range of systems and techniques are available to meet the needs of ventilation, each with its own set of advantages, disadvantages, and applications. Sometimes choice is dictated by local climate conditions or building type. Frequently, price competitiveness and an unwillingness to deviate from the minimum specifications of relevant building regulations or codes of practice can further restrict choice and also limit the opportunity for innovation. To justify a complex strategy, it is usually necessary to demonstrate advantages in terms of improved indoor climate, reduced energy demand, and acceptable “payback” periods. Choice ultimately rests with such factors as indoor air quality (IAQ) requirements, heating and cooling loads, outdoor climate, cost, and design preference. Above all, the selected system must satisfy the needs of design criteria.

The purpose of this chapter is to overview ventilation strategies in relation to these needs. Techniques are reviewed in terms of natural and mechanical ventilation systems, methods to achieve displacement airflow, and approaches to demand-controlled ventilation.

13.2 NATURAL VENTILATION

Background and Applications

Many buildings throughout the world are naturally ventilated. In the past, this has sometimes meant little more than satisfying needs by relying on an arbitrary combination of uncontrolled air infiltration and window opening. Nowadays, ventilation requirements can

be very demanding, as modern systems must provide greatly improved reliability and control. By careful design, it is possible for natural ventilation to provide a satisfactory environment in even quite complex buildings.

Natural ventilation is most suited to buildings located in mild to moderate climates, away from inner-city locations. Essentially, natural ventilation operates in mixing and pollutant dilution mode; there is insufficient flow control to achieve displacement or “piston” flow, although noncritical flow patterns between clean and contaminated zones are possible. Subject to climatic and outside noise constraints, typical applications include

- Low rise dwellings
- Small to medium-size offices
- Schools
- Recreational buildings
- Public buildings
- Warehouses
- Light industrial premises

Specialized natural ventilation systems may be applicable to a wider range of climatic conditions and buildings, including large commercial buildings; much depends on individual circumstances and requirements. A bibliography on natural ventilation and its applications has been produced by Limb (1994a).

Natural Ventilation Mechanisms

For a given configuration of openings, the rate of natural ventilation varies according to the prevailing driving forces of wind and indoor/outdoor temperature difference. Despite this variability, it is possible for satisfactory design solutions to be developed, provided that flexibility in indoor air temperature, airflow rate, and instantaneous ventilation rate can be accommodated.

Driving Forces

Natural ventilation is driven by wind and thermally (stack) generated pressures. Designing for natural ventilation is concerned with harnessing these forces by the careful sizing and positioning of openings.

Wind Pressure. Wind striking a rectangular shaped building induces a positive pressure on the windward face and negative pressures on opposing faces and in the wake region of the side faces. This causes air to enter openings and pass through the building from the high-pressure windward areas to the low-pressure downwind areas (see Fig. 13.1a). Normally very simplistic assumptions must be made about the wind pressure distribution. If more detail is required, such as the pressure distribution acting on complex structures, it may be necessary to resort to wind tunnel methods.

Stack Pressure. A *stack effect* is developed as a result of differences in air temperature, and hence air density, between the inside and outside of the building. This produces an imbalance in the pressure gradients of the internal and external air masses which results in a vertical pressure difference. When the inside air temperature is greater than the outside air temperature, air enters through openings in the lower part of the building and escapes

through openings at a higher level (see Fig. 13.1*b*). The flow direction is reversed when the inside air temperature is lower than the outside air temperature. Calculation of stack pressure is based on the temperature difference between the two air masses and the vertical spacing between openings.

Complementary and Combined Use of Wind and Stack Pressures. Systems need to be designed to ensure that the effects of wind and stack action complement rather than oppose each other. This is accomplished by understanding and exploiting the pressure distribution developed by each mechanism and locating openings to best advantage. Passive stack and atria designs seek to accomplish this objective. Alternatively, the driving forces may be modified by careful inlet design or by providing a shelter belt to reduce wind effect. The typical interaction of wind and stack pressure is illustrated in Fig. 13.2. Ventilation rate at low wind speeds is dominated by the stack effect. As the wind speed increases, wind dominated ventilation takes over. At certain wind speeds, wind pressure may act in complete opposition to stack forces at specific openings, resulting in a small drop in the total ventilation rate.

FIGURE 13.1 Natural driving mechanisms; (a) wind-driven flow; (b) stack-driven flow.

Impact of Wind and Temperature Difference on Natural Ventilation

Influence of Wind and Temperature (Stack Effect) on Ventilation Rate and Air Flow Pattern

FIGURE 13.2 Combined effect of wind and temperature difference on ventilation rate and airflow pattern. While the rate of ventilation can be held almost constant for a range of weather conditions, the pattern of airflow changes. In (a) ventilation is dominated by temperature (temperature-dominant regime). Air enters through the lower openings (1 and 4) and leaves through the upper openings (2 and 3). As the wind increases (b), wind pressure reinforces stack pressure at the windward lower openings (1) leeward upper openings (3), while opposing the stack pressure at the other openings (2 and 4). Although the pattern and magnitude of flow essentially remains unaltered, the flow rate through each opening changes. At (c) the wind exactly opposes stack pressure at openings 2 and 4, leaving flow only through openings 1 and 3. The effective reduction in the number of openings reduces slightly the overall air change rate. This effect is less pronounced as the number of openings increase since it is unlikely that a significant proportion of them would simultaneously experience exactly opposing pressures. At greater wind speeds (d), flow enters the building through the windward side of the building (1 and 2), and flows out through leeward openings (3 and 4). This marks the start of the wind-dominant regime.

The application of *network* calculation techniques, combined with representative weather data for the building locality, enables the natural ventilation performance of individual design solutions to be evaluated.

No Apparent Driving Force. It is theoretically possible for there to be no apparent natural driving force, although, this is unlikely in practice. In winter, stack pressure is developed by indoor space heating; in summer, ever-present turbulence, created by marginal differential air temperatures, will provide continuous airflow through open windows.

Building Structure and Volume

Several aspects of building design, including those described in the following paragraphs, are essential to secure good natural ventilation performance.

Building Airtightness. The building structure should be airtight so that ventilation is confined to airflow through intentionally provided openings only. This permits more accurate design solutions and prevents air infiltration from interfering with ventilation performance. The philosophy, as with all ventilation strategies, is to “build tight and ventilate right.”

The Space as an “Air Quality” Reservoir. The time it takes for a pollutant to reach steady-state concentration is dependent on the volume of the enclosed space. Thus, under certain circumstances, the building can be treated as an *air quality reservoir* in which the impact of a transient source of pollution can be initially accommodated by the enclosed air mass itself. This may be used to compensate for the variable nature of the natural ventilation process and is a key aspect of natural ventilation design. Essentially, it enables good air quality to be maintained without the need for a constant rate of ventilation. This approach may not be satisfactory if emissions from furnishings and fittings within the building present the dominant need for ventilation.

Ventilation Openings

Ventilation openings must be provided to meet all anticipated ventilation needs. The number and size of openings will depend on overall ventilation need and the strength of local driving forces. Since the rate of ventilation is dependent on variable driving forces, provision should be made for the occupant to be able to adjust openings to meet demand. A good design should have a combination of permanently open vents, to provide background ventilation, and controllable openings to meet transient demand. Sometimes automatic controls and dampers are used to adjust ventilation openings. These may be connected to thermal sensors to maximize the potential of night cooling (Martin 1995).

Natural ventilation components include those described in the following paragraphs.

Openable Windows and Louvres. In many buildings, openable windows are the principal component of natural ventilation. They permit the passage of large flows of air for purging or summer cooling. Unfortunately, window designs aimed at maximizing airflow for summer cooling can cause extreme discomfort and energy waste during the heating season if good control of window opening is not possible. Sometimes losses are exacerbated if heating systems are oversized and have poor controls, since window opening is then used as a means to moderate indoor air temperature. Vertical sash or sliding windows are able to provide air above the occupied zone to prevent low-level draughting. Louvres and top-hung windows provide a greater degree of flow control than do large-opening side-hung windows.

Air Vents and “Trickle” Ventilators. Unnecessary air change can be avoided by using “trickle” ventilators (small air vents) in place of window openings for winter ventilation. They typically have an effective area of opening between 4000 and 8000 mm². Ideally they should be permanent openings, although some incorporate manual adjusters. When used by themselves, trickle ventilators provide limited but uncontrolled ventilation. At least one vent per room is normally recommended for naturally ventilated dwellings. United Kingdom recommendations for office buildings are 4000 mm² of opening for each 10 m² of floorspace (BRE 1994). Openable windows or other large openings are needed for summer cooling and rapid air purging. Trickle ventilators should be positioned to promote the entry and rapid mixing of outdoor air. This is necessary to ensure good air distribution and to prevent localized areas of cooling. To prevent discomfort, it is often recommended that vents be located at a high level, above the window and possibly integrated into the window frame. Sometimes ventilators are positioned directly behind wall-mounted heaters or even ducted directly to the heating system. This prevents unauthorized access to the vents and enables the incoming air to be preheated before reaching the occupied zone.

Automatic (Variable-Area) Inlets. Some air inlets respond automatically to various air-quality and climate parameters. These are usually intended for use with passive stack (or mechanical extract) ventilation systems. Typical systems include the following:

Temperature-sensitive vents. The area of opening of the temperature-sensitive vent reduces as the outside air temperature falls. This limits the impact of stack ventilation and prevents a rise in airflow rate as the stack pressure increases.

Humidity-sensitive vents. The humidity-sensitive vent opens in response to increased room humidity to assist in moisture removal. These are popular in some countries.

Pressure-sensitive vents. Various pressure-sensitive vents have been developed, but they are seldom sensitive enough for reliable operation at the normal driving pressures of natural ventilation (i.e., <10 Pa). By contrast, the vent illustrated in Fig. 13.3 (Knoll 1993) has been specifically designed for robust operation at pressure differences as low as 1 Pa. This enables an almost uniform flow rate to be achieved throughout a wide pressure range, thus permitting good control of natural ventilation. The main disadvantage, at present, is cost.

Passive Stacks. *Passive stacks* are vertical ducts that penetrate a room at ceiling level and terminate above roof level. The purpose of such a stack is to enhance temperature difference or stack-driven airflow. Ideally the roof opening is located where wind-action induces a suction pressure, so that airflow is reinforced by wind action (see “Passive-Stack Ventilation”). Cowls may be fitted at the roof opening to promote wind-induced suction pressure and prevent backdraughting. Passive stacks are an important element of controlled natural ventilation systems, especially in dwellings.

Air Vents for Combustion Appliances. Often building regulations specify a minimum area of permanently openable vents which must be included in dwelling rooms fitted with an open-combustion appliance. This is needed to secure combustion supply air and to prevent excessive suction pressures from being developed if a mechanical extractor is in use. It is an essential safety measure, but these vents add to the air change process and can therefore cause additional energy loss. Whenever possible, room-sealed combustion appliances incorporating balanced flues or externally supplied and exhausted air should be installed. Open combustion appliances can be incompatible with energy-efficient building design.

FIGURE 13.3 Pressure-sensitive air inlet. (Courtesy B. Knoll, TNO, The Netherlands.)

Natural Ventilation Techniques

Various techniques or combinations of techniques are used to provide natural ventilation; some of these are described in the following paragraphs.

Cross-Flow Ventilation. Cross-flow ventilation relies on establishing a clearly defined and unimpeded airflow path between the incoming and outgoing airstreams which should pass through the zone of occupancy. Such an airflow pattern is impeded if the building is compartmentalized. Consequently, an open-plan interior is recommended. Examples of cross-flow ventilation configurations are illustrated in Fig. 13.4. Since there is a practical limit that naturally provided ventilation air may be expected to penetrate the building from an opening, limits are applied to the maximum distance from openings. In the past, this limit was assumed to be 2 to 2.5 times the ceiling height (a depth of typically 6 m), although some studies (BRE 1994) have shown that it may be possible to extend this limit to 10 m.

Single-Sided Ventilation. Sometimes ventilation design appears to be *single-sided* in that the only obvious openings are positioned along just one side of the room. True single-sided ventilation through a small opening (see Fig. 13.5a) is driven by random *turbulent fluctuations*. At best, this type of single-sided approach is unreliable and is not recommended as part of a controlled natural ventilation strategy.

Generally, more than one opening may be placed on a single side or a single opening is large enough for air to flow simultaneously through it in both directions (see Fig. 13.5b). Ventilation is then driven by the normal process of wind and stack forces. For these configurations, flow rates may be calculated using standard network calculation techniques. Good spacing between openings is needed to generate reliable air change for practical applications.

Often apparent single-sided ventilation turns out to be *cross-flow* ventilation as illustrated in Fig. 13.5c. In this example, a second flow path exists through joints around internal partitioning. Quite fortuitously, many rooms experience this type of background cross-flow. Internal air vents or open doors will assist this process.

FIGURE 13.4 Cross-flow ventilation.

Passive-Stack Ventilation. Passive-stack systems have been used in many parts of Scandinavia and in other locations throughout Europe primarily for the ventilation of dwellings and, sometimes, nondomestic buildings. Normally they are used to promote the extraction of air from “wet” rooms. Airflow is driven through the stack by a combination of stack pressure and wind-induced suction pressure. Although the rate of airflow is variable, some control of the pattern of airflow is possible, with air entering predominantly through purposely provided trickle ventilators and exhausted through the stack. A separate stack is needed for each room. Occasional backdraughting will occur when the pressure generated in the stack cannot overcome the static pressure of cold outside air sitting above it. This flow reversal, if it does occur, is normally temporary and should not present an air quality or health problem. Sometimes *shunt* ducts from individual rooms or apartments are connected to a central stack, but there is a serious risk of cross-contamination between connected locations.

Careful design is required if passive stacks are to perform correctly. A configuration for a single family house is illustrated in Fig. 13.6. Stack diameter is typically between 100 and 150 mm. Since frictional losses must be minimized, it is preferable for the stack to be completely straight and vertical. At most there should be no more than two bends, and these should not exceed 45°. If flexible ducting is used, it must be cut to the exact length needed to prevent any excess from being coiled. Stacks passing through unheated spaces must be insulated to prevent condensation.

A separate stack is needed for each room in which extraction is necessary. Makeup air should be provided through intentional openings. The stack must terminate in the negative-pressure region above the roof space.

Passive stacks are most suitable for moderate to medium cold climates, where a consistent wintertime driving force can be developed. Studies and further information on the performance of passive-stack systems are described by Shepherd et al. (1994) and Villenave et al. (1994). Stack systems are also used to mitigate radon concentration by venting beneath a building’s foundations. Measurements reported by Saum and Osborne (1990) show that effective reductions in radon concentration are achievable.

Wind Towers. In some countries, where prevailing wind provides a reliable driving force a stack may be configured as a *wind tower*. Openings face the oncoming wind, resulting in wind-driven airflow being ducted into the building.

FIGURE 13.5 Single-sided ventilation: (a) single-sided sealed enclosure; (b) single-sided sealed enclosure with multiple or large opening(s); (c) single-sided unsealed enclosure.

Atria Ventilation. An atrium is essentially a glass-covered courtyard which provides an all weather space for building occupants. They are popular for buildings such as offices and shopping malls, and feature in "passive" low-energy building designs. Natural ventilation can be applied by using the atrium itself as a passive stack. In this case, the atrium is extended above the occupied zone by several meters to ensure that the neutral pressure plane is above the topmost occupied level. Initial sizing of openings can be accomplished

FIGURE 13.6 Stack ventilation (dwellings).

using the simple calculation methods. Thermal calculations may also be necessary to identify the total heat gain. Some designers use computational fluid dynamics to predict the air-flow pattern within the structure.

The basic concepts of natural atrium ventilation are summarized in Fig. 13.7. Building joints must be well sealed to prevent uncontrolled air change and high-velocity draughting. Flow patterns can be disrupted by wind-induced pressures. Automatic damper controls may be needed to adjust inaccessible top openings. Successful examples of large buildings based on natural ventilation of the atrium space are described by Holmes (1985) and Guntermann (1994).

Robustness of Natural Ventilation Design

Natural ventilation solutions should be shown to be robust and capable of meeting indoor air quality and comfort needs throughout the full range of local climate conditions. The minimum ventilation rate needed for satisfactory indoor air quality requirements and the maximum rate needed for summer cooling must be identified. Both needs should be matched against the corresponding prevailing driving forces so that the minimum and maximum opening areas of vents and windows may be determined. Ideally, the minimum need should be satisfied with permanent openings while the maximum need should be met by adjustable openings.

Advantages of Natural Ventilation

- Natural ventilation is suitable for many types of buildings located in mild or moderate climates.
- The open-window environment associated with natural ventilation is often popular, especially in pleasant locations and mild climates.
- Natural ventilation is usually inexpensive when compared to the capital, operational, and maintenance costs of mechanical systems.
- High airflow rates for cooling and purging are possible if there are plenty of openings.

FIGURE 13.7 Stack ventilation (atrium).

- Short periods of discomfort during periods of warm weather can usually be tolerated.
- No plant room space is needed.
- Minimum maintenance.

Disadvantages of Natural Ventilation

- Inadequate control over ventilation rate could lead to indoor air quality problems and excessive heat loss. Airflow rates and the pattern of airflow are not constant.
- Fresh air delivery and air distribution in large, deep plan and multiroomed buildings may not be possible.
- High heat gains may mean that mechanical cooling and air handling will prevent the use of natural ventilation.
- Natural ventilation is unsuited to noisy and polluted locations.
- Some designs may present a security risk.
- Heat recovery from exhaust air is technically feasible (Shultz 1993) but seldom practicable.
- Natural ventilation may not be suitable in severe climatic regions.
- Occupants must normally adjust openings to suit prevailing demand.
- Filtration or cleaning of incoming air is seldom practicable.
- Ducted systems require large-diameter ducts and restrictions on routing.

13.3 MECHANICAL VENTILATION

Background and Applications

Mechanical ventilation systems are capable of providing controlled ventilation to a space. Especially in large commercial buildings, they may be combined with heating,

cooling, and filtration systems. Many systems operate in *mixing* mode to dilute pollutants while others operate in *displacement* mode to remove pollutants without mixing. Some systems incorporate exhaust-air heat recovery techniques to reduce ventilation heat loss. Well-designed systems installed in good-quality buildings can be unaffected by climatic driving forces. Benefits have to be balanced against capital and operational costs, ongoing maintenance needs, and eventual replacement. It is often this balance between cost and performance benefit that dictates the approach to ventilation. Mechanical systems need to be designed to meet the specific needs of the building in which the system is to operate. An integrated design philosophy ensures optimum performance combined with maximum energy efficiency.

Applications include large commercial buildings in almost any climatic region, apartments, single-family dwellings and other smaller buildings located in severe climatic regions, and local intermittent extract ventilation is frequently used to support natural ventilation.

Mechanical Ventilation Components

Mechanical systems are made up of various components, including those described in the following paragraphs and in Chap. 8.

Fans. *Fans* are used to provide the motivating force for mechanical ventilation. Common types are propeller fans for low capacity, and centrifugal and axial fans for high capacity and lengthy duct runs. Fans operate by consuming electrical energy. This energy can represent a very significant factor in the energy budget of a commercial building air-conditioning system. Work reported by BRECSU (1993) indicates that the fan can account for more than half of the system's energy consumption. Energy consumption is dependent on flow rate, pressure drop across the fan (or circulation pump), fan efficiency, and motor efficiency. Fan power is approximately proportional to the cube of the air velocity. This means that halving the velocity of air through a duct will result in an eightfold decrease in fan power. Large cross-sectional area ducting can therefore be beneficial but must be assessed in the context of additional capital costs and space needs. Further control strategies for minimizing fan energy are reviewed by Steimle (1994).

Ducts. Ducting is used to transfer air. Ducts impose a resistance to airflow, thus influencing performance and energy need. The amount of resistance depends on

- The airflow rate through the duct
- Cross-sectional area
- The length of the duct run
- The number and angle of bends
- Surface roughness

The greater the flow resistance, the greater is the fan capacity and electrical energy which is needed to drive a mechanical ventilation system. Transport energy may be reduced by minimizing resistance to air movement. This is achieved by using, for example, low-loss fittings and minimizing flow impedances presented by filters and cooling coils. Ducting which passes through unconditioned spaces should be insulated to prevent thermal losses and condensation risk. They should also be well sealed to prevent the loss of conditioned air. Good systems require electrical power at 1 W or less for each L/s of airflow. Poorly designed systems might need 3 W or more to deliver the same airflow rate.

Diffusers. *Diffusers* are used to discharge mechanically supplied air into the ventilated space. Considerable design effort is needed to ensure that they do not cause uncomfortable draughts. The design specification covers the emission rate, discharge velocity, and turbulent intensity. Examples are reviewed by Nielsen (1989).

Air Intakes. *Air intakes* are the openings at which outdoor air is collected for ducting to a ventilation system. Problems occur if air intakes are located close to contaminant sources (e.g., traffic fumes, local industry, or building exhausts).

Air Inlets. *Air inlets* are passive openings which are used to provide makeup air to a space. They may consist of trickle ventilators or air bricks as used for natural ventilation.

Air Grilles. *Air grilles* are used to capture exhaust air from a space.

Silencers (Noise Attenuators). Noise in mechanical ventilation systems can present considerable discomfort. A concise summary of the problem and cures is presented by Op t'Veld (1993). Direct noise is generated by the system itself, including fan noise, duct propagation, poor mountings, control valves, and aerodynamic noise (through grilles). A system may also be influenced by the transfer through the system of outdoor noise. Efforts to reduce noise include the soundproofing of ducts with sound-absorbing material and the use of *silencers*, which consist of a perforated inner duct, surrounded by mineral wool packing which is enclosed by an outer duct. Both techniques increase flow resistance and therefore incur an energy penalty. Active noise filters are also in the course of development (Leventhall et al. 1995). These create an *antiphase* noise in a space aimed at canceling out existing noise. A microphone placed in the duct, downstream of the fan, detects any generated sound and converts the pressure waves into an electrical signal. An active filter and sound analysis network is used to produce an antiphase audio signal into a loudspeaker positioned further upstream to cancel out the system noise.

Mechanical Ventilation Strategies

Various configurations of mechanical ventilation are in use. Typical configurations are described in the following paragraphs.

Mechanical Extract Ventilation. A fan is used to mechanically remove air from a space. This induces a suction or *underpressure* which promotes the flow of an equal mass of makeup or fresh air into the space through purposely provided air inlets or infiltration openings. If the underpressure created by the extract process is greater than that developed by wind and temperature, the flow process is dominated by the mechanical system. If the underpressure is weaker, then the flow process is dominated by air infiltration. Optimum operational efficiency is achieved by contriving to keep the mechanical pressure at a slightly greater level than the weather-induced pressure. In common with natural ventilation design, best control is established by ensuring that the structure is airtight and that purposely provided air inlets are used to supply makeup air. However, since natural or passive openings are needed, this approach can tolerate a small amount of infiltration opening. Extract systems include those described in the following paragraphs.

Local Extract. Local extract systems are common in many smaller buildings, where they are used to extract pollutants (often moisture) from the source of production. These are typically low-capacity wall, window, and cooker (range) hood fans which vent the contaminated air directly outside. Typical capacities are 25 to 50 L/s. Local extractors are frequently

used to support natural ventilation. Operation is normally intended to be intermittent and may include a time switch or humidity sensor for automatic control. Propeller-type fans are often used. Duct lengths as short as 1 m can impair performance considerably.

Centralized Ducted Extract. Ducted systems provide complete ventilation to a building. The system is operated by a central fan which is connected to extract grilles via a network of ducting (see Fig. 13.8). These systems are used in single-family and apartment dwellings, particularly in cold climates. Extract systems are also used in industry and in hospital environments, where suction pressures are applied to prevent the spread of chemical or microbiological contaminants. In dwellings, extract grilles are located in “wet” rooms while air inlets are located in living and bedrooms. This configuration is especially beneficial in preventing water vapor from penetrating and condensing in the building fabric. In industrial locations extract points are located above heat or polluting sources.

Extract Ventilation with Heat Recovery. Waste heat from the exhaust air may be recovered by using an air to liquid heat pump. These are able to recover between 20 and 40 percent of the energy in the exhaust air for preheating of the domestic hot water. Up to 95 percent of hot water needs may be satisfied in this way (Knoll 1992). Further energy may be extracted if used in conjunction with a “wet” central heating system.

Applications. Mechanical extract systems are used when it is important to prevent localized pollutant sources from contaminating occupied spaces or where cross-contamination from “clean” to contaminated zones is to be avoided. Examples include

Dwellings. Central and local extract systems are used in dwellings. Sometimes they form part of a building retrofit in which passive ventilation ducts are used to carry the extract air.

Factories and laboratories. Extract fume hoods are used to capture contaminants from polluting processes and prevent them from entering occupied spaces.

Limitations and Design Precautions. Excessive underpressures must be avoided. If the building is too tight or there are insufficient makeup openings, either the suction pressure

FIGURE 13.8 Central mechanical extract ventilation (dwellings).

(and hence electrical energy load) will rise or the fan will be unable to deliver the desired airflow rate. High underpressures may cause combustion flues to backdraught and radon or other soil gases to enter the building; they may also cause noise and high-velocity draughts. The adverse effect of excessive suction pressures is summarized in Fig. 13.9 (Hama 1959). Strict controls usually apply to the installation of ducted extract systems in buildings fitted with open-combustion appliances. Canadian Standard CAN/CGSB-51.71-95 (1995) requires that for dwellings fitted with open-combustion appliances, the underpressure not be allowed to exceed 5 Pa. The sizing of openings for optimum underpressure is a very straightforward exercise, based on the relationship between pressure drop and flow rate through an opening.

Potential benefits of extract ventilation must be equated against cost, operational energy, and long-term maintenance needs.

Advantages of Mechanical Extract Ventilation

- Controlled ventilation rates are possible.
- Extraction of pollutants at source reduces the risk of pollutant ingress into occupied spaces.
- The risk of moisture entering walls is reduced.
- Heat recovery from the exhaust- airstream is possible.

Disadvantages of Mechanical Extract Ventilation

- Capital cost is greater than with natural ventilation.
- Operational electrical energy is needed.
- System noise can be intrusive.
- Regular cleaning and maintenance is necessary.
- Internal partitioning can restrict airflow. To ensure unimpeded airflow between the makeup inlets and the exhaust points, air vents should be fitted to internal doors.
- There is a risk of backdraughting from flues.
- The underpressures caused by mechanical extract ventilation can increase the presence of radon or other soil gases in a building by drawing them through the subfloor layer. Ideally, radon control measures should, in any event, be incorporated into buildings located in high-radon areas (Saum and Osborne 1990).
- Fixed air inlets may result in the ventilation rate being influenced by weather conditions. The installation of pressure-sensitive air inlets such as illustrated in Fig. 13.3 can assist in providing a constant airflow rate by further reducing the influence of climate forces.
- Adjustment to individual air inlets could affect flow through other branches of the system.

Mechanical Supply Ventilation

Supply (outdoor air) is mechanically introduced into the building, where it mixes with the existing air. This process induces a positive (i.e., above atmospheric) pressure in the building. Indoor air is displaced through purposely provided and/or infiltration openings. If the system is well designed and good fabric airtightness is achieved, supply ventilation inhibits the ingress of infiltrating air and therefore enables all the incoming air to be precleaned and thermally conditioned.

FIGURE 13.9 Adverse effects of underpressure.

Ducted Systems. Typically the system is ducted, and may be incorporated as part of an air heating or cooling distribution system (see Fig. 13.10). Normally the air is filtered to reduce dust and particulate concentrations. A proportion of the room air escapes through leakage openings and/or purposely provided openings, while the remainder is recirculated for thermal comfort and blended with incoming outdoor air (see also discussion on balanced ventilation). Problems have arisen in the past when fresh air supply dampers have been closed to reduce energy consumption. The same airtightness and vent conditions are needed as for extract ventilation. Optimum performance is maintained by sizing the system to operate just beyond the pressure range developed by wind and temperature.

Task Supply Ventilation. Sometimes supply air is ducted directly to individual occupants where flow rate and comfort conditions can be manually adjusted. Task ventilation is often incorporated into workstation “booths” (Arens et al. 1990).

Applications. Supply ventilation has several important applications where a building needs to be pressurized; these include

Urban ventilation. Supply ventilation is extremely useful in areas where the outdoor air is polluted, since the incoming air may be precleaned by filtration. It is often used in city-center offices where the outdoor air can be conditioned prior to distribution. Air normally needs to be recirculated to ensure adequate transmission of warmth (or “coolth”) to occupants.

Cleanrooms. Since filtration and air cleaning is possible, supply systems have important applications in industrial cleanroom technology. These systems may also be used to maintain pressure differentials between adjacent rooms to prevent cross-contamination.

Allergy control. Supply ventilation can be used to advantage for occupants sensitized to pollutants from outdoor sources (pollen, industrial emissions, etc.). When supply ventilation is used in the home, care is needed to prevent moisture, generated in the dwelling, from penetrating and condensing in the building fabric. This means ensuring that outlet grilles and local extractors are located in these areas and that the internal walls are well sealed.

FIGURE 13.10 Central mechanical supply ventilation.

Limitations and Design Precautions. Although the pressurization characteristics of supply ventilation can inhibit the adventitious entry of pollutants and soil gases into a space, and can minimize the risk of backdraughting, they are rarely recommended for dwellings since there is a risk that indoor-generated water vapor can penetrate and condense in the building fabric.

Extreme care is needed over the siting of air intakes to avoid drawing in outdoor pollutants from local sources. Air intakes must not be obstructed or blocked.

Advantages of Mechanical Supply Ventilation

- Outdoor air can be precleaned and conditioned.
- Good air control is possible.
- Entry of outside pollutants and soil gases is impeded.
- Flue backdraughting risk is reduced.
- Infiltration can be restricted, provided the structure is fairly airtight.

Disadvantages of Mechanical Supply Ventilation

- Problems occur if air intake dampers are blocked or closed, or if air intakes are close to pollutant sources.
- Indoor moisture sources may be driven into the building fabric at risk of condensation. Thus this method is seldom recommended for dwellings.
- Heat recovery is not possible.
- Removal of pollutants at source is not possible.

Mechanical Balanced “Mixing” Ventilation

Balanced “mixing” ventilation combines extract and supply systems as separately ducted networks. Typically, air is supplied and mixed into occupied zones and is extracted from polluted zones (see Fig. 13.11). An airflow pattern is established between the supply to the extract areas, which should be supported by air-transfer grilles between rooms. Balanced systems almost always incorporate heat recovery using a plate heat recovery unit or similar air to air system. This enables free preheating of the incoming air. It is this potential for heat recovery that is often used to justify the additional capital and operating costs. Sometimes an intentional flow imbalance may be introduced to put the building in a slight negative pressure (dwellings) or positive pressure (commercial buildings).

Applications

Dwellings. Balanced ventilation systems are popular in both high- and low-rise dwellings, especially in extreme climatic regions where worthwhile heat recovery is possible.

Offices and Commercial Buildings. Balanced-type systems combined with filtration, air conditioning, and heat recovery are used in office and commercial buildings. Background information on typical configurations for offices is presented by Limb (1994b).

Limitations and Design Precautions. Balanced systems are usually pressure-neutral and are not resistant to infiltration driven by wind and temperature effects. As a consequence, the building must be perfectly sealed for optimum performance. Airtightness needs to be better than 1 ACH (air change per hour) at 50 Pa for effective operation. In structures where the air change exceeds 10 ACH at 50 Pa, balanced ventilation systems with heat recovery could use more delivered energy than could an extract system without heat recovery.

If the climate is mild (i.e., <2500 degree-days), a balanced ventilation system, even operating in a perfectly airtight enclosure, may consume more primary (fossil fuel) energy than can be recovered by air to air heat recovery.

Evidence suggests that duct leakage in unconditioned spaces is often a severe source of energy loss, through poor airtightness. For this reason, ductwork through unconditioned spaces (roof and subfloor areas) should be avoided. Where such duct runs are necessary, ductwork should be insulated and airtight.

Advantages of Mechanical Balanced “Mixing” Ventilation

- This type of ventilation allows heat recovery and preheating of supply air.
- Supply air is targeted to occupied zones, while air is extracted from polluted zones.
- Absence of high suction pressures reduces the risk of backdraughting as well as the entry of radon or soil gas.
- Filtration of the incoming air is possible.

Disadvantages of Mechanical Balanced “Mixing” Ventilation

- Two systems are present, thus doubling installation and operational costs.
- The systems have been shown to require regular long-term maintenance.
- For correct operation, these systems must be installed in airtight enclosures. This reduces safety margins if the system fails to operate correctly or if the occupant unwittingly introduces high-polluting sources into the building.

FIGURE 13.11 Mechanical balanced ventilation (dwellings).

Mechanical Balanced Displacement Ventilation

Displacement ventilation is a form of balanced ventilation in which the supply air displaces rather than mixes with the room air. Preconditioned air at 2 to 3 K below ambient room temperature is introduced to the space at a low level and at a very low velocity (typically 0.1 to 0.3 m/s). Gravitational effects encourage the incoming air to creep at floor level until it reaches a thermal source (occupant, electrical load, etc.). The air then rises around the heat source and into the breathing zone prior to extraction at ceiling level (see Fig. 13.12). This approach is designed to avoid the mixing of air; instead, it *displaces* the air already present within the space. It therefore has a high *air change efficiency*. Air supply diffusers are usually either free-standing or located in the floor. A large total area of diffuser over which the air is uniformly discharged is needed to accomplish the required volume flow rate at low supply velocity.

Applications. Displacement systems have become popular, especially in some Scandinavian and European countries, for applications in offices and public buildings.

Advantages of Mechanical Balanced Displacement Ventilation

- This is a potentially energy-efficient ventilation system.
- Smoke control is possible, maintaining the areas close to the floor free of smoke.

FIGURE 13.12 Balanced displacement ventilation (office). (Courtesy FGK, Germany.)

Disadvantages of Balanced “Displacement” Ventilation

- The availability of floorspace is reduced since occupants must be kept at some distance from floor-standing diffusers and must not place obstructions over diffusers located in the floor. This space restriction puts displacement systems at a disadvantage compared with systems with ceiling-mounted mixing diffusers.
- Precise temperature and airflow control is needed to establish correct operating conditions.
- Upstream pollutants must be avoided. Since there is reduced mixing, pollutants upstream of the breathing zone can become extremely concentrated. Possibilities include floor-level contaminants (e.g., from dirty carpets) and emissions from electrical equipment in the vicinity of an operator.
- Limited heating or cooling capacity of distributed air means that a separate system (e.g., radiant panels) may be needed for heating and cooling.

Demand-Controlled Ventilation

Demand-controlled ventilation (DCV) systems provide a means of automatically controlling the rate of ventilation in response to variations in indoor air quality. Ventilation is therefore provided only when and where it is needed, while at other times it may be reduced to minimize space heating or cooling losses. Essentially, a *sensor* is used to track indoor air quality and to modulate the rate of ventilation to ensure that air quality does not deteriorate. Ideally a *total* air quality sensor is needed which is capable of detecting all pollutants and reacting as soon as the concentration of any individual component exceeds a predetermined threshold level. In reality, technology has yet to reach this stage, while cost imposes

a further limitation. However, where a dominant pollutant can be identified, demand-controlled ventilation has proved to be extremely effective. Specific examples include the control of moisture in “wet” rooms, carbon dioxide sensing in transiently occupied buildings, and carbon monoxide-linked systems in parking garages. These systems are reviewed in detail by Raatschen (1990) and Mansson and Svennberg (1992) as part of the work of IEA Annex 18.

Elements of the System. A demand-controlled system comprises three essential elements (see Fig. 13.13):

- A sensor or group of sensors, designed to monitor the dominant pollutant (or pollutants)
- A control system for adjusting the ventilation rate in response to need
- A conventional (usually mechanical) ventilation system

Demand-controlled ventilation is effective when there is a dominant pollutant specific to a type of activity or locality, that can be monitored and controlled. Often, when sufficient ventilation is provided to dilute or remove the dominant pollutant, other, less easily definable pollutants are, themselves, controlled. The first step of demand-controlled ventilation is to identify the dominant pollutant or pollutants.

Sensors. Sensors are specific predominantly to individual pollutants. The system must therefore be tailored to the dominant pollutant, or, if there is more than one potential pollutant, several sensors may be necessary, with each sensitive to a different range of pollutants. For demand-controlled systems to be effective, sensors must be maintenance-free and should not require postinstallation calibration since it is unrealistic to expect the normal consumer to have the expertise to carry out complex servicing tasks or to lose the benefit of reduced energy costs by high service costs. In other words, to be acceptable to the marketplace, reliability and cost benefit must be demonstrated.

Apart from specialist and expensive industrial applications, the range of sensors suitable for demand-controlled ventilation is limited to a very small number of common pollutants.

FIGURE 13.13 Demand-controlled ventilation (office).

Specifically, these include moisture sensors, carbon dioxide sensors, mixed-gas detectors, particle detectors, and infrared “people” detectors. Timers and thermostats also play a role.

Moisture Sensors. Moisture sensors are common for the home, where they may be used to automatically control or boost extract ventilation in response to the production of water vapor. They respond to either the relative or absolute humidity in a space. They are inappropriate in homes in which the indoor air temperature is allowed to fall below approximately 15°C since ventilation for moisture control becomes ineffective at low temperatures.

Carbon Dioxide Sensors. Although carbon dioxide is itself nontoxic and harmless, even at quite high concentrations, the measurement of CO₂ can provide a useful indicator to the adequacy of ventilation. This is because in environments in which the only source of CO₂ production is metabolic, there is a close correlation between the steady-state concentration of CO₂ and the rate of ventilation. Carbon dioxide sensors are therefore useful for controlling ventilation in certain occupied environments. This is a particularly valuable approach in densely populated buildings, such as offices and public buildings, and in transiently occupied buildings such as shops, theaters, and schools. Typical setpoint or control levels are in the region of 600 to 1000 ppm. This compares with ambient outdoor levels of 350 to 400 ppm. Carbon dioxide systems are unsuitable in areas of smoking, where the dominant pollutant becomes the combustion products of tobacco. Additionally, it is not normally appropriate for the home, where low occupancy densities mean that CO₂ levels seldom rise significantly. Although domestic CO₂ levels as high as 4000 ppm have been measured in bedrooms, these are associated with much more fundamental problems concerning the adequacy of domestic ventilation.

Particle Sensors. Particle sensors monitor the particulate levels within zones. These may be of value in function rooms and other meeting zones in which heavy smoking may take place. Cost, however, is often prohibitively high.

Infrared Presence Sensors. Instead of monitoring pollutants directly, infrared presence detectors have been used to control ventilation systems. In principle, they monitor the movement of people in and out of a space and adjust the ventilation rate accordingly. Such sensors are extremely inexpensive. Results to date (Raatschen 1990) have not been promising, partly because it is difficult for these sensors to maintain a reliable count of the number of persons present.

Mixed-Gas Sensors. A number of mixed-gas detectors have been designed to monitor overall air quality. These sensors respond to various reactive gases such as hydrogen sulphide, carbon monoxide, and various volatile organic compounds (VOCs). They can indicate the presence of occupants or animals but do not distinguish between individual gases and thus, from an air quality perspective, are not necessarily effective for demand-controlled systems.

Sensor Location

Sensors need to be located in the polluting zone and in locations where pollutants are a hazard, either to the building occupant or to the building fabric. Often, the number of sensors that may be used is restricted by the constraint of cost; hence siting may become a compromise. Any compromise that will leave a locality at risk must be avoided.

In buildings with good mixing ventilation, the sensor location is not critical and should be placed for convenience. Sometimes it is placed in the exhaust duct, although this is satisfactory only if air is continuously extracted. Carbon dioxide sensors should not be placed too close to the breathing zone since CO₂ concentration is likely to be artificially high in this region. Moisture sensors should be located in the vicinity of the pollutant source, that is, integral with cooking, washing, or drying appliances and/or located in the vicinity of room extractors.

Sensors for displacement systems should be located close to the breathing zone, at the transition from clean to polluted air. They can also be located in continuously operated exhaust ducts but the set point must reflect the air quality of the breathing zone.

Control Systems. The *control system* relays information from the air quality sensor to the ventilation system. In its most rudimentary form this is simply a switch which is connected to the fan of the ventilation system. When the sensor indicates a need for ventilation, the ventilation fan is switched on.

Ventilation Systems. The ventilation system is usually of conventional mechanical design to which the demand-controlled system is attached. This means that DCV can be retrofitted into many existing ventilation systems. Some demand-controlled sensors can be used in conjunction with natural ventilation.

Applications Demand-controlled systems have been developed for all types of buildings. They are particularly beneficial in locations of transient occupancy or where pollutant loads, specific to an environment, vary over time. The effectiveness of demand-controlled systems depends on identifying the dominant need for ventilation and providing a reliable sensor which is able to track this need.

Demand-controlled systems are effective when:

- Outdoor air supply can be controlled (i.e., minimum infiltration or other losses).
- The occupancy pattern or dominant pollutant is variable.
- Space heating or cooling energy loads can be minimized.
- The controlled pollutant (or pollutants) are dominant.

Advantages of Demand-Controlled Ventilation

- Ventilation rate can be optimized to meet prevailing need.

Disadvantages of Demand-Controlled Ventilation

- Sensors and control systems can be expensive.
- Currently methods are essentially restricted to carbon dioxide and humidity control.
- Although mixed-gas sensors can provide general control, the individual mixture of gas is uncertain.
- High concentrations of harmful pollutants could go undetected.

CHAPTER 14

BUILDING FIRES AND SMOKE MANAGEMENT

John H. Klotz, P.E., D.Sc.

*Fire and Smoke Consulting
McLean, Virginia*

14.1 INTRODUCTION

During fires, smoke often flows to locations far from the fire, endangering life and damaging property. Methods of smoke protection include compartmentation, smoke venting, smoke exhaust, airflow, and pressurization. Compartmentation is probably the oldest form of smoke management, and over the centuries it has been applied for both fire and smoke protection.

Because terminology has been the source of many serious misunderstandings, the terminology used in this chapter is consistent with NFPA 92A (1996), NFPA 92B (1995), and Klotz and Milke (1992). *Smoke* is the airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion, together with the quantity of air that is entrained or otherwise mixed into the mass. This definition includes the air that is mixed into the products of combustion so that the gases that are vented or exhausted from the tops of atria and other large spaces during fires are defined as smoke. An interesting side note is that this definition allows for invisible smoke as results from burning of some gaseous fuels, including hydrogen.

A *smoke management system* is an engineered system that includes all methods that can be used singly or in combination to modify smoke movement. These methods include compartmentation, dilution, airflow, pressurization, and buoyancy. However, a smoke management system that uses pressurization at smoke barriers is called a *smoke control system*. Thus smoke control is a subset of the broader term smoke management.

Common objectives of fire protection systems are life safety, property protection and mission continuity. However, the main focus of the building codes is life safety. Two basic approaches to fire protection are to prevent fire ignition and to manage fire impact. The building occupants and management have the primary role in preventing fire ignition. Building designers may incorporate features into a building to assist the occupants and management in preventing fires. If prevention of fire ignition could be perfectly effective, there would be no need for building features to manage the impact of fires. The history of building fires verifies the importance of features that manage the impact of a fire. These

features include compartmentation, fire suppression, control of construction materials, and smoke management. Figure 14.1 is a fire protection decision tree. More information is contained in the *Fire Protection Handbook* (NFPA 1997a).

14.2 TENABILITY

Almost all smoke management systems are designed to maintain tenable conditions by preventing smoke from coming into contact with building occupants, and the systems discussed in this chapter are based on this approach. An alternative approach allows exposures to smoke provided that the smoky environment is maintained at a tenable level. A *tenability analysis* needs to address exposure to heat and toxic gases. Further, visibility calculations need to be included with the tenability analysis. This is because when people cannot see through smoke, they walk slowly, thus potentially significantly lengthening evacuation time, and they can become disorientated and lost thus prolonging their exposure to toxic gases. For an engineering approach to tenability analysis for building fire situations, see Klote (1999).

14.3 PRESSURIZATION SYSTEMS

A pressure difference across a barrier can control smoke movement as illustrated in Fig. 14.2. Within the barrier is a door. The high-pressure side of the door can be either a refuge area or an egress route. The low-pressure side is exposed to smoke from a fire. Airflow through the gaps around the door and through construction cracks prevents smoke infiltration to the high pressure side. Stairwell pressurization, elevator smoke control, and zoned smoke control are common systems that use pressurization to manage smoke flow.

It is appropriate to consider both a maximum and a minimum allowable pressure difference across a barrier of a smoke control system. The values discussed in this section are

FIGURE 14.1 Simplified fire protection decision tree.

FIGURE 14.2 Pressurization preventing smoke migration at a barrier.

based on the recommendations in NFPA 92A (1996). The maximum allowable pressure difference should be a value that does not result in excessive door-opening forces. The force that a particular person can exert to open a door depends on that person's strength, the location of the knob, the coefficient of friction between floor and shoe, and whether the door requires a push or a pull. Section 5-2.1.4.5 of the *Life Safety Code* (NFPA 1997b) states that the force required to open any door in a means of egress shall not exceed 30 lb (133 N). For this NFPA door opening force, the maximum allowable pressure differences are listed in Table 14.1.

The fire effect of buoyancy of "hot" smoke should be incorporated in the selection of the minimum design pressure difference. This can be done by using the suggested minimum design pressure differences from NFPA 92A (1996) that are listed in Table 14.2. Smoke control systems should be designed to maintain this minimum value under likely conditions of stack effect and wind and when there is no building fire (such as during acceptance and routine testing).

14.4 COMPUTER ANALYSIS OF PRESSURIZATION SYSTEMS

Many network computer programs have been developed that can calculate the airflows and pressure differences throughout a building in which a smoke control system is operating (Sander and Tamura 1973, Yoshida et al. 1979, Evers and Waterhouse 1978, Wakamatsu 1977). The program entitled *Analysis of Smoke Control System* (ASCOS) was specifically developed for analysis of smoke control systems (Klote and Milke 1992).

Possibly the most numerically vigorous, quick running, and easy to learn network program suitable for this application is the public-domain program CONTAM (Walton 1997). While the CONTAM program was initially developed for indoor air quality applications, it has been extensively used for smoke control design applications.

Although each network program has unique features and capabilities, they all have the same basic concepts. A building is represented by a network of spaces or nodes, each at a specific pressure and temperature. The stairwells and other shafts are modeled by a vertical series of spaces, one for each floor. Air flows through leakage paths from regions of high pressure to regions of low pressure. These leakage paths are doors and windows that may be opened or closed. Leakage can also occur through partitions, floors, and exterior walls and roofs. The airflow through a leakage path is a function of the pressure difference across the leakage path. Table 14.3 lists some typical leakage areas.

In network models, air from outside the building can be introduced by a pressurization system into any level of a shaft or even into other building spaces. This allows simulation of stairwell pressurization, elevator shaft pressurization, stairwell vestibule pressurization,

TABLE 14.1 Maximum Allowable Pressure Difference across Doors, in Inches of Water (Pascals)

Door closer force, lb (N)*	Door width, in. (m)				
	32 (.813)	36 (.914)	40 (1.02)	44 (1.12)	46 (1.17)
6 (26.7)	0.45 (112.)	0.40 (99.5)	0.37 (92.1)	0.34 (84.6)	0.31 (77.1)
8 (35.6)	0.41 (102.)	0.37 (92.1)	0.34 (84.5)	0.31 (77.1)	0.28 (69.7)
10 (44.5)	0.37 (92.1)	0.34 (84.5)	0.30 (74.6)	0.28 (69.7)	0.26 (64.7)
12 (53.4)	0.34 (84.5)	0.30 (74.6)	0.27 (67.2)	0.25 (62.2)	0.23 (57.2)
14 (62.3)	0.30 (74.6)	0.27 (67.2)	0.24 (59.7)	0.22 (45.7)	0.21 (52.2)

*Total door opening force is 30 lb (133 N), and the door height is 7 ft (2.13 m).

Source: Table adapted from NFPA 92A (1996).

and pressurization of any other building space. In addition, any building space can be exhausted. This allows analysis of zoned smoke control systems where the fire zone is exhausted and other zones are pressurized. The pressures throughout the building and steady flow rates through all the flow paths are obtained by solving the airflow network, including the driving forces such as wind, the pressurization system, and inside-to-outside temperature difference.

14.5 STAIRWELL PRESSURIZATION

Many pressurized stairwells are designed and built with the goal of providing a smoke-free escape route in the event of a building fire. A secondary objective is to provide a smoke-free staging area for firefighters. On the fire floor, the design objective is to maintain a pressure difference across a closed stairwell door to prevent smoke infiltration into the stairwell.

Stairwells usually are pressurized by a single dedicated fan, but more than one dedicated fan can be used. Also, a fan normally used for some other purpose can be used to pressurize a stairwell in a fire situation. Heating-ventilating-air conditioning (HVAC) system fans have been so used with modulating dampers controlled by differential pressure sensors. However, many smoke control designers feel that the same fans should not be used for both

TABLE 14.3 Typical Leakage Areas of Walls and Floors of Commercial Buildings

Construction element	Tightness	Area ratio ^a
Exterior building walls (includes construction cracks, cracks around windows and doors)	Tight ^b	0.7×10^{-4}
	Average ^b	0.21×10^{-3}
	Loose ^b	0.42×10^{-3}
	Very loose ^c	0.13×10^{-2}
Stairwell walls (includes construction cracks but not cracks around windows or doors)	Tight ^d	0.14×10^{-4}
	Average ^d	0.11×10^{-3}
	Loose ^d	0.35×10^{-3}
Elevator shaft walls (includes construction cracks but not cracks around doors)	Tight ^d	0.18×10^{-3}
	Average ^d	0.84×10^{-3}
	Loose ^d	0.18×10^{-2}
Floors (includes construction cracks and gaps around penetrations)	Tight ^e	0.66×10^{-5}
	Average ^f	0.52×10^{-4}
	Loose ^e	0.17×10^{-3}

^aFor a wall, the area ratio is the area of the leakage through the wall divided by the total wall area. For a floor, the area ratio is the area of the leakage through the floor divided by the total area of the floor.

^bValues based on measurements of Tamura and Shaw (1976a).

^cValues based on measurements of Tamura and Wilson (1966).

^eValues extrapolated from average floor tightness based on range of tightness of other construction elements.

^fValues based on measurements of Tamura and Shaw (1978).

the HVAC system and stairwell pressurization, because the dampers and controls needed only for the stairwell pressurization system may be damaged during HVAC system maintenance or modification. Accordingly, it is not surprising that most stairwell pressurization systems have dedicated fans.

Single Injection

A *single-injection system* is one that has pressurization air supplied to the stairwell at one location. A common injection point is near the bottom as illustrated in Fig. 14.3a. There is the potential for failure if some of the supply air can short-circuit the system by flowing directly out the opened doorway. For this reason, it is recommended that supply inlets be at least one floor above or below exterior doors.

The injection point can be at the top of the stairwell, but this has the potential for smoke feedback into the pressurized stairwell through the pressurization fan intake. Therefore, the capability of automatic shutdown in such an event should be considered.

For tall stairwells, single-injection systems can fail when a few doors near the air supply injection point are open. All the pressurization air can be lost through these open doors, and the system will then fail to maintain positive pressures across doors further from the injection point. To prevent this, some smoke control designers limit the height of single-injection stairwells to eight stories; however, other designers feel this limit can be extended to twelve stories. Network computer analysis is recommended for the design of single injection stairwells in excess of eight stories.

FIGURE 14.3 Single (a) and multiple (b) injection stairwell pressurization systems.

Multiple Injection

Figure 14.3b is an example of a multiple injection system that can be used to overcome the limitations of single-injection systems. In Fig. 14.3b, the supply duct is shown in a separate shaft. However, systems have been built that have eliminated the expense of a separate duct shaft by locating the supply duct in the stairwell itself. If the duct is located inside the stairwell, care must be taken to prevent the duct from becoming an obstruction to orderly building evacuation.

Many multiple-injection systems have been built with supply-air injection points on each floor. These represent the ultimate in preventing loss of pressurization air through a few open doors; however, that many injection points may not be necessary. There is some difference of opinion as to how far apart injection points can be safely located. Some designers feel that injection points should not be more than three floors apart, while others feel that a distance of eight stories is acceptable. For designs with injection points more than three stories apart, the designer should determine by network computer analysis that loss of pressurization air through a few open doors does not lead to loss of stairwell pressurization.

Open Doors

When a door opens in a stairwell pressurization system, the pressure differences across the closed doors can drop significantly. Opening the exterior stairwell door results in the largest pressure drop. This is because the airflow through the exterior doorway goes directly to the outside, while airflow through other open doorways must also go through other building paths to reach the outside. The increased flow resistance of the building means that less air flows through other doorways than flows through the open exterior doorway. The flow through the exterior doorway can be 3 to 10 times that through other doorways, and the relative flow through the exterior doorway is greatest for tightly constructed buildings. Thus the exterior stairwell door is the greatest cause of pressure fluctuations due to door opening and closing.

For densely populated buildings, it can be expected that many stairwell doors will be open during fire evacuation. Accordingly, stairwell pressurization systems in such buildings should be designed to operate with some number of open doors. This design number

of open doors depends heavily on the evacuation plan, and specific guidelines regarding this number would be beyond the scope of this chapter.

Four types of systems intended to maintain acceptable levels of pressurization with all doors closed and with some doors opened are discussed in this section:

- System with constant-supply-air rate and an exterior stairwell door that opens automatically on system activation (Canadian system)
- System with constant-supply-air rate and a barometric damper
- System with variable-supply-air rate
- System using stairwell pressurization in combination with either fire floor venting or fire floor exhaust

Further information about systems designs for open stairwell door is provided by Klote and Milke (1992).

14.6 ELEVATOR SMOKE CONTROL

Objectives of elevator smoke control systems can be to (1) prevent smoke flow through elevator shafts to floors remote from the fire or (2) provide a tenable environment in elevator cars, shafts, and lobbies intended to be used for fire evacuation. The idea that elevators should not be used in case of fire has become generally accepted. However, elevators are recognized as a second means of egress from towers by the *NFPA Life Safety Code* (1997b, Sec. 5-2.13), and there has been interest in the potential of using elevators for fire evacuation of people with mobility limitations. Information about elevator fire evacuation systems is provided by Klote and others (Klote 1995; Klote et al. 1992, 1994).

Network computer programs can be used for design analysis of elevator smoke control systems. The potential effects of open and closed doors on the pressurization systems should be considered. Additional information on these systems is provided by Klote and Milke (1992).

14.7 ZONED SMOKE CONTROL

A building can be divided into a number of smoke zones, each separated from the others by partitions and floors. In the event of a fire, pressure differences produced by mechanical fans are used to limit the smoke spread to the zone in which the fire initiated. The concentration of smoke in this zone goes unchecked. Accordingly, in zoned smoke control systems, it is intended that occupants evacuate the smoke zone as soon as possible after fire detection.

Frequently, each floor of a building is chosen to be a separate smoke control zone. However, a smoke control zone can consist of more than one floor, or a floor can consist of more than one smoke control zone. Some arrangements of smoke control zones are illustrated in Fig. 14.4. When a fire occurs, all the nonsmoke zones in the building, or only zones adjacent to the smoke zone, may be pressurized. When the fire floor is exhausted and only adjacent floors are pressurized, as in Fig. 14.4a, the system is sometimes called a “pressure sandwich.”

A zoned smoke control system can consist of equipment specifically dedicated to smoke control, but it is common to use the HVAC system for zoned smoke control. Network computer programs can be used for design analysis of these systems.

FIGURE 14.4 Some arrangements of smoke control zones.

14.8 ATRIUM SMOKE MANAGEMENT

The atrium building became commonplace in the late 1990s. Other large open spaces include enclosed shopping malls, arcades, sports arenas, exhibition halls, and airplane hangars. The methods described in this chapter also apply to these spaces. For simplicity, the term *atrium* is used here in a generic sense to mean any of these large spaces. The traditional approach to fire protection by compartmentation is not applicable to these large-volume spaces.

The ability of sprinklers to suppress fires in spaces with ceilings higher than 11 to 15 m (35 to 50 ft) is limited (Degenkolb 1975, 1983). Because the temperature of smoke decreases as it rises (due to entrainment of ambient air), smoke may not be hot enough to activate sprinklers mounted under the ceiling of an atrium. Even if such sprinklers activate, the delay can allow fire growth to an extent beyond the suppression ability of ordinary sprinklers. Some studies have been done concerning prediction of smoke movement and temperature in tall spaces (Notarianni and Davis 1993, Walton and Notarianni 1993). Considering the limitations of compartmentation and sprinklers for atriums, it is not surprising that the fire protection community is concerned about atrium smoke management.

Atrium Exhaust

Typically in an atrium fire, a smoke plume rises above the fire and forms a smoke layer under the ceiling. This smoke plume entrains air as it rises, so that the plume mass flow increases with elevation and the plume temperature decreases with elevation above the fire. Figure 14.5 shows an atrium exhaust fan maintaining a clear height below which building occupants can evacuate and the fire service can fight the fire.

For an atrium with a constant fire and negligible heat transfer to the atrium walls and ceiling, the exhaust flow rate can be approximated as

FIGURE 14.5 Atrium smoke management by smoke exhaust.

$$m = C_1 Q_c^{1/3} z^{5/3} + C_2 Q_c \quad (14.1)$$

where m = mass flow rate of atrium exhaust, kg/s (lb/s)

Q_c = convective heat release rate of fire, kW (Btu/s)

z = clear height above top of fuel, m (ft)

$C_1 = 0.071$ (0.022)

$C_2 = 0.0018$ (0.0042)

This equation applies for an atrium fire with an axisymmetric plume, and plumes that bend due to airflow or result from long thin fires would have different atrium exhaust rates. However, for most designs, systems based on an axisymmetric plume are adequate. The clear height is from the top of the fuel to the interface between the “clear” space and the smoke layer. Because a smoke management system generally must protect against a fire at any location, it is suggested that the top of the fuel be considered at the floor level to compensate.

Equation (14.1) is not applicable when the mean flame height of the fire is greater than the clear height. An approximate relationship for the mean flame height is

$$z_f = C_3 Q_c^{2/5} \quad (14.2)$$

where z_f is the mean flame height, m (ft) and $C_3 = 0.166$ (0.533).

The convective portion of the heat-release rate Q_c can be expressed as

$$Q_c = \xi Q \quad (14.3)$$

where Q is the total heat-release rate of the fire and ξ represents the convective fraction of heat release. The *convective fraction* depends on the material being burned, heat conduction through the fuel and the radiative heat transfer of the flames, but a value of 0.7 is often used for ξ . In the absence of better data or specific code requirements, suggested design fire sizes are listed in Table 14.4.

The temperature of the smoke being exhausted is

$$T_s = T_a + \frac{Q_c}{m C_p} \quad (14.4)$$

TABLE 14.4 Suggested Design Heat Release Rates Q for Fires* in Atria or Other Large-Volume Spaces

Atrium and contents	kW	Btu/s
1. Concrete, masonry, steel, iron, aluminum, water fountains, waterfalls, and other noncombustible materials.	2000	1,900
2. Noncombustible materials as in 1 above with 1 sofa and an upholstered chair or 3 upholstered chairs.	5,000	4,700
3. Noncombustible materials as in 1 above with 3 sofas or 6 upholstered chairs.	10,000	9,400

*These design fires include an allowance for the presence of additional short-term combustibles such as cardboard boxes, mattresses, painting supplies, and furniture. Such transient fuel loads have been significant contributors for many major fires.

where T_s = exhaust smoke temperature, °C (°F)

T_a = ambient temperature, °C (°F)

m = mass flow of exhaust smoke, kg/s (lb/s)

Q_c = convective heat release rate of fire, kW (Btu/s)

C_p = specific heat of plume gases, kJ/(kg·°C)[Btu/(lb·°F)]

The exhaust smoke plumes consist primarily of air mixed with the products of combustion, and the specific heat of this smoke is generally taken to be the same as air [$C_p = 1.00$ kJ/(kg·°C) [0.24 Btu/(lb·°F)]]. The exhaust mass flow equation [Eq. (14.1)] was based on strongly buoyant plume theory. For small temperature differences between the exhaust smoke and ambient, errors due to low buoyancy could be significant. This topic needs study, and, in the absence of better data, it is recommended that the plume equations not be used when this temperature difference is small [less than 2°C (4°F)].

The density of smoke gases can be calculated from the ideal-gas law:

$$\rho_s = \frac{p}{RT_s} \quad (14.5)$$

where ρ_s = density, kg/m³ (lb/ft³)

p = absolute pressure, Pa (lb/ft²)

R = gas constant, J/(kg·K) [(ft·lb)/(lb·°F)]

T_s = absolute temperature of the exhaust smoke, K (°F)

Volumetric flow is expressed as

$$V = \frac{C_4 m}{\rho_s} \quad (14.6)$$

where m = mass flow of exhaust air, kg/s (lb/s)

V = volumetric flow of exhaust gases, m³/s (cfm)

ρ_s = density of exhaust gases, kg/m³ (lb/ft³)

$C_4 = 1$ (60)

Figure 14.6 shows the exhaust rate needed to maintain a constant clear height. The major assumptions of the analysis plotted in Fig. 14.6 are

FIGURE 14.6 Atrium exhaust to maintain a constant clear height.

1. The plume has space to flow to the atrium top without obstructions.
2. The heat-release rate of the fire is constant.
3. The fire is located inside the atrium space.
4. The clear height is greater than the mean flame height.
5. The smoke layer is adiabatic.
6. The plume flow and the exhaust are the only significant mass flows into or out of the smoke layer. This means that outside airflow either as leakage or makeup air into the smoke layer is insignificant.
7. The leakage air and makeup air supplied to the atrium are sufficient so that the exhaust fan will be capable of operating as intended.

This approach is for a fire in the atrium space, because this is the space where there often is concern about the effectiveness of sprinklers. Atrium designs in North America seldom consider sprinklered fires in spaces with ceiling heights less than about 5 m (16 ft) a serious threat. When smoke from fires in spaces opening onto the atrium are an issue, the analysis needs to be extended to include a *balcony spill plume*. For example, smoke from a fire in a clothing store in a shopping mall could flow out the store doorway, past a balcony, and upward in the large mall space. For information about balcony spill plume, see NFPA 92B (1995) and CIBSE Guide E (1997). For a design where other assumptions are not appropriate, the analysis presented above should not be used, and a more detailed analysis such as scale modeling or computational fluid dynamics (CFD) may be appropriate.

Atrium Filling

For some very large spaces, atrium smoke filling can eliminate the need for atrium exhaust. This approach consists of allowing smoke to fill the atrium while occupants evacuate the atrium. The smoke layer needs to remain above the heads of the occupants throughout evacuation. This approach applies only to atria for which the smoke filling time is sufficient for

both decision making and evacuation. For information about people movement during evacuation, see Nelson and MacLennan (1995) and Pauls (1995).

The following experimental correlation of the accumulation of smoke in a space due to a steady fire can be approximated by

$$\frac{z}{H} = \frac{C_s - 0.28 \log_e t Q^{1/3} H^{4/3}}{A/H^2} \quad (14.7)$$

where z = height of the first indication of smoke above the fire, m (ft)

H = ceiling height above the fire, m (ft)

t = time, s

Q = heat release rate from steady fire, kW (Btu/s)

A = cross-sectional area of atrium, m² (ft²)

C_s = 1.11 (0.67)

This equation is conservative in that it estimates the height of the first indication of smoke above the fire rather than the smoke interface of the previous section. Equation (14.7) is based on a plume that has no contact with the walls. Because wall contact reduces entrainment of air, this condition is conservative.

Equation (14.7) is appropriate for A/H^2 from 0.9 to 14 and for values of z greater than or equal to 20 percent of H . A value of z/H greater than one means that the smoke layer under the ceiling has not yet begun to descend. For many applications, the results of Eq. (14.7) are outside the acceptable ranges of z/H and A/H^2 . Further, Eq. (14.7) is for a constant cross-sectional area with respect to height. Alternative approaches to this equation are zone fire computer models, scale models, and CFD. Scale models and CFD are discussed later, and zone fire models consist of treating the atrium or other fire room as if it were made up of two zones. An upper zone is the smoke layer, and a lower layer is the “clear” space. For more information about zone models readers are referred to Bukowski (1991) and Friedman (1992).

Natural Venting

For some applications, natural venting can be an economical and reliable alternative to fan-powered atrium exhaust. Extensive research on natural venting has been conducted in the United Kingdom. Considering the cost and reliability advantages, it is surprising that natural venting has had very limited use in North America. For further information about natural venting, including methods of calculation, see Hinkley (1995), CIBSE (1997), and NFPA 204 (1998).

Minimum Smoke Layer Depth

If the smoke layer is not deep enough, air from the clear height layer can flow with the smoke into the exhaust inlet or into the open vent. Mixing lower layer air into the vented or exhausted gases is called “plugholing.” This is of concern because it can result in reduced clear height. Based on research of Hinkley (1995), the minimum depth to prevent plugholing is

$$d = C_6 V_e^{2/5} \left(\frac{T_c + T_{\text{ref}}}{T_s - T_c} \right)^{1/5} \quad (14.8)$$

where d = minimum smoke depth to prevent plugholing, m (ft)

V_e = volumetric flow rate of vent or exhaust, m³/s (cfm)

T_c = temperature of clear height layer, °F

T_s = temperature of smoke layer, °F

$T_{\text{ref}} = 273$ (460)

$C_6 = 0.061$ (0.0935)

The minimum smoke layer depth d is taken from the top of the clear height to the exhaust inlet. In the absence of better information, it is recommended that d/D_e be greater than one, where D_e is the diameter of the exhaust inlet. For rectangular exhaust inlets, use $D = 2ab/(a+b)$, where a and b are the length and width of the inlet.

Stratification and Detection

Often a hot layer of air forms under the ceiling of an atrium as the result of solar radiation of the atrium roof. Although studies have not been made on this *prestratification* layer, building designers indicate that the temperatures of such layers are often in excess of 50°C (120°F). As already stated, the plume temperature decreases with elevation above the fire.

When the average plume temperature is less than that of the prestratification layer, smoke will form a stratified smoke layer under it as shown in Fig. 14.7. When there is a stratified smoke layer, smoke cannot be expected to reach the ceiling of the atrium, and ceiling-mounted smoke detectors cannot be expected to operate. It is recommended that beam detectors be located at a number of levels under the ceiling so that they can detect a stratified smoke layer. Atrium smoke management should be activated by a signal from one of these beam detectors or from a ceiling-mounted smoke detector.

14.9 SCALE MODELING

One option when the methods described above are inappropriate is fire testing in a reduced-scale model, and there is considerable experience with application of physical models to fire technology. Many approaches can be taken to the physical modeling of smoke

FIGURE 14.7 Prestratified layer of hot air prevents smoke from reaching the ceiling.

transport due to fires, including Froude modeling, pressure modeling, and analog modeling. *Froude modeling* preserves the Froude number. *Pressure modeling* is done in a pressure vessel to preserve both the Froude and Reynolds numbers. *Analog modeling* uses different fluids to simulate the buoyancy effects of hot gases (e.g., saltwater with freshwater).

Froude modeling is recognized by NFPA 92B. Accordingly, the discussion in this section is limited to Froude modeling. For further information about fire applications of physical modeling, readers are referred to Quintiere (1989), Heskestad (1972, 1975), Williams (1969), and Hottel (1961).

In Froude modeling, the Froude number is preserved and burns are done in the model with air at atmospheric pressure. The temperature is the same for the model and the full-scale facility. The Froude number can be thought of as the ratio of inertia forces to gravity forces, and it is important because buoyancy is a gravity force that dominates the flow resulting from fires. The Froude number Fr is

$$Fr = \frac{v^2}{gl} \quad (14.9)$$

where v = characteristic velocity
 l = characteristic length
 g = acceleration due to gravity

The scaling relations to convert conditions between the full-scale facility and the model are

$$\begin{aligned} x_m &= x_F \frac{l_m}{l_F} & T_m &= T_F \\ \Delta P_m &= \Delta P_F \frac{l_m}{l_F} & v_m &= v_F \left(\frac{l_m}{l_F} \right)^{1/2} \\ t_m &= t_F \left(\frac{l_m}{l_F} \right)^{1/2} & Q_m &= Q_F \left(\frac{l_m}{l_F} \right)^{5/2} & Q_{c,m} &= Q_{c,F} \left(\frac{l_m}{l_F} \right)^{5/2} & V_m &= V_F \left(\frac{l_m}{l_F} \right)^{5/2} \end{aligned} \quad (14.10)$$

where x = position
 l = length
 T = absolute temperature
 Δp = pressure difference
 t = time
 Q = heat-release rate
 V = volumetric flow rate

and the subscripts are

F = full-scale facility
 m = small-scale model
 c = convective

Froude modeling does not preserve the Reynolds number, but appropriate selection of the size of the scale model can assure that this does not have an adverse effect on the applicability of the modeling. In full-scale applications, the flow in malls, atria, shops, balconies, and corridors is fully developed turbulent flow. The basic characteristic of fully developed turbulent flow is the same over a wide range of Reynolds numbers. The flow at a specific

location in the scale model can have a Reynolds number very different from that at the corresponding location in the full-scale facility, but this does not impact the validity of Froude modeling, provided the flow in the model is fully developed turbulent flow. In Froude modeling, the specific areas of interest need to be determined, and the model needs to be sized such that the flow in these areas is fully developed turbulent. To achieve this, it is suggested that any areas of interest in the scale model be at about 0.3 m (1 ft) or larger.

Froude modeling does not preserve the dimensionless parameters concerning heat transfer, but this fact is mitigated because the temperature is the same for the scale model and the full-scale facility. Froude modeling does not apply to locations of high temperature and low Reynolds number such as the flame in many small-scale models. Thus, for a small fire in an atrium where the flame height is much less than the atrium height, Froude modeling would provide useful information about smoke transport away from the fire but not near the fire. While research has not been conducted to support the extent of applicability of Froude modeling to flames, it is suggested that it not be applied to any regions that are involved in flame.

Reynolds number and heat transfer are explicitly ignored in Froude modeling, but some surface effects can be partially preserved by scaling the thermal properties of the construction materials of which the model is made. The thermal properties can be scaled by

$$(k\rho c)_{w,m} = (k\rho c)_{w,F} \left(\frac{l_m}{l_F} \right)^{0.9} \quad (14.11)$$

where c = specific heat of enclosure materials

k = thermal conductivity of enclosure materials

ρ = density

and the subscripts are

F = full-scale facility

m = small-scale model

w = wall, ceiling, or floor of enclosure

It should be noted that exact scaling of thermal properties is not crucial to achieving useful simulations with Froude modeling. This scaling of thermal properties has only a secondary effect on fluid flow, and considerations of convenient construction and flow visualization may require that some or all surface materials in the model deviate considerably from the ideal values based on thermal property scaling. Further, heat transfer to floors frequently is much less than that to walls and ceilings, and so scaling of the thermal properties for floors is even less important.

14.10 CFD MODELING

Computational fluid dynamics (CFD) is a method of computer modeling that has the potential to produce fluid flow simulations at a level of detail impossible with other methods of computer modeling. Sometimes, CFD is called *field modeling*. Many computer CFD programs have been developed that are capable of simulation of fire-induced flows. Friedman (1992) discusses 10 such computer codes. Advancements in computer hardware and software continue to extend the range of applications for which CFD modeling is practical.

The CFD modeling consists of dividing the flow field into a collection of small cells, and determining the flow at each cell by solving numerically the governing equations of fluid dynamics. These conservation equations are expressed mathematically as a set of simultaneous, nonlinear partial-differential equations. Conditions at walls, floor, ceiling,

openings to the outside and exhaust inlets must be prescribed. These conditions, referred to as *boundary conditions*, are prescribed by assigning to them either a velocity or constraints concerning possible velocities that can be simulated. Flow can be either steady or unsteady.

Fire and smoke transport simulation by CFD modeling requires a high level of expertise, because of the variety and complexity of modeling approaches. A modeling approach includes the form of the governing equations, values of empirical constants, method of fire simulation, cell sizes, heat-transfer assumptions, and type of boundary conditions.

This breadth of modeling approaches makes generalizations about CFD fire applications difficult. The form of the governing equations needs to appropriately weigh the effects of elevated temperatures. Methods of simulating fires include heat generation within the cells and the *mixed-is-burned* model, which simulates gas flowing from a gas burner where combustion is considered complete when the gas is mixed with an appropriate quantity of air. Whatever CFD modeling approaches are used, the approach should be calibrated by performing simulations of full-scale fire experiments. For an introduction to the topic of CFD fire applications, see Klote (1994, App. G).

HUMAN RESPONSES

HUMAN RESPONSES

CHAPTER 15

THERMAL COMFORT CONCEPTS AND GUIDELINES

Alison G. Kwok, Ph.D.

*Department of Architecture
University of Oregon, Eugene*

15.1 INTRODUCTION

As living organisms, humans must be in thermal equilibrium with their environment in order to survive. Human thermal response, perceived as thermal comfort or discomfort, is shaped by four environmental parameters: air temperature, radiant temperature, relative humidity, and air speed; and two personal variables: the heat generated by human metabolic activity and the insulation value contributed by our clothing.

To understand the thermal environment and human response, several interpretations of the word *comfort* are contrasted with the current HVAC engineering definition, one that narrows the factors down to six variables and forms a thermal comfort standard that assumes comfort will be “supplied” within a narrow range of thermal conditions. The current comfort standards are based on the “static” model, in which humans respond only as passive monitors to the thermal environment. Traditional methods of evaluating comfort are reviewed and interpreted. Recent research suggests the formation of an “adaptive” model that views humans as active participants who modify their environments and behavior to achieve comfort.

Today, many people have come to understand and expect consistent and stable thermal qualities provided by mechanical systems. This has not always been the case. Prior to the establishment of a standard by the American Society of Heating and Ventilating Engineers (ASHVE) in 1938, the driving force behind the design of the indoor thermal environment was proper ventilation for health rather than thermal control for comfort. From the 1930s through the 1960s, after the widespread acceptance of air-conditioned buildings, research focused on defining optimum environments for thermal comfort. Various researchers proposed zones of comfortable temperatures for various climates: 21 to 27°C in the United States, 14 to 21°C in Britain, and 23 to 29°C in the tropics (Olgay 1992). Later scientists developed an effective temperature (ET) index that combines the effects of temperature, humidity, and air movement into one number. However, these comfort ranges do not have precise boundaries because of individual variation, age, gender, types of clothing, expectations, and influence from nonthermal factors.

The range of optimum temperatures prescribed by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) Standard 55: *Thermal Environmental Conditions for Human Occupancy* describes a zone of “thermal neutrality” that building occupants should find acceptable—the comfort zone. The term *thermal neutrality* refers to a single temperature derived from experimental data and forms the basis of the current steady-state or “static” model of comfort. It is assumed that humans maintain comfort simply through the balance of heat flow with their immediate environment. However, questions about this conventional model, such as differences in comfort perceptions that might be explained by factors beyond the physics and physiology of heat balance, gave rise to the “adaptive” model of comfort, where humans play an active role in creating their thermal experience (deDear 1994).

This chapter describes the principles and concepts of the human thermal response, the standards and guidelines followed by designers and practitioners, and the impact and implications of current models on the design of indoor thermal environments.

15.2 A DEFINITION OF THERMAL COMFORT

Before air-conditioning technology took hold, thermal well-being was not defined by the specialized word *comfort*. Several interpretations have been attributed to this word, beginning with its root in the Latin derivation of *confortare*, meaning to strengthen greatly. Most dictionaries (and online dictionaries) give several definitions. The first typically is that of assistance, as in “accused of giving aid and comfort to the enemy.” The second is that of consolation in a time of worry, “She was a great comfort to her grandmother in a time of grief.” The third definition describes comfort as contentment, such as a satisfying or enjoyable experience.

Eastern interpretations of comfort contrast with the Western definitions. In the East, humans are thought to achieve well-being through the body’s energy flow and the mind’s serenity (Chuen 1991). The word “comfortable,” or *shu shih* in Chinese, translates to being suitable to a situation. However, there is no East-to-West or vice versa translation for comfort in the thermal sense. Eastern thought seeks to establish inner harmony and balance, often under difficult or adversarial conditions. Those cultivated in the martial arts, such as *tai chi* or *chi kung*, are able to move the body’s energy flow, not only for serenity of mind, but for healing processes and well-being—e.g., acupuncture used to remedy a patient’s malady or as anesthesia for major surgery. In design, the *feng shui* concept offers balance and harmony to believers. Although most design practitioners consider these concepts alternative practices, a better understanding of cultural perceptions of our environment might play an important role in the success of environmental technologies and control.

In *Home*, Rybczynski traces the origins of comfort by examining the evolution of social and cultural factors that shape the experience of comfort in the home and our connections to nostalgic notions. Where traditions eliciting reminders or imaginative ideas of the comfort experience do not exist, many designers, such as Ralph Lauren, make their living creating interiors fashioned to “evoke atmospheres of traditional hominess and solid domesticity that is associated with the past” (Rybczynski 1986).

Comfort now has many layers of meaning, making a precise definition difficult and perhaps unnecessary. In his “Onion Theory of Comfort,” Rybczynski describes comfort as the composite of all the layers, not just the most recent:

It may be enough to realize that domestic comfort involves a range of attributes—convenience, efficiency, leisure, ease, pleasure, domesticity, intimacy, and privacy—all of which

contribute to the experience; common sense will do the rest...recognition [of comfort] involves a combination of sensations—many of them subconscious—and not only physical, but also emotional as well as intellectual, which makes comfort difficult to explain and impossible to measure.

Arguing for environments with physical variations rather than static conditions, Heschong (1979) describes comfort as a relationship between thermal contentment and human imagination. Presenting an example of how we as humans are capable of recognizing, remembering, and adapting ourselves to most thermal experiences, Heschong writes:

There is a basic difference, however, between our thermal sense and all of our other senses. When our thermal sensors tell us an object is cold, that object is already making us colder. If, on the other hand, I look at a red object it won't make me grow redder, nor will touching a bumpy object make me bumpy. Thermal information is never neutral; it always reflects what is directly happening to the body...Our nervous system is much more attuned to noticing change in the environment than to noticing steady states.

Comfort plays on our memory and expectations, and is defined by the thermal associations connected to a place or an object. Heschong continues by reasoning about our need to identify with something that accounts for our state of well-being and lamenting the loss of thermal delight in buildings:

On a lovely spring day we may identify the season itself with our wonderful sense of well-being, as has been done in hundreds of songs about the joys of spring. On a tropical isle that has an ever-perfect combination of balmy breezes, warming sunshine, and shady palms, we would probably come to love the island for providing us with such a fortuitous setting. But in a typical office building, to what can we attribute the all-pervasive comfort of 70°F, 50 percent relative humidity? The air diffuser hidden in the hung ceiling panels?...The engineer who designed the system long ago? The whole vast building itself? Most likely, we simply take it all for granted. When thermal comfort is a constant condition, constant in both space and time, it becomes so abstract that it loses its potential to focus affection.

McIntyre (1980) discusses the need for sensory and physical stimulation and makes a case for fluctuating interior temperatures to “counteract ‘thermal boredom’...It can be argued that achieving a steady optimum temperature is akin to finding the most popular meal at the canteen and then serving it every day.”

Recognizing the difficulty of engineering steady-state conditions for the wide range of human activities, Fitch (1972) raises the notion that humans might subconsciously have a need for thermal variation. He uses the example of a typist performing the same task all day, who might require a different thermal environment at 3 P.M. than at the beginning of the day. Environmental control must accommodate these needs within what Fitch terms the “golden zone” of thermal balance. Environmental controls and mechanical systems have the potential to provide comfort and efficiency for the range of human activities and endeavors. In practice, this is a challenging task, for we are not merely thermodynamic meters, but rather beings with variable needs “tailored to our own psychic and somatic requirements” (Fitch 1972).

We face a paradox of sorts. We expect and often enjoy the stable, constant temperatures and conditions provided by mechanical systems. In certain circumstances conditioning of indoor air is essential to the functioning of particular industries and for the well-being of building occupants. On the other hand, many of these systems are not maintained properly, use unnecessary amounts of energy, and provide occupants with less than desirable conditions.

15.3 HEAT TRANSFER MECHANISMS

For basic survival, humans must maintain homeostasis, or a balance of heat exchange between the body and the environment. An internal body temperature of 37°C is maintained when conditions allow the human body to achieve heat balance with the environment. Humans gain energy from their metabolism and often from the surrounding environment. At the same time we lose energy through convection, radiation, evaporation, and conduction. Unlike cold-blooded reptiles, humans cannot tolerate a wide range of body core temperatures, so over a relatively short period of time heat gains must balance heat losses.

The basic heat balance equation for the human body expresses these gains and losses as the various exchanges that occur between the body and the ambient environment. The equation is expressed by:

$$M - W = E + R + C + K + S \quad (15.1)$$

where M = energy gained from metabolism

W = work accomplished

E = evaporative exchange

R = radiant exchange

C = convective exchange

K = conductive exchange

S = heat energy stored (for heat balance, $S = 0$)

The units of each energy exchange listed above are expressed as rates of heat production or loss over time, e.g., watts (W) per second. Heat losses or gains are calculated for a “standardized” person by using watts per square meter of total body surface area and expressed as units of W/m² (Parsons 1993).

Failure to achieve a balanced heat flow will cause the body temperature to rise if the heat input variables and metabolism are greater than the heat outputs; conversely body temperature will fall if the heat losses were greater than the gains.

15.4 BASIC PARAMETERS

Air temperature, radiant temperature, air speed, and relative humidity are four physical parameters that define the thermal environment and can all be measured directly or calculated from other measurements. Two nonenvironmental parameters, clothing and metabolism, are key personal variables.

Air temperature (dry bulb) is often measured directly by liquid-in-glass thermometers, thermocouples, or resistance temperature devices. Dry bulb temperature can be later used in combination with globe temperature (Fig. 15.1) and air velocity to calculate mean radiant temperature. With respect to the human body, *mean radiant temperature* is defined as the uniform temperature of an imaginary enclosure in which radiant transfer from the human body would equal the radiant heat transfer in the actual nonuniform enclosure (ASHRAE 1997). *Operative temperature* can be calculated from the average of the dry bulb temperature and the mean radiant temperature. Temperature affects comfort in a number of ways and, in combination with the other parameters described in this section, is a key factor in our energy balance, thermal sensation, comfort, discomfort, and perception of air quality.

FIGURE 15.1 Globe thermometer. The sphere contains a thermocouple and measures the heat transferred by convection, conduction and radiation of the surrounding walls and surfaces.

Air speeds are typically measured by omnidirectional anemometer, since air movement may unexpectedly change direction, which would yield inaccurate readings. In mechanically conditioned environments, air velocities are usually fairly low, 0 to 0.5 m/s. Higher and/or fluctuating velocities might cause discomfort because of draft sensations particularly around the neck area of the body. Occupants in naturally ventilated buildings may tolerate air velocities above 0.5 m/s as a means of convective cooling.

Relative humidity affects the evaporation of water from the skin, altering skin temperatures and affecting the body's heat balance. The evolution of the ASHRAE Standard 55 comfort zone shows fairly well-defined temperature boundaries. Humidity limits are less certain in terms of comfort and health and the upper humidity limit of the comfort zone still remains under consideration. Perceptions of humidity and sensitivity to skin moisture are thought to be a function of dew point (a measure of absolute humidity) rather than ambient temperature (Berglund 1989). A variety of psychrometric sensors and hygrometers can measure the moisture content of air.

The *metabolic rate* related to work done during various physical activities (e.g., general office activities, sports, various occupational activities, etc.) will influence comfort. Heat from metabolic activity is expressed in W/m^2 or MET, a unit based on the amount of heat produced by a sedentary average-sized adult (1.8 m^2 of surface area); $1 \text{ MET} = 58.2 \text{ W/m}^2$. Other metabolic rates generated by various activities include: reading 1.0, sitting/typing 1.2, dancing 3.0, cycling or tennis 4.0, going up stairs 6.0 (ASHRAE 1997). Measuring metabolic rate may involve physiological measurements of oxygen consumption, carbon dioxide production, and heart rate, but often comfort researchers ask subjects to self-report activity on questionnaires.

For the most part, human beings dress for comfort. On this premise, one consideration for *clothing* selection is the insulation or permeability provided. The amount of moisture on the skin and the fabric coarseness contribute to the insulation value of clothing and thus to comfort acceptability or dissatisfaction, particularly in humid climates (Berglund 1998). Clothing insulation values are expressed in CLO units, where $1 \text{ CLO} = 0.155 \text{ m}^2 \cdot \text{K/W}$, equivalent to a business suit ensemble. Examples of other garment CLO values include: trousers 0.24, skirt 0.14, short sleeve dress shirt 0.19, sweater 0.25 (ASHRAE 1997).

The interactions of air temperature, moisture content of the air, and heat transfer mechanisms are known as psychrometric processes, and they can be illustrated on a single psychrometric chart. Psychrometrics can explain the various mechanisms of sensible and latent heat exchanges that are fundamentally part of the heat balance equation for skin temperature

and skin moistness. Sensible heat transfer involves radiation, conduction, and convection mechanisms that heat up the temperature of the air. Latent heat involves the energy contained when moisture increases in the air.

15.5 PHYSIOLOGICAL BASIS FOR COMFORT

Maintaining heat balance in the human body involves both voluntary and involuntary physiological mechanisms controlled by effectors and receptors linked by the body's central nervous system. For example, core temperature receptors are located in the hypothalamus in the brain. Effectors are systems representing the body's response to the ambient environment and help to expel or retain heat.

Sweating occurs when the body needs to get rid of excess heat. Sweat, a watery secretion produced by special glands (eccrine) in the skin, wets the skin to allow cooling by evaporation.

Piloerection, commonly called "goosebumps" or "hairs standing on end," occurs when the skin surface becomes cold and attempts to reduce heat loss by trapping a still layer of air between the body and the environment. Since humans have little hair and are clothed, this reaction might not contribute much to thermoregulation, although Parsons (1993) describes the contributory effect of piloerection to clothing insulation under certain circumstances.

Normal metabolism generates heat. However, when the need for heat to maintain balance increases, the nervous system sends signals to the body to increase activity, muscles contract, and the body stiffens. If the body requires more heat, *shivering* begins, which can increase metabolic heat production by 5 times the nonshivering level for short periods.

In many parts of the body, blood is warmed or cooled by circulating through the core or near the skin surface. Blood is diverted to the deeper tissues to conserve heat and to superficial skin layers to lose heat. *Vasodilation* opens the vessels near the skin to increase heat loss to the environment by bringing warmer blood close to the skin. *Vasoconstriction* reduces heat loss by constricting flow to those vessels located in the superficial layers.

15.6 PSYCHOLOGICAL BASIS FOR COMFORT

The thermal environment has a great influence on human behavior, productivity, satisfaction, and well-being. The consequences of humans being unable to maintain heat balance with their environment or expressing dissatisfaction with the conditions of the work environment have led to a great deal of research in matching the six basic parameters (physical and personal) with psychological responses. Engineers have established a range of specified values for HVAC-controlled environments. If building environments stay within the comfort zone, comfort and satisfaction are presumed. "Thermal comfort is that condition of the mind that expresses satisfaction with the thermal environment" (ASHRAE 1992). How do we establish an accurate relationship between physiological responses and the condition of the mind? The most commonly used correlation of comfort is thermal sensation. Thermal sensation is the conscious perception of the body's effort to regulate body temperature. In other words, skin and internal temperatures, skin moisture, and physiological processes all contribute to sensation and our state of satisfaction (Berglund 1997). Since it is not possible to define sensation in physical terms, most researchers use a numeric scale that corresponds to the seven categories of the ASHRAE thermal sensation scale (see Table 15.1).

Comfort is assumed to occur in the "neutral" region of -1 (slightly cool), 0 (neutral),

TABLE 15.1 Rating Scales Commonly Used in Thermal Comfort Research

Scale			Response*				
ASHRAE	−3 Cold	−2 Cool	−1 Slightly cool	0 Neutral	+1 Slightly warm	+2 Warm	+3 Hot
Bedford	Much too cool	Too cool	Comfortably cool	Neither warm nor cool	Comfortably warm	Too warm	Much too warm
Acceptability	Unacceptable		Acceptable			Unacceptable	
Preference (McIntyre)	Want warmer		No change			Want cooler	
General Comfort	Very uncomfortable	Moderately uncomfortable	Slightly uncomfortable	Slightly comfortable	Moderately comfortable	Very comfortable	

*Boxed areas correspond to assumed comfortable perceptions.

to +1 (slightly warm) on the ASHRAE scale. By inference, this is also the area of optimum temperature and maximum acceptability. Other scales used to correlate perceptions of comfort and the physical environment are the Bedford scale (1936) (not commonly used, since it is found to be semantically similar to the thermal sensation scale); McIntyre's (1980) thermal preference scale (want cooler, warmer, no change); thermal acceptability (acceptable, not acceptable); and a six-point general comfort scale (very comfortable to very uncomfortable). Fanger's (1970) method for evaluating thermal environments uses a predicted mean vote (PMV) on the seven-point thermal sensation scale. PMV forms the basis for the ISO 7730 Standard discussed in a later section and can be used to predict comfort via calculation from environmental indices.

Although all these scales and measures can be used to determine acceptability of the thermal environment, the traditional and most commonly used method is the one that equates satisfaction (or acceptability) with the central three categories of the ASHRAE seven-point thermal sensation scale. Under this prescription, Brager et al. (1994) outlined several methods to determine compliance with the 80 percent satisfaction criteria of Standard 55:

1. Ask *directly* by surveying the occupants: "Do you find this environment thermally acceptable?" Determine whether a minimum of 80 percent answered yes.
2. Use thermal sensation scale responses to determine if a minimum of 80 percent of the votes are within the central three categories of a thermal sensation scale (slightly cool, neutral, slightly warm).
3. Compare the extent to which the interior environment meets the specifications of the Standard 55 comfort zone. A base assumption is that for space conditions within the comfort zone, at least 80 percent of the occupants will find the conditions acceptable.
4. Use other scales as indirect measures (e.g., preference, general comfort) and determine whether a minimum of 80 percent of the votes fall into their respective definitions of acceptability.

Using these four methods Kwok (1997) corroborated Brager's approaches and found widely differing results in a study comparing thermal comfort responses from occupants in naturally ventilated and air-conditioned classrooms. For example, if asked directly (method

1 above), regardless of the room being naturally ventilated or air-conditioned, at least 80 percent of the occupants found conditions acceptable. Furthermore, classrooms with conditions well outside of the ASHRAE comfort zone produced the same high acceptability responses as those within the comfort zone. With method 2, where it is assumed that 80 percent of the votes fall within the central three categories of thermal sensation, acceptability fell below the 80 percent criterion.

Thermal preference in combination with direct acceptability might give a more accurate indication of the conditions people really want. Subjects are asked to indicate whether they would prefer warmer, cooler, or no change relative to their current environmental conditions. Studies in the tropics comparing simultaneous votes of thermal sensation and preference scales suggest that neutral thermal sensations are not always the ideal, or preferred, thermal state for people. Kwok (1997) found that in naturally ventilated buildings, 62 percent of the people voting within the three central categories of thermal sensation wanted to feel cooler. The results suggest that neutral thermal sensations do not necessarily correlate with people's ideal or preferred thermal state and that standards based on a goal of neutrality may be inappropriate.

15.7 STANDARDS AND GUIDELINES

Ideal conditions for thermal comfort have been a subject of debate and controversy during the last century. Over time these boundaries for comfort have evolved by taking into account clothing differences between the winter and summer seasons, humidity limits, air movement related to draft discomfort, skin moisture, and related perceptions of health and indoor air quality.

In 1924, the American Society of Heating and Ventilating Engineers (ASHVE) developed the first thermal comfort standards. Based on laboratory studies of unclothed subjects seated in front of a fan, the boundaries of comfort were set at temperatures between 19.4°C (66.9°F) and 24.4°C (75.9°F) at 50 percent relative humidity and depicted on a comfort chart (Brager et al. 1994).

In 1966, ASHRAE Standard 55-1966, Thermal Conditions for Human Occupancy, replaced the 1938 Code of Minimum Requirements for Comfort Air-Conditioning and formally defined thermal comfort as: "The condition of mind that expresses satisfaction with the thermal environment." The condition of mind is determined by a subjective assessment of the acceptability of the environment. Data from laboratory studies set the 1966 comfort zone boundary limits at 22.7 to 25.0°C ambient temperature, 20 to 60 percent relative humidity, and 0.05 to 0.29 m/s air velocity.

The upper boundary of the Standard 55 comfort zone is not clearly defined, as seen in the history of changes from Standard 55-1981, to Standard 55-1992, and finally to Standard 55-1994. In 1981, after research recognized seasonal variations in clothing, Standard 55 showed two comfort zones, one for winter and one for summer. The winter comfort zone temperatures ranged from 20.0 to 23.5°C, to account for people wearing more layers of winter clothing. During the summer slightly higher temperatures ranging 22.5 to 26.0°C, account for people wearing lighter-weight clothing. The upper boundary of the comfort zone for humidity was described in terms of dew point not to exceed 16.7°C. This boundary was explicitly driven by health concerns, with the Standard stating that "...upper and lower dew point limits are based on considerations of comfort, respiratory health, mold growth and other moisture related phenomena" (ASHRAE 1981). Air movement limits were set at 0.15 m/s for the winter, increasing to 0.25 m/s during summertime conditions.

The limits of Standard 55-1992 changed slightly from the 1981 Standard to allow air movement greater than 0.15 m/s in either season, but only if the occupant could control the

source of the air movement. Humidity boundaries kept the lower dew point limit, but changed the upper limit to follow the 60 percent relative humidity line of the psychrometric chart. Again, the change to the humidity boundary was driven primarily by considerations of respiratory health related to mold growth at high humidity levels. The limit, however, was not directly related to thermal comfort and was too restrictive for the conditions provided by evaporative coolers (Berglund 1998).

An addendum to Standard 55-1992 (referred to by ASHRAE as Standard 55a), again outlined modifications to the upper humidity limit. The boundary changed from a 60 percent humidity line to follow the 18°C wet bulb line during the winter and 20°C line during the summer. The key difference is the boundary is no longer tied to nonthermal environmental factors such as microbial growth and respiratory health. Standard 55's current basis is solely "comfort considerations including thermal sensation, skin wettedness, skin dryness and eye irritation" (ASHRAE 1992). This point is critical to discussions about naturally ventilated environments, which often have hot and humid physical conditions that exceed the humidity limit of the Standard 55 comfort zone.

Parsons (1998) provides an overview of current standards and guidelines used internationally by building professionals to assess thermal environments. The International Organization for Standardization (ISO) is primarily concerned with the ergonomics of the thermal environment such as lighting, visual performance, noise and communication, and the combined effects of environmental variables. ISO standards in the area of thermal comfort divide the topic into three categories: hot, cold, and moderate environments.

ISO 7730, Moderate Thermal Environments (ISO 1994) assesses thermal comfort using an index based on the predicted mean vote (PMV) and the predicted percentage dissatisfied (PPD) developed by Fanger (1970). The vote, or thermal comfort prediction, is the average vote (correlated to the seven-point thermal sensation scale) of a large, hypothetical group of subjects. PPD is the percentage of a hypothetical sample population who will be dissatisfied (uncomfortable) in a given environment. With inputs of air temperature, mean radiant temperature, relative humidity, air velocity, and estimates of subject metabolic rate and clothing insulation, computer programs can quickly provide calculations of PMV/PPD.

The two primary standards dealing with building design, ISO 7730 and ASHRAE 55, are roughly synonymous in their definition of thermal comfort, the environmental parameters measured, and the assumption of comfort lying within the central three categories of the thermal sensation scale. The PMV/PPD relationship of ISO 7730 however, represents only an overall thermal response. The 80 percent acceptability criterion of ASHRAE Standard 55 describes the 20 percent range of dissatisfaction as evenly split between general discomfort and local discomfort. Although the PMV/PPD index predicts comfort on the seven-point thermal sensation scale, it also recommends that PPD be lower than 10 percent. Because the PMV/PPD relationship was developed in the laboratory, asymmetrical environmental conditions that might have caused local discomfort were controlled, minimized, or eliminated, and the relationship represents only the general response. For example, when people are asked to vote using the thermal sensation scale in the field, the thermal sensation they are experiencing is a combination of the general and local effects they encounter. Their votes are not likely to distinguish between the two. Therefore field thermal sensation votes combine both general and local discomfort, whereas PMV (using ambient measurements as inputs) predicts only general thermal response.

15.8 CURRENT MODELS

Defining comfort in terms of the ISO or ASHRAE standards, prescriptions, and methodology has produced a debate between two approaches or models of comfort: the "static" and

“adaptive” models. The two approaches not only use different algorithms for calculating comfort zone prescriptions but have contrasting assumptions about the way buildings are designed and how environments are controlled. Ultimately, the models differ in their potential for encouraging energy conservation in buildings.

The rationale of the static model (ISO, ASHRAE) is based on various heat balance models, where a person is a passive recipient of thermal stimuli and the effects of a given thermal environment are mediated exclusively by the physics of heat transfer (de Dear et al. 1997). These assumptions imply that sensations of subjective discomfort are exclusively formulated by the magnitude of response to the thermal environment, such as shivering or sweating. Heat balance models such as PMV, ET*, and SET* take into account only the four environmental variables (air and radiant temperatures, humidity, and air velocity) and two personal variables (clothing and metabolic heat production) and exclude the influence of adaptive behaviors to the indoor climate by the occupant (Fanger 1970). Both ASHRAE 55 and ISO 7730 use the static model with data from laboratory experiments conducted in climate-controlled chambers as a basis for formulating their comfort criteria. Hence, these standards use laboratory-derived models to determine subjective responses to thermal conditions in actual buildings.

Looking at climate in addition to thermoregulatory responses, the adaptive model approach considers a range of responses (behavioral, physiological, and psychological adjustments) building occupants might undertake to achieve thermal comfort. The adaptive approach has a conceptually different basis than just heat exchange between humans and the environment. Nicol (1993) discusses the range of actions (see section below) that we may choose in order to achieve thermal comfort. These actions, or behaviors, in turn may modify internal heat generation or the rate of heat loss from the body, modify the surrounding thermal environment, or involve moving to a different environment.

At a website describing a current ASHRAE-sponsored research project, RP-884, on the adaptive model of thermal comfort, de Dear (1996) explains how our expectations of indoor thermal environments can influence our perceptions of comfort. Several behavioral and psychological processes provide the conceptual basis of the adaptive model. These adjustments, reactions, or responses performed by building occupants are often assigned to three categories of adaptation:

1. *Behavioral adaptation.* The manipulation or adjustment of clothing, body movement, or objects in one’s immediate surroundings to create a more satisfactory state of heat balance for the body. Examples include adding or removing clothing, changing posture, opening or closing windows, adjusting thermostats, using fans, blocking or redirecting air from diffusers, or changing the blinds to block undesirable solar radiation.
2. *Physiological adaptation.* The body’s acclimatization to long-term exposure to thermally stressful environments (hot or cold). Physiological adaptations are changes in the internal settings at which thermoregulatory responses occur. Such physiological responses include vasodilation, vasoconstriction, shivering, and sweating.
3. *Psychological adaptation.* Psychological responses are a complex combination of factors outside the realm of the relationships between the six traditional variables that shape our awareness of the thermal environment. Thermal perceptions may be directly and significantly attenuated by one’s past thermal experiences and expectations of what buildings offer technologically in terms of HVAC systems and architectural design.

Using a schematic diagram developed by Auliciems (see Fig. 15.2), de Dear (1994) describes the processes of the adaptive model. Occupant satisfaction with indoor climate is based upon the experiences and the expectations that the occupant has had with similar buildings or spaces. Thermal history and expectation might then elicit behaviors that assist an individual in making adjustments toward thermal comfort. In reviews of recent thermal

FIGURE 15.2 Adaptive model of thermal comfort. [From (Auliciems 1989), modified by de Dear (1996). (Reprinted with permission from R. A. de Dear, Macquarie University, 1996.)]

comfort studies, de Dear also distinguishes between the responses from naturally ventilated and air-conditioned settings when looking at thermal neutralities.

Figure 15.3 shows the relationship between the ASHRAE recommended and indoor temperatures. It also illustrates the potential of using the adaptive model. Less stringent limits on interior temperatures would allow more latitude for indoor temperature settings, ultimately reducing energy consumption and operational costs in buildings reducing associated greenhouse gas emissions, lowering peak demand for electricity, and reducing the size of cooling plants. The adaptive model would find success when optimum temperatures predicted by the model closely match the temperatures nominated by the building occupants themselves.

Previous reviews by Auliciems (1989) and Humphreys (1976) of thermal comfort studies conducted in various climate zones around the world indicate that indoor comfort temperatures are linked to the prevailing outdoor conditions. In ASHRAE RP-884, de Dear, Brager and Cooper (1994) compiled a database from recent field experiments (including more than 20,000 respondents) and categorized them into three “classes” of experiments depending on the methodology and instrumentation used. This quality control allows data from a variety of building types and climates across the world to be compared in terms of thermal sensation, preference, and acceptability, and between naturally ventilated and air-conditioned buildings.

FIGURE 15.3 The adaptive model concept. (Reprinted with permission from R. A. de Dear, Macquarie University, 1996.)

The results of RP-884 set forth by de Dear, Brager, and Cooper (1997) and other recent developments in thermal comfort research have led to proposals for an “adaptive” model where behavioral responses to optimize comfort (e.g., clothing modification, body posture) are taken into account. Such models may also support a variable temperature standard for buildings with HVAC systems and a separate standard for naturally ventilated buildings that recognize the inherent design differences between the two environments.

CHAPTER 16

THERMAL EFFECTS ON PERFORMANCE

David P. Wyon, Ph.D.

*Johnson Controls Inc.
Plymouth, Michigan*

16.1 INTRODUCTION

The thermal environment in buildings where people work is usually measured and described by HVAC engineers in terms of the physical outcome variables of the systems they install and run, i.e., the indoor air temperature, radiant temperature, relative humidity, and air velocity. From their point of view, the HVAC system has done a good job if these values stay within specified ranges. The “engineering perspective” is thus from inside the HVAC system looking out, and what engineers term “air outlets” are what the rest of us call air inlets, as they let air into that part of the building where we spend our time (as opposed to those parts of the building where the engineers spend their time). In fact, the physical outcome metrics simply describe one point in a process whose goal is our safety, health, comfort, and performance. Our productivity must be able to pay all the costs associated with the building—the capital cost, maintenance, cleaning, ventilation and air conditioning, energy—as well as our own wages and benefits. Sickness absence and substandard performance reduce our productivity. Cost-benefit calculations for investment in indoor environmental quality must compare the cost per year per unit of floor area of a proposed improvement with the benefit, expressed in the same way, of the reduced sickness absence and the improved individual performance that is supposed to result from it. Thermal environmental effects on these outcomes at the level of the individual are described in this chapter, while thermal and air quality effects on health and productivity outcomes at the national economic level are described in Chap. 4 by William Fisk.

The process that ends with these outcomes begins with the transformation of the outdoor climate, by means of the thermal characteristics of the building itself and the operation of the installed HVAC systems, into an indoor climate that is supposed to be suitable for the human activities that take place indoors. This transformation and its immediate outcome are usually described in terms of four parameters—air temperature, radiant temperature, relative humidity of the air, and air movement—parameters that adequately describe the resulting indoor climate in the volumes reserved for human occupancy. These are engineering and architectural matters and are described in other sections of this handbook. The process continues with the transformation of room climate into a physiological effect on the body. The resulting thermal state of the body is usually described in terms of skin temperatures, central body temperature, sweat rate, and skin wettedness. Detailed knowledge of the insulation and the vapor diffusion resistance of clothing, and of the metabolic rate associated with each human activity, is necessary at this stage. These matters are described in Chap. 15, on thermal comfort, by Alison Kwok. The present chapter deals with how thermal effects on performance and productivity arise in the final stages of the process by which energy is used to transform the thermal climate for human purposes.

16.2 THE MECHANISMS THAT CAUSE THERMAL EFFECTS

Thermal discomfort distracts people from their work, and it causes complaints, which generate unscheduled maintenance costs. Many HVAC engineers take the cynical view that there will always be complaints, whatever they do. Recent analysis of complaint logs shows that this is not so: Federspiel (1998) demonstrated that if office temperatures had always been in the 70 to 75°F range (21 to 24°C), 70 percent of “hot and cold call-outs” would not have occurred, which would have reduced maintenance costs by an estimated 20 percent. This cost reduction represents an increase in productivity in itself, which is in addition to the undoubted productivity benefit of reducing thermal discomfort. People who feel uncomfortable lose their motivation to work and tend to take more breaks. Both of these effects reduce productivity. Many of the symptoms characteristic of sick building syndrome (SBS) become more intense and affect a larger proportion of building occupants as air temperatures rise in the 21 to 24°C range (Krogstad et al. 1991). People who do not feel very well do not work very well (Nunes et al. 1993), so SBS will reduce productivity. The sick building syndrome often includes a feeling of dryness and eye irritation. Raised temperatures and air velocities and the low indoor humidity levels characteristic of winter increase evaporation from the eye surface. This makes the eye more sensitive to airborne particulates and other forms of air pollution. Although blink rate usually increases in an attempt to counter reduced tear-film stability, irritation, soreness, observable redness, and chronic eye ache may still result (Franck 1986, Wyon and Wyon 1987, Wyon 1992). Eye discomfort, like thermal discomfort, is distracting: subjects under conditions causing increased eye discomfort are less likely to notice unprepared signals to which they ought to respond—they become less vigilant (Wyon et al. 1995). Cold conditions indoors have no negative effects on the eye, but they do cause vasoconstriction and this reduces skin temperatures. Fingertip sensitivity and the speed of finger movements are below maximum even at thermal neutrality, and other aspects of manual dexterity that can be important for productivity are progressively reduced at temperatures below neutrality—first hand-eye coordination, then muscular strength, as skin temperatures decrease in response either to lower temperatures or prolonged exposure (Meese et al. 1982). These effects can increase the risk of some types of accident (Vernon 1936, Wyon 1993). Uncomfortably warm conditions cause people to exert less effort in an attempt to reduce

their metabolic heat production and avoid sweating. This tends to reduce their level of mental arousal, and they become drowsy, which can increase the risk of other types of accident (Vernon 1936, Wyon 1993). Accidents cause lost time, which together with the direct cost of accidents leads to reduced productivity.

Inferred environmental effects on the level of general mental arousal are often invoked to make sense of observed environmental effects on behavior. Provins (1966) was the first to make a good case for the hypothesis that thermal effects on arousal are the mechanism by which moderate thermal stress indoors can produce such surprisingly large effects on mental performance. The following theoretical discussion is based on Provins' paper but relies also on insights provided by much subsequent research in this area that is reviewed in detail in "Thermal Effects on Mental Performance" below. In the interests of first providing a comprehensive and simplified account that combines all the available evidence and linking it to what engineers and architects need to know in designing workplaces, the arousal theory that is set out in the next three paragraphs occasionally goes a little beyond what can strictly be held to have been proved at this time.

Mental arousal is linked to breadth of attention. The attentional field is narrow at high levels of arousal, broad at low levels. Different tasks require different kinds of attention. Some tasks require concentration, and these are best performed under conditions that permit and encourage a high level of mental arousal. Other tasks require a broad field of attention, and are best performed under conditions that permit and encourage a lower level of mental arousal. For every task, there is an optimal level of arousal. Performance will be reduced both above and below this level. Different tasks have different optimal levels of arousal. Rule-based logical thinking, as required for mathematics and writing computer code, has a high optimal level of arousal. Memory and creative thinking have low optimal levels of arousal. Thermal conditions affect arousal, so different thermal conditions are appropriate for different tasks. Different people have different habitual levels of arousal, and require different environmental conditions for optimal performance of a given task. Noise, bright lighting and glare increase arousal, so they interact with thermal conditions in terms of their resulting effect on performance.

Dealing with distracting signals, whether visual or acoustic, constitutes an unavoidable and demanding secondary task. This extra workload decreases performance of the primary task, or increases the effort required to maintain performance, raising arousal and ultimately leading to fatigue. There are many sources of distraction in open offices where many people work—acoustic telephone signals, visible and audible movement, audible conversations. Mental work that involves association or long and unbroken chains of thought are almost impossible under these circumstances. Logical reasoning, problem solving, mathematics, writing efficient computer code, and composing coherent and grammatical prose all involve long trains of thought. Memory, association, and creative thought all involve association. Once broken by distraction, the train of thought or the association may take minutes or even hours to retrieve. Mistakes will be made more often under distracting conditions, the overall quality of such work will suffer, and the amount achieved in a given time will be reduced. The increased cost of open offices in terms of the reduced productivity to which these effects give rise should be weighed against the savings achieved by housing more occupants per unit of floor area, and the theoretical but as yet unquantified advantages of the increased "teaming" and closer supervision that may or may not occur in open offices. Open offices provide little privacy. This is important to some people, for whom loss of privacy is a stress factor that has the effect of raising their level of arousal.

Most office workers use computers during a substantial part of their working day. Using a computer is a very special kind of work. It involves close attention to detail and to small visual symbols, and therefore has a high optimal level of arousal. Modern computers introduce little delay. They are almost always ready for the next input from the user. This in itself is a stress factor for some people. Close attention to the screen causes a reduction

in blink rate. The eyes of computer users are therefore dryer than they would be if they were doing other kinds of work in the same environment. They are therefore more sensitive to airborne particulates, air pollution, low humidity, air movement, thermal gradients, and raised air temperatures. Unless they and their computer are efficiently grounded, there is usually a static electrical charge between them. This can concentrate airborne pollutants in the facial area and further increase their eye discomfort and thermal sensitivity. Computers impose a particular posture. Computer users are therefore less free to alter their posture than they would be if they were doing other kinds of work in the same environment. This reduces their ability to alter their rate of metabolic heat production adaptively, so their thermal sensitivity is increased. Using a computer efficiently involves rule-based logical thinking, if only to follow the rules of engagement imposed by the programmer. Computer users have a high optimal level of arousal for this reason as well. They exert effort to maintain it under unfavorable environmental conditions and become more rapidly fatigued. These effects ensure that their productivity is particularly sensitive to the thermal environment.

16.3 THERMAL EFFECTS ON SBS AND ON SENSATIONS OF DRYNESS

A survey by Preller et al. (1990) of large numbers of people working in Dutch office buildings showed that individual control of temperature had a significant and positive effect: sick leave due to SBS was as much as 30 percent lower in situations where individual workers could control their own thermal environment, in comparison with situations where they were obliged to accept conditions that were optimum for the group rather than for the individual. Similar studies in U.K. offices by Raw et al. (1990) indicate that self-estimates of efficiency are significantly higher when individuals can control their own thermal climate, or their own ventilation, or the lighting levels where they work, in comparison with similar offices where this is not possible. This study also showed that while two SBS symptoms were quite normal, six SBS symptoms were associated with a 10 percent decrease in self-estimated efficiency. In an experimental study by Nunes et al. (1993) in Canadian offices, workers reporting any symptoms of SBS were found to be working 7.2 percent more slowly on one standardized computer task, designated the continuous performance task or CPT ($P < 0.001$), and to be making 30 percent more errors on another task designated the symbol-digit substitution task or SST. The CPT was a vigilance task in which subjects monitored a series of displays appearing on a computer screen and had to respond to one that had been designated as the target, while the SST was a complex coding task. Forty-seven subjects performed each task once a week for 3 weeks, without supervision, as part of their daily routine. These three papers provide strong and quantitative evidence for the link between SBS and productivity. Any factor that reduces SBS will increase productivity.

The link between sensations of dryness and SBS was established in an observational study by Jaakkola et al. (1989) of 2150 office workers in Finland. Dryness and SBS symptoms increased very markedly with air temperature in the range 20 to 24°C. An intervention experiment by Krogstad et al. (1991) of SBS symptoms experienced by 100 workers in a computerized office at various imposed temperatures in the 19 to 24°C range shows a very marked effect of thermal conditions on SBS. Each thermal condition was maintained for a week. It is quite clear from these new results that virtually all SBS symptoms increase with temperature from a minimum at 20 to 21°C, and in this study the effect was widespread rather than confined to a few sensitive individuals: the proportion reporting headache and fatigue increased from 10 percent at 20 to 21°C to over 60 percent at 24.5°C, and other SBS symptoms, including skin problems, showed similar effects. There appeared to be an increase in the average intensity of most SBS symptoms both below and above 30

percent relative humidity, but humidity was not experimentally altered, and the effect could be spurious, caused by the association of humidity with other factors.

One of the most common complaints indoors in winter in cold countries is that the air feels dry. As this sensation is associated with SBS, it may be considered indicative of effects on productivity. Laboratory studies show that people are ill-equipped to detect humidity as such: they often report a decrease when an increase has been imposed, and vice versa (e.g., Rasmussen 1971). Humidification is very expensive to install and run, and often causes health problems due to condensation on poorly insulated outer walls or even inside building materials, resulting in mold growth. An increase in sick leave due to SBS in humidified offices in Holland reported by Preller et al. (1990) is believed to be a result of these disadvantages.

A major experimental field study by Andersson et al. (1975) in large office buildings in Sweden showed that a 2 K reduction in room air temperatures, from 23 to 21°C, dramatically reduced complaints of dry air, whereas humidification from 20 to 40% RH, while halving complaints of dry air, caused a large increase in complaints that the air was too humid, so the proportion satisfied with the humidity was unchanged. The air in the laboratory studies cited above was extremely clean, and the quite different results obtained in offices suggest that the distress associated with dry air is caused by the inability of dry mucous membranes in the nose, throat, and eyes to deal with airborne dust, at least for some individuals, and that the drying associated with low winter humidity is greatly increased by room air temperatures at the upper end of the conventional range for thermal comfort, 20 to 24°C. SBS symptom intensity was significantly reduced by lowering room temperature by only 1.5 K in an intervention experiment in hospital wards (Wyon 1992). These studies show the positive impact of a quite small reduction of indoor temperature on productivity as indicated by SBS and related symptoms of distress, and as measured by sickness absence due to SBS.

16.4 THERMAL GRADIENTS

The positive effect on sensations of dryness of slightly reducing air temperature seems likely to be due mainly to effects on the moisture balance of the eyes, nose, lips, and facial skin, all of which take place at head height. Similarly, the mechanisms by which SBS is reduced by small reductions in air temperature seem likely to take place at head height, although there may also be a secondary effect on such general symptoms as headache and fatigue that is linked to whole-body heat balance. Vertical thermal gradients are always positive, since hot air rises. In rooms where the airflow must remove a high heat load, and particularly if this is to be done by displacement rather than by complete or partial mixing, air temperature at head height may be 2 to 3 K higher than at floor height. Cold feet and warm air to breathe is the exact opposite of human requirements, and an individual who experiences SBS or sensations of dryness will often be forced to lower the room temperature to such an extent that it will be too cold for whole-body heat balance as well as too cold for the feet. Over 40 percent were found to experience local thermal discomfort even when displacement ventilation had been adjusted to provide preferred whole-body heat loss when 72 subjects were exposed for 1 hour to two typical winter and two typical summer conditions in an office module by Wyon and Sandberg (1990). The experiment on which the recommendations in ISO 7730 are based (Olesen et al. 1979) would have predicted only 5 percent dissatisfied under these conditions. The discrepancy is due to the fact that each subject in the original Danish experiment was allowed to adjust the temperature continuously in the second half of the experiment and could therefore compensate for the discomfort of the imposed thermal gradient.

In a later experiment by Wyon and Sandberg (1996), in which over 200 subjects were exposed for 1 hour to vertical temperature differences of 0, 2, and 4 K per meter, with room

temperatures resulting in the same three states of whole-body heat balance at each vertical temperature difference, local thermal discomfort was found to be unaffected by vertical temperature difference, but highly sensitive to whole-body heat balance. Similar results have recently been reported by Ilmarinen et al. (1992) and Palonen et al. (1992), using only six subjects. These experiments do not deal with the consequences of vertical temperature differences for sensations of dryness or SBS over longer periods, but they do indicate that thermal gradients are a problem only because they lead to an increase in air temperature in the breathing zone. Even if the individual has a choice in the matter, it is an uncomfortable one, between the risk of SBS and a room temperature that is too low for comfort. Whichever is chosen, the end result is likely to be that productivity is reduced by vertical temperature differences.

16.5 THERMAL EFFECTS ON PERFORMANCE IN VEHICLES

Vehicles are not buildings, but they do represent a very common type of enclosed space in which people live and work. It has been shown experimentally by Mackie et al. (1974) that driver performance is reduced by the extreme heat stress experienced in summertime Arizona in vehicles with no air conditioning. In this study there was a significant increase in the number of "moving violations" of the highway code, speed was more variable, and drivers looked less often in the rear-view mirror. As bad driving causes accidents, which cost money, this is a decrease in productivity that is relevant to the cost-benefit analysis of providing air conditioning in areas as hot as Arizona, but not in areas as cold as Sweden. However, a recent study by Wyon et al. (1996) in Sweden demonstrated that driver vigilance is significantly lower at 27°C than at 21°C. Subjects missed 50 percent more of the signals introduced to the driving task either audibly or via the instruments and rear-view mirrors of a specially prepared test vehicle, and their responses to the signals they saw or heard were 22 percent slower. Eighty-three subjects drove the vehicle for 1 hour each on a predetermined route. It was possible to show that the decrement in vigilance performance was significantly greater in the second half-hour, and significantly greater in town than on a motorway. Taking into account the additional heat stress caused by unavoidable direct sunshine on vehicle occupants, 27°C represents a level of heat stress that is exceeded even in Sweden for a very large part of the year. Compartment air temperatures approaching 27°C may even be necessary in winter to counteract local cold discomfort due to cold window surfaces. The conclusion drawn from this experiment was that effective climate control in vehicles and good design of the thermal environment is not a luxury, and should not be an optional extra.

The same test vehicle was driven by a further 100 subjects for 1 hour each in city traffic, with and without an air ionizer in operation (Wyon et al. 1995). The subjects were not even aware of the presence of the ionizer, which had the measurable physical effect of reducing the number of respirable particles in the vehicle air, but only a negligible effect on total dust content of the air. Subjective eye distress as reported on visual-analog scales was significantly less for those 50 subjects who had been randomly assigned to the ionizer-on condition, and there was an accompanying significant increase in driver vigilance as measured in exactly the same way as in the previous experiment. Thus existing thermal and air quality conditions in vehicles have measurably negative effects on the productivity of drivers.

16.6 THERMAL COMFORT AND ITS RELATION TO PERFORMANCE

Thermal conditions providing optimum comfort may not give rise to maximum efficiency. In an experiment by Pepler and Warner (1968) in which normally clothed young American sub-

jects performed mental work at different temperatures, they were most thermally comfortable at 27°C, the temperature at which they exerted least effort and performed least work. They performed most work at 20°C, although most of them felt uncomfortably cold at this temperature.

Another example of the failure of thermal indices and subjective thermal comfort to predict performance is to be found in a series of experiments on heat-acclimatized European men living in Singapore (Pepler 1958). At raised temperatures, performance of a tracking task was consistently worse at 80% RH than at 20% RH, although temperatures had been adjusted so that the conditions were subjectively similar and represented identical levels of effective temperature. Pepler did not claim that this difference was statistically significant, but as Poulton (1970) later pointed out, a reliable performance decrement was found at a lower effective temperature in the humid climate. Thus high humidity reduced performance even under physiologically and subjectively equivalent thermal conditions. These results invalidate the usual assumption that performance effects can always be deduced from studies of thermal comfort alone.

16.7 THERMAL EFFECTS ON ACCIDENTS IN INDUSTRY

Accident rates in temperate zones are lowest at 20°C, increasing by over 30 percent below 12°C and above 24°C. The studies on which this conclusion is based were carried out as forward studies (i.e., recording all relevant data, as opposed to retrospective studies using available recorded data) in munitions factories over periods of 6, 9, and 12 months (Vernon 1936). Accidents increase in adverse working conditions because of a decrease in human efficiency, and it may therefore be assumed that this leads to a decrease in performance. In these studies, moderate heat stress had an adverse effect on men, but a much smaller effect on women. The effect of cold on accident rates was closely similar for men and women, suggesting that similar work was being performed by both groups. The mental performance of male subjects was more adversely affected than that of female subjects by intermediate levels of heat stress in laboratory studies of young adults reported by Wyon et al. (1979). The direction of the behavioral gender difference in these data and in Vernon's accident data is the opposite of the better-known physiological gender difference in response to more extreme levels of heat stress.

Moderate heat stress and fatigue interact to decrease efficiency. In studies of 18,455 English coal miners that were also reported by Vernon (1936), accidents always increased with the number of hours worked in the first 6 hours of a shift, but did so more rapidly at 25 than at 18°C, and more rapidly at 28 than at 25°C. After 6 hours, accidents, and presumably work rates as well, were observed to decline at the two higher temperatures, as the risks involved in maintaining work rates became more obvious to the miners themselves. Moderate heat stress was also found by Wyon (1970) to have a greater adverse effect on the performance of work by Swedish schoolchildren in the afternoon, when they were tired, than in the morning.

Moderate heat stress increases the dependence of accident frequency on age. Vernon (1936) reported that age was barely a factor in accident causation at temperatures below 21°C, but that the relative accident frequency increased by up to 40 percent for older men in the range 22 to 30°C.

16.8 THE EFFECTS OF COLD ON MANUAL DEXTERITY

In a study by Meese et al. (1982), 600 South African factory workers were randomly assigned to work for 6.5 hours at 24, 18, 12, or 6°C in the same clothing ensemble.

Performance of a wide variety of simulated industrial tasks involving finger strength and speed, manual dexterity, hand steadiness, and a variety of well-practiced manipulative skills was found to decline monotonically with room temperature below thermal neutrality. The critical room temperature for unimpaired performance was either 18 or 12°C, depending on the task. Finger speed and fingertip sensitivity were measurably impaired at the air temperature preferred for thermal comfort (18°C), in comparison with the air temperature (24°C) at which finger temperatures were at their maximum value. Finger strength was maintained at 18 and 12°C but was measurably reduced at 6°C. A realistic laboratory simulation of one of the heaviest tasks still performed manually in industry was also part of the series: the proportion of poor welds made with a heavy but counterbalanced spot-welding apparatus was 3 times greater at 6°C than it was at 18°C.

16.9 THE EFFECTS OF HEAT ON LIGHT INDUSTRIAL WORK

The critical temperature for performance in temperate zones seems to lie at about 30°C for normal humidity levels. This conclusion was reached by Pepler (1964) on the basis of studies made in weaving sheds and coal mines by the Industrial Fatigue Research Board in England.

Performance of simulated industrial work is worse at 10°C than at 17°C, and worse at 24°C than at 20°C. These conclusions were drawn respectively by Pepler (1964), from the Industrial Fatigue Research Board experiments, and by Wyon (1974), from the report of the New York State Commission on Ventilation. Note the excellent correspondence of these performance data with the field accident data summarized above. Both experiments were carried out under realistic working conditions, subjects working a full 8-hour day for several weeks. Field experiments in South Africa (Wyon et al. 1982, Meese et al. 1982, Kok et al. 1983) indicate corresponding effects on the many industrial tasks that were studied both above and below thermal neutrality, although the temperature for optimum performance was found to lie as much as 10 K higher for these heat-acclimatized factory workers.

Laboratory tests of rapid skilled arm movement indicate performance decrement at 13 and 29°C in comparison with the level achieved at 21°C. A further and more marked decrement takes place between 29 and 38°C (Teichner and Wehrkamp 1954). The correspondence with field accident data is again good. A deterioration of the ability to perform rapid skilled arm movements is logically an important factor in accident causation in light industrial work.

Although few accidents occur in office work, the mechanisms by which thermal stress causes accidents are still operative. It seems reasonable to conclude that if the lower levels of concentration that occur in warm conditions and the distraction of thermal discomfort that occurs in cold and warm conditions can cause accidents in light industry, they will have negative effects on the performance of office work.

16.10 THERMAL EFFECTS ON MENTAL PERFORMANCE

The subjects in laboratory experiments are too highly motivated to perform well during their short exposures to be characteristic of “real people” in real workplaces, but laboratory experiments have contributed to an understanding of *how* thermal conditions affect mental performance. Tests of “component skills” can be devised that have very different optimal

levels of arousal, whereas a real-world task will usually involve several component skills, obscuring any environmental effects. Provins (1966) was one of the first to formulate the principle that moderate heat stress lowers arousal, while higher levels of heat stress, e.g., above the sweating threshold, raise arousal. There is no corresponding evidence that arousal is raised by moderately cool conditions, below thermal neutrality. Easterbrook (1959) had already summarized a great deal of evidence for the effects of arousal on mental performance, showing that raised arousal leads to reduced cue-utilization, or breadth of attention, whatever the external or internal driving factor may be. Bursill (1958) had already demonstrated that high levels of heat stress reduced breadth of attention, and Hockey (1970) later showed that loud background noise could indeed produce the same effect. It is to be expected that bright lighting would produce a similar effect. These insights as they apply to indoor environmental effects were summarized in more detail than is possible here by Wyon (1978). Climate chamber experiments performed during that period and soon afterward confirmed many of the predictions that follow from the arousal model of how indoor environmental effects can interact, and how they can negatively or positively affect different kinds of mental performance.

Thermal conditions below neutrality are unlikely to have any directly negative effects on mental performance, but there will be a generally distracting and demotivating effect via the mechanism of cold discomfort. Langkilde et al. (1973) found no negative effects on mental performance of room temperatures 4 K below individual neutrality. It might be thought that having cool air to breathe would in itself raise arousal and enhance the performance of tasks with a high optimal level of arousal, but it seems that the thermal state of the body, however achieved, is what determines arousal and thus performance: no difference in the performance of a whole battery of different tasks was found between two conditions of thermal neutrality with very different clothing insulation and air temperature: 0.6 CLO at 23°C and 1.15 CLO at 19°C (Wyon et al. 1975). In other words, thin clothing and warm air is equivalent to warm clothing and cool air, in terms of performance as well as thermal comfort.

Under moderately warm conditions, above neutrality, it is possible to avoid sweating by reducing metabolic heat production. This leads to a lowering of arousal, as subjects relax and generally try less hard to work fast. This is often a completely unconscious response to warmth. Schoolchildren at 27°C (Holmberg and Wyon 1969, Wyon 1969) and students at 27°C (Pepler and Warner 1968, Wyon et al. 1979), and office workers at 24°C (Wyon 1974) all showed decreased concentration and 30 to 50 percent lower performance of tasks requiring concentration at temperatures just below the sweating threshold for sedentary work. Aspects of mental performance with a low optimal level of arousal, such as memory (Wyon et al. 1979) and creative thinking (Wyon 1996a) are improved by exposure to a few degrees above thermal neutrality, but they too are impaired at higher temperatures, closer to and above the sweating threshold. Similar effects are to be expected for unprepared vigilance, which requires the greatest possible breadth of attention. This should not be confused with what is often termed vigilance, the ability to respond rapidly when an expected signal is detected, which is a very simple task with a high optimum level of arousal. Under conditions in which relaxation and reduced arousal would be dangerous, for example when in control of a moving vehicle, even moderate heat stress tends to raise arousal and therefore to reduce unprepared vigilance (Wyon et al. 1996).

Mental performance has been studied as a function of dynamic temperature swings with periods up to 60 minutes by Wyon et al. (1971, 1973, 1979). These three experiments were summarized by Wyon (1979). Subjective tolerance of temperature swings was greater while subjects were working than while they were resting. The performance of routine work requiring concentration was reduced by small and relatively rapid temperature swings (peak-to-peak amplitudes up to 4 K and periods up to 16 minutes). Physiological response to cold appeared to take place faster than response to warmth under these conditions, so

their net effect was equivalent to a slight increase in room temperature in terms of its effect on the rate of loss of heat from the body. Large temperature swings (peak-to-peak amplitudes up to 8 K and periods up to 32 minutes) had a stimulating effect that actually increased rates of working, but thermal discomfort was experienced at the peaks and troughs. For periods of 60 minutes or more, physiological thermoregulation is sufficiently fast to keep pace, and performance is a function of the temperature at any given time. It would seem that there is no advantage in imposing temperature swings in indoor environments designed for mental work. Individual control of the thermal environment for optimal performance is another matter entirely.

The arousal model of environmental effects on performance predicts that noise and bright lighting will interact with thermal stress by increasing arousal. A background of recorded playground noise at 85 dBA removed the beneficial effect of warmth on the performance of a test of creative thinking by 12-year-old boys (Wyon 1969). Intermittent noise (equivalent to 85 dBA) reduced the negative effects of warmth (27°C), while noise removed the beneficial effects of warmth in the performance of two complex tasks by adult factory workers (Wyon et al. 1978). An analogous interaction between lighting intensity and moderate thermal stress was observed by Löfberg et al. (1975) in a climate chamber experiment in which 144 ten-year-old children were exposed to warmth or thermal neutrality at 60, 250, and 1000 lux. Extreme heat stress raises arousal and therefore acts in the same direction as noise and bright lighting. Dim lighting and low levels of monotonous background noise can be assumed to reduce arousal and would be expected to increase the effects of moderate heat stress.

The effects of noise, lighting level, and thermal conditions summarized in this section have been investigated by empirical observation of different aspects of mental performance during exposure to controlled conditions. It should not be assumed that self-estimates of performance, an easily obtained and increasingly popular means of investigating environmental effects in the field, could have been used instead. Subjects have their own mental models of how different factors of the indoor environment affect their performance, and are likely to respond accordingly. These models may be mistaken. Kroner et al. (1992) obtained self-estimates of performance in parallel with objective outcome measures, in order to follow what happened before, during, and after an insurance company moved to a new building. The objective measure was the time taken to resolve insurance claims. During the relative chaos that prevailed in the weeks immediately following the move, self-estimates of performance were unchanged, while the objective measure showed claims were being processed 30 percent more slowly. It is apparent that self-estimates of productivity were wishful thinking in this context. In general, they are likely to be more an indicator of perceived effort than of actual performance.

16.11 THE NEED FOR INDIVIDUAL CONTROL

People differ in their clothing and metabolism, and in the requirements of the work they do at any given time. This means that there will always be differences of opinion as to whether it is too hot or too cold. The ASHRAE (1997) *Handbook of Fundamentals* suggests that an acceptable percentage comfortable would be 80 percent, but does not attempt to predict the degree of individual control that would be necessary to ensure that a higher percentage could achieve thermal comfort. It is simply suggested that the PMV/PPD approach of ISO 7730 (1984) should be used to predict individual differences in thermal comfort sensation. Some years ago, the Scandinavian HVAC Association, SCANVAC (1991), recommended three levels of thermal quality, corresponding to 80, 90, and >90 percent comfortable in terms of whole-body operative temperature. SCANVAC suggested that a range of individ-

ual adjustment of 4 K would be necessary to ensure >90 percent comfortable. Using the value 1.17 K for the SD of individual neutral temperature that was found in an experiment by Wyon and Sandberg (1996), and assuming the usual normal distribution of response, it may be calculated that 99 percent of office workers would be thermally comfortable if the equivalent room temperature provided by their microclimate could be individually adjusted over a range of 6.0 K, 95 percent with 4.6 K, and 90 percent with 3.9 K. Dress codes increase these ranges. In the experiment, 200 subjects wore their habitual office clothing under thermal conditions that were assessed very accurately by measuring the heat loss from a thermal manikin.

It is quite possible to ensure that considerably more than 80 percent will be thermally comfortable in the same air temperature and humidity, simply by providing individual control of a source of radiant heat with a large angle factor to the body, preferably the legs and thighs, and individual control of local air velocity, provided that the air temperature is set to the group mean for thermal neutrality at the prevailing level of humidity. If the air temperature or humidity must be higher or lower than this value at times for reasons of energy conservation or economy, individual control of local thermal radiation temperature and local air velocity will markedly reduce the number of people experiencing thermal discomfort. The benefits in terms of reduced SBS and increased performance are considerable, as set out below.

Wyon (1996b) demonstrated that individual control equivalent to ± 3 K may be expected to improve the performance of mental tasks requiring concentration by 2.7 percent. A decrease of this magnitude (2.8 percent) in the rate of claims processing in an insurance office had been demonstrated by Kroner et al. (1992) when individual microclimate control devices in an insurance office were temporarily disabled. It was also shown that this degree of individual control may be expected to improve group mean performance of routine office tasks by 7 percent, and performance of manual tasks for which rapid finger movements and a sensitive touch are critical by 3 and 8 percent, respectively. Although thermal conditions above the group mean for thermal neutrality will still reduce the group mean performance of mental work, the expected benefits of individual control for group performance are actually larger under warm conditions up to 5 K above the group optimum than they are at the optimum.

The insurance clerks in Kroner's intervention experiment worked in cubicles in an open office. The individual control of which the intervention deprived them was provided by desk-mounted devices connected to supply-air ducts. Nonducted devices requiring only a power connection are more easily moved and can still control local radiant temperature and air velocity. Ceiling-, wall-, and floor-mounted devices are obviously easier to connect to ducts, but are more difficult to adapt to new furniture and partition configurations. They are in many cases remote from centrally placed workstations and may then be unable offer much individual control of the occupant's microclimate.

It is obviously easier to provide complete individual control if there are four full-height walls and a closed door around each person. This is an expensive solution, both in terms of the first cost and of the floor area required for offices and their access by corridor. Open offices that are also used as corridors can accommodate more people in the same floor area at a lower first cost. Communication on a minute-by-minute basis is better between team members who occupy the same room than if they were all in separate offices, and this is advanced as an argument in favor of open offices. At the same time, advocates of the "virtual team" proclaim that remote communication allows team members to be in different cities, even different continents, while still maintaining face-to-face visual and acoustic contact, and that this allows each person to act as a member of several teams simultaneously.

It is possible to imagine some kinds of office work in which such intimate contact would be an advantage—e.g., project work under time pressure, in which most tasks are fairly superficial and team members are therefore interchangeable—but it is easy to show that the

visual and acoustic distraction so generated must have a very negative effect on more familiar kinds of office work, particularly when the work is not superficial and could not be performed adequately under time pressure. This will be the case when levels of arousal must be under individual control to deal with the changing requirements of tasks involving such disparate skills as memory, creative thinking, prose composition, concentration, logic, and problem solving that draws on the long experience that is unique to each individual.

It should not be forgotten that tasks that might be simple for one person may be difficult for another, and that environmental sensitivity is at its greatest when the individual is under stress, as the spare capacity required for the “secondary task” of dealing with environmental sources of irrelevant information is then at a minimum. This can be the case for anyone, at any time, and for any task, depending on the other demands that the person’s life inside and outside the office are making at that time.

Facility managers find that open offices, with or without partial-height partitions that can be moved with the furniture to create new constellations of cubicles and team spaces, are more compatible with a high “churn rate”—the rate at which an office must be reconfigured to meet the demands of new tenants. This cost and time saving, the reduced facilities cost per occupant of high density occupation, and the alleged productivity advantage for project team work performed under time pressure are on the credit side of open offices. They must be balanced against the risk that there will be negative effects on most other kinds of office work. Cubicles provide visual screening, but very little acoustic screening. Everybody who has ever worked in a large library knows what a high level of discipline and consideration is required for this to be possible. These courtesies are in short supply in open offices. Telephones ring, conversations are held, visitors arrive and leave all the time. Any interruption affects everybody to some extent. The performance of many tasks will clearly be reduced, but how much does this matter? There is a real need for the resulting cost in terms of reduced productivity to be quantified under realistic conditions.

16.12 ESTIMATING PRODUCTIVITY FROM PERFORMANCE

As computers and other office machines take over much of the routine and repetitive work, office workers have moved on and are now expected to perform a much greater variety of tasks involving the judgment, experience, and initiative that computers are unable to provide. Until relatively recently it was at least theoretically possible to measure office productivity in terms of the number of lines typed, figures entered or checked, carbon copies made, etc. for all but higher-level executives. Office workers are now doing much higher level work that is difficult to quantify. A survey was conducted in 1998 by the Center for the Built Environment at the University of California at Berkeley to make an inventory of the metrics that are routinely used by managers to quantify office productivity, with a view to using them in subsequent research to study environmental effects. This study revealed the surprising fact that no such metrics appear to exist. Managers appear to be content to rely on subjective judgment of human performance rather than on objective measurement and analysis. This is in strong contrast to their approach to financial matters. Either it has escaped them that their staff represent their largest expense item, or they find that it is impossible to quantify the cash value of their input to the business operation now that they are no longer doing such routine jobs.

However much their jobs have changed, office workers still use all of the “component skills” that have been identified in this chapter—reading speed, memory, creativity, logic, etc. The problem is to use the known effects of a given thermal environment on component

skills to predict overall productivity. This will require a level of activity analysis that has not yet been achieved. It will be necessary to discover what proportion of each employee's time is spent in performing tasks for which each component skill is critical. It will also be necessary to assign at least a relative cash value to the performance of each task. These proportions and these task values can then be used as weighting factors to combine the performance degradation that a given thermal condition is expected to cause into an overall estimate of the resulting effect on individual productivity. Group productivity degradation in response to changes in the thermal environment can then be calculated assuming a normal distribution of individual neutral temperatures about the group mean. This complex calculation could most conveniently be part of a computer application program. Wyon (1996b) estimated the expected effects of individual control on group productivity assuming different component skills were critical, but did not carry out any activity analysis of office work. A computer applications program in which the underlying assumptions of task value, time weighting, and component skill criticality could be varied would be an aid to understanding and a useful decision tool for investment in environmental quality. The result should be expressed as an outcome metric of productivity that is as close as possible to the "bottom line" or net value of the operation.

Once estimates of productivity under various assumptions can conveniently be made, it will be necessary to validate them. This can most efficiently and conclusively be achieved by intervention experiments in the field, using each group of employees as their own control to eliminate the effects of the differences that always exist between preexisting groups, such as the "group chemistry," the morale, and the quality of management. Intervention experiments involve making repeated and reversible changes, for example, in the thermal environment. Before-after studies are much easier to arrange, for example, by taking advantage of an already planned and financed HVAC system upgrade or renovation, but they provide little evidence of causation, as some external factor such as the weather, the season or the market conditions for a business operation might have changed simultaneously by chance. It is not possible to measure or even identify all factors that might have affected the outcome variable, but repeated and reversible intervention can reduce almost to zero the probability that any other factor could have changed synchronously with the intervention. If irreversible changes such as upgrades or renovations are all that is available, an alternative approach is to stagger them in time, assigning each building, room, or group area at random to its place in the sequence and recording the outcome metrics simultaneously over time in them all. The probability that any other factor could be so sequenced between the objects of study by chance is almost as small as the probability that its influence would change reversibly in synchrony with repeated interventions by chance.

The need for repeated and reversible interventions, or for multiple groups in the "staggered irreversible intervention" approach, implies that each such experiment must inevitably be of long duration, possibly several months, and the fact that so many uncontrolled factors in each individual's life can also affect productivity implies that a large number of employees must be studied, scores if not hundreds. Such an experiment would probably be prohibitively expensive if subjects had to be paid for their participation, or if a new system of obtaining artificial productivity metrics had to be developed and installed. It will therefore be doubly advantageous to experiment in "the real world"—less costly and more valid. This should be done using outcome metrics that are routinely recorded, such as the rate at which insurance claims are processed, the average call-time at call-centers, counter clerk/customer interaction time, daily sales figures, etc. There is a great deal of current interest in setting up such validation experiments, and it is highly probable that some will have been reported by the time a revision of this handbook is undertaken.

CHAPTER 17

THE IRRITATED EYE IN THE INDOOR ENVIRONMENT— PHYSIOLOGY, PREVALENCE, AND CAUSES

Søren K. Kjærgaard, Ph.D.

*Department of Environmental and Occupational Medicine
Aarhus University
Århus, Denmark*

17.1 MORPHOLOGY AND PHYSIOLOGY OF THE OUTER EYE

To discuss eye irritation it is important to understand the more specific characteristics and the physiology of the outer eye. The outer eye differs from the other mucosal membranes in several ways, which partly are related to its specific functions. In contrast to the nose, and partially the mouth and throat, the eyes do not have the task of temperature and humidity regulation of inhaled air, which is the function of the nasal turbinate and the special vascularization of the nasal mucosa. Neither does it have filtering functions, another function of the nasal turbinate and the ciliated epithelium. One basic function of the outer eye is to protect the vision by preservation of the cornea. Some important parameters are discussed below as are their relevance in indoor environments. In particular, the difference between conjunctiva and cornea and the formation of the tear fluid and tear film are discussed. A comprehensive overview of the functions of conjunctiva, cornea, tear film, and related diseases can be found in, e.g., Holly (1986a), Norm (1983), and Rohen and Lütjen-Drecoll (1992).

Conjunctiva and Cornea

A major and visible difference between the conjunctiva/sclera and cornea of the eye is the nonvascularization of the cornea, due to the need for undisturbed light transmission. This makes the nourishment and waste disposal of the cornea a special problem, as this has to happen either intraocularly or through exchange via the tear film, which continuously is exchanged by secretions from the different glands and is redistributed over the cornea and conjunctiva by blinking.

The conjunctiva can be divided in two ways, the bulbar and the tarsal conjunctiva or the exposed and unexposed area—the last division related to the fact that the area kept wet by the tear film has a special relevance.

Both the cornea and the conjunctiva consist of squamous epithelium cells on the exposed areas, which turns into columnar epithelium in the tarsal parts of the conjunctiva (Rohen and Lütjen-Drecoll. 1992). The surface cells are typically linked together with very stable and nonpenetrable tight junctions (Rohen Lütjen-Drecoll. 1992), meaning that exchange with the exterior in general is a controlled process. The surface cells are covered by a thin layer of mucin (1.4 μm on conjunctiva and 0.8 μm on cornea) that plays an important role in establishment of the tear film (Fig. 17.1). The mucin consists primarily of glycoproteins, which are secreted mainly from the goblet cells widely distributed in the conjunctival epithelium.

Changes in the epithelium of the eyes can be measured by using a slit lamp (a binocular microscope) and vital stains. The most used vital stains in indoor air studies are Rose-Bengal (or Lissamine-Green B), which stains dead and damaged epithelium cells. Also fluorescein has been used for detection of microepithelial holes in the cornea, as it cannot penetrate the cells or the tight junctions (Norn 1983). A newer method to assess changes in the epithelium cells uses filter paper imprints (impression cytology) in which the outermost cell layer is peeled off (Nelson and Wright 1986, Prah et al. 1994). The imprint is then assessed, e.g., for cell types (goblet cells, epithelium cells, etc.) by microscopy. However the method depends on the pressure, the paper quality, and the duration of paper application, which calls for standardization (see also Chap. 26).

Tear Fluid and Tear Film

The tear fluid and the 6- to 10- μm -thick tear film (Fig. 17.1) are of major importance for keeping the eye functional and nonirritated. The tear fluid produced by the lachrymal glands, together with lipids and mucin, constitutes the tear film. This three-layer film is formed by the eye blink and covers the exposed part of the eye. The basic physiologic tear flow is very low, and is supposed to come mainly from the accessory tear glands located in the tarsus. It is estimated to be around 1 μL per minute (Baum 1986) and the amount contained at the eye surface is around 10 μL (Rohen and Lütjen-Drecoll 1992). Any excess fluid is drained from the eye through the tear canal, which ends up in the nose.

The film keeps the exposed parts moist, and transports O_2 and nutrients to the cornea and CO_2 and exuded metabolic products from the cornea. Furthermore, it has an important function, in combination with the blink movement: to remove settled particles, excess mucus, and cellular debris (detritus) from the eye surface. During the process these will be captured by the mucus thread situated under the lower eyelid and slowly moved toward the eye canthus, where the thread dries up and falls off or is removed by the hand (Norn 1983).

The three layers of the film (Fig. 17.1) are organized with an outermost lipid layer produced mainly by the meibomian glands located in the eyelid, a watery layer from the tear glands, and an innermost mucus layer from the goblet cells. Dysfunction of the three types of glands involved, or in the formation of the tear film, is associated with the different dry eye diseases (Sjögren's syndrome, keratoconjunctivitis sicca, etc.). These diseases are

FIGURE 17.1 A cross section of the outer eye with tear film.

known to give symptoms similar to what is described in the indoor air studies; however, their prevalence is so low that they cannot alone explain the findings.

As it is understandable from the description above, a stable tear film is essential for the eye. However, it is dependent on many factors including the environment (Norn 1983, 1992). For example, oily substances (ricinus oil, paraffins) can decrease stability (Gluud et al. 1981, Norn 1977), probably through adherence to the mucus layer or through damage to the lipid layer structure. In the first hypothesis, the suggested mechanism is that the lipid adhered to the surface of the eye interferes with the adherence of the overlying watery layer, producing a local dry spot (Holly 1986b). The second suggests that lipophilic substances such as oils and *n*-decane vapor (Kjærgaard et al. 1989a, Kjærgaard 1990) destroy the intermolecular binding within the phospholipid layer. Both mechanisms may be valid, depending on the actual exposure. Sedimentation of particulates may, if they are captured by the mucus layer, interact with the film, especially if they are hydrophobic. This is supported by the findings that tear film stability is decreased by house dust exposure (Pan et al. 1999, Møhlhave et al. 1995).

Besides malfunctions of the tear glands, the meibomian glands, and the goblet cells, the other parameters involved are anatomical: eyelid-eyeball junction, blinking manner, curvature of the cornea, and the smoothness of the corneal surface. Furthermore, there is evidence for evaporation affecting the tear film stability, as people living under warm, dry air conditions have a lower tear film stability than people living in temperate, humid air conditions (Paschides et al. 1998). However, a climate chamber study could not prove a temperature effect with temperatures from 18 to 26°C and 45 percent humidity (Møhlhave et al. 1993b). This may indicate that humidity is the more important factor. Draught may exert similar effects by increasing evaporation.

Incidence of dry eyes increases with age (Seal and Mackie 1986, Hikichi et al. 1995), especially among women (McCarthy et al. 1998). This is probably due to decreased pro-

duction of the tear fluid, mucus, and lipid or, though still not documented, due to prolonged exposure to oils, creams, and eye makeup (Gluud et al. 1981, Franck and Skov 1989, Kjærgaard et al. 1993b). Tear film stability has been believed to be independent of age and gender (Norn 1986), until recently. However, unpublished data (the author's) seems to indicate some decrease in film stability by age in the general population, as do studies on Chinese populations (Cho and Yap 1993). This is supported by studies on more selected populations (Vitali et al. 1994, Puderbach and Stolze 1991).

Several methods exist for the determination of tear film stability, the standard method being installation of a specified amount of sodium fluorescein (e.g., 10 μ L of 1%), which in cobalt blue light visualizes the surface of the film. Under observation in a slit lamp, time is measured from formation of the film (a blink) to breakup time (BUT) of the film (observed as dark spots in the yellowish stain) (Norn 1983, 1986). Hence BUT is a clinical measure of tear film stability and related to irritation (Kjærgaard 1992a). Methods to measure BUT and results and reproducibility of measurements are described in more detail in Chap. 26. Only a brief summary is included here. The method has been slightly varied in many different studies (Marquardt et al. 1986). Another substantially different method (noninvasive BUT measurement) is based on a grid (or concentric rings) of white light focused on the tear film. In this method, time is measured from film formation until observation of a blur in the gridlines or the rings (Mengher et al. 1985, 1986). Finally, Wyon and Wyon (1987) have suggested an easy method where the subject focuses on a spot, keeping the eye opened voluntarily. BUT is then measured as the time the eye is kept open. This is not a real BUT but a correlate, although not one to one.

Inflammation and Immunology

The eye is protected by the immune system like other mucosal surfaces. This means that in case of tissue damage or presentation of antigens, there is an immune-system response. This response includes the normal cellular response seen by infections, as indicated by the polymorphonuclear neutrophils and lymphocytes often found in the tear fluid (Norn 1983, 1986; Bron 1986). Furthermore, there are a vast amount of immune-active substances in the tear fluid. Among the most important are lysozyme, lactoferrin, tear albumen, and immunoglobulins, mainly IgE, IgA, and IgG (Allansmith and Ross 1986). Cytokines involved in inflammation and modulation of inflammation are identified in the tear fluid too.

The inflammatory cells in the tear fluid are normally sampled by pipettes either by suction (Norn 1983) or by sampling small volumes of tears (e.g., 10 μ L) from the eye canthus by using capillary tubes (Bron 1986). Impression cytology can of course be used here too. Different techniques and counting methods will not be discussed here. Inflammatory markers like cytokines may be assessed by analyses directly on the sampled tear fluid; however, quantification depends on the production of tear fluid and eventual stimulation of the flow by the sampling itself. A new application for impression cytology sampling is the use of the so-called RT-PCR amplification technique, for quantification of the different cytokine synthesis in the mucosal cells (Prah et al. 1994). This method will be independent of the stimulation, but is expensive.

A well-known sign of inflammation is hyperemia, which can be assessed by direct observation. However, more objective assessment uses standardized photography of the conjunctiva and subsequent comparison or evaluation of the photographs either by panels or by computerized methods (Kjærgaard and Pederson 1989b; Kjærgaard et al. 1990; Kjærgaard 1990; McMonnies and Ho 1991; Ogle and Cohen 1996). Analyses have revealed an association with exposures in occupational settings, and that the number of visible vessels in the conjunctiva is associated with both increasing age and blood pressure (Kjærgaard 1990).

Nerve System

The nerve system responsible for eye irritation is the first branch of the fifth cranial nerve (nervus trigeminus), which innervates the surface of the eye with both mecano receptors and pain receptors. The last group is believed to be responsible for the irritation response through the naked nerve fibers (C fibers) closely associated with the epithelium. There is so far no good method for direct assessment of the neural activity *in vivo*, as there is for the nose using negative mucosal potentials (Kobal 1985).

Sensory irritation responses are assessed by subjective methods; however, an improvement of these are eye-only exposures as developed in the last decade (Cometto-Muñiz and Cain 1995, Kjærgaard et al. 1992). These methods use, e.g., CO₂ as a model irritant. The irritation response in the eyes seems to depend on age, but so far it seems that there is no difference between the two genders when irritation intensity or thresholds are assessed with CO₂ as irritant (Kjærgaard 1990, Kjærgaard et al. 1992). However, data suggest an increased susceptibility in hay fever patients also outside the pollen season, and in subjects reporting to be sick building syndrome (SBS) patients (Kjærgaard 1990).

17.2 EYE IRRITATION AND INDOOR AIR POLLUTION

Epidemiology

Unfortunately, most studies dealing with indoor air-related symptoms do not distinguish the different symptoms but aggregate them in groups related to type and not organ. Therefore, we have only limited information on the symptom questions most often posed regarding eyes. These are mainly: “eye irritation,” “eye dryness,” “watering eyes,” or runny eyes.” In some questionnaires there are also questions about “tired eyes,” “sandy eyes,” “burning eyes,” and “eye strain.” In some cases, the term *irritation* is explained as a stinging, itchy, or painful feeling, as, for example, in the Örebro questionnaire (Anderson 1993). Furthermore, there are very different approaches on the recall period, which can, for example, be contemporary (Groes et al. 1995), 4 weeks (Groes et al. 1995), 3 months (Anderson 1993), or even a year (Skov et al. 1987). Finally, authors use different kinds of scaling, typically ordinal scaling like “never, sometimes, often,” or “daily, once a week, once a month, none.” They all are referring to an incidence value within the period. Others use intensity scaling on either visual analog scales or simple ordinal scales like “none, slightly, strong, very strong irritation.” Further confusion arises because some investigators make the questions conditional, that is, they ask the question only for the symptom presence during work. To get an overview of the prevalence, the development over time, and to make causal inferences, it is important that in the future some standardization takes place and that the symptoms are reported in the literature not simply as aggregate scores.

Although the problems described above make it difficult to determine a relationship, it seems that symptoms related to the eyes are very prevalent in “sick buildings.” They have led to the invention of the “office eye syndrome” (Franck 1986) and “pollution kerato-conjunctivitis” as suggested by Norn (1992). However, as long as there is no strong and specific causal link between the offices or pollution and the symptoms, one should be careful using such terms.

The sensory irritation of the mucous membranes in eyes is probably one of the most important symptoms in the sick building syndrome, as it is a very prevalent symptom, with prevalence proportions ranging up to and above 50 percent (Table 17.1). American office workers from buildings in which an investigation had been requested (3245 workers in 100

TABLE 17.1 Prevalence Proportions of Eye Irritation in Different Epidemiological Studies*

Study population and numbers	Question and period	Proportion	Reference
Danish office workers selected from different problem and nonproblem buildings. Intervention study with a year between measurements. First year 119, second year 128 (59 and 66% women respectively).	Eye symptoms, twice a week or more, 1-year period Eye irritation, on sampling day Runny eyes, on sampling day	24% (1989); 32% (1990) 23% (1989); 16% (1990) 5% (1989); 6% (1990)	Kjaergaard et al. 1992b
Danish healthy population (including hay fever) invited by announcements: 108 (allergy 62%, women 62%, age <40 70%). Preinvestigation for climate chamber study.	Eye irritation, twice a week or more Runny eyes, twice a week or more One-year period	45% 33% 	Hauschildt et al. 1999*
Danish healthy population (including hay fever) invited by announcement: 113 (allergy 46%, women 51 %, age <40 50%). Preinvestigation for climate chamber study.	Eye irritation, twice a week or more Runny eyes, twice a week or more One-year period	31% 15% 	Kjaergaard et al. 1995†
Random sample of subjects from the Central Person Register in Aarhus County. Preinvestigation for climate chamber study. 182 nonallergic, nonsmokers (women 52%, age <40 63%).	Eye irritation, sometimes or often Three-month period	29.9%	Kjaergaard et al., unpublished data
1346 Canadian office workers (1995), †	Dryness, irritation or burning	17.8%(1991); 13.7%(1992); 13.7% (1995)	Brisson et al. 1996

167 workers and 2500 visitors at a library in Stockholm.	Eye irritation, often lasting 3 weeks Eye irritation right now	Visitors 25%; workers 35% Visitors 16%; workers 25%	Lundin 1991
American schoolteachers (random selection), estimated at 440 (23.5% males).	Eye irritation	12.1%	Godish et al. 1996
3245 American office workers (requested investigation) in 100 buildings.	Dry/itching/irritated eye	Median 30%; males 21%; females 37%	Mendell et al. 1996
3507 Danish workers in 14 town halls (68% women).	Work-related eye irritation (twice a week or more) One-year period	Total 12.8%; males 8.0%; females 15.1%	Skov et al. 1987
6537 European office workers from 56 buildings in 9 countries.	Dry eye within last month Watery eye within last month Dry eye, now Watery eye, now	39% (28–47)* 17% (10–30) 26% (20–33) 7% (10–30)	Groes et al. 1995
Random sample of Swedish 20–67-year-old population: 466 (51% women).	Eye irritation within last three months	16%	Nordbäck and Edling 1991

*Range for the nine countries.

†The prevalences are not shown in this paper, but calculated especially for this table. The reference is to the climate chamber study.

‡Estimated from prevalence ratios.

buildings) show a median prevalence proportion at 30 percent (Mendell et al. 1996). In European office buildings (6537 workers in 56 buildings in 9 countries; Groes et al. 1995) the prevalence proportion varies between 28 and 47 percent for dry eyes in the last month, while watering eyes range between 10 and 30 percent.

Even in a normal population of nonsmoking, nonallergic Danes there is a 3-month prevalence proportion of eye irritation (daily or sometimes) of 30 percent (unpublished data). Other data sets showed a 1-year recall in a randomly selected normal population (including smokers and allergic) of 35 percent for eye irritation and 14 percent for runny eyes.

Since most epidemiological studies are limited in design and exposure assessment with regard to causal inference about exposures and since only few authors have analyzed eye symptoms alone, material about this organ is very scarce.

Experimental Studies

Several experimental studies have been done to assess the eye irritation potential of indoor VOCs (Hempel-Jørgensen et al. 1998, 1999a, 1999b; Cometto-Muñiz and Cain 1995). The most pronounced results are that exposure concentrations needed to provoke eye irritation in general are very high in these short-term exposures. Even prolonging exposures to, e.g., 3000 mg/m³ *n*-butanol for up to an hour does not induce eye irritation compared to clean air, although it seems to induce conjunctival hyperemia (Hempel-Jørgensen 1998, 1999a). Using the eye-only procedures, as in the studies above, has the advantage that there is no odor bias (blinding is therefore possible) as seen in epidemiological studies and also in climate chamber studies.

Most of the climate chamber studies on normal nonreactive VOCs do not show sensory eye irritation as a pronounced effect (Kjærgaard and Pedersen 1989b; Kjærgaard et al. 1991, 1995, 1999; Mølhave et al. 1986, 1991, 1993a; Hudnell et al. 1992). Likewise, normal house dust particles (levels up to 500 µg/m³ and aerodynamic diameters between 0.1 and 10 µm) do not produce significant sensory eye irritation in two of three studies (Mølhave et al. 1995, Hauschildt et al. 1999, Pan et al. 1999). However, reactive species like formaldehyde can produce eye irritation in low concentrations in eye-only exposures, which match the findings in indoor environments (Hempel-Jørgensen et al. 1996). A climate chamber study on total emissions around 1 mg/m³ from painted linoleum flooring, carpets, and vinyl flooring did not show significant eye irritation (Kjærgaard et al. 1999). In a similar study by Johnsen et al. (1991), they found an increased eye irritation during exposure to some of the emissions, but the change was not contrasted against the clean air exposure and therefore was inconclusive. In Wolkoff et al. (1992) there was a marked increase in dry eye sensation by exposure to emissions from office machines. However, the measured exposure had both particles and strong irritants like formaldehyde and ozone.

17.3 PHYSIOLOGICAL CHANGES OF THE OUTER EYE MEASURED IN INDOOR-RELATED STUDIES

Several epidemiological and experimental studies have assessed the relation between measurable physiological parameters and the ones described in the previous section and in Chap. 26. They are summarized in Tables 17.2 and 17.3. As seen in Table 17.2, there is no strong and reproducible association between exposures and responses in the field studies. A basic problem is that the exposure assessment very often is limited, and that the studies are cross-sectional.

However, it seems that some types of VOC exposures can reduce BUT, while others may increase epithelium damage, and that house dust has similar effects (Table 17.3). Inflammatory response (cells and hyperemia) has been found too. In general, one must

TABLE 17.2 Overview of Physiological Findings in the Eyes and Their Association to Indoor Exposures in Epidemiological Studies*

Reference	Type and number of subjects	Design	Measurements	Major findings
Franck 1986	Office workers: 169	Cross-sectional	BUT ED	BUT and ED associated with period prevalence of irritation.
Franck and Skov 1989	Office workers: 169; referents: 112	Cross-sectional	FOAM	Different among referents and office workers. Associated with period prevalence of irritation.
Kjærgaard and Brandt 1993a	Librarians: 53	Cross-sectional	BUT ED Redness FOAM	BUT and ED different from reference material. BUT and makeup use associated with acute sensation of irritation.
Kjærgaard et al. 1993b	Office workers: 92	Prospective	BUT ED Redness FOAM PMNs	PMNs increased with increased use of video display terminals and increased dust sedimentation. ED increased by increased dust exposure and makeup.
Wiesländer et al. 1999	Geriatric-hospital workers: 88	Cross-sectional	BUT (self-reported)	BUT was reduced at occurrence of dampness and ammonia under carpet, and increased by ventilation increase.
Muzi et al. 1996	Hospital workers: 86; referents: 74	Cross-sectional	BUT Tear flow Redness	BUT and tear flow were lower among hospital workers in the sick building.
Muzi et al. 1998	Office workers: 163; sick building referents: 87	Cross-sectional	BUT Tear flow	BUT was reduced in sick building.

BUT = break-up time (tear film stability); PMNs = polymorphonuclear neutrophils; ED = epithelial damage. FOAM = foam bubbles in the medial and lateral eye canthus.

conclude that exposure levels in climate chamber studies are above what is normally seen in indoor environments, suggesting that these exposures do not explain epidemiological findings themselves. Furthermore, the reproducibility of findings is not convincing to a degree that makes it possible to draw strong conclusions about causality.

17.4 IRRITATION INDOORS AND RELATION TO AIRBORNE POLLUTANTS

In conclusion, it is difficult to argue for a direct causal relationship between indoor exposures and direct stimulation of trigeminal C-fibers in the eye. This indicates other possible explanations for pollution-induced sensory irritation effects observed in IAQ field studies:

- Effects seen may be due to exposures to reactive species (possibly surfactants) not measured by traditional sampling methods.
- Effects are induced through inflammatory reactions either as a direct toxic effect, or by drying of the eye produced by degradation of the tear film.
- Effects are manifested in individuals having conditions modifying susceptibility. These hypothetical risk factors have not been identified.

The first hypothesis, advanced by Wolkoff et al. (1997), suggests that reactive species are produced from nonreactive species by oxidants like nitrogen oxides and ozone. This is supported by some animal studies (Wolkoff et al. 1999) and indirectly by some epidemiological studies. The second hypothesis is supported by some of the experimental and epidemiological studies indicating such effects on the eyes, especially in the form of tear film degradation and increase in inflammatory cells (see Tables 17.2 and 17.3). The third hypothesis has only been investigated in few studies on hayfever patients (Kjærgaard et al. 1995, Hauschildt et al. 1999) and asthmatics (Johnsen et al. 1991). A study on SBS persons compared to non-SBS persons showed differences indicating a higher response among SBS persons (Kjærgaard 1990). However, only slight increases of irritation were seen and only in some of these studies. So, the proportion of eye irritation cannot be explained as an increase in these groups alone. The findings by Franck (1986) and Kjærgaard et al. (1993a) give support to the hypothesis that susceptibility is increased among persons with epithelium damage and/or decreased stability of the tear film, especially if eye makeup is used simultaneously. But again, the studies were cross-sectional, which makes causal inference difficult.

The last hypothesis further emphasizes the need of handling eye irritation separately from other irritation effects, by the indication of a physiological parameter as the causal link between the exposure and the irritation sensation.

It is possible, of course, that reporting irritation is related not to airborne pollution, but to other environmental or individual parameters. Possibilities include air movements, working at VDTs, use of contact lenses, and use of eye makeup (Jaakkola and Jaakkola 1999; Kjærgaard et al. 1992b, 1993a, 1993b). Also diseases like allergy, Sjögren's syndrome, and keratoconjunctivitis sicca are all well-known causes of sensory irritation.

CHAPTER 18

LIGHTING

RECOMMENDATIONS

Dale K. Tiller, D.Phil.

*University of Nebraska
Omaha, Nebraska*

18.1 INTRODUCTION

Natural and artificial lighting are ubiquitous features of the built environment. Light banishes darkness, promotes health, gives form to architecture, and helps people work and move safely about occupied spaces. Given the importance of lighting systems it is not surprising that a substantial body of recommended-practice documents, standards, and codes exists that attempts to codify good lighting practice. This chapter will present an overview of the principles covered in more exhaustive detail by these documents.

The two professional societies that are most active in the world of lighting recommendations are the Illuminating Engineering Society of North America (IESNA), and the Commission Internationale de l'Éclairage (International Commission on Illumination—abbreviated CIE). Both publish extensive collections of recommended-practice documents, standards, and codes. The IESNA is perhaps best known for its *Lighting Handbook*, a comprehensive manual of lighting practice (IESNA 1993). Both the IESNA (<http://www.iesna.org>) and the CIE (<http://www.cie.co.at/cie/home.html>) have sites on the Internet World Wide Web, that provide quick access to detailed publication catalogues for these organizations, and information about current programs.

Other national and municipal organizations complement the work of IESNA and CIE. Table 18.1 lists some of the other organizations that have a role in regulating lighting practice in North America and around the world, along with their Internet Website address and self-described mandate.

The recommendations set down by professional societies are usually developed through a consensus process. Committees of experts study a topic area and prepare recommended-practice documents. Recommendations are based on relevant research findings complemented by the professional judgment of committee members. In an ideal case, recommendations would be based solely on research findings. However, research is usually limited to very specific questions and results often have limited generality, so professional judgment and consensus help to shape the contents of recommended-practice documents, codes, and standards.

TABLE 18.1 Selected Organizations That Publish Recommended-Practice Documents, Codes, and Standards*

Organization Name	Description	World Wide Web URL
American Society for Testing and Materials (ASTM)	ASTM has developed and published 10,000 technical standards, which are used by industries worldwide.	http://www.astm.org
American Society of Heating, Refrigeration and Air-Conditioning Engineers (ASHRAE)	An international organization whose purpose is to advance the arts and sciences of heating, ventilation, air conditioning, and refrigeration.	http://www.ashrae.org
American National Standards Institute (ANSI)	A private-sector, nonprofit, membership organization whose mission is to promote the use of U.S. standards internationally and to encourage the adoption of international standards as national standards where these meet the needs of the user community.	http://www.ansi.org
Association Française de Normalisation	French Standards Association: promotes and facilitates the use of standards.	http://www.afnor.fr
British Standards Institution (BSI)	Provides secretarial and technical support for BSI standards committees. BSI ensures the views of British industry are represented in international and European standards development.	http://bsi.org.uk
Chartered Institute of Building Service Engineers (U.K.) (CIBSE)	CIBSE is a learned society charged with researching and publishing information about the built environment and with accrediting engineers at work there and in associated industries.	http://www.cibse.org
Canadian Codes Centre	Provides secretarial and technical support for the Canadian Commission on Building and Fire Codes and its related committee operations.	http://codes.nrc.ca/codes/home_E.shtml
Commission Internationale de l'Éclairage (CIE)	International Commission on Illumination. CIE is an independent organization devoted to international cooperation and exchange of information among its member	http://www.cie.co.at/cie/home.html

	the built environment worldwide through development and promotion of uniform codes and standards; enhancement of professionalism in code administration and facilitation of acceptance of innovative building products and systems.	
International Electrotechnical Commission	The International Electrotechnical Commission is the international standards and conformity assessment body for all fields of electrotechnology.	http://www.ies.ch/home-e.htm
Illuminating Engineering Society of North America	An independent not-for-profit professional organization dedicated to all aspects of the art and science of illumination.	http://www.iesna.org
Standards Australia	Standards Australia is an independent, not-for-profit organization whose primary role is to prepare Australian Standards through an open process of consultation and consensus in which all interested parties are invited to participate.	http://www.standards.com.au/
The Southern Building Code Conference International	SBCCI is an internationally recognized model code organization dedicated to serving state and local governments and the building industry through the promulgation and maintenance of performance-based standard codes and by providing technical and educational support services.	http://www.sbcci.org

*The Standards Council of Canada (<http://www.scc.ca/>) and IHS Global Engineering Documents (<http://global.ihs.com>) offer useful search engines for those interested in identifying documents related to specific aspects of lighting.

The legal status of these documents varies with jurisdiction. For example, the Illuminating Engineering Society of North America (IESNA), the International Commission on Illumination (CIE), and the Canada Occupational Safety and Health (COSH) Regulations define required lighting levels for different types of work. In Canada, the COSH Regulations are particularly important for Canadian federal government workplaces, as

they have legislative force behind them. The COSH Regulations, or any of the documents produced by the IESNA and CIE, are sometimes adopted or complemented by state or provincial and municipal codes and standards that specify legal requirements. In other jurisdictions, or in the case of particular lighting applications, professional society documents outline recommended practice.

Good lighting consists of a blend of lighting system technology that has been engineered to meet energy and human requirements. Current recommended-practice documents, codes, and standards are based on a mix of (1) visually *relevant* but *difficult* to measure and apply concepts (e.g., luminance) and (2) visually *irrelevant* but *easy* to measure and apply concepts (e.g., illuminance). The effectiveness of a lighting system will depend on the light source itself, any special characteristics of the viewer or person using the lighting system, and the unique characteristics of the task or object being illuminated.

Although it is beyond the scope of this work to provide detailed information concerning recommendations for specific lighting applications, the remainder of the chapter will highlight the salient features of lighting systems, people, and tasks that affect the acceptability of lighting systems used in office applications. Interested readers with a specific lighting application in mind should first consult the IESNA *Lighting Handbook* and the Internet World Wide Website of the CIE (<http://www.cie.co.at/cie/home.html>) for pointers to more detailed technical guidance.

After reviewing lighting systems technology, the chapter will examine the basic concepts that define light and its measurement. Important features that will influence the acceptability of an office lighting installation, such as distribution, color, glare, luminance ratios, and visibility, will then be discussed. A brief survey of measurement tools and techniques will follow, describing some of the tools and methods by which compliance with relevant codes, standards, and recommended practice is determined. The chapter concludes with a brief overview of research findings related to the more psychological aspects of lighting and lighting for subjective effect.

18.2 LIGHTING SYSTEM TECHNOLOGY

Artificial light is generated through the conversion of electrical energy into visible radiation, typically through one of three basic processes: incandescence, gas discharge/fluorescence, or induction.

Incandescence is the most familiar process by which electrical energy is converted to visible light, and is embodied in the familiar incandescent lamp, commonly used in residential applications. When an electric current is passed through a tungsten wire filament inside a glass envelope that contains an inert gas or vacuum, the wire filament radiates visible light and heat (mostly heat). Incandescent lighting systems are inefficient: only about 10 percent of the electrical energy is converted to visible light, while the remaining 90 percent is dissipated as heat. Incandescent lamps have a short life, as the wire filament usually breaks after 1000 to 2000 hours of use.

More complicated incandescent systems are available that offer extended lamp life. The tungsten filament in a conventional incandescent lamp slowly evaporates as the lamp is used, and it eventually breaks. Adding halogen to the gas that fills the lamp results in a chemical reaction that prolongs filament life, by redepositing the evaporated tungsten back onto the filament. Tungsten-halogen lamps have a longer life, typically 2000 to 6000 hours.

Gas discharge lamps incorporate more complicated technology than incandescent lamps. This family of lamps includes the familiar fluorescent lamp, low- and high-pressure sodium lamps, and high-intensity-discharge mercury vapor and metal halide lamps.

In a typical fluorescent lamp, an electric current is passed through a glass tube containing mercury vapor at low pressure, along with a small amount of inert argon gas. The electric current excites the gas inside the tube, which causes it to emit ultraviolet radiation. The ultraviolet is in turn converted into visible light by the phosphor powder that coats the inside of the glass tube. The color of the light produced by a fluorescent lamp is determined by the properties of the phosphor powder coating. The performance of a fluorescent lighting system (how much light is emitted per unit of input electrical power) will vary as a function of several variables: electrical supply characteristics, luminaire design, ambient temperature, airflow patterns, and the possible combined effects of all these influences (IESNA 1993). Fluorescent lamp life is generally 10,000 to 25,000 hours, depending on lamp type and ambient operating characteristics.

Besides color, the other salient feature that distinguishes fluorescent lamps is diameter. Thinner fluorescent lamps are brighter. Lamps are classified according to their diameter in eighths of an inch: A so-called T12 lamp therefore has a diameter of $1\frac{1}{2}$ inches. Most lamps sold in North America today are 1-inch-diameter, energy-efficient T8 lamps. Even thinner-diameter lamps are available, offering more flexibility in lighting deployment and design than hitherto possible.

Fluorescent and most other gas discharge lamps require a supplementary piece of electrical equipment called a *ballast* to ensure proper operation. The ballast helps start the lamp by initiating the flow of electric current at ignition, and regulates the flow of electricity to the lamp once it has been started. Each ballast is designed to work with a particular lamp size and wattage. Several ballasts will often be available for a particular lamp; these will vary in the method by which the lamp is ignited and operated. The label on the ballast indicates which lamps are compatible.

Older ballasts, so-called magnetic ballasts, consist of a core and coil assembly. A laminated steel transformer core is wrapped with a copper or aluminum wire winding. Other electrical components may also be included in the circuit to regulate lamp start-up and other operating characteristics. This assembly is covered with a nonconducting compound to provide electrical insulation. Magnetic ballasts operate the lamp at the same frequency as the alternating current electrical supply, which in North America is 60 Hz (50 Hz in Europe). This means that the light output from the lamp flickers at the same frequency. Although this flicker is not perceived by most people, there is some evidence that a more comfortable visual environment is provided if fluorescent lamps are operated at a higher rate of flicker than is possible with magnetic ballasts (Wilkins et al. 1988).

Newer *electronic ballasts* consist entirely of electronic or solid-state components. These ballasts operate the lamp at much higher frequencies, usually from 25 to 40 kHz. Most of the commercial and industrial lighting systems being designed or installed in North America today use electronic ballasts. Lighting systems equipped with electronic ballasts are more energy-efficient than those operating with magnetic ballasts, and they produce a more comfortable visual environment (Wilkins et al. 1988).

Compact fluorescent lamps are a special type of fluorescent lamp developed as a replacement for incandescent lamps. Compact fluorescent lamps are more energy-efficient than incandescent lamps, and they last much longer (around 10,000 hours). However, they have a higher purchase cost than incandescent lamps, and since they are fluorescent lamps, it is important to ensure that the ambient operating conditions under which they will be used will not compromise lamp operation or life (Collins et al. 1992; Ouellette, 1993b, 1994).

Induction lamps are a relatively new lighting technology. These lamps use an induction coil rather than an electric current to excite the gas contained within the tube to emit ultraviolet radiation. As with standard fluorescent lamps, the ultraviolet is then converted into visible light by the phosphor powder that coats the inside wall of the glass tube. Although they have not yet achieved the same market penetration as other lamp types, induction lamps offer several advantages over other lamp technology. Because induction lamps have no electrodes, longer lamp life is possible (60,000 hours claimed by one manufacturer).

Lamp manufacturers offer a plethora of variations on these basic lamp types, each designed for a specific application niche. Most manufacturers offer online catalogues on their Internet World Wide Websites. Every year IESNA devotes a single issue (usually the March edition) of its monthly magazine *Lighting Design and Application (LD + A)* to a Lighting Equipment and Accessories Directory. This is an excellent reference for those seeking contact information for most North American lamp manufacturers.

The most significant recent regulatory change in North America that has affected the manufacture and use of lighting systems technology was the passage in 1992 of the Energy Policy Act in the United States and the Energy Efficiency Act and Energy Efficiency Regulations in Canada. Details on the Energy Policy Act of 1992 can be obtained online at <http://thomas.loc.gov> (search for Bill H.R. 776.ENR under the 102nd 1991–1993 Session; the Canadian Energy Efficiency Act is also available online at <http://canada.justice.gc.ca/FTP/EN/Laws/Chap/E/E-6.4.txt>.

Both acts set minimum performance standards that lighting systems must achieve before they can be sold in their respective markets. Some products have been discontinued and are no longer available for use in North America as a result.

Lamps are usually mounted inside a luminaire, which is a specially designed enclosure that holds the lamp in place. Luminaire design is a complex engineering task that requires knowledge of optics and heat transfer. Some luminaires incorporate venting features that dissipate the heat generated by the lamps. Proper heat dissipation improves lamp performance and lamp life. Many luminaires also incorporate special features that have been designed to direct the flow of light to the task area: for example, parabolic metal louvers are carefully designed systems that direct the lamplight downward from the luminaire in an attempt to reduce glare from ceiling lighting systems on visual display terminal (VDT) screens. The most familiar example of a luminaire is the common fluorescent troffer that appears in office ceilings the world over. Luminaires are often designed for specific lamps and applications. It is important to ensure that the lamp and luminaire are compatible, especially in retrofit applications where one lamp type is being replaced by a newer technology (e.g., replacing incandescent lamps with compact fluorescent lamps). Incompatible lamp and luminaire combinations can compromise lamp life and performance, and in some rare instances might even present a safety hazard.

Luminaire manufacturers also offer a wide range of products. Again, the *Lighting Design and Application* annual Lighting Equipment and Accessories Directory is an excellent reference.

Having briefly reviewed lighting system technology, we now turn to consider the basic concepts that are the foundation of lighting codes, standards, and recommended-practice documents.

18.3 BASIC LIGHTING CONCEPTS

Visible light is a small segment of the electromagnetic spectrum, extending from about 380 nanometers (nm) to 760 nm. The measurement and characterization of electromagnetic radiation without regard to wavelength is called *radiometry*. The measurement and characterization of visible light is called *photometry*.

Photometric units are unique in the world of physical metrology, in that they are defined with reference to a psychophysical phenomenon, in addition to the physical quantities used in their definition. All photometric units incorporate a weighting factor that reflects the ability of each wavelength within the visual range to elicit a visual sensation. This weighting factor is required to account for the psychophysical observation that different wavelengths having the same radiant energy will not appear equally bright to a human observer. Two curves have been developed to characterize the human subjective brightness response to light of different wavelengths. Figure 18.1 depicts these two curves.

FIGURE 18.1 Standard spectral luminous efficiency functions.

Two curves are necessary to reflect the fact that human sensitivity to lights of different colors varies slightly from daytime to darkness. The *photopic correction curve* applies to conditions that prevail at daytime lighting levels: by convention, this curve is called the V_λ curve. This curve applies at light levels above 3 candelas per square meter (cd/m^2). The *scotopic correction curve* applies when the eye is in a dark-adapted condition at nighttime; by convention, this curve is called the V'_λ curve, and it applies when ambient light levels are below $0.001 \text{ cd}/\text{m}^2$. Ambient light levels between 0.001 and $3 \text{ cd}/\text{m}^2$ fall within the so-called mesopic range; ongoing work to define the spectral sensitivity of the eye at mesopic levels continues.

The applicable weighting factor for each wavelength is taken into account in the definition of photometric units, which are used to characterize visible light. The most commonly used units are total flux (lumens), light level or illuminance (lux), and photometric brightness (luminance). Two other important quantities are light distribution and color.

The amount of light radiated in all directions by a light source is described by the number of lumens emitted by the lamp (also referred to as the *luminous flux*). The lumen output of a lamp is determined by placing the lamp inside a large sphere, the inside of which has been coated with a spectrally flat white powder or paint coating. The electrical operating characteristics of the lamp under test are precisely defined and controlled. A special photodetector that has been calibrated to measure lumens is mounted on a small port located at the side of the sphere. The lumen output is the basic quantity used by manufacturers to describe and differentiate lamps, and often appears on the sales material accompanying the lamp. The ratio of the light output (lumens) to the electrical energy supplied to the lamp (watts) defines the luminous efficacy of the light source.

Lumen output and lamp efficacy are important, but they tell us nothing about the amount of light being delivered to a task area, where it is required. The quantity used to describe the amount of light falling on a surface is illuminance. The SI unit of illuminance is the lux, which is defined as the luminous flux falling on 1 m^2 of surface area, perpendicular to the light source. The intensity of light falling on a surface varies with the angle of incidence, with intensity falling off as a function of the cosine of the angle of incidence. The intensity is reduced because the projected surface area of the plane of incidence increases as the angle

varies from perpendicular. The relationship between the angle of incidence and intensity is referred to as the cosine law. The Imperial unit of illumination is the *footcandle*: 1 footcandle is equivalent to 10.76 lux.

Most codes, standards, and recommended-practice documents specify lighting requirements in terms of average illuminance on a specific plane. The requirements that apply to a particular task are determined after an *illuminance selection procedure*, which is a method used to tailor the lighting to the needs of the occupants of a space. IESNA, the COSH Regulations, and CIE all define illuminance selection procedures.

The current IESNA illuminance selection procedure considers the following variables in setting recommended illuminance levels:

- The difficulty of the visual task
- The age of the observer
- The importance of speed and accuracy to the work being performed
- The reflectance of the task and task background

The designer or illuminating engineer needs to know these characteristics before a recommended illuminance can be determined. The year 2000 edition of the IESNA *Lighting Handbook* is expected to broaden the list of features and outcomes specified by the illuminance selection procedure, which should result in more differentiated illuminance recommendations. Complete details on the IESNA illuminance selection procedure are available in the current edition of the *Lighting Handbook*.

The COSH illuminance selection procedure is simpler than the IESNA procedure. It legislates average light levels for Canadian government workspaces according to the type of work or tasks being performed in an area and the frequency of work at the location (whether it is performed intermittently or regularly). The complete text of the COSH requirements is available online at <http://canada.justice.gc.ca/FTP/EN/Regs/Chap/L/L-2/SOR86-304.txt>.

Although illuminance measurement units incorporate a weighting factor that reflects the spectral sensitivity of the human visual system, the eye does not see illuminance. The eye sees illuminance reflected from the surface of objects. Luminance, specified in SI units of candelas per square meter (cd/m^2) is a measure of the illuminance reflected from a surface. Imperial units are known as foot-lamberts, with $1 \text{ cd}/\text{m}^2$ equivalent to 0.29 foot-lamberts. Luminance is also sometimes referred to as *photometric brightness*, and it is a measure of the amount of light seen. Luminance is sometimes specified as a requirement in lighting codes, standards, and recommended-practice documents; however, it does not appear as often as illuminance. This is probably because luminance is more difficult and time-consuming to measure than illuminance. Despite this fact, lighting design and illuminating engineering is more concerned with the pattern of luminance in a space than the pattern of illuminance, which should be thought of as a handy proxy measure.

18.4 DISTRIBUTION

The ability of the lighting system to deliver light where it is required is influenced by the design of the luminaire. For example, a screw-in incandescent lamp will often provide more light on a table top, than will the equivalent compact fluorescent lamp. A compact fluorescent lamp incorporates a ballast at the base of the lamp, which will occlude the light coming from the lamp. In contrast, the light coming from an incandescent lamp is not blocked by a similar obstruction. Even though the two lamps may have the same lumen output, the compact fluorescent lamp will provide less illumination at the task because the

ballast prevents some of the light from reaching the task. Two lamps with the same lumen output will not necessarily achieve identical performance.

The effect of the luminaire on the distribution of light is characterized by luminaire manufacturers according to standardized measurement procedures. The resulting photometric reports show the relative distribution of light intensity in all directions coming from the lamp and luminaire system. The lighting system (lamp and luminaire assembly) is mounted in a large apparatus that rotates the assembly through several standard angles and positions. Light output is measured by a calibrated photodetector at each of a series of standard angles, and the resulting information is presented as a graphical polar plot that helps the lighting designer or illuminating engineer visualize the field of light that will be provided by the lighting system. Manufacturers make these data available in tabular form as part of their catalogues and provide them on computer media for input to lighting design software tools that are used in the design process to model the illumination delivered to a space by different lighting system options.

Photometric data sheets are available from luminaire manufacturers. IESNA maintains an online photometric library at their Internet Website (<http://www.iesna.org>). Numerous private laboratories are equipped to undertake photometric measurements on new or custom lighting systems; several are listed in the *Lighting Design and Application* annual Lighting Equipment and Accessories Directory.

18.5 COLOR

One of the most important features to the end user of a lighting system is color, including the ability of the lighting system to effectively render color. Good color is important to a variety of applications: Grocery and other retail require lighting that makes products appear natural and appealing; accurate color rendition can be crucial in medical and dental diagnosis. Light source color is described by three concepts: spectral power distribution, color temperature (measured in kelvins), and color rendering index.

The perceived color of an object is the color of the light reflected from the surface of the object. Colored objects that are illuminated with a light source that is deficient in the predominant color of the object will therefore appear colorless and dull. A common example of this phenomenon is the appearance of automobiles under some types of street lamp, which although energy-efficient, emit light in a very narrow bandwidth and so make colors appear dull. The spectral power distribution (SPD) of a lamp source describes the radiant power emitted by a light source for each wavelength over the visual range of the electromagnetic spectrum. The SPD of a lamp source is important in applications with demanding requirements for color discrimination.

Some investigators have claimed that the SPD of a lamp source will positively influence a variety of human psychosocial and health outcomes. Others have argued that the evidence offered to support these claims overstates the importance of SPD as a causal factor in these outcomes (Veitch 1994).

Color temperature (characterized in kelvins) is used to describe the appearance of the light source itself. The Kelvin temperature scale comes from physics, and describes temperature in terms of an imaginary black metal bar. As the black metal bar is heated and the temperature increases, it changes color from dull to bright red to blue, and then to white when it is hottest. Table 18.2 describes the color temperature associated with several common light sources. The color temperature of fluorescent lamps is usually printed in the lamp itself, and also appears on literature describing other lamp types. Lamps are available in a wide range of color temperatures.

TABLE 18.2 Light Source Color Temperature

Light source	Color temperature, kelvins
Clear sky	10,000
Overcast sky	7,000
Daylight fluorescent	6,000
Cool white fluorescent	4,000
Warm white fluorescent	3,000
Incandescent (100 W)	2,900
High-pressure sodium	2,100
Candle flame	1,800
Low-pressure sodium	1,700

Early work (1944, cited in Bodmann 1967) suggested distinct preferences for different color temperature lamps at different light levels, with warm colors preferred at low light levels and cool colors preferred at higher light levels. More recent studies have failed to replicate these findings (Cuttle and Boyce 1988, Davis and Ginthner 1990), and so the earlier design recommendations should be taken as tentative at best.

The color rendering index (CRI) is a measure that has been developed to describe the appearance of colored objects compared to their appearance under a reference or standard incandescent lamp. The color rendering index is obtained by a standard procedure, and it can range in value from 0 to 100. A CRI of 100 indicates a source that renders colors as well as the reference source, while a CRI less than 50 indicates poor color rendition, and a light source that should not be used where color discrimination is required. Table 18.3 lists CRI for many common light sources.

18.6 VISIBILITY

A central paradox of most lighting recommendations is that they are currently based on, and expressed in terms of, measurement units that only partially relate to the salient features of objects in the world that elicit a visual response. For example, the continuing and widespread use of illuminance as a design criterion probably owes most to the fact that it is easy and relatively inexpensive to measure, even though the human visual system is insensitive to illuminance.

Several attempts have been made to place the foundations of lighting recommendations on a more rational and empirical basis. Visibility models are mathematical equations that relate measured aspects of a visual stimulus to the ability to perform some type of visual task. Several models have been developed: Rea's Relative Visual Performance model (Rea 1986, Rea, Boyce et al. 1987, Rea and Ouellette 1991) has been influential in the IESNA community; the Visibility Level model has been adopted by CIE (1981).

Other models have been developed, based on the unique requirements of specific tasks. For example, Inditsky et al. (1982) developed a model that predicts detection of objects located in different parts of the visual field. Yonemura and Tibbot (1981) proposed a model of visual conspicuity. Gallagher and Lerner's (1983) model relates visual complexity, defined in terms of the different contributions of various spatial frequency components of a visual scene, to an individual's nighttime driving ability. Finally, Overington (1976) developed a model of visual information processing that has been applied to tasks such as target acquisition while flying.

TABLE 18.3 Color Rendering Index of Common Light Sources

Light source	CRI	Color rendering
Incandescent lamp	97	Excellent
Fluorescent, full spectrum, 7500 K	94	Excellent
Fluorescent, cool white deluxe	87	Excellent
Compact fluorescent	82	Excellent
Fluorescent, warm white deluxe	73	Good
Metal halide (400 W, clear)	65	Good
High-pressure sodium (250 W, deluxe)	65	Good
Fluorescent, cool white	62	Good
Fluorescent, warm white	52	Fair
Mercury vapor (phosphor coated)	43	Poor
High-pressure sodium	32	Poor
Mercury vapor (clear)	22	Poor
Low-pressure sodium	—	Undefined

Source: From Economopolous and Chan (1991).

The illuminating engineering community has tended to treat different visibility models as being in competition with one another. A more sensible approach might be to treat the different models as individual tools that can be applied in different contexts, deferring the question of which model is “most valid” until further research has been completed. All the models that have been proposed share the same limitations: the stimulus features that are input to the models are difficult to measure, the mathematics involved in the models are difficult to calculate, and the generality of each model beyond the stimulus conditions used in development remains uncertain.

Most tasks that require good visibility also have other nonvisual requirements that must be satisfied to achieve successful performance. It is useful to think of task performance as consisting of at least four components: visual, motor (eye movements, reaching, placing, etc.), cognitive (mental processes involved in perceiving), and motivational (attitude toward the job, etc.). If any of these components are missing, then performance will be impaired even under conditions of good visibility. On the other hand, the effects of poor visibility might be compensated for by highly motivated, enthusiastic workers.

Visibility models assess only the visual component of task performance. They do not provide an assessment of the relative importance of the other nonvisual components of task performance, which must also be taken into account in evaluating the success of a lighting installation.

As a result of all these considerations, the status of visibility models as a basis for lighting codes, standards, and recommended practices remains tentative at this time.

18.7 GLARE

Glare refers to the detrimental effect of an extraneous light source in the field of view that affects one’s ability to see or perform other visual tasks. The most common example of glare is the effect of headlights from oncoming traffic at night, which is referred to as *direct glare*. Glare can be a problem in a variety of other contexts besides roadway lighting, such as aviation, lighting for sports events, and office lighting.

Direct glare can cause immediate physical discomfort and, in the context of transportation lighting, can be life-threatening. The best remedy for direct glare is to shield the offending light source from the field of view.

Other forms of glare exist, which, although uncomfortable, are not as physically dangerous or painful. With the increased use of visual display terminals (VDTs) in offices, reflected glare has become a widespread problem. Before the advent of the desktop computer and VDT, most office tasks used matte or glossy paper viewed on a horizontal surface. The computer screen is a specular curved surface that is viewed at a vertical angle. The specular surface of the screen reflects an image of the scene it faces—which includes luminaires in the ceiling.

Bright images of luminaires that appear on the video display screen are problematic for several reasons. They form a contrast-reducing veil over the characters on the video display screen that may compromise worker productivity. Since the video display screen is curved, the images of luminaires that are reflected in the screen appear to be located *behind* the plane of the screen. The mechanisms of the human eye that help maintain focus and are used to judge distance may fluctuate between reflected images and text on the display screen itself, producing an intermittent or constant apparent blurring of the screen text characters. The rapid shift in focus between the screen text and the luminaire image appearing behind the screen may compromise the speed of visual processing.

It is interesting to note that great pains are taken to eliminate images of reflected luminaires on video display screens for civilian and military air traffic control, where the consequences of error could be catastrophic. For more common office tasks that juxtapose paper tasks with the video screen, resolving the problem of reflected images of ceiling luminaires by decreasing the level of ambient illumination, as in air traffic control, is unacceptable because this compromises the visibility of paper tasks. Nevertheless, it is important to tailor the lighting system to task demands for office lighting as for other applications where the consequences of error could be catastrophic. Tailoring the lighting system to maximize task visibility holds out the prospect of improved productivity, since it takes the eye and brain time to process visual information. If the lighting system is designed with best visibility in mind, then the time required to see will be minimized.

Industry has provided a range of equipment that is intended to meet the competing demands of video display and paper tasks. Computer manufacturers provide low-reflectance video display screens; a range of other devices that are mounted on the front of the video display unit itself are available to reduce the luminance of reflected images of ceiling luminaires. Manufacturers of lighting equipment provide a range of luminaire and diffuser options that are intended to completely eliminate or reduce the luminance of reflected images of ceiling luminaires (e.g., parabolic louvers, polarizing lenses, indirect lighting systems). Newer flat-panel computer display terminals are less susceptible to this type of reflected glare, and as they become more widespread they will help alleviate this problem.

Veiling reflections are a type of glare that reduces the contrast and visibility of tasks located flat on the work plane. Tasks printed on glossy paper are more susceptible to veiling reflections than those printed on matte paper. Veiling reflections are caused by an interaction between the flat task and the location of luminaires in the ceiling. Luminaires located in the so-called offending zone, in which light strikes the task and is reflected back at the observer at a 90° angle, will cause veiling reflections. Veiling reflections are remedied by careful task location to avoid the 90° “mirror angle” as much as possible.

Glare has been the subject of extensive research, and CIE publishes several documents that cover glare control in various applications (CIE 1976, 1979, 1983a, 1983b, 1990, 1994, 1995).

18.8 LUMINANCE RATIOS

Characteristics of the area adjacent to a visual task can also affect the visibility of the task. Research on the influence of areas surrounding visual tasks began in 1842, when “Lister found...vision to be improved by holding a sheet of paper behind a test object” (Lythgoe

1932). Subsequent systematic investigations into the effects of varying task-to-surround luminance ratios (TSLR) on the performance of visual tasks near threshold have reported that surrounds brighter or darker than the immediate task area produce performance decrements (Lythgoe 1932; Cobb 1914, 1916; Cobb and Geissler 1913; Johnson 1924; Luckiesh and Moss 1939).

The proximity of the surround to the task is also important. High TSLR values are less important to threshold visibility the farther the surround is from the visual task (Adrian and Eberbach 1969, Luckiesh 1944). However, there is little consensus regarding the critical values of the spatial-luminous properties of the task and surround areas for threshold visibility. Cobb and Moss (1928) suggested that surround influence was negligible beyond 8 to 16° visual angle in the performance of a suprathreshold visual task. In contrast, Luckiesh (1944) speculated that surround effects would not be significant for surrounds beyond 30° visual angle.

McCann and Hall (1980) measured contrast sensitivity to sinusoidal gratings surrounded by areas of different sizes and brightnesses. Like many others before them, they showed that the luminance of the surround should be the same as the average luminance of the task (i.e., the sinusoidal grating) for optimum performance. Unlike earlier investigators, however, they showed that the area of the surround important to contrast sensitivity depended on the size (spatial frequency) of the target. Small gratings needed only small surrounds but large gratings needed large surrounds for optimal performance of this threshold task. Thus, the influence of the surrounding field does not depend on its absolute size, but rather on its size relative to the size (spatial frequency) of the visual target. McCann and Hall's findings clearly indicate how TSLR impacts threshold visibility, but there is little evidence concerning the importance of TSLR on suprathreshold visual performance.

Other researchers have studied the effects of varying TSLR on preferences rather than on visual performance (Bean and Hopkins 1980, Roll and Hentschel 1987, Touw 1951, Tregenza et al. 1974, Van Ooyen et al. 1987). Two clear outcomes emerge from this research: (1) preferred TSLR values vary greatly, depending on the surface being evaluated and (2) people seem to prefer surround areas slightly darker than the task area, which seems in contradiction to the threshold performance data that indicated that the surround area should be approximately equal to that of the task.

Rea et al. (1990) conducted an experiment to examine the importance of areas surrounding a task, absolute light level, and task contrast to suprathreshold visual task performance. They demonstrated that the luminance and size of the surrounding field were less important than either task contrast or overall light level to visual task performance under the experimental conditions studied. Therefore the reflectance of areas that surround a task will have at most a slight influence on suprathreshold visual performance.

18.9 MEASUREMENT TOOLS

A variety of photometric measuring devices are available to establish whether lighting systems meet the requirements set down by codes, standards, and recommended-practice documents. Interested readers are encouraged to consult the *Lighting Design and Application* annual Lighting Equipment and Accessories Directory to identify meter manufacturers. CIE publishes two informative documents that describe the calibration and testing of photometric measurement devices (CIE 1982, 1987).

Luminance and illuminance meters combine photometric detectors and components into calibrated systems that respond to light following the V_λ spectral response function and cosine correction law. Since electronic and physical detectors have spectral response functions that bear little resemblance to the human spectral response to light, all luminance and

illuminance photometers incorporate a physical or electronic filtering device that attempts to tailor the spectral response of the detector to the V_λ response function. It is important to note that since luminance and illuminance meters are calibrated by using incandescent lamps, the response of the meter may vary when measurements are collected under other lamp sources (e.g., fluorescent lamps). For example, Ouellette (1993a) compared four different illuminance meters and found relative photometric errors from 1 to 11 percent when comparing measurements collected under 12 compact fluorescent and 2 incandescent lamps.

The solution to this problem is to use an expensive photometer known as a *spectroradiometer* to measure illuminance and/or luminance. These devices measure the absolute spectral distribution of the source, and then calculate luminance or illuminance according to the applicable human spectral response curve. Spectroradiometers are expensive and delicate instruments, and so their application to field measurements is rare. Practitioners should therefore at least be aware that source dependence can cause error in measuring narrow-bandwidth sources or strongly colored objects.

Illuminance meters are generally hand-held devices that incorporate an integrated or remote light-sensitive photodetector head. A remote photodetector head has at least two advantages over an integrated photodetector: (1) the detector can be mounted on a tripod or other device to ensure that it is level and (2) since it is possible to mount the detector at a distance from the technician taking the reading, one avoids reflections from bright clothing and/or shadows.

There are two types of luminance meters. Hand-held spot meters consist of a calibrated photodetector and lens system that the user focuses on the location of interest, and then notes the luminance value that appears on a display. More recently, computerized systems have been developed that use image processing technology and digital cameras to measure luminance. These systems allow investigators to collect digital images of entire scenes that have been calibrated for luminance and size, and then apply image analysis techniques to the data composing the image (e.g., Rea and Jeffrey 1990). Although these devices provide an unprecedented data collection and analysis opportunity, they are not widely used in illuminating engineering. Digital video photometers are still very expensive (around US\$20,000 at time of writing), and there are no lighting requirements that cannot be verified by using less expensive technology.

18.10 MEASUREMENT TECHNIQUES

The ability of lighting systems to adequately illuminate spaces for work and other activities has traditionally been assessed in terms of illuminance at a specified plane. Testing protocols have been developed that purport to accurately characterize the mean illuminance of a space or area by taking a smaller sample of illuminance measurements (e.g., IESNA 1993, CIE 1986), and attempts have been made to validate these protocols (e.g., Bean and Esterson 1966, Carter et al. 1989, Einhorn 1990). Both the IESNA (1993) and CIE (1986) protocols claim to characterize the entire illuminance profile of a given space to within 10 percent accuracy, from only 10 or 20 sample measurements, with the location of the measurement points depending on the nature of the lighting system and other features of the space.

Individual measurement protocols have also been developed for those criteria that rely on luminance, rather than illuminance (e.g., glare, visibility calculations, visual comfort probability). Complete details on these methods are available in the IESNA *Lighting Handbook* and the publications of the CIE (<http://www.cie.co.at/cie/home.html>). Table 18.4 presents a checklist developed by IESNA that outlines some general prerequisites that should apply to all field measurement programs.

TABLE 18.4 Lighting Survey Checklist

-
- Use IESNA recording sheets to note other important factors (e.g., surface reflectances, lamp type).
 - Photometer calibration should be current.
 - Photometer should be cosine/color corrected.
 - Detector should be level.
 - Ambient temperature should be between 15 and 50°C.
 - Take care to not cast shadows or reflect light on the detector.
 - Switch fluorescent lighting on for at least 1 hour before measuring.
 - Exclude daylight by closing blinds or taking measurements at night.
-

18.11 LIGHTING FOR SUBJECTIVE EFFECT

We have seen that lighting codes, standards, and recommended-practice documents typically prescribe the quantity and quality of illumination required to perform different visual tasks. Ensuring that designed spaces are pleasant and facilitate occupant behavior remains outside the purview of these documents, because our understanding of the relations between subjective reactions and which aspects of the physical environment cue them remains primitive. Consequently, lighting for subjective impact has remained more an art than an engineering discipline. Not only is this true for complicated and subtle subjective effects that might be cued or enhanced by lighting, such as using the lighting in a restaurant to enhance feelings of intimacy, it is also the case for other subjective reactions that relate to more basic perceptual processes, like apparent brightness.

Brightness perception has a long history of research, both in illuminating engineering, and especially in that branch of psychology known as psychophysics [e.g., see Stevens (1976) for a review]. Psychophysics is the measurement of the perceived physical characteristics of a carefully measured stimulus, using well-defined behavioral responses from human observers. Illuminating engineers and lighting designers share this interest, because knowing what factors mediate brightness judgments could help in the more effective and efficient illumination of spaces.

Visual psychophysics has succeeded in establishing predictive functional relationships between physical measures of very simple light fields and quantitative perceptual effects [see Stevens (1976) for a review], and several attempts have been made to apply these models to realistic interiors (e.g., Bodmann and LaToison 1994; Hopkinson 1959; Marsden 1969, 1970).

Acknowledged limitations exist with all these models as far as their application to illuminating engineering is concerned. Bodmann (1992) noted that the practical application of his model was “of course limited to simple stimulus patterns...much work remains to be done before we can evaluate more complex scenes in terms of brightness” (Bodmann 1992, p. 33). Marsden (1969) concluded his earlier review with the statement that despite the undeniable progress of psychophysics, “all that can be predicted at the moment is a somewhat anarchical situation” (p. 181) regarding application of these models to illuminating engineering.

These models have been unsatisfactory because the visual fields that make up room interiors are more complex than the simple patches of light used in psychophysical experiments. Despite the undeniable progress made by psychophysicists, a comprehensive understanding of the relationships between the different features that can appear in a simple patch of light (e.g., different contrast gradients) and perceived brightness still remains to be achieved (Gilchrist 1994, Kingdom and Moulden 1989). Consequently it may be premature to expect that models from the psychophysical laboratory will be robust enough to also serve the illuminating engineering community.

There has traditionally been one main obstacle to the application of psychophysical models to illuminating engineering and lighting design. This is the problem of characterizing the visual stimulus. Traditional spot luminance meters provide an incomplete specification of the visual parameters believed to be important in brightness perception in interiors. Using conventional photometry it could take months to specify the characteristics of a real space or complex visual scene. Computerized digital photometers and image analysis (discussed above) allow for rapid, precise, and comprehensive measurements of luminance, contrast, and other aspects of the visual environment. In theory it should be possible to use these new tools to characterize a complex visual scene, and model the influences of single and combined photometric measures on subjective impressions. In practice, however, most of these new systems are not well-suited for application in real interiors, mainly because the fields of view of the lens systems used in these devices are not wide enough to capture a detailed image of a complete space. Until very recently, no measurement systems were available for measuring color as well as luminance. Nevertheless, the availability of these new tools makes clear the inadequacies of psychophysical models, because divergent predictions could result by using different areas of a visual scene as input to the models.

A more accurate characterization of the visual stimulus is crucial to a better understanding of visual adaptation. In the context of work in such diverse fields as visibility, perceived brightness and psychological aspects of lighting research, visual adaptation is a poorly defined concept used to account for the observation that the relationship between brightness and luminance depends in some way on the distribution of luminances in the field of view. Luminance distributions are easier to characterize when the visual stimulus is a uniform patch of light, as in psychophysical experiments. The luminance distributions that make up the complex nonuniform patterns of bright and dark areas presented by more realistic scenes have remained intractable to traditional photometry, but in theory can now be more accurately characterized by using computerized measurement technology.

18.12 PSYCHOLOGICAL ASPECTS OF LIGHTING

Investigators working within the “psychological aspects” tradition have adopted a different approach to identifying what aspects of lighting are responsible for different subjective effects. Instead of concentrating on painstaking definition of the physical stimulus, as had been the case with psychophysics, these investigators used subjective rating techniques to characterize the psychological responses that could be cued by illuminated interiors. By more accurately characterizing psychological effects, they believe it would then be possible to work backward, and identify what aspects of illuminated spaces cued the observed psychological effects.

In the 1970s John Flynn in the United States initiated a research program that established a series of design recommendations which are still followed (see Table 18.5) (e.g., Flynn et al. 1988), and which have received the *imprimatur* of the IESNA (IESNA 1993). Flynn consistently and repeatedly concluded that the apparent brightness of interiors was determined by “the perceived intensity of light on the horizontal activity plane” (Flynn 1977, p. 8), a different conclusion than that drawn by the psychophysicists. This would suggest that for extremely complex visual fields, such as might be observed in interior spaces, the function relating luminance to perceived brightness was linear. If true, problems with photometry and the specification of visual adaptation could be ignored by designers since the apparent brightness of a room would depend solely on the amount of light falling on the horizontal surfaces in the space.

This idea was difficult to reconcile with the results from psychophysics, and contradicted other earlier and contemporary work on psychological aspects of lighting. Other

TABLE 18.5 Lighting Reinforcement of Subjective Effects

Subjective impression	Reinforcing lighting modes
Impression of <i>visual clarity</i>	• Bright, uniform lighting mode • Some peripheral emphasis, such as high-reflectance walls or wall lighting
Impression of <i>spaciousness</i>	• Uniform, peripheral (wall) lighting • Brightness is a reinforcing factor, but not a decisive one
Impression of <i>relaxation</i>	• Nonuniform lighting mode • Peripheral (wall) emphasis, rather than overhead lighting
Impressions of <i>privacy or intimacy</i>	• Nonuniform lighting mode • Tendency toward low light intensities in the immediate locale of the user, with higher brightness remote from the user • Peripheral (wall) emphasis is a reinforcing factor, but not a decisive one
Impressions of <i>pleasantness and preference</i>	• Nonuniform lighting mode • Peripheral (wall) emphasis

studies had demonstrated that the apparent brightness of spaces could also be influenced by light source color (Kruithof 1944, cited in Bodmann 1967; Bodmann et al. 1963; Cuttle and Boyce 1988; Davis and Ginthner 1990; Kanaya et al. 1979), and lamp color rendering (Aston and Bellchambers 1969, Bellchambers and Godby 1972, Boyce 1977, Kanaya et al. 1979).

In general, research on the psychological aspects of lighting has established that spatial distribution of light (Bernecker and Mier 1985, Collins et al. 1990, Perry et al. 1987, Rowlands et al. 1985) and intensity, measured as either luminance or illuminance (Flynn 1977, Rothwell and Campbell 1987, Shepherd et al. 1989), will reliably affect perceived brightness, and so will lamp source color or lamp color rendering, although to a lesser degree. The design utility of this information has been limited by at least three important factors. First, different studies have sometimes produced contradictory results. For example,

- Kruithof's (1944, cited in Bodmann 1967) often-cited work was recently questioned by Cuttle and Boyce (1988), and Davis and Ginthner (1990)
- Rowlands et al. (1985) claimed that the appearance of a luminaire is unimportant, whereas Bernecker and Mier (1985) showed the appearance of a bright element on a luminaire can have an effect on perceived brightness.

While these contradictions probably stem from the impossibility of simultaneously studying all the factors that might influence perceived brightness, they have slowed the transfer of research findings to design practice, which needs well-established principles.

Second, as with psychophysical experiments, the inability to specify precisely visual adaptation and limitations with photometry have frustrated researchers. If the distribution of luminances within a space will influence perceived brightness, then the range and variation in luminances within a space are of interest. Accurate measures of range and variation require more luminance data than are practical to collect with a spot luminance meter.

Finally, investigators working within the tradition of psychological aspects of lighting research have relied on subjective rating data to draw conclusions about what makes spaces appear bright or gloomy. This is problematic if the eventual goal is a set of recommenda-

tions that specify perceived brightness–luminance relationships, because subjective ratings only give information about the rank ordering of a set of stimulus conditions, not the magnitude of the difference that exists between them. While it is interesting to know that subjects will rate one space as brighter than another, designers and illuminating engineers also need to know how much brighter, since without this information it is difficult to balance the costs of different design decisions with the return in subjective effect.

CHAPTER 19

THE ACOUSTIC ENVIRONMENT: RESPONSES TO SOUND

Tyrrell S. Burt, Ph.D.

*Royal Institute of Technology
Stockholm*

19.1 INTRODUCTION

Sources of noise in an office environment include heating, ventilating, and air-conditioning (HVAC) systems, speech, and office equipment. These can have effects on annoyance, speech intelligibility, and performance, and could be a factor in sick building syndrome. The emphasis here is on the effects of noise, which is usually defined as unwanted sound. This chapter will be limited to the office environment, and so will not consider effects such as hearing loss or other physiological effects resulting from exposure to high levels of noise. Nor will it consider the effects of vibration.

HVAC systems produce noise of fairly low frequency, extending into the infrasound region. The biological effects of infrasound have been studied mainly with respect to very high levels for short durations. Currently there is no information available on the long-term effects of lower levels, such as those encountered by office workers. A comparison of the literature on infrasound and on sick building syndrome shows a similarity in the description of symptoms. Therefore infrasound is potentially a cause of some of the symptoms of sick building syndrome.

Many people involved in building investigations have little expertise in acoustics, and so this aspect is often overlooked in a building investigation. Most investigators would like a simple, single-figure measure of the acoustic environment. The A-weighted decibel scale (dBA), first derived in 1927, is the most commonly used figure. In the right circumstances, and as long as its limitations are understood, dBA can provide a useful indication of the acceptability of the acoustic environment. But it does not take account of low frequencies and infrasound. Thus a measure that has been useful for decades is now beginning to show weaknesses in modern buildings, and new measures are needed to account for the characteristics of new, technically sophisticated buildings.

19.2 ACOUSTIC FUNDAMENTALS

Sound Propagation

Sound consists of energy generated by a source and transmitted by pressure fluctuations of the medium through which it travels. The pressure fluctuations can be described in terms of the velocity, frequency, and wavelength. The number of fluctuations (cycles) per second is the *frequency* in hertz (Hz). Subjectively, it is the pitch of a pure tone: The greater the frequency the higher the pitch. The distance between points of equal pressure is the *wavelength*. The *velocity* of the pressure wave is given by:

$$v = f\lambda \quad (19.1)$$

where v = velocity, m/s

f = frequency, Hz

λ = wavelength, m

The velocity of sound in air is proportional to the square root of the absolute temperature, but almost independent of air pressure. For air, it is normally taken as 340 m/s (the value at 14°C). The wavelengths of various frequencies at this temperature are given in Table 19.1. Note the long wavelengths in the infrasound region below 20 Hz: A 20-Hz wave is 17 m (56 ft), and lower frequencies are longer.

Octave Bands

An octave band is a frequency band with the upper frequency twice that of the lower frequency. Thus for a center frequency of f , an octave band ranges from $f/\sqrt{2}$ to $f \times \sqrt{2}$; e.g., the octave band centered on 1000 Hz ranges from 707 Hz to 1414 Hz. Once one band is fixed, the rest become fixed. The International Organization for Standardization (ISO) has agreed on centering the octave bands at 1000 Hz, which gives the center frequencies shown in Table 19.1. The octave bands can be further divided into one-third-octave bands.

The normal range of human hearing covers roughly 10 octave bands, from 20 to 20,000 Hz, although the frequencies are not cut off sharply at each end. The sensitivity of the ear

TABLE 19.1 Wavelengths of Various Frequencies of Sound in Air at 14°C

Frequency, Hz	Wavelength, m	Wavelength, ft
8	42.5	139.44
16	21.25	69.72
31.5	10.79	35.41
63	5.40	17.71
125	2.72	8.92
250	1.36	4.46
500	0.68	2.23
1,000	0.34	1.12
2,000	0.17	0.56
4,000	0.09	0.28
8,000	0.04	0.14
16,000	0.02	0.07

varies with frequency, and higher levels are required at the frequency extremes for a tone to appear equally loud as a tone at 1000 Hz. The normal audible range is shown in Fig. 19.1.

Weighting Curves

The sensitivity of the ear varies also with the loudness of a sound. Three weighting curves, the A, B, and C curves, have been devised to approximate the ear's varying sensitivity with frequency over three ranges of loudness, Fig. 19.2. (Another curve, the D-weighting curve, was later added for aircraft noise.)

The A-weighting curve is based on loudness curves measured by Bell Laboratories in 1927. It is defined by standards such as those set by the International Electrotechnical Commission (IEC) in 1961 and 1973. Originally it was meant only for low sound levels, below 55 decibels (dB). B-weighting was for levels from 55-85 dB, and C-weighting for levels over 85 dB (Porges 1977). In practice, A-weighting (dBA) is now used in most noise regulations, and C-weighting is used with sound reproduction systems. The C-weighting scale is similar to the linear scale (dBLin) with no weighting.

One of the reasons A-weighting has become so popular is that it provides a single-figure measurement of the acoustic environment that approximates the sound heard by the ear. For many applications, this is enough. But a dBA reading does not closely resemble the loudness of complex sounds. Also, Fig. 19.2 shows that the A-weighting curve gives large attenuations at low frequencies. Therefore A-weighting should not be used in noise assessments of mechanical ventilation systems, which have strong components in the low-frequency and infrasound regions. Using the A-weighting scale can show a reduction in noise levels when silencers are fitted or other remedial measures are taken; often the energy has merely been shifted to a lower frequency, outside the range of A-weighting.

Because of the limitations of weighting networks, a more detailed knowledge of the frequency spectrum is needed for analytical work. There have been many attempts over the years to devise methods that consider the frequency spectrum and still allow the acoustic environment to be expressed with a single value (Warring 1983, Blazier 1995). The result has been a confusing number of acceptability criteria. The various curves are often at odds, especially in the low-frequency region (if they even extend that far). They apply only to

FIGURE 19.1 Normal audible range, showing how the sensitivity of the ear decreases toward the frequency extremes. Adapted from Szokolay (1980).

FIGURE 19.2 Weighting curves, from Iqbal et al. (1977). Note the large attenuation given by A-weighting at low frequencies (50 dB at 20 Hz, more at lower frequencies).

continuous noise, with no fluctuations and no unusual shapes in the spectrum. In spite of more sophisticated techniques for indicating loudness, dBA measures are as good as any unless there are unusual spectra (Porges 1977).

Unusual spectra include the low frequencies produced by HVAC systems (Hegvold and May 1978). Some information about the low-frequency content of a sound is given by (dBLin - dBA). If this value is greater than 20 dB, then complaints are likely to occur (Leventhall 1980, Broner 1994). More detailed information about the low-frequency content and unusual spectra are best obtained by plotting the frequency spectra, rather than by using single-figure criteria. Spectra can be plotted by attaching an octave band or one-third-octave band filter to a sound level meter, and recording the levels in the different bands.

Sound Levels

The magnitude of sound energy may be expressed either as power, intensity, or pressure. Sound *power* is the total rate of acoustical energy produced by a source, in watts (W). This is the value quoted by equipment manufacturers for their products. Sound *intensity* is the rate of energy flow through an area normal to the flow, W/m^2 . It is a vector quantity that describes both the magnitude and direction of the energy flow. Sound *pressure* is the value of the pressure variation, in pascals (Pa). It has magnitude but no direction. Because the pressure fluctuates above and below a static value, the sound pressure level is taken as the root-mean-square pressure of a full cycle.

The three quantities vary over wide ranges; e.g., sound power varies from 10^{-12} W for the threshold of hearing to 10^4 W for a turbojet engine. Therefore logarithmic ratios are used so that all three terms can be expressed as *levels* in decibels:

$$\text{Sound power level} = 10 \log_{10} \left(\frac{P}{P_0} \right) \text{ dB} \quad (19.2)$$

$$\text{Sound intensity level (SiL)} = 10 \log_{10} \left(\frac{I}{I_0} \right) \text{ dB} \quad (19.3)$$

$$\text{Sound pressure level (SpL)} = 10 \log_{10} \left(\frac{p}{p_0} \right)^2 = 20 \log_{10} \left(\frac{p}{p_0} \right) \text{ dB} \quad (19.4)$$

where P = sound power, W

I = sound intensity, W/m²

p = sound pressure, Pa

I_0 = reference intensity = 1 pW (10^{-12} W) (10^{-13} W has been used in the United States)

p_0 = reference pressure = 20 μ Pa (20×10^{-6} Pa = 20×10^{-6} N/m²)

A decibel figure must always have a reference value. If it is not stated, it is taken as 20 μ Pa for SpL.

The sound pressure level, SpL, is the measure most often encountered in guidelines and regulations. Sound intensity (as distinct from sound intensity *level*) is measured as the product of the instantaneous SpL and particle velocity of an imaginary particle in the sound field. It is only recently that instruments have been developed to measure intensity. The sound intensity *level* has the same numerical value as the sound pressure level in air.

An office environment has continuous noise, such as HVAC noise, and fluctuating noise, such as speech and office machinery. Fluctuations can even arise in HVAC noise from unstable fan operation, or “beats” between two fans operating at nearly the same speed. Fluctuating noise is difficult to measure on a sound level meter. Various methods have been proposed for recording the noise over periods of time, and integrating the results in different ways. A bewildering number of measures and acceptability criteria have been proposed. Possibly the most useful measure of the acceptability of fluctuating noise is L_{eq} , the equivalent (continuous) sound level, recommended by the ISO. It is the level of steady sound that would contain the same energy as the time-varying sound. It usually refers to A-weighted energy, but not always. If the sound is steady, continuous, and has no unusual frequency spectra, then L_{eq} is similar to dBA. For its measurement, an *integrating sound level meter* is needed (Warring 1983).

The noise sources in an indoor environment can thus be measured by using a sound level meter with an octave band filter for steady noise, and an integrating sound level meter for fluctuating noise. HVAC systems can generally be considered as steady noise sources, and the levels should not exceed, e.g., 40 dBA in offices in Sweden. Typical noise levels in offices are fluctuating noises of 50 to 70 dBA, although short-term peaks of over 80 dBA occur (Keighley 1970). Most of this has its source within the room, and consists of noise due to speech, the peaks being due to noise from machinery, e.g., telephones ringing.

19.3 NOISE FROM HVAC SYSTEMS

HVAC Noise Sources

The noise in an HVAC system comes from the fan unit, the ductwork, and the terminal devices. Terminal devices at the end of supply ducts are called diffusers, those at the begin-

ning of exhaust ducts are registers, grilles, or mushrooms. Most HVAC noise is due to turbulent flow acting on blades, vanes, and casings (Neise 1992). The components that generate the most noise are the supply and exhaust fans (Hoover and Blazier 1991).

The fan should be selected to operate at the point of maximum aerodynamic efficiency, which is also the optimum point acoustically (Iqbal et al. 1977, Graham and Hoover 1991). Designers often try to use large, slow-moving fans to reduce noise. But fan noise is not just a function of the rotational velocity, it is also a function of the tip speed, which increases with increasing diameter. Undersized fans with high shaft speeds are noisier than fans operating at maximum efficiency; oversized fans with low shaft speeds produce more low-frequency noise.

In the fan unit itself, the noise comes from several sources (Neise 1992):

- The effect of the fan blade displacing air—the blade thickness noise
- Pulsation as moving blades pass stationary cutoffs at the outlet—the blade frequency
- Vortices from the trailing edge of the fan blades
- Mechanical noise, e.g., worn bearings
- Rotating stall

Rotating stall occurs when the flow rates are low across the fan blades. The side of the blade facing the flow is the pressure side, the other is the suction side. The flow stops on the suction side of one blade, which changes the angle of attack on the next blade and stalls the flow there as well. A stall cell builds up that moves around the blade in the opposite direction to rotation and produces low-frequency pressure pulsations.

A fan can be fitted in a scroll or a plenum chamber, Figs. 19.3 and 19.4. A plenum chamber has a slightly lower efficiency than a scroll, but it is physically shorter and can therefore fit in confined spaces. The choice of fan is greater so that more efficient and therefore quieter fans can be selected. Noise is further reduced by lining the plenum box with acoustic absorbing material.

Noise can also radiate out from ducts (breakout noise) and be transmitted from room to room via the HVAC ductwork (flanking transmission), Fig. 19.5. Any tees, bends, struts, or other features close to the fan inlet or outlet increase turbulence and thus increase noise levels. Diffusers at the end of supply ducts produce a fairly high-frequency hissy noise. Dampers placed behind diffusers result in more noise. Variable air valves (VAV) are a dominant source of noise, due to the pressure drops; the levels can be high enough for speech interference. They produce broadband noise peaking at 125 Hz.

Noise estimations for HVAC systems are usually based on:

- The sound pressure level quoted by the manufacturer
- The silencer attenuation according to the manufacturer's data
- The effects, both positive and negative, of the ductwork and fittings, usually calculated from a textbook

The difference between this calculated noise and the actual noise of the installed HVAC system is called the *installation effect* (Bolton 1992). Nowadays fan manufacturers are required to provide noise levels both under standardized conditions and in systems. Even so, acoustical ratings of HVAC products are more useful for comparing products than for investigating performance in installed systems (Ebbing and Blazier 1997). A difference between the installed noise and the fan test standard can be due to factors other than the installation effect:

- Measurement technique and accuracy
- Manufacturing tolerances (the installed fan may be different to the tested fan)

FIGURE 19.3 A scroll fan, centrifugal with backwardly curved blades.

FIGURE 19.4 A plenum fan.

- Data limitations, e.g., the frequency range below 100 Hz is often not given
- Variability between testing laboratories

Control of HVAC Noise

Because A-weighting attenuates low-frequency noise readings, dBA is not recommended as a diagnostic tool for HVAC noise. Complaints about HVAC noise are related more to the quality of sound than the level, e.g., unbalanced spectra producing rumble or hiss, and using time-averaged A-weighted sound levels may not identify the reason for complaint (Blazier 1995).

Noise reduction is usually aimed at either reducing turbulence, or reducing the fan's response to turbulence. Solutions are usually specific for one type of fan, so general recommendations cannot be made (Bolton 1992). Sound transmission in ducts needs to be reduced without reducing or altering the flow. *Passive* noise control involves adding damping material and silencers. It is not effective at low frequencies because of their long wavelengths.

Active noise control feeds a counteracting signal into the duct to cancel the main signal. Active control allows the most effective fan configuration to be chosen, and the noise to be attenuated afterward. The system can adapt to changing frequencies (Mendat et al. 1992).

FIGURE 19.5 Breakout and flanking noise from ducts, and diffuser noise.

The effect is limited to waves that have a wavelength greater than the largest duct diameter, which usually means frequencies below 250 Hz. Active noise control systems can attenuate both broadband and narrowband (blade) frequencies. To work effectively, however, the air-flow must have a low velocity (<8 m/s) and minimal turbulence, conditions which are often not met in modern HVAC systems.

The most effective way of reducing HVAC noise is by good system design. Corrections carried out after installation are often difficult and expensive. Good design includes selecting the best fan and designing for low pressure drops (Guenther 1998). From the viewpoint of both noise and efficiency, it makes more sense to adjust fan speeds than to throttle the flow with VAV dampers. Diffuser noise can be reduced by increasing duct diameter or increasing diffuser size (Hoover and Blazier 1991).

19.4 INFRASOUND

HVAC systems produce noise in the low-frequency and infrasound regions. The levels involved vary, but occupants can be exposed to 80 to 90 dB. Whether long exposures to such levels is harmful is still not known; most research into the biological effects of infrasound has been carried out at higher levels. Some investigators reported symptoms such as fatigue, dizziness, irritation, and nausea from exposure to infrasound, and implicated infrasound as a cause of allergies and nervous breakdown (Gavreau 1968). The descriptions seem remarkably similar to some descriptions of sick building syndrome (Finnegan et al. 1984). Review articles on the effects of infrasound have been produced by Händel and Jansson (1974), Westin (1975), Harris et al. (1976), and Broner (1978), and a book has been edited by Tempest (1976). Infrasound has been a controversial subject, with some authors reporting alarming effects from exposure to infrasound, and others saying the effects have been exaggerated.

The Nature of Infrasound

Although the audible range is usually quoted as 20 to 20,000 Hz for humans, there are no sharp cutoffs at the frequency extremes. The ear becomes progressively less sensitive to lower frequencies, so that the threshold is about 70 dB for a 20-Hz sound. Below 19 Hz, tonal quality is lost as tones lose their smoothness (analogous to flicker in vision). Below about 15 Hz, the sound is perceived as a pumping noise. Below 10 Hz, there are only tac-

tile sensations in the ear. Curves of equal loudness, equal annoyance, and hearing thresholds for infrasound have been determined (Whittle et al. 1972, Yeowart 1976, Møller and Andresen 1983); see Fig. 19.6. The curves converge somewhat in the infrasound region and the slope flattens out; i.e., once the auditory threshold is reached, slight increases seem very loud and annoying. Equally, modest reductions may be all that is needed to remove the effects. Various attempts have been made to produce the best weighting curves for low frequencies (Brüel 1980), but there is still no standard.

Natural infrasound is mostly below 2 Hz, and is produced by thunder, earthquakes, and volcanoes. The energy can be propagated over large distances. One of the few attempts to study the effects of natural infrasonic waves was carried out in Chicago, to see if there were any effects on traffic accidents or absenteeism among schoolchildren. Some correlation was found (Green and Dunn 1968). The effects of natural infrasound on humans are probably minimal, because the wavelengths at 1 Hz are so large in relation to human size (Westin 1975). At one time Sweden had working limits of 110 dB for the 2- to 20-Hz range. Such a limit is rather impractical, as it could result in work stoppages just because a strong wind is blowing against a building (Brüel 1980).

Artificial infrasound can occur in many settings. A car travelling on a motorway with the window open can have a sharp peak at 16 Hz. A bus typically produces a spectrum with a peak in the 63-Hz band at around 90 dB, which translates into a 10- to 20-Hz band indoors when the bus is passing at 50 km/h. Trains produce around 100 dB at 100 Hz, which can affect the driver's alertness, although it is not usually a problem for the passengers. Indoors, the main source is HVAC systems (Leventhall 1980).

Effects of Infrasound

Although some work was done on the biological effects of infrasound in the 1930s, e.g., by the Nobel prize winner George Von Békésy in 1936, interest in the field then

FIGURE 19.6 Curves of equal loudness for the infrasound region (Møller and Andresen 1983). The phon is a unit of subjective loudness whose values have been standardized to coincide with the decibel scale at 1000 Hz.

declined. Revival in interest came with the advent of supersonic aircraft and sonic booms, and with concerns about the effects of rockets used in the space programme. This resulted in several studies over about a decade starting in 1965. Many articles appeared in the nonscientific press during this period, resulting in some skepticism about the effects that persists to this day. Even the results from scientific studies were inconsistent, because infrasound is difficult to produce under experimental conditions and difficult to measure.

The first experiments (Mohr et al. 1965) showed that exposures up to 150 dB could be tolerated for short periods (2 minutes). Sources included loudspeakers in a reverberation chamber and a J57 turbojet engine with afterburner in an F102A aircraft. Some of the effects reported from very low frequencies (5 to 10 Hz) were chest wall vibration, gag sensations, and changes in respiratory rhythms. Exposure to frequencies of 50 to 100 Hz resulted in mild nausea, headaches, choking, coughing, visual blurring, and fatigue. Although there was much individual variation, all subjects reported severe postexposure fatigue that could only be resolved by a night's sleep.

Studies showed that infrasound is transmitted poorly via air to the body organs (von Gierke and Nixon 1976), and that any possible effects are mostly due to pressure effects in the ear (Westin 1975). Comparisons of deaf people with normal people indicated that low-frequency noise affects the cochlea (Yamada et al. 1983).

Tests carried out at more moderate intensities around 125 dB produced drowsiness, lack of concentration, nausea, postexposure fatigue, and headache (Evans 1976). Frequencies of 15 to 20 Hz produced respiratory difficulties, sensations of fear, and cutaneous flushing. In one study, levels as low as 85 to 110 dB could produce violent and sudden attacks of nausea at 12 Hz, even in people who were skeptical about the effects of infrasound (Brown 1973). There is even some anecdotal evidence of complaints at levels as low as 65 dB (Tokita 1980), and it is still possible that such low levels can have psychological rather than physiological effects.

These reports were some of the more worrisome about infrasound to come out, because they suggested that everyday levels of infrasound could cause problems in some people, especially those with balance disturbances or other middle ear problems (Tempest 1976). Levels of 115 dB can occur in a car on a motorway, and it was postulated that some motorway accidents were the results of increased reaction times, lethargy, drowsiness, and euphoria produced by infrasound.

Several investigators began to suggest that the effects had been exaggerated (Harris and Johnson 1978). Tests carried out at 144 dB for 8 minutes had failed to show detrimental effects (Slarve and Johnson 1975), although some subjects reported drowsiness and a decreased ability to concentrate. One reason for the controversy may be the assumption that the effects due to infrasound increase linearly with increasing levels. However, there is some evidence to the contrary. Levels below 120 dB may have a depressive effect, and higher levels an arousal effect (Broner 1978). A typical office environment has the lower levels. The depressive effects at lower levels could account for symptoms such as fatigue and lack of concentration.

Sensitive people have a lower threshold to infrasound, a phenomenon reproducible under laboratory conditions, and show changes in respiration rate and the alpha wave rhythm. People with a cold can experience nausea and vomiting when exposed to infrasound (Okai et al. 1980). People who develop an allergy whereby they become sensitive to very low levels of a stimulus frequently have a spillover effect and become sensitive or allergic to other stimuli. Allergic people should therefore be considered a risk group for sensitivity to infrasound, until more information is available (Burt 1998).

By 1980, more buildings were being constructed with tight sealing and mechanical ventilation to save energy. People thus began to spend more time in closed spaces ventilated

by low-frequency pulsed air (Borredon 1980). Unfortunately, interest in infrasound began to decline at about the same time. The acoustic environment in modern, tightly sealed buildings with mechanical ventilation has received little study, and almost none with respect to sick building syndrome.

To this day there have been very few studies about the effects of longer durations of infrasound at more moderate intensities, such as those encountered by many office workers. One study tested subjects for two working weeks (8 hours a day for 10 days) at levels of 70 to 125 dB, and frequencies of 3 to 24 Hz, both pure tone and band. Measurements were made of several physiological parameters such as ECG, blood pressure, respiration, and epinephrine and norepinephrine in urine. The physiological parameters were not significantly altered, but several subjects reported subjective effects such as reduced concentration, increased tiredness, headache, and tenseness (Ising 1983).

19.5 THE EFFECTS OF INDOOR NOISE

In addition to noise from HVAC systems, the indoor environment has other sources of noise. These include speech, noise from equipment, and outdoor or community noise.

Community noise includes the noise from aircraft, trains, and traffic. In an indoor environment, such noise becomes a problem only if it penetrates the building envelope. In modern, well-sealed buildings, this usually only occurs if the windows are opened. If the windows are kept closed to shut out community noise, then it becomes important that the HVAC systems are working as intended, and that their noise levels are not excessive. There have been reports where shutting the windows and turning on HVAC systems resulted in higher noise levels than with the windows open and the HVAC system switched off (Lee and Khew 1992).

Community noise is a large field, with specialists for aircraft noise, traffic noise, noise assessments of building sites, etc. Modern, well-sealed buildings with double or triple glazing are fairly well insulated from outdoor noise, and so the effects will not be considered further here.

Most standards and recommendations for noise were made for industrial environments, as were most of the noise reduction measures. The number of places with high noise levels is now decreasing, but the number of places with moderate levels is increasing. These include office buildings, where average noise levels vary from about 50 to 80 dBA (Keighley 1970). At these levels, the risks for hearing damage and physiological effects are slight. Instead, the effects of noise on psychosocial factors like *annoyance*, *speech*, and *work performance* become important (Guignard 1965, Kjellberg 1990).

Annoyance

Annoyance to noise is a subjective reaction, and therefore needs to be measured by human opinion. Annoyance is due to the degree of noisiness plus the respondent's assessment of other factors like fluctuations, emotional content, visual cues, and novelty (May 1978). Because of individual differences, annoyance assessments need to be based on surveys of many people rather than studies of a few individuals (Borredon 1980).

The view has been expressed that annoyance responses are little more than fickle responses of cranks or unstable persons. But there is a large body of evidence now available showing consistent increases in reported annoyance with increasing noise. Moreover, these surveys have shown that there is little relationship between annoyance and personality traits such as neuroticism or stability, or factors like type of employment and income.

Even directing attention to a noise source, e.g., by a survey or by media exposure, has little effect on the results. Nor does directing attention away from noise, e.g., by using a “concealed” questionnaire which purports to be about other environmental matters (Large et al. 1982).

Annoyance to a noise usually increases with time, contrary to the popular belief that adaptation takes place (Kjellberg 1990). It is often assumed that annoyance increases with increasing loudness, but a noise need not be loud to be annoying, e.g., an insect buzzing around one’s head. Also, loud noises can be regarded as pleasurable, e.g., loud music. Thus the type of noise is probably more important than the noise level in determining annoyance.

Three kinds of annoyance can be described (McLean and Tarnopolsky 1977):

- Subjective, or feelings of being bothered, angered, or having privacy invaded
- Interference, or disruption of activities
- Stress annoyance, resulting in the symptoms of stress such as headache, tiredness, irritability, and lowering of morale

Other factors affecting annoyance are fluctuating, unpredictable, and uncontrollable noise. An important factor in controlling noise is the *perception* of control, i.e., the feeling “I can do something about it” (Hirsch 1973). If people know that they can turn the noise off, the noise is more acceptable. A person operating a machine controls the noise it makes, and therefore can deal with the noise better than someone else hearing the same noise. The two people will also have different attitudes to the noise. Surveys showed, for example, that those who were in favor of the Concorde project were less annoyed by its noise than those who were opposed (Kjellberg 1990).

Infrasound and low-frequency noise become annoying when the masking effect of higher frequencies is absent (Leventhall 1980). This can happen with the transmission of signals through walls, which attenuates the high frequencies. Accommodation to such low-frequency noise seems more difficult than to noise of higher frequencies, and can produce typical stress symptoms of headache; pains in neck, arms, and legs; and digestive disorders. Susceptible people are more sensitive to the annoyance effects (Broner 1978) and so annoyance can be considered a feature of infrasound.

Speech

Background noise can interfere with speech communication, and the higher the noise the more the voice has to be raised for satisfactory communication. Background noise includes irrelevant speech, which can be disruptive because of its informational content. However, even incomprehensible speech is annoying (Kjellberg 1990). This has been demonstrated with unknown foreign languages, or even with tapes played backward (Jones and Broadbent 1991). There appear to be some aspects of speech that distinguish it from other kinds of noise. Thus vocal music is more disruptive than instrumental music. The effects of irrelevant speech are independent of the level once it is higher than 55 dBA (Jones 1990).

Speech consists of vowel sounds, mostly at frequencies of 125 to 2000 Hz, and consonants, which are at higher frequencies of 3000 to 6000 Hz. The effective speech frequency range is 600 to 3000 Hz, and a loss of information outside this range does not severely reduce intelligibility (Guignard 1965). Unfortunately, noise-induced hearing loss affects frequencies around 3000 to 4000 Hz, thus affecting the ability to hear consonants.

The level of speech depends on vocal effort and is different for male and female voices. The maximum loudness of male voices occurs around 400 Hz, and for female voices around 900 Hz. Normal speech, when measured at intervals of $\frac{1}{8}$ second, covers a range of nearly 30 dB. However, speech levels are usually measured and expressed in terms of

the long-time (60 seconds) root-mean-square pressure (Kryter 1970). Typical levels are given in Table 19.2.

Speech must be clearly articulated, and the listener needs good hearing, in order to be intelligible. Articulation indices exist, although they can have a lot of correction factors and still not accurately predict the intelligibility of a speaker; some voices have spectra that are harder to understand than others. Therefore indices are seldom used today.

Speech interference levels (SILs) were devised as long ago as 1956 (Beranek 1956). The SIL is the maximum level of noise that allows speech without interference. It is measured as the average sound pressure level of the three octave bands centered on 500-, 1000-, and 2000-Hz octave bands. More bands have been tried, but the results are almost identical to three bands. A common recommendation is that the SIL should be more than 12 dB below the level of speech to avoid interference (McLean and Tarnopolsky 1977).

Background levels of 30 to 40 dBA have a minimal effect on the speech level required for clear articulation, and the maximum recommended background level for classrooms, for example, is around 47 dBA (Lee and Khew 1992). After that, a speaker needs to raise the voice by about 0.5 dB for every 1-dB increase in background noise. Loud speech above 75 dBA becomes less intelligible than normal speech. Also, at this point the background level would be above 60 dBA, and high background levels also reduce intelligibility (Keighley 1970).

People with hearing losses are more affected by irrelevant speech than those with normal hearing; i.e., they have more difficulty in a “cocktail party environment.” Also, they are usually more annoyed than people with normal hearing. Thus the idea that they won’t be annoyed if they cannot hear the noise is wrong (Kjellberg 1990).

The above guidelines are for a steady situation. In the real world, sounds vary with time, resulting in time-varying interference with speech. There can also be effects involved other than pure masking. For example, a noise can force a listener to concentrate more on receiving the signal correctly, and less on comprehension (Hockey 1978). The effects on acceptability are difficult to determine, but the Environmental Protection Agency in the United States describes $L_{eq} = 45$ dBA as an acceptable level for speech indoors.

Performance

Performance effects are distinct from annoyance effects. The effects of noise on performance can be positive or negative, depending on the type of noise, task demands, familiarity with the task, whether the task is verbal or not, conflicting demands, duration of the task, and effects on morale as a result of managers’ concern for workers. Sudden changes in noise levels produce a temporary performance loss, as do noise bursts and unfamiliar noise. Continuous or familiar noise has little effect on familiar tasks. Irrelevant noise, rather than

TABLE 19.2 Typical Sound Pressure Levels, dBA, for Speech at a Distance of 1 Meter

Type of speech	Male voice	Female voice
Whisper	20–30	20–25
Low voice	50–60	45–55
Normal voice	65–68	60–65
Raised voice	70–75	68–70
Loud voice	75–80	70–75
Shouting	>85	75–85

Source: Adapted from Warring (1983).

noise that is part of the work, reduces efficiency. High frequencies affect performance more than low frequencies do (Jones and Broadbent 1991).

Performance is usually measured by various short-term psychological task tests carried out in a laboratory. The results do not always translate well into actual working places and over 8-hour working days (Hockey 1978). Nevertheless, several investigators have shown that noise (excluding speech) need not affect performance, or that the effects are surprisingly small. The performance of simple tasks may actually be improved by noise, but performance is impaired in complex or high-information-load tasks. Cognitive tasks (verbal learning, memory, mental arithmetic, etc.) can be affected by 70 to 80 dB, i.e., the levels found in offices.

A subject can compensate for raised noise levels by concentrating harder. However, there is usually a price to be paid. The extra effort can be demonstrated as physiological stress. If the stress levels stays the same, then the work rate worsens. If the work rate stays the same, then more mistakes are made, judgment is impaired and irritability increased (McLean and Tarnopolsky 1977).

Noise can affect the rate or process of learning. During a lecture, more learning takes place when the narrator implies some emotion, regardless of visual or other supporting media. The kind of emotion is irrelevant; more learning can be shown to occur even when the speaker is contemptuous of the subject matter. Music can also assist in learning, because it elicits an emotional response. Again, the process is effective whether the subjects like the music or not. Audio stimuli are more effective than visual stimuli in inducing a response (Burris-Meyer 1971).

Office workers seldom pay attention to HVAC fan noise, but they are very relieved when it stops. Tests have shown HVAC noise can adversely affect performance, and that stopping the noise can lead to an improvement in performance (Kjellberg and Wide 1988). Exposure to infrasound at moderate levels (90 dB) has been shown to degrade performance gradually (Kyriakides and Leventhall 1977). However, other investigators have said that infrasound which is not perceived subjectively has no effect on performance, comfort, and general well-being (von Gierke and Nixon 1976).

Performance is adversely affected by a loss of control over the situation, and the effects are less if subjects know they can terminate the noise. The level of control affects a worker's attitude to both the noise and the work (Jones and Broadbent 1991). It was shown above that the degree of control can also affect annoyance. The level of individual control therefore affects many aspects of office work.

19.6 ACCEPTABLE INDOOR NOISE LEVELS

The above descriptions should indicate that it is no simple matter to recommend noise limits. Any given level will have different affects on annoyance, speech intelligibility, and performance, the difficulties being compounded by differences between individuals. Nevertheless, there have been several attempts to recommend acceptable noise limits indoors. Table 19.3 gives some examples of approximate instantaneous levels in dBA. For fluctuating noise levels, the figures can be regarded as reasonably accurate L_{eq} levels.

Typical levels exceed most recommendations by about 5 to 10 dB. There usually has to be a compromise between maintaining performance and keeping costs reasonable (Warring 1983). HVAC noise should not exceed the levels in Table 19.3. Note that a noise can still be within a recommended value and be found to be disturbing by one or more occupants, e.g., fluctuating noise levels and unusual spectra. The figures in Table 19.3 are therefore to be used as a guide, and not adhered to rigidly. It should not be assumed that all is well if the measured values do not exceed recommended values.

TABLE 19.3 Some Recommended Acceptable Levels, dBA

19.7 ACOUSTIC MEASUREMENTS

Instruments

Sound Level Meters. A simple sound level meter consists of a microphone, an amplifier and a readout facility. Because sound consists of pressure fluctuations above and below a static value, the signal is usually rectified in the form of the root mean square of the averaged signal. An attenuator is fitted so that levels can be measured in 10-dB steps, thus a wide range of levels can be covered. All sound level meters have an A-weighting filter. More versatile instruments can have several weighting networks. An integrating sound level meter is the same as a basic sound level meter, but with the added facility of storing, or logging, measured values over a period of time. The signal is averaged to give the equivalent sound level L_{eq} .

Frequency Analysis. Many sound level meters have a facility for attaching an octave band filter set. A series of readings can then be taken at the different octave band settings to give a crude frequency analysis. For more accurate analysis, a one-third-octave filter can be used, which gives 3 times as many individual bands as an octave analysis. Even a third-octave analysis will produce a spectrogram with “steps” from one band to the next. Greater detail can be achieved by a narrowband analysis. This is often performed by using a single filter with a constant bandwidth, regardless of the frequency. The filter is swept slowly across the desired frequency range. Such analyses are more tedious to perform, and may not be justified in a routine analysis of building acoustics (Burns 1968). The narrower the frequency band chosen, the more time is needed for the analysis.

More recently, real-time frequency analyzers have become available. These can display the levels in all the chosen frequencies simultaneously. The analysis is quicker than with swept analyses, but the instruments are expensive and the resolution poorer. They are useful for measuring sounds with transient events, which may be missed by a swept analysis. They are not necessary for the measurement of continuous noise like HVAC noise.

Recording Results. A sound level meter, with or without a filter, may be connected to a graphic level recorder, which is usually calibrated with a logarithmic potentiometer to give the output in dB. Different kinds of chart paper can be used, including paper with a fre-

quency scale. To obtain a frequency spectrogram, the speed of the paper feed is synchronized to the rate at which the frequencies are swept by the filter.

A sound level meter, frequency filter, and level recorder together can be bulky and difficult to use under field conditions. This was particularly true of earlier instruments. For a field study, the best procedure is to make tape recordings of the sound. These provide a permanent record of the acoustic measurements that can be analyzed under less pressing conditions in the laboratory. In recent years, portable digital audio tape (DAT) recorders have become available, with linear responses down to the infrasound region. They are no bigger than the familiar “Walkman” tape recorders. Their use allows much bulky equipment to be left in the laboratory, as the only items needed for the field measurements are the DAT recorder and the sound level meter. In using a tape recorder, a known sound level signal must be recorded first. During playback, the measuring level is set to the known signal level.

Combination Instruments. Over the past 10 years, computer technology has enabled great strides to be made in the development of acoustic instruments. Many sound level meters are manufactured as integrating meters that enable a large number of measurements to be stored. The meter can display the results individually in a display window, or be connected to a desktop computer with a suitable program (e.g., Excel from Windows). The results can then be read on the computer screen, or printed out with the computer’s printer. These meters can measure several parameters simultaneously, e.g., dBA, dBC, L_{eq} , maximum, minimum and peak levels, plus various other parameters used in the measurement of community noise. More advanced versions incorporate third-octave filters and can give real-time analyses in the instrument’s display window. The computer programs allow the results to be displayed graphically or as a table, and provide notification of noncompliance with standards. Thus the array of sound level meter, filter, and graphic level recorder can be reduced to a single hand-held instrument that can be connected to a desktop computer. These instruments are more flexible than older models and make it easier for acoustics to be included in building investigations.

A measure of low-frequency content is given by some meters as $L_C - L_A$ for steady noise, or $L_{Ceq} - L_{Aeq}$ for fluctuating noise. However, because there has not been much interest in measuring infrasound since the early 1980s, many modern meters do not go lower than 20 Hz. This is likely to change if future investigations show that infrasound is a commonly occurring problem in building acoustics.

Examples

Figure 19.7 shows a tracing of a recording taken at an occupant’s workstation in an office. The figure shows the audible range scanned in one-third octaves, followed by the various weighted values. Figure 19.8 shows a narrowband analysis of the same recording done with a filter covering the range 1 to 2000 Hz.

In Figure 19.7, there are 50-dB peaks in the audible range at 35 and 50 Hz, the A-weighted value is 46 dBA, the B-weighted value is 51 dBB, the C-weighted value is 60 dBC, and the unweighted (Lin) value is 64 dB (dBB is no longer used). The A-weighted level is above most limits for private offices, but within the limits for general offices; see Table 19.3. However, this is a recording of what is predominantly HVAC noise, and is probably too high for most occupants. The level is almost high enough to begin interfering with speech. Contributions from other noise sources are usually fairly easy to identify: the noise from a computer is shown by the peak at around 300 Hz.

The unweighted value of 64 dB is higher than any peak in the audible range, and provides the clue that there is some more energy outside the audible range. This energy can be seen in Fig. 19.8, with peaks of 65 dB at 8 and 18 Hz, in the infrasound region. The difference

FIGURE 19.7 One-third-octave spectrogram of a recording at a desk in an office, showing the audible range (20 to 20,000 Hz) (Burt 1996). On the right are the dB levels for three weighted scales: dBA = 46, dBB = 51, dBC = 60, dBLin (unweighted) = 64.

FIGURE 19.8 Narrowband analysis of the same recording as in Fig. 19.7, showing part of the audible range (20 to 2000 Hz) and the infrasound range (below 20 Hz) (Burt 1996).

between the unweighted and A-weighted levels is thus $65 - 46 = 19$ dB, i.e., close to the 20-dB limit suggested above as the level where low frequencies could become a problem.

Figure 19.9 compares tracings from adjacent supply and exhaust terminals in a system where the supply and exhaust fans are identical but working in opposite directions. Note that the levels are all unweighted. Levels at exhaust terminals are lower than at supply terminals, and there is less energy in the infrasound region. Experience has shown that exhaust-only ventilation systems are usually more acceptable than supply-and-exhaust systems, and this is one possible reason. The supply ventilation fans produce noise spectra typical of centrifugal fans, with most of the energy being in the region below 100 Hz. The energy is airborne and not structureborne. The effects on people will therefore be due only to pressure effects on the inner ear, and not vibration effects on the whole body or involving individual organs.

Figure 19.10 shows the effects of reducing fan speeds. There is some noise reduction that could be beneficial, although the effects in the infrasound range are slight. The effect is not general, as reducing fan speeds may cause a fan to operate outside the range of its optimum aerodynamic efficiency, which would increase the noise.

Figure 19.11 shows the effects of shutting the windows and doors to a room. Large reductions occur in the low-frequency and infrasound range. There are two reasons. One is that an open window can result in a room acting like a Helmholtz resonator. This effect occurs when a closed volume (the room) is connected to a much larger space (outdoors) by a duct (the window). Air movement in and out of the window causes a resonance to be set up in the room. Closing the window reduces the effect. The other reason is that the entire building can be acting as a resonance chamber for the noise. The wavelength of a 10-Hz wave is 34 m, see Eq. (19.1), so a building with this internal dimension will emphasize this frequency. Closing the door shuts the room off from the rest of the “resonance chamber.” The result of closing both windows and doors is a reduction of 25 dB at around 10 Hz.

FIGURE 19.9 Narrowband spectrograms of recordings made at HVAC supply and exhaust terminals located in an office room (Burt 1998). The supply and exhaust fans in this system are identical, but working in opposite directions.

Figure 19.12 compares tracings at the supply grille and occupant's desk. The levels at 10 Hz do not decline much from the supply grille to the occupant's workstation. This is probably due to standing waves being set up in the long corridors in the building. Standing waves (as opposed to travelling waves) occur when sound waves are reflected. If two waves travelling in opposite directions are in phase, they will reinforce each other. The wavelength of the reinforced wave is the distance between the reflecting surfaces. The effects are seldom noticed in ordinary buildings, but unexpected resonances can be set up at low frequencies. The total length of this building is 68 m, with each half being supplied with air by a separate fan. Thus each fan supplies 34 m, which is the wavelength of a 10-Hz wave. The occupant in this room is being subjected to a 10-Hz wave of over 70 dB for the entire working day. The effects of long-term exposure to such levels are still unknown.

19.8 CONCLUDING REMARKS

Modern HVAC systems often have long ducts and large pressure drops, so that large fans are needed to move air through them. Large centrifugal fans can produce considerable amounts of energy in the low-frequency and infrasound regions. A good idea of the amount of energy in the lower frequencies is given by the difference between the unweighted and A-weighted levels (or the difference between the C-weighted and A-weighted levels—they are almost the same). If the difference is greater than 20 dB, then the level of low-frequency noise is probably sufficiently high to cause complaints.

FIGURE 19.10 Spectrograms at supply terminal, showing effect of reducing fan speeds (Burt 1998). Most of the reduction is in the audible range, and the effect in the infrasound region is slight (with this system).

FIGURE 19.11 Spectrograms showing the effect at a desk of closing windows and doors (Burt 1998). The greatest reduction (25 dB) occurs in the infrasound region.

FIGURE 19.12 Spectrograms at supply terminal and desk in the same room (Burt 1998). The sharp peak in the infrasound region at around 10 Hz could be due to some dimensions of the building coinciding with the wavelength of this frequency.

A crude frequency analysis of the acoustic environment indoors can be carried out with a sound level meter equipped with an octave band filter and the results plotted manually. A one-third-octave filter will show more detail. A frequency spectrogram can be obtained by connecting the acoustic filter to a printer, both instruments sweeping the frequencies at the same rate. The shape of the frequency spectrum can provide some insight into the noise that would not be obtained by simply measuring dBA (Kryter 1970).

Control of low-frequency noise is difficult. Normal acoustic insulation has little effect at these frequencies. The two methods available are source control and active noise control. Source control may involve changing the ventilation fans, which may be an expensive and unattractive option for the building owner. Active noise control systems are still being developed, and are currently difficult for most people apart from the manufacturer to use. Even so, they offer one of the most promising methods of noise control in problem buildings, and represent a cheaper option than changing fans. They have a further advantage in allowing a greater choice of fans at the design stage. The quietest fan is the one working in the range of its optimum aerodynamic efficiency.

CHAPTER 20

PHYSICOCHEMICAL BASIS FOR ODOR AND IRRITATION POTENCY OF VOCs

J. Enrique Cometto-Muñiz, Ph.D.

*Chemosensory Perception Laboratory
Department of Surgery (Otolaryngology)
University of California—San Diego
La Jolla, California*

20.1 THE SENSORY RECEPTORS FOR OLFACTION AND CHEMESTHESIS

Our awareness of the presence of airborne chemicals around us relies principally on two sensory systems: olfaction and chemesthesis (also known as the common chemical sense, see Green and Lawless 1991, Green et al. 1990). The sense of smell gives rise to the perception of odors, whereas chemesthesis gives rise to the perception of what we like to call pungent sensations or pungency. These sensations include tingling, piquancy, burning, freshness, prickling, irritation, stinging, and the like.

Smell is mediated by the olfactory nerve (cranial nerve I). The olfactory receptor cells are neurons present in the olfactory epithelium, a small patch of tissue located in the extreme upper back portion of the nasal cavity (Fig. 20.1, right side). Most of the epithelium covering the rest of the nasal cavity is respiratory epithelium. Olfactory receptor neurons (ORNs) constitute, then, a portion of nervous tissue in direct contact with our environment. From one end, the bipolar ORNs send a dendrite to the surface of the epithelium where it ends in an olfactory vesicle with protruding cilia immersed in the mucus covering the epithelium. From the other end, ORNs send an axon that joins other axons from neighboring cells to form the olfactory nerve. The nerve runs through perforations on the cribriform plate of the ethmoid bone and reaches the olfactory bulb where they make the first synapse of the pathway within structures called glomeruli. From there, the olfactory pathway continues to a number of higher centers in the central nervous system.

Chemesthesis on the mucosae of the face (nasal, ocular, and oral) is principally mediated by the trigeminal nerve (cranial nerve V). The reception structures for facial chemesthesis

FIGURE 20.1 *Left.* Innervation of the ocular, nasal, and oral mucosa by branches of the trigeminal nerve. (*From Silver and Finger 1991.*) *Right.* Showing the olfactory region of the nasal cavity (hatched area) innervated by the olfactory nerve. (*From Mygind et al. 1982.*)

are free nerve endings from sensory branches of the trigeminal nerve (Fig. 20.1, left side). It is believed that polymodal nociceptors on those nerve endings are principally responsible for their chemical sensitivity (Silver and Finger 1991). Thus, chemesthesis is closely related to the somatic sensory system, particularly pain. Nociceptors are present in nerve endings of axons belonging to C and A δ fibers (Martin and Jessell 1991). All sensory branches of the trigeminal nerve originate on the Gasserian or semilunar ganglion.

Symptoms of nose, eye, and throat irritation figure prominently among the complaints mentioned by occupants of polluted environments (Mølhave et al. 1991), for example, in the condition known as the sick building syndrome (Apter et al. 1994, Kostianen 1995). Research on the functional characteristics and physicochemical basis of chemical sensory irritation in humans will reveal important information to understand and prevent these unwanted reactions (Cometto-Muñiz and Cain 1992).

20.2 FUNCTIONAL SEPARATION OF ODOR AND IRRITATION

The independent study of olfaction and nasal irritation is hampered by the fact that virtually all volatile compounds can stimulate both sensory systems (cf. Cometto-Muñiz et al. 1989). It all depends on the dose, as a central axiom in toxicology states. At low concentrations of inhaled chemicals, only odor is apparent. As the concentration increases, pungency begins to join in (see Cometto-Muñiz and Hernández 1990). The critical issue entails defining the boundary between a purely olfactory response and an olfactory plus chemesthetic response, and then relating those responses back to relevant properties of the chemical stimulus. Given these considerations, it is difficult to assess nasal pungency thresholds in subjects with a normal sense of smell (i.e., normosmics) since they would have to judge when a sensation becomes barely pungent in the context of an often quite strong odorous background.

In order to dissect the olfactory from the trigeminal threshold response to volatile organic compounds (VOCs) we have resorted to: (1) use of subjects with no olfaction (i.e., anosmics), (2) measurement of eye irritation thresholds, and (3) measurement of nasal localization thresholds. The response of eye irritation is mediated by the trigeminal nerve. The response of nasal localization, or lateralization, entails the ability to determine which nostril (left or right) received a chemical vapor and which one plain air upon simultaneous stimulation. Nasal localization is also mediated by the trigeminal nerve.

Use of Anosmic Subjects

Some individuals, for one reason or another, have never had or have lost their sense of smell. They are called anosmics. This condition may be permanent or temporary. In the studies of homologous chemical series described below (that is, studies of series of compounds sharing a common chemical functional group, for example, alcohols) we have resorted to testing congenital and head-trauma anosmics because of the stability of their anosmic condition. Congenital anosmics are persons who have never been able to smell, as far as they can remember, with no history of any particular event that might have caused their anosmia and an otherwise normal neurological and cognitive function. Head-trauma anosmics are persons who lost their olfactory sense after a blow to the head. Although a percentage of these patients recover their olfaction partially or totally, if improvement has not occurred within 6 to 12 months after the trauma, it is unlikely that it will occur at all (Costanzo and Zasler 1991). Other pathologies can also produce anosmia (see Cain et al. 1988) but might do it only on a temporary or recurring basis.

In our studies of the sensory properties of homologous chemical series we have measured *odor thresholds* in *normosmics*, i.e., subjects with a normal sense of smell, and have measured *nasal pungency thresholds* in *anosmics*, for whom odor would not interfere. To select normosmic and anosmic participants we have used the Connecticut Chemosensory Clinical Research Center (CCCRC) test of olfactory function (Cain 1989).

Measurement of Eye Irritation Thresholds

Although avoidance of odor biases provided a strong rationale for the study of anosmics, it was not guaranteed that their nasal pungency thresholds reflected the true trigeminal sensitivity of normosmics. An alternative way to look at the chemesthetic stimulation potency of chemicals in normosmics and, at the same time, to avoid olfactory interference, consisted in measuring *eye irritation* thresholds. The trigeminal nerve also provides the ocular mucosa with chemical sensitivity.

Eye irritation thresholds measured in normosmics were compared with nasal pungency thresholds measured in anosmics, using the same representative members of various chemical series, identical psychophysical procedure, and a similar stimulus-delivery technique (Cometto-Muñiz and Cain 1995). The outcome showed that, overall, both thresholds fell close to each other (Fig. 20.2). This suggested a similar chemesthetic sensitivity in both mucosae, though it was interesting to find that, for more than one series, the eye continued to respond to members for which the nose had sometimes failed to respond, for example: 1-octanol, octyl acetate, and geraniol (see Fig. 20.2). It was later shown that eye irritation thresholds for homologous alcohols (Cometto-Muñiz and Cain 1998) and selected terpenes (Cometto-Muñiz et al. 1998b) are virtually identical in normosmics and anosmics (Fig. 20.3), supporting the notion that anosmics do not have any significant trigeminal sensory impairment in the ocular mucosa compared to normosmics.

Measurement of Nasal Localization Thresholds

Early investigations suggested that human subjects, via their sense of smell, could tell which nostril received a chemical stimulus when a puff of air entered one nostril and, simultaneously, the chemical entered the other (von Bèkesy 1964). Later, it was demonstrated that such nasal localization (or lateralization) was possible not through olfaction but through nasal chemesthesis, that is, through activation of the trigeminal nerve (Kobal et al. 1989, Schneider and Schmidt 1967). This phenomenon provided an opportunity to look at the comparative sensitivity of nasal chemesthesis in normosmics and anosmics.

Recent studies employing homologous alcohols (Cain and Cometto-Muñiz 1996, Cometto-Muñiz and Cain 1998) and selected terpenes (Cometto-Muñiz et al. 1998b) have revealed marginally lower nasal localization thresholds in normosmics compared to anosmics, but the difference failed to achieve significance (Fig. 20.4). Thus, any difference in nasal chemesthetic sensitivity between normosmics and anosmics, if real, appears small. Altogether, the data suggest that nasal detection (i.e., nasal pungency) thresholds in anosmics or nasal localization thresholds in either group do indeed reflect the concentration at which a substance starts to elicit a trigeminal response in subjects with normal olfaction. It seems, then, that trigeminal sensitivity is similar between normosmics and anosmics both in the ocular and in the nasal mucosa.

FIGURE 20.2 Comparison of nasal pungency (filled squares, continuous lines) and eye irritation (triangles, broken lines) thresholds for homologous alcohols, acetates, ketones, alkylbenzenes, selected terpenes, and cumene. Bars indicating standard deviations are sometimes hidden by the symbol.

20.3 CHEMOSENSORY DETECTION THRESHOLDS ALONG CHEMICAL SERIES

The strategy of separating the olfactory from the trigeminal response to airborne chemicals via testing anosmics, testing eye irritation, and testing nasal localization, was complemented by an orderly selection of the substances to study. First, we were interested in selecting compounds proved to be ubiquitously present indoors (Brown et al. 1994, Wolkoff and Wilkins 1993). Second, given the broad chemical diversity of those compounds, we needed to systematize their investigation in order to facilitate the extraction of physicochemical trends from the observed sensory potency trends. To that effect we began a systematic study of the sensory properties of homologous chemical series where physicochemical properties change orderly from one member to the other and where carbon chain length constitutes a convenient "unit of change."

Aliphatic Alcohols

Among the substances studied were the aliphatic primary *n*-alcohols (Cometto-Muñiz and Cain 1990) and a few aliphatic secondary and tertiary alcohols (Cometto-Muñiz and

FIGURE 20.3 Comparison of eye irritation thresholds in normosmics (empty circles, continuous lines) and anosmics (filled circles, broken lines) for homologous alcohols, cumene, and selected terpenes. Bars indicating standard deviations are sometimes hidden by the symbol.

Cain 1993). Figure 20.5 shows that both nasal thresholds, odor and pungency, tended to decline with increasing carbon chain length of the *n*-alcohols, a tendency that will be repeated on all series tested. Odor thresholds declined at a higher rate than pungency thresholds. Nasal pungency thresholds reached a “cutoff” point within the homologous alcohols where the ability of a homolog to evoke pungency began to fade. This occurred at the level of 1-octanol for which the anosmics, as a group, failed to reach a pungency threshold in 25 percent of instances. Switching the alcohols functional group (HO) to a secondary carbon (1-propanol to 2-propanol, 1-heptanol to 4-heptanol, and 1-butanol to *sec*-butanol) or to a tertiary carbon (1-butanol to *tert*-butanol) raised both the odor and pungency thresholds. Figure 20.5 also reveals two features that will be repeated on all series tested: (1) The difference between normosmics and anosmics was not simply an artifact of averaging since there was no overlap of thresholds between any single normosmic and any single anosmic for any stimulus. (2) Variability in odor thresholds (i.e., among normosmics) was much higher than in nasal pungency thresholds (i.e., among anosmics), as shown by the size of the standard deviation (SD) bars. In most cases variability among anosmics was so low that the SD bar is hidden by the plot symbol.

FIGURE 20.4 Comparison of nasal localization thresholds in normosmics (empty circles, continuous lines) and anosmics (filled circles, broken lines) for homologous alcohols, cumene, and selected terpenes. Bars indicating standard deviations are sometimes hidden by the symbol.

Acetate Esters

Figure 20.6 shows odor and nasal pungency thresholds for homologous *n*-acetate esters and a couple of branched homologs (Cometto-Muñiz and Cain 1991). As in the outcome for *n*-alcohols, both thresholds declined with carbon chain length, odor thresholds declined at a higher rate than pungency thresholds (at least for the first four homologs), there was no overlap between both types of thresholds (see SD bars), and odor threshold variability was higher than that for pungency. In addition, odor thresholds tended to reach a plateau after butyl acetate whereas pungency thresholds showed a cutoff at octyl acetate, which failed to be detected by two of the four anosmics. Decyl and dodecyl acetate failed to be detected by three of the four anosmics. The branched butyl acetates (*sec* and *tert*) did not show a robust or systematic increase or decrease in their thresholds compared to the unbranched homolog.

Ketones

Thresholds for the ketone series are presented in Fig. 20.7 (Cometto-Muñiz and Cain 1993). Most trends in thresholds common to alcohols and acetates, as listed in the previous

FIGURE 20.5 Odor (empty circles) and nasal pungency (filled circles) thresholds for homologous alcohols. Only *n*-homologs are joined by a line. The broken line shows the homolog for which pungency begins to fade (1-octanol) producing a cutoff effect in the series (see text). Bars indicating standard deviations are sometimes hidden by the symbol.

paragraph, continued to hold for the ketones. Here, both odor and nasal pungency thresholds reached a plateau at the level of 2-heptanone, and there was no cutoff effect in pungency at least up to the highest homolog tested, 2-nonanone.

Alkylbenzenes

Figure 20.8 depicts odor and pungency thresholds for the alkylbenzenes (Cometto-Muñiz and Cain 1994b). Many of the features seen for *n*-alcohols, *n*-acetates, and ketones were also seen here (e.g., decline of both kinds of threshold with carbon chain length, larger variability for odor thresholds, no overlap between both threshold types) but, in the alkylbenzenes, the plateau in odor thresholds and the cutoff in pungency thresholds began very early in the series: Both effects appeared at the level of propyl benzene.

FIGURE 20.6 Odor (empty circles) and nasal pungency (filled circles) thresholds for homologous acetates. Only *n*-homologs are joined by a line. The broken line shows the homolog for which pungency begins to fade (octyl acetate), producing a cutoff effect in the series (see text). Bars indicating standard deviations are sometimes hidden by the symbol.

Aliphatic Aldehydes

Thresholds for aliphatic aldehydes are shown in Fig. 20.9 (Cometto-Muñiz et al. 1998a). As with all previous series, we see that odor and pungency thresholds declined with carbon chain length, odor thresholds were more variable (as reflected in larger SD bars), and there was absolutely no overlap in thresholds between individual subjects in the normosmic group and those in the anosmic group. The gap between odor and pungency remained relatively uniform between 4 orders of magnitude for butanal and pentanal, and 5.6 orders of magnitude for octanal. A cutoff for nasal pungency appeared at the level of octanal, since two of the four anosmics failed to detect this compound in some instances.

FIGURE 20.7 Odor (empty circles) and nasal pungency (filled circles) thresholds for homologous ketones. Bars indicate standard deviations.

Carboxylic Acids

Figure 20.10 shows odor and nasal pungency thresholds for carboxylic acids (Cometto-Muñiz et al. 1998a). It can be seen that all the usual features of odor and pungency thresholds along homologous series, summarized in the previous paragraph, also hold for the acids. The gap between odor and pungency grew from 1.6 orders of magnitude for formic acid to 5.2 orders of magnitude for octanoic acid. A cutoff for nasal pungency began to appear with hexanoic acid, where one of the four anosmics consistently failed to detect it, and extended to octanoic acid, where two of the four anosmics consistently failed to detect it.

Selected Terpenes

In a recent investigation we have departed from the study of homologous series and chose to study a group of terpenes and the structurally related compound cumene (Cometto-Muñiz et al. 1998b). The selected terpenes provided an opportunity to look at structure-activity relationships in sensory responses to chemicals from a slightly different view, including the effects of structural isomerism, e.g., linalool ($C_{10}H_{18}O$) versus geraniol

FIGURE 20.8 Odor (empty circles) and nasal pungency (filled circles) thresholds for homologous alkylbenzenes. Bars indicating standard deviations are sometimes hidden by the symbol.

($C_{10}H_{18}O$), and optical isomerism, e.g., R(+)-limonene versus S(–)-limonene, on olfactory and chemesthetic thresholds. Figure 20.11 presents odor and nasal pungency thresholds for the substances tested, and shows that, for a number of them, nasal pungency thresholds could not be consistently elicited.

20.4 DESCRIPTION AND PREDICTION OF CHEMOSENSORY THRESHOLDS VIA PHYSICOCHEMICAL PROPERTIES

Using data reported in the literature, Devos et al. (1990) have compiled, standardized, and averaged human olfactory thresholds for 529 compounds. There is a significant correlation ($r = 0.75$, $p \leq 0.01$) between our odor thresholds and the average values from the Devos et al. compilation, for the 45 compounds common to both sources (Fig. 20.12). Our thresholds, spanning a range of 9 orders of magnitude, offer better resolution across

FIGURE 20.9 Odor (empty circles) and nasal pungency (filled circles) thresholds for homologous aldehydes. The broken line shows the homolog for which pungency begins to fade (octanal), producing a cutoff effect in the series (see text). Bars indicating standard deviations are sometimes hidden by the symbol.

compounds than the averages from the compilation, which span over 5 orders of magnitude. Most likely, averaging across studies accounts for much of the constriction in range in the compiled data. On average, our thresholds, representing the point of 100 percent detection, lie 1 order of magnitude above those from the compilation, which presumably represent the points of 50 percent or 75 percent detection. Our data compose one of the largest sets obtained by using a uniform methodology, procedure, and instructions on small but intensively tested groups of subjects. The approach gives the whole data set a robust internal cohesion in comparisons across compounds, and provides a solid basis to derive physicochemical determinants of sensory potency among VOCs, for example, in the form of quantitative structure-activity relationships (QSAR) (Abraham et al. 1996, 1998a, 1998b).

The results for homologous series presented in Figs. 20.2, and 20.5 through 20.10 show clearly the importance of lipophilicity in sensory potency. As each of these series progresses, the members become less water-soluble and more lipid-soluble. The concomitant sensory result is a decrease in the threshold concentration or, in other words, an increase in sensory potency. This holds for both the olfactory and the trigeminal responses. The increase in potency does not continue indefinitely, and comes to an end differently for odor than for nasal pungency. In most series, odor thresholds tend to reach a plateau or, at least, to slow down their rate of decrease. Nasal pungency thresholds, instead, reach a cutoff point from where on pungency fails to be elicited with certainty.

FIGURE 20.10 Odor (empty circles) and nasal pungency (filled circles) thresholds for homologous carboxylic acids. The broken line shows the homolog for which pungency begins to fade (hexanoic acid), producing a cutoff effect in the series (see text).

Recently, a particular type of QSAR based on a solvation model approach (Abraham 1993a, 1993b) has been used to reveal the physicochemical parameters that best explain the sensory results obtained. The solvation equation contains a maximum of five physicochemical descriptors: excess molar refraction (R_2), dipolarity/polarizability (π_2^H), overall or effective hydrogen-bond acidity ($\Sigma\alpha_2^H$), overall or effective hydrogen-bond basicity ($\Sigma\beta_2^H$), and gas-liquid partition coefficient on hexadecane at 298 K (L^{16}). Application of the solvation equation to our odor thresholds has had only moderate success (Abraham 1996), leaving a relatively large amount of unexplained variance: about 20 percent, although no other odor QSAR model has done better than this (see Cometto-Muñiz et al. 1998a). The solvation equation applies only to “transport” processes, that is, those in which either the distribution of a solute between phases or the rate of transfer of a solute from one phase to another forms the key step. The equation does not apply to processes where the key step is a specific stimulus-receptor interaction. In the present case, the solute refers to the odorant stimulus, and the phases involved are the various biophases through which the stimulus travel on entering the nose: different mucus layers, membrane of olfactory neurons, interstitial fluid, etc. The modest performance of the solvation model when applied to odor thresholds suggests that the olfactory response relies only partially on stimulus-transport processes, and that certain

FIGURE 20.11 Odor (empty circles) and nasal pungency (filled circles) thresholds for selected terpenes and cumene. Out of 32 instances of measurement across four anosmics, the pinenes, the limonenes, gamma-terpinene, and geraniol failed to reach a nasal pungency threshold in most instances, *p*-cymene failed in 56 percent of instances, linalool failed in 31 percent of instances, and cumene failed in 22 percent of instances. Delta-3-carene and 1,8-cineole virtually never failed to evoke a nasal pungency threshold in the anosmics.

key steps must rely on more restricted and specific odorant-receptor interactions, like those derived from the size and shape of the molecule. This suggestion is in line with preliminary data indicating that addition of a new descriptor that is a function of the maximum length of the molecule can improve the robustness of the solvation equation for odor (Abraham et al. 1997).

In contrast to the odor case, the solvation equation has done very well to describe and predict nasal pungency (Abraham et al. 1996, 1998a) and eye irritation (Abraham et al. 1998b) thresholds, that is, the two responses mediated by the trigeminal nerve. The success of the equation indicates that these chemesthetic responses in the face do rely heavily on transport processes that carry the airborne irritant from the vapor phase to the biophase where trigeminal nerve activation takes place. The most updated version of the equation for nasal pungency (Abraham et al. 1998a) reads as follows:

FIGURE 20.12 Comparison between our odor thresholds ($\square$) (Cometto-Muniz and Cain 1990, 1991, 1993, 1994b; Cometto-Muniz et al. 1998a, 1998b), sorted in descending order, and those compiled, standardized, and averaged by Devos et al. (1990) ($\bullet$). The correlation between both sets is high and significant ($r = 0.75$, $n = 45$, $p \ll 0.01$).

$$\log (1/\text{NPT}) = -8.519 + 2.154 \pi_2^H + 3.522 \sum \alpha_2^H + 1.397 \sum \beta_2^H + 0.860 \log L^{16}$$

$$n = 43 \quad r^2 = 0.955 \quad \text{sd} = 0.27 \quad F = 201$$

where 1/NPT = reciprocal of the nasal pungency threshold (NPT) in ppm

n = number of data points (VOCs)

r = correlation coefficient

sd = standard deviation in log 1/NPT

F = F statistic

The four physicochemical descriptors (π_2^H , $\sum \alpha_2^H$, $\sum \beta_2^H$, L^{16}) are as defined above. The descriptor R_2 is absent since it did not achieve statistical significance. In turn, the equation for eye irritation (Abraham et al. 1998b) reads as follows:

$$\log (1/\text{EIT}) = -7.918 - 0.482 R_2 + 1.420 \pi_2^H + 4.025 \sum \alpha_2^H + 1.219 \sum \beta_2^H + 0.853 \log L^{16}$$

$$n = 54 \quad r^2 = 0.928 \quad \text{sd} = 0.36 \quad F = 124$$

where 1/EIT is the reciprocal of the eye irritation threshold (EIT) in ppm and all terms and descriptors are as defined above.

We have mentioned that the results illustrated in Figs. 20.2, and 20.5 to 20.10 point out the importance of lipophilicity for sensory potency. The QSAR analysis confirms the outcome since the term that reflects the lipophilicity of the stimulus, that is, the descriptor L^{16} (the gas-liquid partition coefficient on hexadecane at 298 K), accounts for 52 percent of the variation on odor thresholds, 55 percent of the variation on nasal pungency thresholds, and 63 percent of the variation on eye irritation thresholds in the respective equations. Nevertheless, lipophilicity cannot explain the appearance of the cutoff point in nasal pungency. At least two mechanisms may account for such cutoffs (Franks and Lieb 1990): a purely physical mechanism whereby the maximum available quantity of vapor-phase stimulus falls below the threshold, and a biological mechanism whereby the stimulus lacks a key property to trigger reception or transduction. For example, beginning at a certain point in a homologous series the molecules could become too large to interact effectively with a target site or to fit into a binding pocket of a carrier or a receptive macromolecule. Comparison of data predicted by the nasal pungency solvation equation listed above with experimental data and physicochemical data (e.g., saturated vapor concentration) can help to distinguish between the two mechanisms (Cometto-Muñiz et al. 1998a).

20.5 CHEMOSENSORY DETECTION OF MIXTURES

Occupants of indoor spaces are exposed to dozens, perhaps even hundreds, of VOCs. Sensory irritation in buildings does not seem to come about only from frank irritants, such as formaldehyde. It appears, instead, that irritation might arise from the aggregate effects of many VOCs with different degrees of chemical reactivity. The extent to which mixtures of VOCs can evoke agonistic effects in olfaction and chemesthesis becomes, then, an important issue.

The outcome from studies of homologous chemical series has shown, in every case, that the larger homologs (e.g., 2-heptanone), not usually considered particularly irritating compared to the smaller homologs (e.g., acetone), have, in fact, a stronger sensory potency because of their much lower odor and nasal pungency thresholds. Keeping this observation in mind, a recent study (Cometto-Muñiz et al. 1997) explored possible agonistic sensory

effects among the components of five different mixtures: Two of them had three components, two had six components, and the last mixture had nine components. One of the three-component mixtures and one of the six-component mixtures contained relatively small homologs from different series, the other three- and six-component mixtures contained larger homologs from different series. The nine-component mixture contained both small and large homologs, also from different chemical series. The results showed that the mixtures achieved threshold when none of the components had reached its *individual* threshold concentration, indicating the existence of agonism among chemicals. The degree of agonism tended to increase with number of components and with the lipophilicity of such components (as a rule, larger homologs, having long carbon chain lengths, are more lipophilic than smaller homologs, having short carbon chain lengths). Overall, agonism was stronger for the chemesthetic modalities, particularly eye irritation, than for the olfactory modality.

Another recent investigation (Cometto-Muñiz et al. 1999) focused on the binary mixture of 1-butanol and 2-heptanone, but studied it in detail by varying the relative ratios of the two components in a systematic way. Also, instead of measuring thresholds according to a fixed criterion of performance, the study measured, for the two single chemicals and their various mixtures, complete detectability functions spanning the range from chance detection to virtually perfect detection. Again, the outcome indicated the presence of agonism for all three sensory end points explored: odor, nasal pungency, and eye irritation.

20.6 NEEDS FOR FURTHER RESEARCH

From a methodological perspective, in order to advance our knowledge of the physicochemical basis for the odor and irritation potency of VOCs, we need to understand the role that different chemical-delivery techniques play in the sensory results obtained. In the simplest systems, the tested vapors are presented from an enclosed container to the nose or eyes. There are many examples of this design, one of them being the “squeeze bottles” (Cain 1989). The technique can be compared to what in olfactory studies is called “static” olfactometry (Cain et al. 1992). Use of face masks fed from small chambers that contain the chemical stimulus (or stimuli) constitute the next level of complexity for delivery systems. Here, the vapor flows carried by a dilution gas, generally odorless air, toward the face of the subject. The procedure resembles what in olfactory studies is called “dynamic” olfactometry (Cain et al. 1992). Finally, whole-body environmental chambers constitute the most representative system for obtaining environmentally realistic sensory responses to VOCs. Preliminary data indicate that sensory thresholds decrease as we move from squeeze bottles to face masks and from them to whole-body chambers. Issues of cost, ease of use, and pace of experimentation call for the selection of simple and versatile systems for sensory testing whose results can be extrapolated to those of environmental chambers. Future research should clarify the relationships among sensory responses—particularly thresholds—obtained with these various techniques, and establish the generality of such relationships across chemicals.

Another important topic for further research is a systematic study of mixtures (Cometto-Muñiz et al. 1997, 1999). We need to understand the role that number of components and chemical identity of such components play in the sensory responses to mixtures, in particular at concentrations near detection thresholds for odor, nasal pungency, and eye irritation. Given the large number and variety of VOCs present indoors, this task seems enormous. Perhaps a productive approach might consist on the initial detailed study of very simple mixtures, i.e., binary, ternary, quaternary, combined with a realistic physicochemical modeling. The model should ideally possess descriptive ability for tested sub-

stances, predictive ability for untested substances, and ability to adjust incrementally, providing more accurate predictions, as data for new substances are incorporated.

All the results discussed in this article represent short-term (1- to 3-second) exposures. Nevertheless, indoor exposures linger for days, months, and even years. It has been shown that odor sensations fade quite rapidly with time (adaptation) whereas chemesthetic sensations can build up for 30 or more minutes (temporal integration or summation) before adaptation begins to be produced (Cain et al. 1986, Cometto-Muñiz and Cain 1984, 1994a). Understanding the time course of these sensory responses over long periods of time represents another challenge for future studies on indoor air.

20.7 SUMMARY

It is widely acknowledged that among the likely causes for building-related complaints, the aggregate effect of a variety of VOCs deserves particular attention (Apter et al. 1994, Hodgson et al. 1994, Kostiainen 1995, Rothweiler and Schlatter 1993). Among the various symptoms evoked, sensory irritation not only figures prominently but also lends itself to psychophysical measurement in humans (Cometto-Muñiz and Cain 1992, Hudnell et al. 1992, Kjærgaard et al. 1992, Mølhave et al. 1991).

Our lab has a particular interest in studying the functional characteristics of the senses of smell and sensory irritation in humans (Cometto-Muñiz and Cain 1992, 1996). Our approach entails a stimulus strategy and a response strategy. From the perspective of the stimulus we have chosen to test families of chemicals, typically homologous series (e.g., acetate esters) but also more diverse groups (e.g., terpenes). Homologous series provide a convenient "unit of change," represented by carbon chain length, along which physicochemical properties change in an orderly fashion, allowing us to relate those changing properties with the sensory outcome. From the perspective of the response, we have resorted to separate the olfactory from the trigeminal response of the nose by testing subjects lacking olfaction, i.e., anosmics, for whom odor does not interfere. The applicability to normosmics of the nasal trigeminal responses obtained from anosmics was initially suggested by the similarity of eye irritation thresholds in both groups, and further supported by the similarity of nasal localization thresholds in both groups (Cometto-Muñiz and Cain 1998).

In the studies described, use of a uniform sensory methodology, procedure, and instructions in a small but intensively tested group of subjects has been combined with selection of a wide range of VOCs relevant to indoor air. The results have permitted us to build a strong QSAR, based on a solvation model, that describes and predicts nasal pungency and eye irritation thresholds for VOCs by using a maximum of five general physicochemical descriptors (Abraham et al. 1998a, Abraham et al. 1998b). Modeling of odor thresholds via the solvation equation has been less successful. This can be taken as an indication that some key steps on the odorant-receptor interaction rely on more specific stimulus properties than those reflected on the five general physicochemical descriptors.

Finally, we discuss the outcome of experiments comparing the sensory impact of VOCs presented singly and in mixtures of up to nine components. The results showed various degrees of agonism among the components of the mixtures. Such agonism allowed detection of the mixtures when their constituents were present at concentrations below their individual thresholds. As the number and the lipophilicity of the components increased, so did their degree of agonism.

ACKNOWLEDGMENTS

Preparation of this article was supported by the Center for Indoor Air Research and by research grant R29 DC 02741 from the National Institute on Deafness and Other Communication Disorders, National Institutes of Health. I am grateful to Dr. William S. Cain for many fruitful discussions over more than 10 years of mutual collaboration. Thanks are also due to Dr. Michael H. Abraham for his insights and lead role in the analysis of structure-activity relationships.

CHAPTER 21

RESPONSE TO ODORS

Richard A. Duffee

Martha O'Brien

Odor Science & Engineering Inc.

Bloomfield, Connecticut

21.1 THE NOSE AND HOW IT SERVES US

The nose is the first internal surface to encounter the ambient air. It is a critical component of the body's defense mechanisms. It begins to warm and moisten the air on its way to our lungs. Fine hairs and nasal structure remove some of the particles, including pollens, bacteria, fungi, and dust. The epithelium transitions from skin to squamous epithelium to ciliated secretory lining. The specialized features of the nasal epithelium function by presenting a protective barrier. Inhaled noxious materials can be absorbed in the fluid layer along with particles and conveyed by cilia transport and swallowed or otherwise removed (e.g., by sneezing).

The nose serves other important functions as well. Through connections to the inner ear, we maintain air pressure balance. The act of yawning can move small volumes of air through the eustachian tube to the inner ear. Sinuses also serve as air passages and drains connecting the nose to the brain, orbit, and palate. While the actual role of nasal sinuses is still obscure, phonetic, respiratory, olfactory, thermal, and mechanical (including intersinus pressure balancing) roles have been hypothesized.

The nose is innervated by the olfactory nerve (the first cranial nerve), the *nervi terminales*, the trigeminal nerve (fifth cranial nerve) and autonomic nerves (see Fig. 21.1). The olfactory and trigeminal nerves serve as the primary sensory nerves in the nose. This complex nerve structure controls many functions including secretion, respiratory constriction or dilation, respiration (panting, mouth breathing), sneezing, and submersion reflex. Interestingly, the sneeze response tells us about the interconnection of the nervous system. Stimulation of the optic-trigeminal nerve by sunlight causes some persons to sneeze. Stimulation of the nasal nerves has induced sensation in the face, arms, and elsewhere.

To learn more about the physiology and pathology of the nose, the reader is referred to a book edited by Donald Proctor and Ib Anderson called *The Nose, Upper Airway Physiology and the Atmospheric Environment*, published by Elsevier Biomedical in 1982.

FIGURE 21.1 Location, structure, and pathways of olfactory system. (From Sherwood L. 1989. *Human Physiology: From Cells to Systems*. 1st ed. Reprinted with permission of Brooks/Cole Publishing, a division of Thomson Learning.)

21.2 HOW DO WE SMELL?

Located in the ceiling of the nasal cavity out of the airflow channel are the olfactory receptor nerves (see Fig. 21.1). Along with mucous-secreting cells and basal cells, they make up the odor detection apparatus. The receptor portions of the olfactory neuron resemble cilia that extend to the mucosa surface. The finding sites on these ciliated nerves await specific molecules that diffuse from the inspired airstream under normal breathing. Direct transport of air is affected by sniffing that creates turbulence and opens up passages by the turbinates. Switching to oral breathing can mitigate the intensity of malodorous compounds. When reaching the mucosa, odorous molecules must be dissolved before binding to activate a neural impulse. The impulse moves into the olfactory bulb in the brain, which is a complex neural structure. This second-stage processed signal then travels to the limbic system and the thalamus-cortex regions of the brain. The limbic cortex region affects behavioral reactions associated with smell, whereas the thalamus-cortical region is conscious interpretation of smell. Many of us share the experience of recalling a memory when we encounter a particular odor.

Human sense of smell, although not as highly developed as in other mammals, can distinguish thousands of different odors. Binding sites, it is speculated, have distinct shape and size, that match the geometry of the odorant molecule. It has been proposed that there are seven primary odors: musky, putrid, pungent, camphoraceous, ethereal, floral, and pepperminty.

As discussed in other chapters of this book, our sensitivity to and ability to discriminate odors diminishes in the presence of continuous exposure. The sense recovers rapidly on termination of exposure. Our sense of smell is also influenced by the conditions of the ambient air. In Chap. 22, it is shown that odors are discerned more readily in cooler, drier air than in warm moist conditions. Sensory smell can be temporarily disrupted by respiratory infection or head trauma, and there is a general decrease in sensitivity with age. Natural gas is scented with sulfurous compounds (such as methyl mercaptan) to provide rapid detection of gas leaks. Most of us can smell the objectionable odor at subparts per billion concentrations. The elderly, however, need higher concentrations to evoke a signal. When investigating odor complaints, intersubject variability needs to be considered.

The rest of this chapter discusses how odors are measured both in the laboratory and in the field, and how to use odor perception as a tool in identifying sources of odors in the indoor environment. In addition, the characteristic odor of many compounds can be used to identify their composition. Odor characteristics of compounds typically perceived in the indoor environment are listed along with their possible sources. For further understanding about odors, both indoors and outdoors, the reader is referred to another McGraw-Hill publication, Rafson (1998), *Odor and VOC Control Handbook*.

The sensation of odor has four properties: odor concentration, odor intensity, odor quality or character, and hedonic tone. Three of these are quantifiable by sensory measurement techniques, while the fourth, odor quality or character, is not. Odor character, however, is probably the most important property of the odor sensation in the indoor environment. From the perspective of the occupants of the space, a perceived unfamiliar odor is frequently the trigger for concerns about indoor air quality. For the persons investigating complaints about poor indoor air quality, however, the odor character is the principal clue to the identity and potential effects of the odorous compounds, and also their probable sources.

Odor Concentration

Odor concentration (sometimes referred to as *odor pervasiveness*) is a measurable property of the odor sensation. It is measured in terms of the number of dilutions with odor-free air needed to reduce an odor to either its detection threshold or recognition threshold. The detection threshold is commonly defined as that concentration of an odor (or odorant) in air at which a specified fraction of the human population (typically 50 percent) is capable of discriminating between the odorous sample and odor-free blanks on the basis of some indefinable difference. The recognition threshold is defined as that concentration of an odor (or odorant) in air at which a specified fraction of the population (typically 50 percent) can discriminate between the odorous sample and odor-free blanks on the basis of some perceived odor. The recognition odor threshold is usually a factor of 2 to 5 times higher than the detection threshold.

Odor concentration, accordingly, is measured in self-explanatory units of “dilutions-to-threshold,” abbreviated D/T. If the odor is sufficiently strong, i.e., more than 10 D/T, a sample of the odorous air can be collected (e.g., in a Tedlar bag) and the odor concentration measured by dynamic dilution olfactometry in accordance with the requirements of ASTM Method E679-91, *Standard Practice for Determination of Odor and Taste Thresholds by a Forced-Choice Ascending Concentration Series Method of Limits*. In this method the sample is brought to a panel, usually comprising eight to ten

individuals proved to be at least of average sensitivity and free of any measurable specific anosmia (extreme insensitivity or inability to detect a particular odor character), for the evaluation of various sensory parameters. Known dilutions of the odor sample are prepared by mixing a stream of odor-free air with a stream of the odor sample.

A panelist is presented usually with three identical sniff ports, two of which provide a stream of odor-free air and the third one a known dilution of the odor sample. (Some olfactometers have only two ports, one being a blank.) Unaware of which is which, the panelist is asked to identify the sniff port that is different from the other two, i.e., that contains the odor.

The analysis starts at high odor dilutions. Odor concentration in each subsequent evaluation is increased, by a factor varying between 1.4 and 3 depending on the design of the olfactometer. Initially a panelist is unlikely to correctly identify the sniff port that contains the odor. As the concentration increases, the likelihood of error is reduced and at one point the response at every subsequent higher concentration becomes consistently correct. The odor concentration at which this consistency is first noticed represents the detection odor threshold for that panelist.

The panelists typically arrive at threshold values at different concentrations. Statistics are applied and usually the odor levels (dilution factor) at which 50 percent of the panel can correctly select the odorous sample is determined. Any specified percentage, however, can be determined. The value is expressed as the dilutions-to-threshold ratio, or simply as D/T.

The dynamic dilution olfactometry measurement method is usually used only for samples collected at the source of odorous emissions such as stacks or vents at a manufacturing facility or the surfaces of wastewater treatment ponds or landfills. Indoor air odors are rarely strong enough to use this technique, as below 10 D/T the precision and reliability of dynamic dilution olfactometry rapidly decreases because of trace level background odors associated with sample collection and storage. The concentration of indoor and ambient odors, therefore, is more appropriately measured by a hand-held device known as a *scentometer*, shown schematically in Fig. 21.2. By breathing through the scentometer, an observer introduces ambient air into the device where it is diluted in various ratios with odor-free air. Odor concentration is determined from the dilution ratio at which the odor first becomes detectable in breathing through the scentometer.

The major advantage of measuring odor concentration is that the resulting values can be used with dispersion or ventilation models to determine the degree of control or ventilation rate needed to eliminate either nuisance odor levels or detectable odors.

Odor Intensity

Odor intensity refers to the perceived strength of the odor sensation. Odor intensity is measured by a matching standards procedure using *n*-butanol as the reference substance. The method is described in ASTM Method E544, *Recommended Practice for Referencing Suprathreshold Odor Intensities*. The method describes a butanol intensity olfactometer with eight sniff ports where the *n*-butanol concentration doubles at each successive level, although the intensity of the perceived butanol odor increases more slowly. Another version of the *n*-butanol intensity scale is described in this method, one that uses 12 concentrations of aqueous butanol solutions in widemouthed jars or flasks, with the butanol concentration again doubling at each successive level.

A field kit consisting of eight bottles of aqueous butanol solutions, with the intensities identical to those perceived on the butanol olfactometer, has been developed by Odor Science & Engineering, Inc. (Bloomfield, CT). The concentrations of *n*-butanol are such that the concentration of *n*-butanol in the vapor above the solutions corresponds to the steps on the butanol olfactometer. Immediately prior to use, the bottle is vigorously shaken to assure that the equilibrium between the liquid and the gas phase has been established. The

FIGURE 21.2 Schematic of the scentometer.

bottle is then brought close to the nose, opened, sniffed, and closed. The intensity of the odor in the bottle is compared with the intensity of the odor being observed. The bottles are always used in order of increasing intensity.

The intensity property of the odor sensation is perhaps most directly related to odor nuisance, as any odor will be judged objectionable if it is strong enough, irrespective of whether it is normally considered pleasant. Measures of increasing odor intensity are useful in locating the sources of indoor odors. Odors of widely different types can be compared on the butanol scale just like the intensities of the lights of different colors can be compared to the intensity of a standard, e.g., white light. Odor character and hedonic tone are ignored in that comparison.

Odor intensities are also routinely measured as part of the dynamic dilution olfactometry measurements. The relationship between odor concentration and intensity can be expressed as a psychophysical power function also known as *Steven's law*. The function is of the form:

$$I = aC^b$$

where I = odor intensity on the butanol scale

C = the odor level in dilution-to-threshold ratio (D/T)

a, b = constants specific for each odor, with the value of the exponent b usually less than 1

The major significance of the psychophysical function in odor control work is that it determines the rate at which odor intensity decreases as the odor concentration is reduced (either by atmospheric dispersion, ventilation, or an odor control device). The function can therefore be used in predicting the reduction in odor concentration that is required to bring the odor intensity down to a desired level, judged not objectionable.

Odor Character

This property of the odor sensation refers to our ability to distinguish among different odors. It is not quantifiable, only descriptive. We use three types of descriptors: (1) general descriptions of the quality of the odor sensation such as sweet, pungent, acrid, fragrant, sickening, warm, dry, rancid, or sour; (2) with reference to sources such as almond-like, mothball-like, banana-like, fishy, skunk, sewage, or paper mill; and (3) with reference to a specific chemical, e.g., methyl mercaptan (rotten cabbage), butyric acid (rancid cheese or butter), or cyclohexane (gasoline). A relatively extensive list of odor character or quality descriptors is shown in Table 21.1.

Character is the most important property of the odor sensation for determining the source of an odor in complaint investigations. Because of this, individuals doing odor monitoring should not have any specific anosmia and should be familiar with the odor character of potential emission sources within the area.

Hedonic Tone

The hedonic tone of an odor sensation relates to the degree of pleasantness or unpleasantness of the sensation. It is measured usually by means of category estimate scales or magnitude estimate techniques. Such measurements, however, are usually confined to the laboratory and primarily to odors that are intended to be pleasant such as in perfumery. While this property of odor, by definition, seems to determine objectionability, in reality the frequency, time, intensity, character, and our previous experience with the specific type of odor determine our response.

21.3 APPLICATION OF ODOR MEASUREMENTS IN INDOOR ENVIRONMENTS

Odors often precipitate concern about indoor air quality. Because human sensitivity to odor is much greater than that of instrumental methods—we can readily detect some odors at concentrations in the part per trillion range, whereas our best analytical techniques are limited to approximately 0.1 part per billion—and furthermore most odors are complex mixtures of odorants rather than a single compound, sampling the indoor air for subsequent chemical analysis to identify the odorous compounds is most often a fruitless exercise. Identification of the odorous compounds, therefore, depends largely on our ability to rec-

TABLE 21.1 List of Odor Character Descriptors

fragrant	vanilla-like	sweaty
fecal (like manure)	almond-like	floral
burnt, smoky	yeasty	herbal, green, cut grass
cheesy	etherish, anaesthetic	honey-like
sour, acid, vinegar	anise (licorice)	like blood, raw meat
turpentine	dry, powdery	fresh green, vegetables
ammonia-like	medicinal	disinfectant, carbolic
orange (fruit)	aromatic	buttery (fresh)
meaty (cooked, good)	like burnt paper	sickening
cologne	musty, earthy, moldy	caraway
sharp, pungent, acid	bark-like, birch bark	camphor-like
rose-like	light	heavy
celery	burnt candle	cook, cooling
mushroom-like	warm	wet wool, wet dog
metallic	chalky	perfumery
leather-like	malty	pear (fruit)
cinnamon	stale, tobacco smoke	popcorn
raw cucumber-like	incense	raw potato-like
cantaloupe, melon	mouse-like	tar-like
eucalyptus	oily, fatty	black pepper-like
mothball-like	bean-like	gasoline, solvent
banana-like	cooked vegetable	burnt rubber-like
sweet	geranium leaves	fishy
urine-like	spicy	beer-like
paint-like	cedarwood-like	rancid
rope-like	minty, peppermint	seminal, sperm-like
sulfidic	like cleaning fluid	fruity (citrus)
fruity (other)	lemon (fruity)	dirty linen-like
putrid, foul, decayed	kippery (smoked fish)	woody, resinous
caramel	musk-like	sauerkraut-like
soapy	crushed grass	garlic, onion
chocolate	animal	molasses
alcohol-like	dill-like	chemical
creosote	green pepper	household gas
peanut butter	violets	tea leaf-like
stale cork-like	lavender	cat urine-like
pineapple (fruit)	fresh tobacco smoke	nutty (walnut etc.)
fried chicken	peach (fruit)	coffee-like
burnt milk	laurel leaves	wet paper-like
sewer odor	sooty	crushed weeds
rubbery (new rubber)	bakery (fresh bread)	oakwood, cognac-like
grapefruit	grape juice-like	eggy (fresh eggs)
bitter	cadaverous (like a dead animal)	maple syrup
seasonings (for meat)	apple (fruit)	soupy
grainy (grain-like)	clove-like	raisins
hay	kerosene	nail polish remover
fermented (rotten) fruit	cherry (berry)	varnish
sour milk

ognize odor characters. Similarly, recognition of odor character may be the first indication of possible sources. Indoor odors are rarely strong enough to use dynamic dilution olfactometry to measure odor concentration. Measurements of hedonic tone are essentially irrelevant unless the solution to the odor complaints is to use odor counteractants or modifiers.

In responding to odor complaints, investigators should ask occupants to characterize odors (describe what they smell like) along with times and locations of detection. If the perception of odors by the occupants seems to have a periodicity, then temperature effects on the materials in the environment need to be considered.

After interviews, the further steps in investigating indoor odors are: (1) detect the odor and determine its character to indicate potential sources; compare to descriptions by the occupants; (2) measure the odor intensity; (3) with knowledge about the ventilation system and air distribution, attempt to follow the direction of increasing odor intensity to the source.

If odor detection is intermittent, then it may imply that pressure changes are causing fluctuations in a leaking source or altered flow directions. Investigations might include collecting suspected material sources. These samples should be placed in individual containers, e.g., Tedlar bags with fixed volumes of odor-free air. After equilibrium is established in the vapor concentration above the material surface, odor character and intensity in the head space in the containers can be determined. Repeat the process at different temperatures to verify the contribution of the materials to the indoor odor.

As mentioned above, it is most important to recognize the odor. Almost all odorants are organic compounds. The only significant inorganic odorants are hydrogen sulfide and ammonia. The most odorous organic compounds are those with sulfur, nitrogen, or oxygen in the molecule. Table 21.2 presents a list of typical odor characters and related chemical classes associated with odor nuisance complaints regardless of whether the source of the odor originates outdoors or within the indoor environment. Some common sources of these odors are also indicated on this table. All of the compounds listed, or the classes of compounds, have recognition odor thresholds in the low part per billion (ppb) range, and some are detectable at subppb levels.

21.4 INDOOR ODOR SOURCES, ODOR COMPOUNDS, AND THEIR CHARACTERISTICS

Table 21.2 contains the classes of compounds most frequently associated with nuisance odor complaints in the ambient air. Many of these odors cause odor complaints in the indoor environment as they are introduced into the space via the ventilation system or through open doors or windows. Table 21.3 focuses on the principal sources of indoor-generated odors. The table lists the compounds, their characteristic descriptions, chemical formulas, molecular weights, approximate recognition odor thresholds, and odor characters. The odor threshold data are considered approximate, since published odor thresholds vary so widely—over a range of as much as 5 orders of magnitude—and because the resulting value in experiments aimed at determination of odor threshold is so dependent on the methodology used. Ideally, the odor threshold should represent the concentration of odor that would be perceived by a stated percentage of the population in open, ambient air settings. Almost none of the published odor threshold values represent that type of exposure.

21.5 SUMMARY

Odors enrich our everyday life. The smell of coffee in the morning, the fragrance of perfume, the bouquet of wine, all are pleasurable. Malodors are also a part of our environment.

TABLE 21.2 Typical Odor Character Descriptors and Associated Chemical Class

Odor character	Chemical class	Typical sources
Rotten eggs	H ₂ S	Refineries, WWTPs*, landfills
Barnyard, manure	Sulfides especially dimethyl sulfide (DMS), dimethyl disulfide (DMDS)	Sewage, sludge, composting, landfills
Rotten cabbage	Methyl mercaptan	Pulp mills, refineries, petrochemical manufacturing plants, gas odorant leak
Onions	Propyl	
Skunk	<i>n</i> -butyl	
Natural gas	<i>t</i> -butyl	
Fishy, urine	Amines, e.g., trimethyl amine	Pigment manufacturer, dyes, WWTPs, compost, landfills
Cadaverous	Cadaverene	
Ammonia	Ammonia	
Fecal	Skatole, indole	
Solvents	Ketones	Petrochemical manufacturer, coatings, plastic extruding and molding
Paints	Esters	
Turpentine	Aromatics	
Plastic	Styrene	
Airplane glue	Acrylates	
Rancid, sweaty, body odor, cat urine	Organic acids such as butyric, valeric, phenyl acetic	Food processing, pharmaceutical manufacturing, dirty clothes, stale tobacco smoke
Musty, moldy, damp basement	quinones, oxygenated compounds in the C ₆ –C ₁₀ range, some esters	Insecticides, weed killers, medicinals, pigment manufacturer, air-conditioning systems
Phenolic, creosote	Phenols, cresols, xylenes	Curing of phenolic resins, wire enameling, electric motor overhauling, creosote and tar applications, smoke
Burnt, smoky, wet ash	Aldehydes, guaiacol, juniper oil	Junipers, burning operations, wood smoke
Sharp, irritating, pungent	Formaldehyde, acetic acid (vinegar), sulfur dioxide, carbonyl sulfide, ozone	Furniture, plywood, combustion, processes, matches, smoke, electronic devices, carpeting

*WWTPs = wastewater treatment plants.

TABLE 21.3 Indoor Sources of Odors, Odorous Compounds, and Their Characteristics

Source	Odorous compound names	Formula	MW	Characteristics	
				Geom. mean recognition	Odor character
Air cleaning devices (ionizers, purifiers)	Nitrogen dioxide	NO ₂	46.01	0.8 (approx.)	Bleach
	Ozone	O ₃	48.00	0.02 (approx.)	Pungent, thunderstorm
Air-conditioning systems	Mesityl oxide	C ₆ H ₁₀ O	98.14	—	Sweet, musty
	Benzoquinone	C ₆ H ₄ O ₂	108.09	0.4	Musty
	Diacetyl alcohol	C ₆ H ₁₂ O ₂	116.16	1.1	Sweet, musty
	Furfuryl alcohol	C ₆ H ₆ O ₂	98.10	8	Etherish
Bathrooms	Skatole	C ₉ H ₉ N	131.17	—	Fecal
	Indole	C ₈ H ₇ N	117.14	—	Fecal
	Methyl mercaptan	CH ₃ S	48.11	0.001	Rotten cabbage
Bleach (laundry)	Sodium hypochlorite	NaOCl	74.44	—	Bleach
Carpeting	Ethyl acrylate	C ₅ H ₈ O ₂	100.11	0.004	Plastic, ester
	Methyl acrylate	C ₃ H ₆ O ₂	86.09	0.01 (approx.)	Sharp, airplane glue, plastic
Cleaners	Acetone	C ₃ H ₆ O	58.08	130	Sweet, nail polish remover
	Ammonia	NH ₃	17.03	17	Pungent, irritating
	Alcohols (e.g., isobutyl)	C ₄ H ₁₀ O	74.12	9	Musty, sweet
	α -pinene	C ₁₀ H ₁₆	136.23	0.03	Pine

Cigarette, cigar smoke	Numerous alcohols, aldehydes, ketone, acids, e.g.:				
	Acetaldehyde	C_2H_4O	44.05	0.07	Pungent
	Acrolein	C_3H_4O	56.06	2	Piercing, sharp, pungent
	Adlyl alcohol	C_3H_6O	58.08	2	Sharp, mustard
	Cyclohexanone	$C_6H_{10}O$	98.14	0.1	Sharp, sweet
	Acrylic acid	$C_3H_4O_2$	72.06	1.0	Rancid, plastic
	Formaldehyde	CH_2O	30.03	0.6 (approx.)	Waxy, oily
	Octanol	$C_8H_{18}O$	130.2	20	
	Alkanes and aromatics, e.g.:				
	Hexane	C_6H_{14}	86.17	150 (approx.)	Gasoline
Gasoline	Toluene	C_7H_8	92.13	11	Paint, sour
	Example: methyl parathion	$C_8H_{10}NO_5-PS$	263.23	0.01 (approx.)	Pungent, musty
	Naphthalene	$C_{10}H_8$	128.16	0.50 (approx.)	Mothballs
	<i>p</i> -dichlorobenzene	$C_6H_4Cl_2$	147.01	—	Mothballs
	Toluene	C_7H_8	92.13	11	Paint, sour
	Xylene	C_8H_{10}	106.16	1 (approx.)	Sweet, paint
	Methyl isobutyl kenone (MIBK)	$C_6H_{12}O$	100.16	2	Sharp
	Methyl ethyl ketone (2-butanone)	C_4H_8O	72.10	17	Sharp
	<i>n</i> -butyl acetate	$C_4H_{12}O_2$	116.16	0.02	Banana-like, sweet
	Nitrobenzene	$C_6H_5NO_2$	123.11	0.4	Almonds, shoe polish
Shoe polish, waxes					

Odors can warn us of toxic gases, contaminated food, or fire. Odors can disturb our concentration, diminish productivity, evoke symptoms, and, in general, increase a dislike for a particular environment. When disturbing and unexpected odors occur in schools or office settings, it is not surprising that occupants expect remediation. So when investigating odor complaints, keep in mind the following principles:

1. Odor sensation depends on the concentration (number of molecules) available to the olfactory receptors.
2. Environmental conditions, such as air temperature and humidity, modify odor perception.
3. Odor perception is a complex process involving the central nervous system that can evoke psychological and physiological responses.
4. Sense of smell varies greatly among persons and can decrease with age.
5. The sense of smell quickly fatigues with continuous odor exposure, but recovers rapidly.
6. Odors blend when mixed, making individual recognition difficult.
7. Mixtures of odors are complex. Depending on the compounds, a lower detection threshold is possible but less intense odors have marginal effects.

CHAPTER 22

PERCEIVED AIR QUALITY AND VENTILATION REQUIREMENTS

Professor P. Ole Fanger, D.Sc., h.c.

*International Centre for Indoor Environment and Energy
Technical University of Denmark
Lyngby, Denmark*

Since the 1930s the major objective in ventilating offices, lecture halls, schools, and similar buildings has been to establish an indoor air quality that is perceived as acceptable to the great majority of people. The present section reviews the historical background for using the acceptability concept and discusses briefly the human senses that allow people to perceive the quality of the air they breathe. Human bioeffluents are major pollutants in many spaces occupied by people. For a long time, they were assumed to be the exclusive pollutants in nonsmoking spaces, and the impact of human bioeffluents on acceptability will be discussed in detail in Sec. 22.2. Studies during recent decades have demonstrated that other sources, e.g., the building, can also contribute significantly to indoor air pollution. To express the load caused by such other pollution sources, new sensory units were introduced in the 1980s, and they are defined and discussed in Sec. 22.3. Emissions from the building, including furniture and HVAC equipment, contribute to the pollution load on the air in a space, and this load will be reviewed in Sec. 22.4. Another source of indoor air pollution is tobacco smoking, which has a health impact on people and provides a sensory load on the indoor air, requiring extra ventilation.

For the design of ventilation systems it is essential to determine the required ventilation rate. Section 22.5 presents a method for calculating the ventilation required to obtain a certain desired perceived air quality in a space, based on the load caused by the sensory sources in the space. This section also contains examples of calculations in practice in different types of space. Some adaptation takes place with time when people are exposed to odorants, while little adaptation occurs when people are exposed to sensory irritants. The impact of adaptation on perceived air quality and ventilation requirements is discussed in Sec. 22.7. Previously it was generally assumed that the perceived air quality was exclusively a function of the chemical composition of the air. However, recent studies have documented a strong impact of temperature and humidity on the perception of air quality. This is discussed in Sec. 22.8. Methods for measuring perceived air quality and sensory loads are finally presented in Sec. 22.9.

22.1 HISTORICAL BACKGROUND

The philosophy behind ventilation has since the late 1700s been that humans are the major source of pollution in nonindustrial spaces. The bioeffluents emitted by human beings needed to be diluted to acceptable levels by proper ventilation of the space. During the 1800s, the air exhaled by humans was believed to be toxic. Carbon dioxide was for a long period believed to be the toxin until Pettenkofer (1858) showed that it was harmless in the concentrations occurring indoors. During the rest of the century another substance, “anthropotoxin,” was claimed to be the toxic chemical in the expired air (Brown-Séquard and D’Arsonval 1887). A paradigm shift occurred around 1900 when it was finally proved that bioeffluents are not toxic. The dominant philosophy behind ventilation during the first third of the twentieth century was based on the fear of spread of contagion. At this time, it had been demonstrated that people with certain diseases emit pathogenic microorganisms, and to reduce the risk of contagion it was felt essential to dilute the concentration of microorganisms in indoor air by means of a high ventilation rate (Billings 1893). In the 1930s it was recognized that the major transfer of contagion was not airborne, and a new paradigm change took place in the philosophy behind ventilation. From then until the present day, ventilation has been designed to provide an acceptable perceived air quality. The pollution source was still believed to be human occupants but the focus was now changed to the odor caused by human bioeffluents.

22.2 BIOEFFLUENTS

Bioeffluents are emitted from the human body by respiration, metabolic processes, and bacterial decomposition on the skin. Bioeffluents comprise carbon dioxide and hundreds of volatile organic compounds (VOCs). Each of the VOCs usually occurs in small concentrations with a modest sensory impact, but together they provide the characteristic human body odor. The body odor was first investigated systematically by Yaglou et al. (1936) in their classical studies at Harvard School of Public Health. Yaglou studied different numbers of persons who were seated in an experimental chamber ventilated by outdoor air at different rates. The subjects entered the chamber and judged the perceived air quality on different scales, including one on odor intensity. From the results, Yaglou was able to recommend ventilation rates per person required to provide a certain acceptable odor intensity in a space. Yaglou’s data have been the basis for ventilation standards and guidelines in many countries for more than 50 years.

Yaglou’s experiments were repeated under modern conditions and with a much larger number of subjects in the 1980s and 1990s. In these studies the subjects were asked directly to assess the acceptability of the air. Figure 22.1 shows the results of European studies providing the percentage of subjects who perceived the air to be unacceptable (percent dissatisfied) as a function of the ventilation rate. This figure is the basis of European guidelines for ventilation rates in buildings (ECA 1992, CEN 1998). Different levels of air quality may be selected, corresponding to different percentages of dissatisfied, as shown in Fig. 22.1. Quality A thus requires $10 \text{ L}/(\text{s} \cdot \text{standard person})$, corresponding to 15 percent dissatisfied; quality B requires $7 \text{ L}/(\text{s} \cdot \text{standard person})$, 20 percent dissatisfied; while quality C at 30 percent dissatisfied requires only $4 \text{ L}/(\text{s} \cdot \text{standard person})$. Figure 22.1 applies for sedentary European adults in thermal comfort, but similar studies with North Americans (Cain et al. 1983) and Japanese (Iwashita et al. 1990) showed very similar results (Fig. 22.2). The American ventilation standard 62 (ASHRAE 1999) is also based on Fig. 22.1.

FIGURE 22.1 Dissatisfaction caused by a standard person (1 olf) at different ventilation rates. The curve is given by the following equations:

$$PD = 395 \cdot \exp(-1.83 \cdot q^{0.25}) \quad \text{For } q \geq 0.32 \text{ L/(s} \cdot \text{standard person)}$$

$$PD = 100 \quad \text{For } q < 0.32 \text{ L/(s} \cdot \text{standard person)}$$

22.3 SENSORY UNITS

There are pollution sources other than human beings that pollute the indoor air. Building materials, carpets, furniture, and office machines may all emit pollutants, usually a large variety of volatile organic compounds. Indoor air may therefore often contain hundreds of VOCs from such sources. The VOCs may be perceived by the olfactory sense situated in the upper part of the nasal cavity and by the general chemical sense. The olfactory sense is sensitive to odors. The general chemical sense is located on the mucous membranes in the nose and in the eyes, and it is sensitive to sensory irritants in the air.

Each VOC will typically occur at very low concentrations, often below the odor threshold and below the sensory irritation threshold, but together the many VOCs may still cause significant deterioration to the perceived air quality. The building, including furnishing etc., provides a sensory load on the air in line with the people occupying a space. To express this sensory load in a simple way, Fanger (1988) suggested expressing the load in “equivalent standard persons.” The sensory load caused by one standard person (Fig. 22.1) was named 1 olf (from latin *olfactus* = olfactory sense). Figure 22.3 illustrates the idea: an unoccupied room provides a sensory load of 4 olfs if the pollution from the room in itself is perceived equivalent to four standard persons (i.e., generates equal dissatisfaction). If three persons actually occupy the room (Fig. 22.3), the total sensory load on the air will then be 7 olfs and the ventilation should be designed to handle this total sensory load.

FIGURE 22.2 Percentage of dissatisfied persons as a function of the ventilation rate when human bioeffluents are the exclusive pollutants. Studies from European (Fanger and Berg-Munch 1983, Berg-Munch et al. 1986), North American (Cain et al. 1983), and Japanese (Iwashita et al. 1990) studies show remarkable agreement.

FIGURE 22.3 An example illustrating the sensory pollution loads in an office.

Another sensory unit, pol (from Latin *pollutio*), was introduced to express the perceived air quality. One pol is the perceived air quality in a space with a sensory load of 1 olf ventilated by 1 L/s. The perceived air quality in pol is the inverse of the ventilation rate per standard person (olf) in a space:

$$1 \text{ pol} = 1 \frac{\text{olf}}{\text{L/s}}$$

$$1 \text{ decipol} = 1 \text{ dp} = 0.1 \text{ pol}$$

Figure 22.4 shows the relation between perceived air quality in decipols and percent dissatisfied.

22.4 SENSORY POLLUTION LOAD

The sensory pollution load from people is given in Table 22.1. The load increases with people's activity load because of sweating and higher respiration. The load is higher for kindergarten and schoolchildren because of their higher activity and perhaps poorer hygiene.

Environmental tobacco smoke (ETS) contains around 5000 chemical compounds in small concentrations, and it is impossible to judge the sensory load from the contributions of the individual compounds. It is the combined effect of all compounds that counts and this has been investigated by Cain et al. (1983) and Iwashita (1992). An average smoker who smokes 1.2 cigarettes/hour provides a sensory load on the air of approximately 6 olfs. In a room with 20 percent smokers, for example, the average load of the occupants will thus be 2 olfs per occupant, as shown in Table 22.1. Note that ETS has a well-documented negative impact on people's health, which should be considered in addition to the sensory impact.

FIGURE 22.4 The relation between perceived air quality in decipol and percent dissatisfied.

TABLE 22.1 Sensory Pollution Loads

	olf/occupant
Adults: Sedentary, 1–1.2 met*	
0% smokers	1
20% smokers†	2
40% smokers†	3
Adults: Physical exercise	
Low level, 3 met	4
Medium level, 6 met	10
High level (athletes), 10 met	20
Children	
Kindergarten, 3–6 years, 2.7 met	1.2
School, 14–16 years, 1–2 met	1.3
	olf/m ² per floor
Building	
Low-polluting building	0.1
Non-low-polluting building	0.2

*met = a unit for human activity (metabolic rate), where sedentary relaxed activity corresponds to 1 met.

†Average smoking rate 1.2 cigarettes per hour per smoker.

The sensory pollution load from the building (including furnishing and HVAC system) is also provided in Table 22.1. It can be estimated as 0.1 olf/m² per floor for low-polluting buildings where materials have been selected carefully (CEN 1998). For non-low-polluting buildings, it is recommended that a sensory pollution load of 0.2 olf/m² per floor be used, but the load may easily be higher if materials are used for a building without considering the emission of pollutants.

In a recent study, Wargocki et al. (1999) demonstrated that the use of a low-polluting building compared to a non-low-polluting building improves the perceived air quality and the productivity of office workers significantly and decreases sick building syndrome (SBS) symptoms. This result was later confirmed in an independent study by Lagercrantz (2000). There are thus several good reasons for avoiding unnecessary pollution sources in practice.

Design for a low-polluting building requires careful selection of building materials. Guidelines are provided in CEN report CR 1752 (CEN 1998) based on sensory and chemical emission testing. Research on emissions from materials is in progress in many countries.

22.5 VENTILATION REQUIREMENT

The total sensory load on the air is found by adding the load from people, building, and, if smoking occurs, ETS. Studies on these three typical kinds of pollution source have shown that addition of the sensory pollution loads provides a reasonable estimation of the total sensory load on the air in a space (Wargocki et al. 1996). How the building load should be found from data based on small-scale laboratory studies of individual building materials is still to be determined. Research is in progress. It should be noted that although sensory pollution loads in a space may be added, odor intensities or percent dissatisfied are *not* additive.

Example 1. An office with an occupancy of 0.07 persons/m² per floor [persons/(m² · floor)] is designed as a low-polluting building. Determine the ventilation required for a desired air quality of level C (30 percent dissatisfied, Fig. 22.1).

Sensory pollution load:

Persons:	0.07 olf/(m ² · floor)
Building:	<u>0.1 olf/(m² · floor)</u>
Total:	0.17 olf/(m ² · floor)

According to Fig. 22.1, the perceived air quality level C requires 4 L/(s · standard person) [4 L/s · olf]. Required ventilation: $0.17 \cdot 4 = 0.7 \text{ L/(s} \cdot \text{m}^2\text{)}$.

If smoking is allowed with an average of 20 percent smokers among the occupants, the sensory load will be increased by 0.07 olf/m² and the required extra ventilation will be $0.07 \cdot 4 = 0.3 \text{ L/(s} \cdot \text{m}^2\text{)}$.

Example 2. A conference hall with an occupancy of 0.5 persons/(m² · floor) is designed as a low-polluting building. Determine the ventilation required for a desired air quality of level B (20 percent dissatisfied, Fig. 22.1)

Sensory pollution load:

Persons:	0.5 olf/(m ² · floor)
Building:	<u>0.1 olf/(m² · floor)</u>
Total:	0.6 olf/(m ² · floor)

According to Fig. 22.1, the perceived air quality level B requires 7 L/(s · olf). Required ventilation: $0.6 \cdot 7 = 4.2 \text{ L/(s} \cdot \text{m}^2\text{)}$.

22.6 A GENERALIZED COMFORT MODEL

The simplified calculations shown above assume that the outdoor air for ventilation is clean and that there is perfect mixing between ventilation and room air. If these assumptions do not apply, the following generalized comfort model can be used to calculate the required ventilation rate:

$$Q_c = 10 \cdot \frac{G_c}{C_{c,i} - C_{c,o}} \cdot \frac{1}{\epsilon_v}$$

where Q_c = the ventilation rate required for the desired perceived quality of the indoor air, L/s

G_c = sensory pollution load, olf

$C_{c,i}$ = desired perceived indoor air quality, dp

$C_{c,o}$ = perceived outdoor air quality at air intake, dp

ϵ_v = ventilation effectiveness

Example 3. An office similar to that shown in Fig. 22.3 with a total sensory pollution load of 7 olf is ventilated for a desired air quality of category A. A mixing ventilation system is applied with a ventilation effectiveness of 1.0. The office is situated in a town with good outdoor air quality (0 dp).

According to Fig. 22.1, the perceived air quality level A corresponds to 1 dp.

Required ventilation:

$$Q_c = 10 \times \frac{7}{1 - 0} \times \frac{1}{1.0} = 70 \text{ L/s}$$

22.7 ADAPTATION

Since Yaglou et al. (1936), it has been customary to design the ventilation in a space so as to provide an air quality that is perceived as acceptable from the first moment after entering the space (unadapted persons). However, some adaptation takes place after entering a space. The odor decreases significantly while the sensory irritation is usually constant and may even increase after some time. This means that a rather large adaptation takes place for exposure to bioeffluents and some to environmental tobacco smoke (ETS), while little adaptation, if any, takes place for exposure to pollutants from the building (Gunnarsen and Fanger 1992). For calculation of the ventilation required for adapted persons, one may as a rough approximation multiply the sensory load from people by a factor of 0.33, and from ETS by a factor of 0.66, while the load from the building is unchanged.

Example 4. An office is similar to that described in Example 1 above. Calculate the ventilation required for adapted persons.

Sensory pollution load (adapted):

Persons:	$0.02 \text{ olf}/(\text{m}^2 \cdot \text{floor})$
Building:	$0.1 \text{ olf}/(\text{m}^2 \cdot \text{floor})$
Total:	$0.12 \text{ olf}/(\text{m}^2 \cdot \text{floor})$

Required ventilation: $0.12 \cdot 4 = 0.5 \text{ L}/(\text{s} \cdot \text{m}^2)$. Extra ventilation for smoking: $0.66 \cdot 0.3 = 0.2 \text{ L}/(\text{s} \cdot \text{m}^2)$.

22.8 ENTHALPY

The perceived air quality was for a long period assumed to depend exclusively on the gaseous pollutants in the air, and it was exclusively the olfactory and the chemical sense that were responsible for the perception of the air. The thermoreceptors in the nose, sensitive to air temperature and humidity, were ignored. But recent studies (Berglund and Cain 1989; Fang et al. 1998a, 1998b; Toftum et al. 1998) have documented a strong impact of temperature and humidity on perceived air quality. Fang et al. (1998a, 1998b) found that the perceived air quality depends on the enthalpy of the air. Keeping the enthalpy in a space at a moderate level compatible with thermal comfort for the entire body is beneficial. A moderate enthalpy of the inspired air provides a convective and evaporative cooling of the nasal cavity which contributes to the air being perceived as more fresh and pleasant. Besides the olfactory and chemical senses, the thermal sense in the nose has an important influence on perceived air quality. This means that it is beneficial to maintain a moderate temperature and humidity. It will provide an improved perceived air quality and a lower required ventilation. Field studies (Andersson et al 1975) have confirmed that moderate temperatures and humidities improve the perception and have furthermore documented that SBS symptoms decrease under such conditions.

22.9 MEASUREMENTS

As yet there are no instruments available that can measure perceived air quality directly. Panels of subjects judging the air quality just after entering a space have been used since Yaglou et al. (1936). One can use an untrained panel of impartial subjects who enter the space and judge the acceptability of the air quality (ASHRAE 1999). It is recommended that an acceptability scale be used (Fig. 22.5). From the average panel vote, perceived air quality in decipols can be found from these equations:

$$PD = \frac{\exp(-0.18 - 5.28 \cdot ACC)}{1 + \exp(-0.18 - 5.28 \cdot ACC)} \cdot 100$$

$$C = 112 \cdot [\ln(PD) - 5.98]^{-4}$$

where PD = percentage of dissatisfied with the air quality

ACC = mean vote of air acceptability (from -1 to +1, see Fig. 22.5)

C = perceived air quality, dp

The sensory pollution load in a space can then be determined from the perceived air quality (in decipols) and the outdoor ventilation rate.

Example 5. An unoccupied conference room with a floor area of 45 m² is ventilated by 80 L/s of outdoor air. An untrained panel of 20 impartial subjects assessed the air quality immediately after entering the room, using the acceptability scale (Fig. 22.5). The average panel vote was +0.4. Determine the sensory load of the unoccupied conference room.

HOW DO YOU ASSESS THE AIR QUALITY?

PLEASE MARK ON THE SCALE

FIGURE 22.5 An acceptability scale recommended for use by an untrained panel.

The percentage of dissatisfied is calculated from the average panel vote:

$$PD = \frac{\exp(-0.18 - 5.28 \times 0.4)}{1 + \exp(-0.18 - 5.28 \times 0.4)} \times 100 = 9\%$$

The perceived air quality (in dp) is determined from the percentage of dissatisfied:

$$C = 112 \times [\ln(9) - 5.98]^{-4} = 0.5 \text{ dp}$$

The sensory load (in olf/m²) of the unoccupied conference room is:

$$G = 0.5 \times \frac{80}{10} \times \frac{1}{45} = 0.1 \text{ olf/m}^2$$

With a sensory load of 0.1 olf/m² · floor, the room may be classified as low-polluting.

This chapter is concerned with laboratory animal bioassays that can be used to evaluate air-borne chemicals and their mixtures. The emphasis is on stimulation of trigeminal or vagal nerve endings, but other bioassays relevant to indoor air quality (IAQ) problems are included.

23.1 INTRODUCTION

Two comprehensive reviews are available on the anatomy and physiology of trigeminal nerve endings in the cornea and nasal mucosa as they relate to sensory irritation (Alarie 1973a, Nielsen 1991). These afferent nerve endings are stimulated by a wide variety of air-borne chemicals to produce in humans a sensation of stinging or burning, commonly termed *sensory irritation*. At higher concentrations a reflex inhibition of respiration occurs to reduce the dose of the offending agent to the lower respiratory tract. These sensory nerve endings are unmyelinated, C-fiber type, and are located just a few micrometers from the surface of the nasal mucosa (Finger et al. 1990). Thus they are easily accessible to airborne chemicals. As presented previously (Alarie 1973a, Nielsen 1991), stimulation of these

nerve endings serves as a warning. They are among the earliest ancestors of biological environmental chemical receptors (Nielsen 1991). The conducting airways of the lung and the alveolar area are also richly innervated (Alarie 1973a). The pulmonary vagal afferent nerve endings, C-fiber type, are stimulated by a wide variety of inhaled or injected chemicals (Alarie 1973a, Vijayaraghavan et al. 1993). They can be stimulated directly by vagal nerve ending stimulants which elicit reflex effects very quickly or after an inflammatory reaction induced by injected or inhaled chemicals, i.e., pulmonary irritants, which elicit the same reflex effects more slowly (Alarie 1973a, 1981c; Schaper and Detwiler 1991; Vijayaraghavan et al. 1993; Boylstein et al. 1995; Krystofiak and Schaper 1996). These reflex characteristic modifications of the breathing pattern will serve to limit penetration of the offending chemicals to the deep lung because of a reduced alveolar ventilation (Alarie 1973a).

With such rich afferent innervation at all levels of the respiratory tract, bioassays taking advantage of this innervation can be used to elucidate the effects of airborne chemicals. Recordings from these afferent systems can be done, e.g., trigeminal or vagal nerve recordings during exposure to sensory or pulmonary irritants (Ulrich et al. 1972, Silver et al. 1991, Belmonte et al. 1991, Anton et al. 1991, Chen et al. 1995, Sekizawa et al. 1998, Ho and Lee 1998). However, bioassays based on characteristic reflex modifications of the breathing pattern due to trigeminal or pulmonary vagal nerve ending stimulation are easier to manage for toxicological investigations. The conducting airways also contain smooth muscle that can be stimulated directly or via vagal afferents. Characteristic modifications of the breathing pattern can be recognized during smooth muscle constriction (Alarie et al. 1990, Vijayaraghavan et al. 1993). Stimulation of these afferent systems occurs at much lower concentration and with much shorter duration of exposure than required to produce recognizable pathological changes and is more relevant to human complaints or subjective symptoms (Alarie 1966, Buckley et al. 1984, Alarie and Schaper 1988, Zissu 1995). The word *irritation* is correctly used for both stimulation of nerve endings (sensory irritation) or smooth muscle as well as for pathological changes such as tissue inflammation, as given in any medical dictionary. However, it is used incorrectly to describe the corrosive action of some gases or vapors on the respiratory tract, e.g., sulfur dioxide, ammonia, and methyl isocyanate, that results from single high exposures in accidents. It is important to differentiate these different "irritation" effects, particularly in the context of indoor air quality problems. Clearly, both sensory irritation, as will be described here, and tissue inflammation (Hempeljorgensen et al. 1998) are relevant to IAQ problems but certainly not a corrosive effect. Both sensory irritation and tissue inflammation are reversible following removal of the offending agent, whereas tissue corrosion is not.

This section will present bioassays that rely upon stimulation of nerve endings at different levels of the respiratory tract due to a direct action of airborne chemicals on these nerve endings (sensory irritation of trigeminal afferent system and of vagal afferents) or indirect stimulation of vagal nerve endings (pulmonary irritation) due to an inflammatory reaction induced by airborne chemicals at the alveolar level. Bioassays to recognize stimulation of smooth muscle or inflammatory reactions along the conducting airways of the lung will also be described. All of them are relevant to IAQ problems.

23.2 BIOASSAY FOR EVALUATION OF SENSORY AND PULMONARY IRRITATION

The bioassay for evaluation of the potency of airborne chemicals as sensory irritants (S) or pulmonary irritants (P1 and P) (Alarie 1966) is firmly based on the work of Kratschmer

(1870) done a century ago and many subsequent investigations (Alarie 1966, 1973a; Vijayaraghavan et al. 1993). With stimulation of trigeminal nerve endings in the nasal mucosa, a reflex inhibition of expiration occurs. A characteristic pause [now called *braking* or *breaking* and abbreviated TB (Vijayaraghavan et al. 1993)] occurs following inspiration as shown in Fig. 23.1 and expiration is delayed. This delay is due to closure of the glottis preventing air to escape from the lung after a normal inspiration (Alarie 1966, 1973a). It is better illustrated by using a pneumotachograph to measure tidal volume (VT), (as further discussed in Chap. 24 in regard to Fig. 24.2) than when using a pressure body plethysmograph to measure VT as shown in Fig. 23.1. However, with either measurement system, the duration of this pause is proportional to the intensity (or logarithm of the exposure concentration) of the stimulus. This pause results in a net decrease in respiratory frequency f , or breaths/minute (BPM). Since it was easier to count BPM than to measure the duration of this pause, BPM was used to define the intensity of the response, while the characteristic pause was used to indicate the nature of the effect [i.e., sensory irritation (S)] (Alarie 1966). Using several exposure concentrations for a particular chemical and measuring the decrease in BPM for groups of four mice at increasing exposure concentrations, a concentration-response relationship could be established (Alarie 1966). To determine the potency of each chemical evaluated, the concentration calculated to decrease BPM by 50 percent (RD50) was obtained (Alarie 1966).

With stimulation of pulmonary vagal, C-fiber type nerve endings, two distinct changes in the respiratory pattern can be observed. The first phase (P1) occurs with stimulation of low intensity (or low exposure concentration) and is characterized by rapid shallow breathing, i.e., a decrease in tidal volume and a decrease in both the duration of inspiration (TI) and duration of expiration (TE). There is no characteristic modification of the VT waveform as during S. This first phase of the reaction to a pulmonary irritant is usually not very pronounced in mice and slightly more pronounced in rats (Vijayaraghavan et al. 1993, 1994; Arito et al. 1997; Hubbs et al. 1997). It is prominent in guinea pigs, dogs, rabbits, and humans as demonstrated with the classic pulmonary irritants such as phosgene, ozone, nitrogen dioxide, paraquat aerosol, etc. (Alarie 1966, 1973a, 1981c; Alarie and Schaper 1988; Alarie et al. 1990). This first phase is then followed by the second phase (P), which is characterized by the addition of a pause (TP) of increasing duration at the end of active expiration, also described as a pause between breaths, as shown in Fig 23.1. This will be further elucidated in Chap. 24, Fig. 24.2. This second phase (P) pattern is much more prominent in mice (Alarie 1981c; ASTM 1984; Schaper et al. 1989; Schaper and Brost 1991; Vijayaraghavan et al. 1993, 1994) than in the other species noted above. Thus TP can be used to indicate the pulmonary irritating nature of inhaled chemicals in this species, while the first phase (P1) is more appropriate to use in the other species. The P1 effect in these other species, particularly the guinea pig, can be amplified by challenging the animal with 10% CO₂, just as it is amplified in humans by exercise (Alarie and Schaper 1988). This CO₂ challenge increases the sensitivity of the bioassay (Alarie 1966, Alarie and Schaper 1988, Alarie et al. 1990, Castranova et al. 1996). This will be addressed specifically in Sec. 23.12.

As the duration of the pause between breaths increases in mice, and more numerous pauses between breaths occur with increasing exposure concentrations, a net decrease in BPM will occur. Thus the potency of a pulmonary irritant in mice can be expressed as the concentration necessary to decrease BPM by 50 percent (RD50P) because of this increasing TP (Weyel et al. 1982, Weyel and Schaffer 1985, Schaper and Detwiler 1991, Schaper and Detwiler-Okabayashi 1995). The same phenomenon will occur to some extent in rats (Arito et al. 1997) but no concentration-response relationship is available in this species. In fact, rats are a poor choice to study pulmonary irritation with this bioassay. Their P1 effect is slightly more pronounced than in mice while their P effect is less pronounced than in mice. To study pulmonary irritation, it is best to use mice or guinea pigs for their P or P1

FIGURE 23.1 Typical tracings obtained in mice held in body plethysmographs when using a pressure transducer to measure VT. Normal pattern is shown in the top tracing, including two brief periods of fluctuations due to body movements of the animal. The second tracing shows the lengthening of the expiratory phase of respiration due to sensory irritation (S). The bottom tracing shows the pause between breaths, characteristic of pulmonary irritation (P). Included is a tracing showing mixed patterns of S and P but this is very seldom observed. The Y axis represents pressure (uncalibrated) with upward and downward deflections representing inspiration and expiration, respectively, and the X axis is time. (From Ferguson *et al.* (1986). Reprinted with permission from Academic Press.)

effects, respectively. Rats and guinea pigs are also a poor choice to study sensory irritation because of their lower sensitivity than mice (Schaper 1993).

A bioassay using mice was developed initially to rapidly evaluate thousands of chemicals that had been synthesized as potential tear gas candidates (sensory irritants) and at the same time to eliminate those with pulmonary irritating effect. Various laboratory animals were tested with known human sensory and nonsensory irritants and known human pulmonary and nonpulmonary irritants. The mouse was selected as the most appropriate species to recognize the possible effects of these two effects, S and P (Alarie 1966).

23.3 TECHNICAL DESCRIPTION OF THE SENSORY AND PULMONARY IRRITATION BIOASSAY

A detailed description of the bioassay is given in Alarie (1966) and ASTM (1984). The assay requires monitoring respiratory movement continuously, i.e., tidal volume, in unanesthetized mice in order to observe characteristic changes in the normal breathing pattern (Fig. 23.1) and then to calculate the decrease in BPM. The simplest way to accomplish this is to use a body plethysmograph (sometimes called a head-out plethysmograph where the body is enclosed within a chamber while the head protrudes out through what may be considered for practical purposes an airtight seal) with a pressure transducer attached to it as shown in Fig. 23.2. With this arrangement, the pressure change created in the plethysmograph due to breathing is proportional to VT. If the animal holds its breath at the end of inspiration as a result of the trigeminal reflex, it creates the characteristic change to the VT waveform during expiration as shown in Fig. 23.1.

The usual procedure is to attach four body plethysmographs to a small exposure chamber into which the chemical to be evaluated is introduced. Then, the level of response is taken as the maximum decrease in BPM obtained as the average of four mice simultaneously exposed at a particular concentration. Using several exposure concentrations the maximum decrease in BPM, based on an average of four mice, is plotted versus the logarithm of each exposure concentration. From linear least-squares regression analysis, the concentration resulting in a decrease in BPM by 50 percent was calculated to yield RD50 or RD50P, depending on the characteristic change (TB or TP) of the breathing pattern as noted above. For sensory irritants, it is generally best to set the duration of exposure at 30 minutes so that a maximum decrease in BPM is observed. Normally this will be observed within 15 minutes or even faster, followed by a plateau, but with some slow-acting chemicals, an exposure period of 3 to 4 hours may be required (ASTM 1984). With some chemicals, a maximum response may be followed by a fade in the response instead of a plateau. For pulmonary irritants it is best to set the duration of exposure at 3 hours since the reaction develops more slowly than with sensory irritants (Weyel et al. 1982, Weyel and Schaffer 1985, Schaper and Detwiler 1991, Schaper and Detwiler-Okabayashi 1995, Krystofiak and Schaper 1996). Investigators have also used much shorter exposures or repeated exposures, to explore conditions related to specific requirements or problems (Alarie 1966; Kane and Alarie 1977; Sangha and Alarie 1979; Kane and Alarie 1979a; Schaper and Brost 1991; Anderson and Anderson 1997, 1998a).

23.4 VALIDATION OF THE SENSORY AND PULMONARY IRRITATION BIOASSAY AND APPLICATIONS

Any bioassay must be validated. Validation refers to correct predictions (correlation) of negative and positive findings between the qualitative response obtained with the bioassay and the qualitative response obtained in humans. It is not necessary that the response in the bioassay and the response in humans be the same; it is only necessary that a type of response in a bioassay be predictive of a type of response in humans. A formal validation was undertaken for sensory irritation by evaluating 51 chemicals in mice and humans. The results showed perfect predictions; chemicals inducing the characteristic postinspiratory pause in mice produced symptoms of sensory irritation in humans, while those that did not were found to be nonirritating by humans (Alarie 1973a, Kane et al. 1979b). A less formal

FIGURE 23.2 Schematic diagram of exposure chamber to which four body plethysmographs are attached to obtain the average breathing frequency of four mice. [From Barrow et al. (1976). Reprinted with permission from Heyden & Son, Ltd.]

validation was also undertaken from a literature search, by inspecting the results reported by investigators from either human exposures under controlled laboratory conditions or from accidents. All commonly known sensory irritants in humans, e.g., formaldehyde, acrolein, sulfur dioxide, ammonia, etc., induced positive reactions in mice (Kane et al. 1979b). The same was obtained for complex mixtures, e.g., smoke from burning materials, synthetic photochemical smog mixtures, or mixtures of volatile organic chemicals (VOCs) commonly found indoors (Barrow et al. 1978, Kane and Alarie 1978, Anderson and Coogan 1994, Alarie et al. 1996). Thus the bioassay can be reliably used to qualitatively evaluate the sensory irritating properties of single chemicals or complex mixtures, the latter usually being the case with IAQ problems.

No formal validation is available (or possible for ethical reasons) for pulmonary irritants but a less formal validation from literature review has been conducted as for sensory irritants. Known pulmonary irritants in humans such as phosgene, nitrogen dioxide, ozone, paraquat aerosol, leather conditioner aerosol, etc. have been evaluated in a variety of laboratory animals. The reflex reaction results have been extremely consistent, i.e., always positive (P1 or P effects) in animals regardless of the species (Alarie 1973a, 1981c; Alarie and Schaper 1988; Alarie et al. 1990; Arito et al. 1997; Hubbs et al. 1997). Thus unknown chemicals or mixtures can be reliably investigated by this bioassay to qualitatively recognize both sensory (S) or pulmonary irritation (P1 or P).

This bioassay, when using a body plethysmograph with a pressure transducer to measure VT (Alarie 1966, ASTM 1984), could not be used to detect airflow limitation (A), i.e., a lower than normal expiratory airflow along the conducting airways, because it did not measure airflow velocity. Airflow limitation is very important to recognize in the context of IAQ and will be addressed below (Sec. 23.12).

In 1984, Subcommittee E 35.26 on Safety to Man of the American Society for Testing and Materials (ASTM 1984) approved the mouse bioassay to recognize and quantify the S and P effects as a standard ASTM method. It received the designation "E 981," expanded to "E 981-84" for the year when it was approved. Recognition of the P1 or A effects was not included, nor was the use of other animal species. It has been reviewed and reapproved every 5 years since, as required for all ASTM standard methods.

23.5 CALIBRATION OF THE SENSORY AND PULMONARY IRRITATION BIOASSAY AND APPLICATIONS

One of the goals of occupational and environmental toxicology is to establish safe levels of exposure to chemicals by first assessing their potency for a particular toxic effect, using a validated bioassay. For bioassays, the classic way to obtain potency is to statistically derive the exposure concentration that will result in half the maximum elicitable response. For this bioassay in mice, the concentration is RD50 or RD50P, as given above. On the basis of an RD50 or RD50P value, a safety factor can be applied as a guide to a concentration that is unlikely to induce responses in humans. Kane et al. (1979b) compared RD50 values for 11 commonly used industrial chemicals to their threshold limit values (TLVs) established to prevent adverse health effects in workers. They then suggested that the results of the mouse bioassay could be quantitatively extrapolated to humans:

- At the RD50: intolerable sensory irritation
- At $0.1 \times \text{RD50}$: slight sensory irritation
- At $0.01 \times \text{RD50}$: minimal or no sensory irritation

Thus, TLVs to prevent sensory irritation from occupational exposures might be set between 0.1 and $0.01 \times \text{RD50}$.

Alarie (1981a, 1981b) proposed setting the TLV halfway between 0.1 and $0.01 \times \text{RD50}$ on a logarithmic scale. RD50 was simply multiplied by 0.03 to suggest an appropriate TLV. An excellent correlation was found between $0.03 \times \text{RD50}$ and the TLV for the first 21 chemicals evaluated (Alarie 1981a, 1981b). This was further confirmed for a total of 41 chemicals (Alarie and Luo 1986) and later expanded to 89 chemicals (Schaper 1993). The RD50 and TLV values for these 89 chemicals are presented in Table 23.1. Schaper (1993) published 154 RD50 values for these 89 chemicals (Table 23.1), as some of them were evaluated several times using different stocks or strains of mice in different laboratories, and thus some chemicals listed in Table 23.1 have more than one entry for RD50. The correlation between $0.03 \times \text{RD50}$ and the TLV values for these 89 chemicals is presented in Fig 23.3. It shows that as a rule, $0.03 \times \text{RD50}$ is an excellent starting point to estimate a TLV. A TLV may need to be lower than $0.03 \times \text{RD50}$ to prevent other possible toxic effects, but it cannot be higher.

TABLE 23.1 Threshold Limit Values (TLVs) of 1991–1992 for 89 Chemicals for Which RD50 Values Have Been Obtained in Different Mice and Different Laboratories^a

The estimated TLVs for each chemical, from $0.03 \times \text{RD50}$, is also presented with the difference between actual and estimated TLVs. Also, the basis for establishing each TLV to prevent critical toxicological effects is presented.^b

^aAdapted from Schaper (1993).

^bFrom ACGIH (1998).

^cEach value was obtained from different mice and/or laboratories as listed by Schaper (1993).

^dIt should be noted that some of the chemicals listed were evaluated in the aerosol form rather than vapor, but all concentrations are given in ppm for potency comparison and for the regression analysis in Fig. 23.3.

^eAbbreviations: IR: irritation; PE: pulmonary edema; LI: liver; VI: vision; LU: lung; BL: blood; OT: ototoxicity; OC: ocular; KI: kidney; CA: cancer; SE: sensitization; CO: corrosive; CNS: central nervous system; CVS: cardiovascular system; RE: reproductive; NEO: neuropathy, ocular; NE: neuropathy; GI: gastrointestinal.

^fFrom addition of all values in this column.

A notable exception to the general rule established by Alarie, as noted in Fig. 23.3, is hexachlorobutadiene (HCB). This chemical has a TLV of 0.02 ppm. From $0.03 \times \text{RD50}$, its TLV would be 8 ppm. Its TLV was based on gavage of rats with HCB at 0.2 mg/kg per day which resulted in kidney tumors (ACGIH 1991). How this oral ingestion was translated into an inhalation exposure to prevent irritation is unexplained (ACGIH 1991), and whether or not kidney tumors in rats are predictive of kidney tumors or other systemic effects in humans is unknown. Later, DeCaurriz et al. (1988) noted kidney tubular necrosis in mice exposed only once to HCB at 7.2 ppm for 4 hours. This is a realistic exposure model, but whether or not this effect in mice is qualitatively or quantitatively predictive of the same or other systemic effects in humans is unknown. Regulatory policy has accepted positive findings in unvalidated and uncalibrated animal models as predictive of the same effect in humans at the same exposure concentration (ACGIH 1991). Industrial toxicologists have adopted the same policy (Keller et al. 1998). Nevertheless, it should not be concluded that this outlier invalidates the general rule.

TLVs were originally established to protect male adult industrial workers against adverse health effects as a result of exposures at work. TLVs represent exposure limits over a 40-hour work week. Individuals in nonindustrial indoor settings are likely to be less tolerant at low levels of sensory irritating chemicals than industrial workers, not because they are more sensitive than industrial workers but because they are not as familiar with such exposures (Dalton et al. 1997, Wysocki et al. 1997). After an extensive literature review, Nielsen et al. (1995) proposed that a factor of 4 to 40 below $0.03 \times \text{RD50}$ be used as a guideline for indoor environments. Adjustment depends upon the potency of each chemical as a sensory irritant and an in-depth evaluation of other possible toxicological effects. These are equivalent to

FIGURE 23.3 Linear least-squares regression analysis for the logarithm of $0.03 \times \text{RD50}$ versus the logarithm of the TLV for 89 chemicals, for which a total of 154 RD50 values are available, as listed in Table 23.1. The regression line (solid), 95% confidence interval lines (dashed), and 95 percent prediction interval lines (dotted) are presented as well as the regression equation. Modified from Schaper (1993).

RD50/133 and RD50/1333, respectively, and would take into consideration the differences between industrial workers and the general population noted above. This approach was used to prepare indoor air guideline values for organic acids (Nielsen et al. 1998b), phenols (Nielsen et al. 1998c), and glycol ethers (Nielsen et al. 1998a). Taking the above into consideration, the earlier suggestions (Alarie 1981a, 1981c) are now incorporated and expanded to the following quantitative extrapolations in humans:

- At $10 \times \text{RD50}$: severe injury, possibly lethal
- At $1 \times \text{RD50}$: intolerable sensory irritation
- At $0.1 \times \text{RD50}$: some sensory irritation
- At $0.03 \times \text{RD50}$: suggested TLV, minor sensory irritation if any
- At $0.01 \times \text{RD50}$: no sensory irritation
- At $0.001 \times \text{RD50}$: no effect of any kind

The RD50/133 to RD50/1333 are slightly more conservative than 0.01 and $0.001 \times \text{RD50}$ originally proposed and listed above as recommended indoor levels (RILs). The more conservative RD50/1333 might be used when little toxicological data are available from animal or human studies.

Alarie et al. (1996) offers guidance on a recommended indoor level for individual chemicals or mixtures of volatile organic chemicals. They suggest the RIL be used in the context of solving IAQ problems, not as a permission to introduce chemicals into homes, offices, or buildings. Thus when complaints of sensory irritation are occurring and the RIL is exceeded for a particular chemical or for a mixture of chemicals, investigators might suspect that sources of airborne volatile chemicals are responsible for these complaints of sensory irritation.

For pulmonary irritation, there has been no formal calibration as done for sensory irritation. The safety factor applied when a decrease in respiratory rate of 50 percent (RD50P) due to a pause between breaths caused by pulmonary irritants has been suggested to be RD50P/60 (Weyel et al. 1982, Weyel and Schaffer 1985) for industrial workplaces. This approach was used for aerosols produced from metalworking fluids and their components (Schaper and Detwiler 1991, Schaper and Detwiler-Okabayashi 1995, Krystofiak and Schaper 1996, Detwiler-Okabayashi and Schaper 1996). This will be specifically discussed in Sec. 23.6.

23.6 ADAPTATION OF THE ASTM E 981 STANDARD METHOD FOR INVESTIGATING MIXTURES

One of the major goals of the ASTM E 981 standard method is to allow evaluation of complex mixtures without knowing their composition.

The ASTM E 981 standard method, like the original bioassay (Alarie 1966), provides for (1) an exposure chamber operated under dynamic conditions (although it can be used under static conditions with proper precautions), (2) a means of recording the breathing pattern of mice and (3) a way to recognize the S or P effect from the breathing pattern of unanesthetized mice. Any gas, vapor, or aerosol can be introduced into the exposure chamber for evaluation of its effect. In indoor cases where mixtures of VOCs emitted from products or processes are suspected, these mixtures can be introduced directly into the exposure chamber by coupling mixture generating systems to the ASTM E 981 standard method exposure chamber.

23.7 MIXTURE GENERATING SYSTEMS

Many different types of emission chambers or systems have been used in combination with the ASTM E 981 standard method, including those for testing materials used indoors. Valuable toxicological results have been obtained with simple and inexpensive systems.

Emission Chambers or Systems

The first mixture generating system attached to ASTM E 981 was a simple glass aquarium (Kane and Alarie 1978). Ultraviolet (UV) lights were placed within this aquarium for irradiation of nitrogen dioxide with saturated or unsaturated short-chain aliphatic hydrocarbons to produce mixtures representative of photochemical smog. Air from the aquarium was introduced into the exposure chamber at various times during UV irradiation of each mixture, for evaluation of their sensory or pulmonary irritating properties. The results obtained in mice correlated with sensory eye irritation results obtained in humans exposed to similar mixtures (Kane and Alarie 1978). Then, a glass aquarium was used to evaluate several mixtures from products or processes relevant to IAQ problems. Some of these results have been published, as given in Table 23.2, but many remain unpublished.

In each case listed in Table 23.2, the investigators adapted the glass aquarium or a similar system to suit the particular product or process in order to simulate either actual use conditions or to maximize emissions. The latter was achieved by product source loading to

air volume ratios higher than what is suspected for actual use or by raising the aquarium temperature (up to 80°C) to increase volatilization. Temperature (up to 80°C but not higher, to prevent thermal decomposition of products) may cause changes in the percentage composition of the mixture, since the vapor pressure–temperature relationship is different for each chemical emitted. This disadvantage is, at times, offset by the need to rapidly assess the sensory and pulmonary irritation properties of different products. When doing so, the air temperature of the exposure chamber should be below 55°C. Some products may emit a fairly significant amount of water vapor when using an increase in temperature, resulting in 100% relative humidity (RH) in the exposure chamber as well as condensation on its wall. The combination of 55°C and 100% RH is without sensory or pulmonary irritation effect in mice, but water condensation is undesirable. To obviate this problem, products have been conditioned in sealed chambers containing a desiccant prior to testing. Despite such difficulties, this approach is warranted to simulate, for example, emissions produced in a closed car on a hot summer day.

Any mixture generating system can be attached to the exposure chamber of the ASTM E 981 standard method, provided that fresh air is provided ($<1\%$ CO₂) and that no negative pressure is created in the exposure chamber to interfere with the normal breathing pattern of the exposed animals. This last requirement is much more important than CO₂ content in the exposure chamber. Mice are unaffected by CO₂ up to 3%. However, breathing against a negative pressure will trigger a pulmonary reflex reaction very quickly in mice (Alarie, unpublished).

Fire Models

Smoke or smoke residues after a fire may present some IAQ problems. Two small-scale fire model systems have been used in conjunction with the ASTM E 981 method to test fresh smoke from a variety of burning materials for investigation of their irritating properties. In the first model, a furnace was used with continuous ventilation. The samples to be investigated were placed in the furnace at room temperature and submitted to an increasing temperature of 20°C/min until complete burning of the sample or 900°C was reached. Smoke from pyrolysing and flaming samples was then cooled (55°C or below) and directed into the exposure chamber (Barrow et al. 1978, Alarie and Anderson 1979). The second system consisted of a steel enclosure into which a radiant energy source was placed to ignite the samples to be evaluated. By varying the radiant energy and ventilation in this enclosure, a wide range of burning conditions were explored (Caldwell and Alarie 1990a, 1990b, 1991). Using these systems, the irritating properties of smoke produced by a wide variety of materials was established. The following were investigated, among many others: wood, wool, rigid polyurethane foam, polymethyl methacrylate, nylon, polytetrafluoroethylene, phenol-formaldehyde foam, and urea-formaldehyde foam. The results for the sensory irritating potency of some of these mixtures were compared with known sensory irritants as shown in Table 23.3. They indicate possible IAQ problems during cleanup operations or reentry of occupants after a fire. Care must be taken to avoid sensory irritation problems due to deposited smoke, which can contain highly potent sensory irritants.

Thermal Decomposition of Plastics

In general, plastics are not exposed to high heat in the normal indoor environment, except in relation to accidents. However a variety of uses can generate emissions, e.g., wrapping books etc. in shrink film, cutting plastic films with a hot wire, various hobbies requiring the application of heat to plastic resins.

TABLE 23.3 Sensory Irritation Potency of Freshly Generated Smoke from Plastics in Comparison to Some Known Sensory Irritant

Smoke from	Potency (RD50), mg/L
Douglas fir	0.24
Flexible polyurethane foam	0.06
Fiberglass-reinforced polyester	0.14
Polytetrafluoroethylene	0.25
Polyvinylchloride (plasticized)	0.19
Chemicals	
Toluene diisocyanate	0.0028
Chlorine	0.027
Sulfur dioxide	0.31
Ammonia	0.21
Hydrogen chloride	0.45

Source: Modified from Barrow et al. (1978).

In the furnace described above, widely used plastics were heated at normal processing temperatures to evaluate the sensory irritating properties of their thermal decomposition products (TDPs) (Schaper et al. 1994). The processing temperatures varied between 200 and 300°C. The RD50s found (in mg/m³) were as follows: acrylonitrile-butadiene-styrene (ABS, 21.1); polypropylene-polyethylene copolymer (PC), 3.51; polypropylene homopolymer (HP), 2.60; plasticized polyvinylchloride (PVC), 11.5. If RD50/1333 is used to prevent complaints of sensory irritation in indoor environment as explained above, the potency of TDPs would indicate that a very low level of exposure (2 to 16 µg/m³) can contribute to sensory irritation complaints when overheating of common plastics occurs for whatever reasons. Furthermore, a single high exposure to TDP can produce long-lasting pulmonary effects (Wong et al. 1983).

Aerosols of Metalworking Fluids and Their Components

In machining operations (e.g., cutting, drilling, grinding), metalworking fluids (MWFs) are used as lubricants and/or coolants. There are four basic types of MWFs: straight oils (60 to 100 percent petroleum oil), soluble oils (30 to 85 percent oil in water), semisynthetic (2 to 20 percent in water) and synthetic (0 percent oil). Semisynthetics and synthetics contain numerous chemical additives and are diluted in large volumes of water. With the high temperatures and pressures of machining operations, submicrometer-sized aerosols may be formed from MWFs, which then become airborne. Although typically found in the workplace, MWFs may be used in home or school workshops in smaller quantities but for similar purposes. Thus their aerosols could contribute to odors, irritation, and respiratory effects in such settings.

With the ASTM E 981 method, the irritating properties of aerosolized MWFs were evaluated, including 20 of the components used in various formulations (Schaper and Detwiler 1991, Schaper and Detwiler-Okabayashi 1995, Krystofiak and Schaper 1996, Detwiler-Okabayashi and Schaper 1996). Also, repeated exposures (5 consecutive days) were con-

ducted (Schaper and Detwiler 1991). The results of these studies indicated that aerosols of MWFs, their components, and various mixtures of these components induced the S effect in a concentration-dependent manner. Furthermore, most of these aerosols also produced pulmonary irritation in a concentration-dependent manner, but somewhat later in the exposures (2 to 3 hours). From their potency as pulmonary irritants (RD50P), their suggested industrial exposure levels varied between 1 and 10 mg/m³. Further reduction would be appropriate for indoor air but an RIL has not yet been arrived at for the P effect, as described above for the S effect. According to their potency as sensory irritants (RD50), their RIL would vary between 0.05 and 0.5 mg/m³.

23.8 NATURE OF SENSORY IRRITATING VOCs

The database of Schaper (1993) contains 144 commonly encountered VOCs evaluated for their potency as sensory irritants, i.e., RD50. A variety of physicochemical parameters ("descriptors"), either determined experimentally or estimated, can be used to describe the properties of molecules including VOCs. These 144 VOCs were separated into two groups: nonreactive VOCs (NRVOCs), acting via weak physical (*p*) interactions with the trigeminal nerve endings receptor, and reactive VOCs (RVOCs), acting via chemical (*c*) reaction with the trigeminal nerve endings receptor (Alarie et al. 1998). These chemicals are presented in Table 23.4 with the letter *p* or *c* identifying chemicals in each set and the relevant physicochemical descriptors available for each. Such groupings (NRVOC, or *p*, and RVOC, or *c*) were arrived at by using Ferguson's (1939) proposal, that when the ratio P^{RD50}/P^0 is >0.1 a physical (*p*) mechanism is most probable, while when the ratio is <0.1 a chemical (*c*) mechanism is most probable for stimulation of the sensory irritant receptor (Nielsen and Alarie 1982, Alarie et al. 1998). Here, P^0 is the saturated vapor pressure and P^{RD50} is the exposure concentration producing a decrease in BPM by 50 percent for each NRVOC or RVOC listed in Table 23.4, units for both P^0 and P^{RD50} being mmHg or ppm, resulting in a unit-independent ratio. A review of Table 23.4 will show that the *p* chemicals are NRVOCs, and are used as solvents, while the *c* chemicals are RVOCs, electrophiles, weak acids, or weak bases (Alarie et al. 1998) and are therefore capable of chemically reacting with the sensory irritant receptor, which has nucleophilic centers, among other characteristics (Nielsen 1991). Table 23.5 presents the groups and subgroups to which the chemicals in Table 23.4 belong. It is useful for matching unevaluated chemicals with closely related evaluated chemicals. The *c* chemicals have further been grouped under five fundamental organic reaction mechanisms (Alarie et al. 1998) as discussed in Sec. 23.11.

23.9 NATURE OF THE TRIGEMINAL RECEPTOR OR RECEPTOR PHASE

A wide variety of nonreactive (*p*) sensory irritants (NRVOCs) is shown in Table 23.4. The solvation equation of Abraham et al. (1990) formulated as a linear free energy relationship (LFER) or quantitative structure-activity relationship (QSAR) can be a very useful aid to understanding the nature of the trigeminal receptor or receptor phase in combination with the set of *p* chemicals listed in Table 23.4 and definitions of their mechanisms of action. The equation was written as follows:

$$\log SP = \text{constant} + r \times R_2 + s \times \pi_2^H + a \times \sum \alpha_2^H + b \times \sum B_2^H + l \times \log L^{16} \quad (23.1)$$

Source: Alarie et al. (1998), with correction on the number of aliphatic unsaturated ether from 1 to 2.

The dependent variable, log SP, is some physicochemical property (SP) of a series of VOCs (NRVOCs or RVOCs) (solutes) in a given system or phase. Log SP can be related to the gas-liquid partition coefficient L for a number of solutes in an organic solvent such as hexadecane. Also, SP can be the potency, i.e., RD50, of a series of NRVOCs in a biological system. If so, it becomes a quantitative structure-activity relationship (QSAR) analysis instead of LFER. The independent variables representing physical properties of the NRVOCs in Eq. (23.1) are

- R_2 = excess molar refraction; represents the tendency of a solute to interact with a phase through π or n -electron pairs
- π_2^H = dipolarity/polarizability; a dipolar solute will interact with a dipolar phase and a polarizable solute will interact with a polarizable phase
- $\Sigma\alpha_2^H$ = overall or effective hydrogen-bond acidity; a hydrogen-bond acid will interact with a basic phase
- $\Sigma\beta_2^H$ = overall or effective hydrogen-bond basicity; a hydrogen-bond base will interact with an acidic phase
- L = the solute gas-liquid partition coefficient (Ostwald solubility coefficient) on hexadecane (L^{16}). It is a measure of the lipophilicity of a solute, and by definition $L = 1.0$ for hexadecane at 298 K

The coefficients of this equation are calculated from multiple linear regression analysis (MLRA). Their value reflects the complimentary properties of the biophase. Greater details on these physicochemical properties and their use in other biological systems can be found in Abraham (1996) and Abraham et al. (1998a, 1998b).

Because each coefficient obtained via MLRA represents complementary characteristics of the solute and the trigeminal receptor or receptor phase, their sign and magnitude must follow correct chemical principles. If the potency is expressed as RD50, the sign must be negative, while if potency is taken as $1/\text{RD50}$, as is often done in QSAR analysis, the sign should be positive. The magnitude must also fall within the limits established for biological phases as shown in Table 23.6. As discussed by Abraham (1996), examples could be water or oil. From Table 23.6, water is highly dipolar ($s = 2.63$), is a strong hydrogen-bond acid ($b = 4.50$) but not lipophilic ($l = -0.25$). On the other hand, olive oil is somewhat dipolar, has zero acidity, but is highly lipophilic. Thus the application of this solvation equation with NRVOCs has mechanistic implications. Solving Eq. (23.1) for a series of NRVOCs (Alarie et al. 1995) using hexadecane (L^{16}) or olive oil [$L(\text{oil})$] yielded the fol-

TABLE 23.6 Values for the Constant c and Coefficients r , s , a , b , and l in Eq. (23.1) Obtained with NRVOCs in Different Biological Phases at 310 K

Phase	c	r	s	a	b	l
Water	-1.36	1.05	2.63	3.74	4.50	-0.25
Plasma	-1.48	0.49	2.05	3.51	3.91	0.16

Source: Abraham and Weathersby (1994).

lowing results with $p < 0.05$ as the criterion to accept as significant the contribution of each physicochemical descriptor given above:

$$\log RD50 \text{ (ppm)} = 6.90 - (1.49 \times \pi_2^H) - (2.37 \times \Sigma \alpha_2^H) - (0.761 \times \log L^{16})$$

$$r^2 = 0.88, n = 75 \quad (23.2)$$

$$\log RD50 \text{ (ppm)} = 6.66 - (0.776 \times \pi_2^H) - (1.15 \times \Sigma \alpha_2^H) - [0.85 \times \log L \text{ (oil)}]$$

$$r^2 = 0.88, n = 75 \quad (23.3)$$

These results suggest that the receptor or receptor phase is moderately dipolar, quite basic, and highly lipophilic (Abraham et al. 1990, Alarie et al. 1995).

This mechanistic approach can then be simplified for practical applications such as investigation of IAQ problems by using a single independent variable: lipophilicity, represented in equation (23.1) by L^{16} or $L(\text{oil})$, since these descriptors are of higher importance in Eq. (23.1) (Alarie et al. 1995). When lipophilicity is used alone, it has been demonstrated that olive oil is a better choice as the solvent than hexadecane (Alarie et al. 1995). Both $L(\text{oil})$ and L^{16} values are listed in Table 23.4.

23.10 ESTIMATING EQUATIONS TO DERIVE THE SENSORY IRRITATING POTENCY OF NRVOCS

Single Chemicals

From the above, we can estimate the potency of any NRVOC (see below for reservations) if $L(\text{oil})$ is known, by using the following equation and as shown in Fig. 23.4 (Alarie et al. 1995).

$$\log RD50 \text{ (ppm)} = 591 - [0.799 \times \log L \text{ (oil)}] \quad r^2 = 0.83, n = 75 \quad (23.4)$$

While many $L(\text{oil})$ values are available, a more readily available physicochemical descriptor for NRVOCs of IAQ concerns is vapor pressure (P^0). $L(\text{oil})$ and P^0 values have been shown to be inversely correlated (Alarie et al. 1995) and RD50 values can be estimated from the following equation and as shown in Fig 23.5 if P^0 values are available.

$$\log RD50 = 2.693 + (0.887 \times \log P^0) \quad r^2 = 0.83, n = 59 \quad (23.5)$$

Finally, molecular weight (MW) and P^0 are inversely correlated (Alarie et al. 1996) and MW can be used with the following equation:

$$\log RD50 = 5.36 - (0.02 \times MW) \quad r^2 = 0.61, n = 50 \quad (23.6)$$

There is an obvious decline in the r^2 value when MW is used, but this descriptor is always available and can be used if the other two, $L(\text{oil})$ and P^0 , are not. Because of the imprecision (± 1 log unit) when MW is used, this descriptor should not be used to estimate the potency of an NRVOC. However, for a mixture of NRVOCs the individual errors will cancel out toward the mean. The higher the number of NRVOCs in the mixture, the better the estimate of its potency will be. This approach will be used below.

The above equations were developed from specific data sets listed in Table 23.4 and Table 23.7, and the best estimates will be for untested chemicals closely related to them. It is known that there is a maximum size or volume for NRVOCs to fit the sensory irritant receptor. NRVOCs at nonane and above become ineffective (Kristiansen and Nielsen

FIGURE 23.4 Linear least-squares regression analysis for log L (oil) versus log RD50 values for nonreactive VOCs. The regression line (solid) and 95 percent prediction interval lines (dotted) are presented, as well as the regression equation. [From Alarie *et al.* (1995). Reprinted with permission from Academic Press.]

1988) and therefore these equations should be used for small MW NRVOCs. Also, the trigeminal receptor has some stereospecificity as shown by the fact that *d*- α -pinene is a sensory irritant while *l*- α -pinene is practically inactive (Kasanen *et al.* 1998). Since pinenes are nonpolar and not capable of hydrogen bonding, the only basis for stereospecificity is the spatial arrangement of the trigeminal receptor pocket. Furthermore *cis-trans* activity/inactivity has been demonstrated for a congeneric series of sensory irritants (Alarie 1990). Thus some cautions should be applied when using the above estimating equations.

Mixtures with Unknown or Known Constituents

IAQ problems may be related to a specific RVOC such as formaldehyde, or NRVOC such as toluene. More frequently numerous chemicals are identified, each at a low concentration. In many instances the concentration (ppm or mg/m^3) of these chemical mixtures is reported as a total (TVOC), calibrated as methane or toluene equivalents. The individual constituents are unknown. If the TVOC mixture consists of only NRVOCs, or the RVOCs present can be analyzed separately, the average MW for the mixture of NRVOCs would be around 100 (Alarie *et al.* 1996). This is presented in Alarie *et al.* (1996). VOCs described there and as listed in Table 23.7 were between 30 and 170 MW, and the average was 100.

FIGURE 23.5 Linear least-squares regression analysis for $\log P^0$ versus $\log RD50$ for p (nonreactive; circles) and c (reactive; squares) chemicals listed in Table 23.4. The regression and 95 percent prediction interval lines are presented, as well as the regression equation. (Reprinted with permission from Springer-Verlag.)

Also, the average MW for the mixture in Table 23.8 is 108. Therefore the potency of the NRVOC mixture, from the TVOC concentration reported as toluene ($MW = 92$) can be estimated from Eq. (23.6) given above, using an average MW of 100 to estimate the potency of the mixture (Alarie et al. 1996). From this estimated potency and TVOC concentration measured as toluene, we can then compare the results to the RIL value of a hypothetical NRVOC chemical having an MW of 100 (Alarie et al. 1996) and decide whether or not the concentration of the mixture reported as TVOC using toluene for calibration is likely to be responsible for sensory irritation complaints. Alarie et al. (1996) proposed the use of Eq. (23.7) instead of Eq. (23.6) obtained from the data set given in Table 23.7 to estimate RD50 of an unknown mixture of NRVOCs. The data set in Table 23.7 contains some chemicals, such as aliphatic saturated aldehydes (excluding formaldehyde) and aliphatic saturated acetates, that have some chemical reactivity and thus would be more representative than just the p chemicals listed in Table 23.4.

$$\log RD50 \text{ (ppm)} = 4.941 - (0.018 \times MW) \quad r^2 = 0.52, n = 72 \quad (23.7)$$

Thus if $MW = 100$, $RD50 = 1383$ ppm. The RIL, $RD50/1333$, would be ≈ 1.0 ppm (4.0 mg/m^3). If the TVOC concentration is reported as methane instead of toluene, these values need to be multiplied by 6. Values found in normal nonindustrial environments are much below this estimated 1.0 ppm or 4.0 mg/m^3 (Mølhave and Nielsen 1992).

If the constituents of the VOC mixture and their concentrations are known, we can estimate the potency (RD50) of each ingredient (if they are NRVOCs) from either $L(\text{oil})$, P^0 , or MW as given above or use the experimentally obtained RD50 if available (Alarie et al.

TABLE 23.7 Values for Molecular Weight (MW), Vapor Pressure ($\log P^0$), and Sensory Irritation Potency (RD50) for 72 Volatile Organic Chemicals*Fifty-two are nonreactive and twenty (aldehydes, acetates) have slight reactivity.**

*From linear regression analysis, the equations to estimate RD50 are: $\log \text{RD50 (ppm)} = 4.941 - (0.018 \times \text{MW})$, $n = 72$, $r^2 = 0.52$, $s = 0.492$, and $\log \text{RD50 (ppm)} = 2.584 - (0.613 \times \log P^0)$, $n = 72$, $r^2 = 0.62$, $s = 0.436$.

Source: Modified from Alarie et al. (1996).

1996). Obviously, the experimentally obtained RD50 can be used for either NRVOCs or RVOCs as needed. From the estimated potency and concentration of each chemical in the mixture, we can then estimate whether or not the mixture would create an IAQ sensory irritation problem (Alarie et al. 1996). In order to do so we must assume that: (1) at low concentration the additivity rule is applicable and (2) a threshold concentration exists below which no sensory irritation will occur.

Thus the equation for additivity and a maximum recommended indoor level can be set as follows, with $[C]$ representing the airborne concentration of each chemical in the mixture and its corresponding RIL:

$$\text{RIL}_{\text{total}} = [C_1]/\text{RIL}_1 + [C_2]/\text{RIL}_2 + \dots [C_n]/\text{RIL}_n \quad (23.8)$$

If the sum is higher than 1, RIL for the mixture is exceeded and complaints of sensory irritation are to be expected. To test this concept, a RIL value of RD50/1333 was used for each ingredient of a mixture of NRVOCs that had been evaluated and found to induce sensory irritation in humans under controlled laboratory conditions on two separate occasions with

different human volunteers (Otto et al. 1990, Prah et al. 1998). The results of the calculations are presented in Table 23.8 and show an RIL value above 1, i.e., 8.7, in accord with the findings of sensory irritation in exposed human volunteers.

Mixtures of Microbial Volatile Metabolites

Microbial volatile organic chemicals (MVOCs) produced by fungi and bacteria have been suspected as a cause of sensory irritation, as recently analyzed by Pasanen et al. (1998). They listed 27 VOCs or MVOCs measured in test rooms and their concentrations. An RIL value was calculated for each, either from experimentally derived RD50s or by using the estimation equations noted above. From the concentration and RIL values of each chemical, and using Eq. (23.8) for summation, they concluded that it is very unlikely that MVOCs will, exclusively, contribute to complaints of sensory irritation except under unusual circumstances. MVOCs are fairly common simple organic chemicals that can be generated from other sources, and therefore their addition is obviously undesirable. Their relevance was also determined by obtaining RD50 values for some MVOCs (1-octen-3-ol, 3-octanol and 3-octanone) and for a mixture of five MVOCs (Korpi et al. 1999). Again it was concluded that taken alone or in combination they are very unlikely to contribute, by themselves, to complaints of sensory irritation. An interesting finding was that the mixture of five MVOCs was slightly more potent (a factor of 3.6) than estimated from the potency of the single ingredients. This factor is too small to be of practical significance given the low concentration of MVOCs under normal circumstances (Pasanen et al. 1998) unless there is a trend toward higher than additivity with an increasing number of MVOCs (or VOCs) in a mixture. Such a trend has been reported in humans (Cometto-Muñiz and Cain 1997) exposed to mixtures of two, six, and nine NRVOCs, but again this higher-than-additivity trend was small. Given the fact that RD50/1333 is very conservative in establishing an RIL and that MVOC concentrations are very low, this slightly higher than additivity does not appear to be important to consider. Recently, Wilkins et al. (1998) exposed mice to volatile emissions from *Stachybotrys chartarum* growing in closed chambers. Little, if any, effect was obtained even with a very high loading factor.

23.11 ESTIMATING EQUATIONS TO DERIVE THE SENSORY IRRITATION POTENCY OF RVOCs

Estimating the potency of RVOCs is more difficult since both lipophilicity and chemical reactivity play a role (Alarie et al. 1995, 1998). It has been shown that if a measure of chemical reactivity can be obtained in a model system, RD50 values were highly correlated with the measure of chemical reactivity, and the difference in potency of a congeneric series could be explained via the Hammett equation (Alarie 1973b, Tarantino and Sass 1974). However, this applied only to reactive chemicals in the aerosol form. For the vapor form as for the RVOCs listed in Table 23.4, Alarie et al. (1998) developed a theoretical framework capable of accommodating (1) the phase distribution between the exposure concentration (vapor phase) and the nasal mucosa phase and (2) a measure of the chemical reactivity to arrive at estimation of potency using both variables. The phase distribution was accounted for by P^{RD50}/P^0 correction as described above from Ferguson's rule, and the chemical reactivity descriptor must then be obtained for each set of chemicals, depending on their reactivity mechanism, or by using a measured or estimated reactivity value.

QSAR for Chemically Reactive Allylic Compounds with the Pharmacophore $\text{CH}_2 = \text{CH-C-Y}$, Where Y is a Hydrogen Bond Base

For this group, consisting of acrolein, allyl acetate, allyl alcohol, and allyl ether (all listed in Table 23.4), tested in the same laboratory, the Hammett equation sigma value (σ_p) for each chemical was obtained from Hansch et al. (1991) and used to describe the variation in their chemical reactivity for correlation with their potency. The following results were obtained (Alarie et al. 1998):

$$\log P^{\text{RD50}}/P^0 = (-2.4417 \times \sigma_p) - 4.265 \quad r^2 = 0.99, n = 4 \quad (23.9)$$

This is encouraging but the number of chemicals is too low for a final conclusion. Furthermore, in these allylic chemicals, steric and electronic effects must be taken into consideration when the α -carbon has a substituent other than hydrogen (Alarie et al. 1998). Thus the application is limited.

QSAR for Chemically Reactive Chemicals with the Pharmacophore $\text{Y-CH}_2\text{-Halogen}$

This group of chemicals consisted of (1) allyl chloride, iodide, and bromide; (2) benzylchloride, iodide, and bromide; and (3) *-o*-, *-m*-, and *-p*-chlorobenzyl chloride. These are listed in Table 23.4. Here the reactivity of the halogen leaving group ($\text{LE}_{\text{Halogen}}$) measured in a model system was combined with the P^0 value of each chemical to arrive at the following results (Alarie et al. 1998):

$$\log \text{RD50} = -1.706 + (0.732 \times \log P^0) - (0.710 \times \log \text{LE}_{\text{Halogen}}) \\ r^2 = 0.98, n = 9 \quad (23.10)$$

The relationship between potency (RD50), vapor pressure ($\log P^0$) and chemical reactivity ($\log \text{LE}_{\text{Halogen}}$) can be visualized in Fig. 23.6.

Saturated Aliphatic Acetates

For saturated aliphatic acetates (as listed in Table 23.4), particularly short, straight-chain acetates, their hydrolysis to yield acetic acid as the active irritant is a possibility (Alarie et al. 1998). Abraham et al. (1998a) used their hydrolysis rate (k_{rel}), experimental or estimated values, to illustrate this possibility and explain why they are more potent than predicted from their P^0 values as shown in Fig. 23.7 and described by the equation given in Fig. 23.7. This analysis was also based on using the P^{RD50}/P^0 correction to explain the higher-than-expected potency (excess potency) as given in Fig. 23.7.

Saturated Aliphatic Amines

The approach taken for these chemicals (methyl to heptyl amines) listed in Table 23.4 was to correct for their measured RD50 over the estimated RD50 value from their respective P^0 value, by matching them to their respective nonreactive saturated alcohols. A constant factor of 20 in excess potency was found for this series of amines. Excess potency is simply the ratio between the estimated potency (RD50) calculated from each chemical P^0 value and the experimentally obtained RD50 value or to the difference to a respective nonreactive chemical (Alarie et al. 1998). This empirical factor of 20 is thus a measure of reactivity of these amines in this biological system and can serve as a guide to develop a mechanistic approach (Alarie et al. 1998).

FIGURE 23.6 Mesh plane relationship between potency ($\log RD50$), vapor pressure ($\log P^0$), and chemical reactivity ($\log LE_{\text{Halogen}}$). [Modified from Alarie *et al.* (1998).]

The results for RVOCs obtained so far and summarized above cannot be generalized as in the case of NRVOCs, since the mechanism of chemical reactivity is different for each group. Nevertheless the results explain why RVOCs can be much more potent than NRVOCs as shown in Fig. 23.5. There are many RVOCs listed in Table 23.4 and plotted in Fig. 23.5. A semiquantitative estimate of the potency of untested RVOCs can be arrived at by comparing them with those already evaluated (using Table 23.5) until more general equations can be derived.

23.12 BIOASSAYS TO EVALUATE ASTHMATIC REACTIONS AND AIRWAYS HYPERREACTIVITY OR HYPERRESPONSIVENESS (AHR)

Asthma is now defined (American Thoracic Society 1993) as: "1) a condition characterized by variable airflow obstruction and the individual's clinical status varies from time to time; 2) the airflow limitation is partially or completely reversible with appropriate therapy; 3) the condition is associated with airway hyperresponsiveness to irritants such as dust, fumes, gases or smoke; 4) in many cases, environmental or occupational exposure to specific sen-

FIGURE 23.7 Linear least-squares analysis (solid line) of excess potency versus krel (relative rate constant for alkaline hydrolysis) and 95% confidence interval lines (dotted lines). Excess potency was calculated as the difference between log RD50 estimated from P^0 values for each chemical and the experimental RD50 value. [Modified from Abraham et al. (1998a).]

sitizers provokes airway inflammation, which, on repeated exposure may become chronic and irreversible.”

There is a relevant bioassay that can be used to rapidly evaluate possible immunological sensitization that can result in bronchoconstriction during challenge by inhaled chemicals. This assay uses the guinea pig (Ratner et al. 1939), since this species provides a dramatic airflow limitation or bronchoconstriction effect (A) on inhalation challenge by an antigen. Simple observation of the animal or an index reflecting the breathing difficulty of sensitized guinea pigs during challenge by the antigen can be used (Karol et al. 1978). A measure of resistance to airflow or a measurement of airflow limitation during expiration are preferable to quantify the response. This can be accomplished via direct measurement of resistance to airflow along the conducting airway of the lung, which necessitates the use of an intrathoracic catheter to measure transpulmonary pressure (Amdur and Mead 1958). The use of flow-volume loops (or curves) during normal breathing or whole-body plethysmography, which are noninvasive procedures, are more convenient for toxicological investigations (Alarie and Schaper 1988, Alarie et al. 1990). Secondly, before a serious degree of airflow limitation or bronchoconstriction develops, the typical reaction in guinea pigs (Alarie 1981c) as well as in humans (McFadden and Lyons 1968), is characterized by rapid shallow breathing (Alarie 1981c) described in animals as the P1 reaction as noted above and described as “phase II asthmatic severity” in humans (Weiss 1975). The P1 effect can be easily measured during flow-volume curve measurements or with whole-body plethysmography as described below and can be used as an index of a positive response during inhalation challenge with an antigen (Karol et al. 1978; Alarie et al. 1990). In challenging a sensitized guinea pig the reaction will progress from P1 to A, but if the animal is highly

sensitized the P1 reaction will hardly be seen and only the A effect is observed (Alarie and Schaper 1988).

A disadvantage of using guinea pigs is that the antibody type responsible for the reaction is IgG₁ rather than IgE as in humans (Zhang et al. 1997). Thus several investigators have used mice, which produce IgE antibodies on sensitization by a foreign protein such as ovalbumin (Renz et al. 1992). On inhalation challenge, mice will develop an inflammatory reaction but bronchoconstriction as in the guinea pigs and humans has not been reported. During this inflammatory reaction, airways hyperreactivity or hyperresponsiveness (AHR) exists (Renz et al. 1992) and is demonstrated via challenge with an aerosol of methacholine in the same manner as in humans (Hamelman et al. 1997). Thus while the mouse model is lacking in the A effect during challenge with an antigen—it also lacks this effect with histamine challenge (Martin et al. 1998)—it can be used to demonstrate and study AHR which is an equally important component of asthma. However, Neuhaus-Steinmetz et al. (2000) have recently obtained results indicating that in BALB/c mice, the A effect can be obtained if repeated aerosol exposures to an antigen (ovalbumin) are conducted. This repeated exposures protocol not only defined an acute A effect during exposure to the antigen but also a decline in pulmonary function with multiple exposures. The Brown Norway rat is another relevant model. It has been demonstrated that IgE antibodies, the A effect, an inflammatory reaction and AHR can be elicited in this strain of rats with a foreign protein or a low molecular weight chemical such as trimellitic anhydride acting as a hapten (Yu et al. 1995, Watanabe et al. 1995, Schneider et al. 1997, Underwood et al. 1997, Cui et al. 1997, Wilkins et al. 1998). Therefore, there is the possibility of determining the potency of allergens and ranking them by using this rat strain or BALB/c mice.

Asthma is of obvious importance in IAQ problems because so many high molecular weight natural products, or simple chemicals acting as haptens, have been shown to induce asthma via immunological mechanisms in humans (Bardana, Jr., et al. 1992, Chang-Yeung and Malo 1993). In order to arrive at a validated and calibrated animal model that can realistically predict human response and just as importantly provide guidelines for exposure levels, both sensitization and challenge must be conducted, using the inhalation route in relevant animal models. Appropriate methods are available to recognize and quantitate the effects of allergens during challenges (P1 or A effects). Furthermore, there appears to be a wide range in their potency as allergens. For example, the TLV for subtilisins (proteolytic enzymes used in detergents) is set at 6×10^{-9} g/m³ (ACGIH 1998). This is an extremely low airborne concentration. In comparison, the concentration of ovalbumin used to sensitize guinea pigs is 0.01 to 0.03 g/m³ (Alarie et al. 1990). A ranking of the potency of indoor natural allergens is needed in order to set priorities and determine their importance in IAQ problems.

23.13 RECOGNITION OF RAPID, SHALLOW BREATHING (P1) AND AIRFLOW LIMITATION OR BRONCHOCONSTRICTION (A) EFFECTS

Instead of using a body plethysmograph as described above to characterize the breathing pattern of unanesthetized mice or other laboratory animals, a whole-body plethysmograph can be used as shown in Fig. 23.8. This system is in effect a closed chamber, into which an animal is placed with no restraint needed (Wong and Alarie 1982). The inlet and outlet (diameter and length) through which air is continuously flowing are arranged so that the fast pressure wave created by each breath is not lost to the outside and can be measured by a pressure transducer or microphone (Wong and Alarie 1982, Alarie and Schaper 1988, Alarie et al. 1990). With such an arrangement, contaminated air can be passed through the whole-body plethysmograph to study the possible P1 or A effects.

Because the pressure wave created with each breath is more complex in its origin than the pressure wave measured in a body plethysmograph (Alarie et al. 1990) modifications of the normal breathing pattern are somewhat more difficult to interpret and quantify. However, there are definite advantages to this bioassay system, particularly for chronic studies of airborne contaminants, since measurements can be made repeatedly with no restraint imposed on the animal (Ellakkani et al. 1984, Ellakkani et al. 1987) or to follow the corrosive effects of a single high exposure to a particular chemical or mixture (Wong and Alarie 1982; Wong et al. 1983, 1984; Ferguson and Alarie 1991).

This system is better suited for inactive animals such as guinea pigs than active animals such as mice (although see below) because body movements greatly interfere with waveform analysis. It is not well suited to recognize the S effect but it is ideal to recognize and quantify the P1 effect since waveform analysis is not needed to recognize this effect. It is very suitable to recognize and empirically quantify the A effect.

Flow-volume curves measured during normal breathing can be easily obtained in guinea pigs, mice, or rats (Alarie et al. 1987, 1990; Vijayaraghavan et al. 1993; Pauluhn 1998) and have been used to recognize and quantify the P1 and A effects. The only difference between this system and the ASTM E 981 method described above is that VT is measured by integrating airflow during normal breathing of the animal in a body plethysmograph by attaching a pneumotachograph (to measure airflow) instead of a pressure transducer to measure pressure created by each breath (Vijayaraghavan et al. 1993). This measurement system is ideal for evaluating the P1 effect and to recognize and quantify the A or P effects. Unlike the whole-body plethysmograph, it is also ideal for the evaluation of the S and P effects. Thus it is the best system to evaluate all possible effects: S, P1, P, or A effects, but there is a need for restraint at the neck of the animal. This system has now been computerized, and will be fully described in Chap. 24.

Recognition and Quantitation of the P1 Effect

Since the P1 effect is simply a reduction in VT (tidal volume), TI and TE (duration of inspiration and expiration) with no characteristic changes to the breathing pattern, but resulting in

FIGURE 23.8 Lateral view of a whole-body plethysmograph. This arrangement is a flow-through system that permits continuous measurement of the pressure (ΔP) due to each breath in an unrestrained, unanesthetized guinea pig while breathing air, a mixture of 10% CO_2 (balance 20% O_2 , 70% N_2) or during exposure to various gases or aerosols. A small animal ventilator is used for calibration. [Modified from Wong and Alarie (1982).]

an increase in BPM with a reduction in VT, both methods given above (whole-body plethysmography or measurement of flow-volume curves) can be used to evaluate this effect, and a variety of known human pulmonary irritants have been evaluated with such systems as listed in Table 23.9. Here, a decline in VT and an increase in BPM, due to the decrease in TI and TE, have been used to evaluate the potency of single chemicals or mixtures. Also, the increase in BPM is accentuated by challenging exposed guinea pigs with 10% CO₂, just like exercise-induced tachypnea occurs in humans following exposure to pulmonary irritants (Alarie and Schaper 1988). Thus we have a good validation of the bioassay to evaluate unknown chemicals or mixtures. However, no attempt has been made to calibrate the level of the P1 response obtained in guinea pigs (or mice or rats) to safe levels of exposure in humans.

Of interest is that this bioassay, with CO₂ challenge to amplify its sensitivity, was used recently to investigate an IAQ episode resulting from the use of a leather conditioner spray product that resulted in hundreds of complaints of breathing difficulties and visits to emergency centers immediately after the product was introduced on the market (Smilkstein et al. 1992, Kulig et al. 1993, Burkhart et al. 1996, Hubbs et al. 1997). This pulmonary irritation

TABLE 23.9 Airborne Chemicals Investigated in Guinea Pigs, Mice, or Rats to Characterize Rapid Shallow Breathing

Caused by pulmonary irritation or airflow limitation due to bronchoconstriction by using whole-body plethysmography or flow-volume curves. Some of these investigations also added CO₂ challenge to magnify the effect.

effect resulted from the simple change of the main solvent from the old formulation 1,1,1-trichloroethane, to a new solvent, isooctane. This was done to comply with the 1990 Amendments to the Clean Air Act regarding ozone depletion. Because of the much lower vapor pressure of isooctane (about 2 mmHg versus trichloroethane about 127 mmHg) this solvent was inhaled in droplet form when the product was used indoors with poor ventilation. Droplets (but not vapors) of such solvents (aliphatic hydrocarbons, chlorinated or fluorinated aliphatic hydrocarbons) reaching the alveolar wall will displace pulmonary surfactant, inducing an inflammatory reaction resulting in the P1 effect very quickly if inhaled at a high concentration (Alarie et al. 1975). The P1 effect was easily recognized in guinea pigs and rats exposed to the new product, while the old product was inactive (Hubbs et al. 1997). This qualitative correlation reinforces the validity of using the P1 effect in laboratory animals as a predictor of pulmonary irritation in humans.

Recognition and Quantitation of the A Effect

The A effect can be easily recognized because the pressure wave due to each breath created in a whole-body plethysmograph is modified in a very characteristic way. This modification is due to compression of the air in the lung caused by reduction in the diameter of the conducting airways by smooth muscle contraction (bronchoconstriction or airways constriction) and/or an inflammatory reaction and mucus accumulation (Alarie and Schaper 1988, Alarie et al. 1990) and resulting in a much *slower* expiratory phase than normal to compensate for the higher resistance to airflow created by the decrease in airway diameter (Vijayaraghavan et al. 1993). A typical example of this characteristic change is shown in Fig. 23.9. Although it is remarkably easy to recognize and semiquantitatively evaluate the degree of the A effect in Fig. 23.9 just from observation, a quantitative measurement of the effect is more difficult. As shown in Fig. 23.9, a simple increase in the pressure wave, provided that a characteristic modification of the expiratory phase is observed can be sufficient. Recently, an empirical index to quantify the A effect was proposed (Hamelman et al. 1997, Chong et al. 1998) taking into account both the increase in amplitude of the pressure wave and the lengthening of the expiratory phase. A simple and direct measurement will be described in Chap. 24.

23.14 COUGHING

Complaints of coughing and dry throat are often associated with IAQ problems. The whole-body plethysmograph was used to evaluate such an IAQ problem which occurred in an office building. Inappropriate dilution of a carpet shampoo, consisting mainly of sodium lauryl sulfate, resulted in a residue in the carpet. The major complaints from the occupants was coughing and dry throat, caused by reentrainment in air of the residue (Kriess et al. 1982). Sodium lauryl sulfate was aerosolized and passed through the whole-body plethysmograph with guinea pigs as shown in Fig. 23.6. Coughing was easily induced, recorded, and quantitated (Zelenak et al. 1982). From the concentration-response relationship obtained, the potency of sodium lauryl sulfate was compared to citric acid which is commonly used to elicit the cough reflex in humans (Stone and Fuller 1995). It was found to be 6 times more potent than citric acid. It is of interest to note that detergents and surfactants are widely used in homes and offices. Their skin and eye irritation potential have been widely studied but their potential for irritation of the respiratory tract has received scant attention (Nielsen et al. in press).

FIGURE 23.9 Top panel: Typical recording of ΔP for a guinea pig placed in a whole-body plethysmograph. When challenged with 10% CO₂, ΔP increases as well as respiratory frequency. During challenge with a histamine aerosol there is an increase in ΔP and a decrease in respiratory frequency due to a characteristic prolongation of expiration. The increase in ΔP in this case is due to air expansion and compression greater than in normal conditions, caused by bronchoconstriction. This has been experimentally confirmed from simultaneous measurement of transpulmonary pressure (Alarie et al., 1990).

Bottom panel: The increase in ΔP can be used as an index of bronchoconstriction during challenge by an aerosol of trimellitic anhydride (TMA) in a sensitized guinea pig. Note that ΔP increases during both 10% CO₂ and TMA challenges; however, the breathing pattern is completely different. The breathing pattern during TMA challenge is similar to the breathing pattern during histamine challenge. Similar results were obtained in guinea pigs sensitized with konjac flour (Werley et al., 1997). [Modified from Alarie et al. (1990).]

23.15 CONCLUSIONS

Reliable bioassays are available to investigate IAQ problems related to irritation of the respiratory tract. Unlike the great sensitivity achievable in analytical chemistry, the bioassays are not particularly sensitive. Exposure concentrations higher than typically found indoors are necessary to elicit a response in these bioassays. Their advantage is their relevance in predicting human reactions to either single chemicals or complex mixtures. It is encouraging that CO₂, used as a corneal sensory irritant, produced comparable effects in humans and cats (Chen et al. 1995) and that CO₂ can be used to reliably determine the sensory irritation sensitivity of human subjects in an objective and quantitative manner (Shusterman and Balmes 1998). The specific topic of sensory irritation in humans is addressed in other chapters in this handbook.

With a better understanding of the nature of VOCs, NRVOCs, and RVOCs, and the nature of the trigeminal receptor or receptor phase, it is now possible to integrate analytical chemistry results with reasonable estimates of potency for sensory irritation by mixtures and arrive at reasonable estimates to guide IAQ investigators and prevent the occurrence of IAQ problems.

ACKNOWLEDGMENTS

We thank M. Hirkulich for her help in preparation of this manuscript and Dr. M. H. Abraham for his collaboration regarding physicochemical descriptors.

CHAPTER 24

COMPUTERIZED ANIMAL BIOASSAY TO EVALUATE THE EFFECTS OF AIRBORNE CHEMICALS ON THE RESPIRATORY TRACT

Yves Alarie, Ph.D.

*University of Pittsburgh
Pittsburgh, Pennsylvania*

This chapter describes the use of a computerized system for a bioassay (Alarie 1966, ASTM 1984) that is used extensively for evaluating the effects of airborne chemicals on the respiratory tract as described in Chap. 23. The emphasis is on its use to evaluate more complex effects than those described in Chap. 23, and its greater reliability. In some instances a greater sensitivity is also achieved by using a computerized system. Its applicability in preventing or investigating IAQ problems due to irritation of the respiratory tract is described, and guidelines are provided for investigators using this new approach.

24.1 INTRODUCTION

The mouse bioassay (Alarie 1966), which became ASTM E 981 standard method (ASTM 1984), as described in Chap. 23 has now been automated and can be used with mice, guinea pigs, or rats. The inspiratory and expiratory airflow rates defining the normal breathing pattern of these laboratory animals are digitized, stored, and processed by a series of five computer programs written in FORTRAN and running under DOS on a 486 PC or higher (Vijayaraghavan et al. 1994, Boylstein et al. 1995). A rule-based computer analysis scheme classifies each breath from each mouse, guinea pig, or rat as normal (N) or in one of eight abnormal categories according to a formal analysis of the breathing pattern (Vijayaraghavan et al. 1994; Boylstein et al. 1995, 1996; Alarie 1998).

This completely obviates operator subjectivity in the recognition of recorded abnormal breathing patterns as in using the original bioassay (Alarie 1966, ASTM 1984). Also, because tidal volume (VT, mL) is obtained via integration of airflow (V, mL/s) during inspiration (VI) and expiration (VE) for each breath, it is now possible to recognize and quantify bronchoconstriction or airflow limitation (A) that occurs during smooth muscle contraction or inflammatory reactions along the conducting airways of the lung. Thus the effects of airborne chemicals are recognized and quantified at each of the major portions of the respiratory tract:

- *Upper respiratory tract*: sensory irritation (S), also obtainable from ASTM E 981
- *Conducting airways of the lung*: bronchoconstriction, airways constriction or airflow limitation (A), not obtainable from ASTM E 981
- *Alveolar level*: first phase of pulmonary irritation (P1), not obtainable from ASTM E 981
- *Alveolar level*: pulmonary irritation (P), also obtainable from ASTM E 981 but with less sensitivity

The computer programs recognize each effect noted above (S, A, P1, and P) and the following combinations of effects, i.e., S + A, S + P, P + A, and S + A + P, forming a total of eight abnormal categories. A summary of the rule-based decision tree to diagnose each breath is presented in Fig. 24.1. The rationale and description of the rules shown in Fig. 24.1 will be presented in detail.

24.2 DESCRIPTION OF THE METHOD

Exposure System

The exposure system is the same as in the original bioassay (Alarie 1966) and the ASTM E 981 standard method (ASTM 1984) using a group of four animals for each experiment. The body plethysmograph for mice is shown in Fig. 24.2. A minor change is that the plethysmographs are detachable from the exposure chamber. This makes it easier to manipulate the animals into them and to check the appropriateness of the neck collar. It obviates too much restraint at the neck, which may result in blood flow restriction as sometimes occurred (Werley et al. 1996). Second, instead of attaching the plethysmograph to the exposure chamber, a head dome can be connected to the plethysmograph as shown in Fig. 24.2. It is convenient to evaluate small volumes of contaminated air, by passing the air through the head dome at 50 mL/min instead of using the exposure chamber with an airflow from 2 to 20 L/min when mice are used. The same system can be used with guinea pigs or rats, as shown in Fig. 24.3 with an airflow of 2 L/min when using the head dome and 10 to 20 L/min when using an exposure chamber.

Airflow (V) Measurement; Inspiratory and Expiratory Airflows (VI and VE)

A calibrated pneumotachograph (Fleisch Model 3.0 or 4.0 or Hugo Sachs type 378/1.2) is attached to the top or back port of each body plethysmograph. A differential pressure transducer is attached to each pneumotachograph (Vijayaraghavan et al. 1993). A continuous airflow of 170 mL/min is maintained into each plethysmograph and pneumotachograph, by a vacuum pump set to operate at 18 inHg when pulling air through a critical orifice (27

gauge needle). This critical orifice is attached to a port (exhaust port in Figs. 24.2 and 24.3) of each plethysmograph. The use of this constant airflow is optional. It was used originally to optimize the frequency response of the system (Vijayaraghavan et al. 1994). Identical results are obtained without this constant bias flow through the plethysmograph and pneumotachograph. Calibration of airflow must be done before each experiment by passing 170 mL/min (2.8 mL/s) through each pneumotachograph, using the same vacuum pump setting and critical orifice. This airflow is about the maximum VI and VE reached by a mouse during normal breathing and is convenient to use, although an investigator may use a slightly different setting. The voltage change created by this airflow, from zero flow, is then entered as the calibration factor for the analog-to-digital converter card and used by the collection program MAKEVDVT for all calculations. The same procedure is used for guinea pigs or rats with a continuous airflow of 2 L/min, substituting a 20 gauge needle for the 27 gauge needle as the critical orifice.

Recording and Digitization of VI and VE

The analog signal (V) from the differential pressure transducer attached to the pneumotachograph is amplified and recorded on a Gould WindoGraf or other appropriate recorder. The signal is simultaneously digitized by an analog-to-digital (A/D) converter card (DAS-16 from Keithley Metrabyte or CYDAS-16 from Cyber Research; other A/D cards will not work with the computer program MAKEVDVT described below) inserted into a 486 PC. The sampling rate (digitization) is set at 500 samples/s for the V signal of each mouse, and these digitizations are stored on the hard disk of the PC.

Recognition and Quantitation of S, A, P Effects, Their Combinations, and the P1 Effect

The rationale is based on previous findings of numerous investigators, fully described by Vijayaraghavan et al. (1993, 1994) as well as in the description of the original bioassay (Alarie 1966) and a comprehensive review of it (Alarie 1973). As shown in Fig. 24.4, the VT wave during quiet breathing obtained from digital integration with time of V (VI and VE) resembles that of a sine wave. The duration of the top of the wave (abbreviated TB for duration of braking) can be obtained by measuring the distance (time) between the lines drawn (**D** in Fig 24.4) connecting 0.25 and 0.75 VTI and 0.75 and 0.25 VTE, at maximum VT. This distance is from P2 to P3. To obviate errors due to possible noise, maximum VT is taken as 98 percent of VT. The duration of the bottom of the wave (abbreviated TP for duration of the pause) is obtained the same way (P4 to P5 in **D**), and again, to obviate possible error due to noise, the bottom of the wave is set as 2 percent of VT. As shown in **A** there is no actual braking or pausing for the normal breath. Rather, TB and TP values calculated for normal breaths will be used by the computer program to diagnose whether or not a breath is N, S, or P depending on the increase in TB or TP, respectively, from the normal or control values. During S or P, these values will increase, as shown in **B**, **E**, and **F**. To recognize A, there is no obvious change in the VT waveform pattern as in S and P. However, there is a prolongation of the time of expiration (TE), and thus V decreases during expiration. Thus the A effect is recognized by a decrease in V at 0.5 VTE as shown in **C**. The V value obtained at 0.5 VTE has been abbreviated VD (Vijayaraghavan et al. 1994) and more recently EF50 for mid-expiratory flow rate (Neuhaus-Steinmetz et al. 2000). VD will be used here. A complete depiction of the variables measured during each respiratory cycle is presented in Fig. 24.5.

FIGURE 24.2 Body plethysmograph for mice that can be attached to an exposure chamber or used with a head dome as shown here. A pneumotachograph to measure airflow during each breath is attached to the top port and air is pulled continuously via the exhaust port. Shown in the insert is a catheter tip transducer, which can be added as an option to obtain transpulmonary pressure, which permits the measurement of airflow resistance and dynamic lung compliance. The dimensions given are for animals from 22 to 32 grams but the neck collar should be adjusted accordingly. [From Vijayaraghavan et al. (1993). Reprinted with permission from Springer-Verlag.]

24.3 ACQUISITION AND PROCESSING OF DATA

A diagram of how the computer programs operate and interact is presented in Fig. 24.1. The computer programs and their functions are (Boylstein et al. 1995, Alarie 1998):

- **MAKEVDVT:** This program digitizes the V signal (and saves these digitization files) and calculates VT by integration with time. It also calculates all the other variables given in Table 24.1 and depicted in Fig. 24.5. It displays the results on a video terminal for each 15 s of data collected during each experiment. It also creates a binary file (*.BIN) of the collected data for each experiment.
- **HISTVAR:** This program imports a *.BIN file and produces histograms and summary statistics of the results, as well as ASCII files of the results, for each variable measured for each breath collected during the entire experiment.
- **TABLEVT:** This program imports a *.BIN file and creates time-response graphs for all the variables measured and breath classifications arrived at, and creates ASCII files of these results. The ASCII files are for the mean of each variable measured for all the breaths occurring in each 15-s collection period and the percentage of breaths in each classification during each 15-s collection period.

FIGURE 24.3 Body plethysmograph for guinea pigs that can be attached to an exposure chamber or used with a head dome as shown here. The dimensions given in millimeters are for animals of 350 to 500 grams but the collar dimensions should be adjusted accordingly. The pneumotachograph and differential pressure transducer are attached and the critical orifice is attached on the exhaust port as shown.

FIGURE 24.4 $\dot{V}$ signal and integrated $\dot{V}$ to yield VT. A horizontal line at zero flow (A) separates airflow during inspiration (VI), upward, from airflow during expiration (VE), downward. A, normal condition, breath classified as N. B, during exposure to a sensory irritant: elongation of TB, breath classified as S. C, during exposure to a bronchoconstrictor: reduction of VD, breath classified as A. E, during exposure to a pulmonary irritant: reduction of VT, TI, and TE, breath classified as P1; also TP begins to increase. F, during exposure to a pulmonary irritant: reduction in VT and TI still present, elongation of TP, breath classified as P. D, hand-drawn VT wave showing how TB and TP are measured by the computer program from sampling points during inspiration and expiration and VT minimum and maximum. [From Vijayaraghavan et al. (1994). TABLE 24.1 Variables Calculated by the Computer Program MAKEVDVT
From measurements (digitizations) of airflow (V) during inspiration and expiration (VI, VE). Includes their use in breathing pattern analysis for breath classification in categories other than normal (N)^a.

Variables used for abnormal breath classification	Abb ^b	Unit	Definition	Type of abnormal breath classification for which the variable is used and abbreviations for each classification ^c	Requirement for the variable for breath classification in comparison to $\bar{X}$ control value	JDE for classification ^d	JDE for variable ^e
Time of braking	TB	s	Duration of the top of the VT wave	S: sensory irritation Basis: reflex reaction from stimulation of trigeminal or laryngeal nerve endings	Value for the breath is $> \bar{X} + 2 \text{ SD}$	S = 2%	TB = 20%
Airflow at 0.5 VTE	VD or EF50	mL/s	Airflow during expiration at 0.5 VT	A: airflow limitation Basis: lengthening of expiration to compensate for an increase in airflow resistance	Value for the breath is $< \bar{X} - 1.5 \text{ SD}$	A = 9%	VD = 14%
Time of pause	TP	s	Duration of the bottom of the VT wave	P: pulmonary irritation Basis: reflex reaction from stimulation of pulmonary vagal type-C nerve endings	Value for the breath is $> \bar{X} + 2 \text{ SD}$	P = 2%	TP = 12%

Tidal volume	VT	mL	Amount of air inhaled/exhaled per breath	P1: pulmonary irritation, phase I Basis: same as P, low stimulation	Value for the breath is $< \bar{X} - 1.5 \text{ SD}$	P1 = 2% ^e
Duration of inspiration	TI	s	Time from minimum to maximum VT	P1: pulmonary irritation, phase I Basis: same as P, low stimulation	Value for the breath is $< \bar{X} - 1.5 \text{ SD}$	P1 = 2% ^e
Duration of expiration	TE	s	Time from maximum to minimum VT	P1: pulmonary irritation, phase I Basis: same as P, low stimulation	Value for the breath is $< \bar{X} - 1.5 \text{ SD}$	P1 = 2% ^e
Respiratory frequency	BPM or <i>f</i>		Number of breaths occurring during a collection period of 14 s, converted to BPM ^f when TP is sufficiently large	Not used but will increase during P1, decrease during S and A and decrease during P when TP is sufficiently large		BPM = 12%

^aModified from Boylstein et al. (1996) and Alarie (1998).

^bAbbreviation.

^cThe combination classifications S + A, P + A, P + S, and S + P + A are also made when two or more of the appropriate variables meet the criteria for each individual classification of the combinations. It should be noted here that during sham exposures these combination classifications are zero or very close to it. An arbitrary value of 2 percent is probably adequate to use, rather than use the statistical procedures for arriving at a JDE for the single classifications. A value of 2 percent will prevent declaring a spurious positive effect.

^dThe values listed are applicable to the data for a group of four mice, and the time series of data points have been analyzed by using the MLEGCY program, with a recurrence filter of 3 for the classification analysis. For more details see Alarie (1998).

^eThe variables VT, TI, and TE are used to arrive at the P1 classification. During sham exposures the P1 classification is zero or so close to it that an arbitrary value of 2% is probably adequate rather than use the statistical procedures to arrive at a JDE for the single classifications. A value of 2 percent will prevent declaring a spurious positive effect.

^fBreaths/minute.

FIGURE 24.6 Airflow ($\dot{V}$) and tidal volume (VT) waves printed by the DRAWVDVT program, from collected digitization files made by the MAKEVDVT program for one animal during a 3-hour exposure to the same concentration of an airborne mixture formed by aerosolization of a metalworking fluid (MWF). This figure illustrates the progression of effects during exposure. **A:** During preexposure baseline period, a horizontal line is drawn at zero flow, inspiration upward and expiration downward. A vertical line is drawn on each breath on the airflow signal to indicate the calculated VD value. Vertical lines are drawn on each VT wave to indicate the calculated TB and TP values. Also a letter is printed below each VT wave to indicate the breath classification arrived at by the computer program. **B, C, and D:** During exposure to MFG showing the effect initially categorized as A or P + A and progressing to a moderate and severe P effect. [From Boylstein et al. (1995). Reprinted with permission of Springer-Verlag.]

24.4 VARIABLES MEASURED, DATA MANAGEMENT, AND DATA PRESENTATION

The MAKEVDVT program is used to initiate the experiment. While storing the digitizations of the V signal and calculating VT, this program also calculates five other variables for each breath and for each exposed animal as given in Table 24.1 and depicted in Fig. 24.5. These are: duration of inspiration (TI), calculated from 2% of VT to 98% of the VT wave, duration of expiration (TE) calculated from 98% of VT to 2% of the VT wave, duration of braking (TB) as explained above and shown in Fig. 24.5, duration of the pause (TP) as explained above and shown in Fig. 24.5, and finally VD as explained above and shown in Fig. 24.4, part C. It should be noted here that both TB and TP are always part of TE (Boylstein et al. 1995). If only the active portion of TE (segment $T_4 - T_3$ in Fig. 24.5) is needed, TB and TP are subtracted from TE. The number of breaths occurring in a collection period (each collection period is 15 s) is obtained as a count and saved as breaths/minute (BPM). A file is created for each variable and for each animal. The values in these files, for a particular experiment, are separated to include the baseline or control period, the exposure period and the recovery period. Prior to initiating the MAKEVDVT program, a value must be entered to determine the length of the baseline period. This is typically 15 min (60×15 -s periods), and thus each file will contain the values for approximately 3500 breaths for each mouse (1300 breaths for each guinea pig) for each variable, except for BPM which will have 60 values, one for each period when a baseline period of 15 min is used.

The average (Xw) and the standard deviation (SD) for each variable and for each animal are then calculated from all the breaths collected during the baseline period and the Xw is made equal to 100 percent. This value is used as the CONTROL value for each variable. Time-response plots are then prepared by TABLEVT and MLEGCV using point-by-point deviation from 100 percent for all the data collected during the baseline, exposure, and recovery periods. The maximum response or the plateau response for each variable during each exposure to a chemical or mixture of chemicals is then obtained from these time series plots.

24.5 BREATH CLASSIFICATION DIAGNOSIS AND DATA ANALYSIS

As shown in Fig. 24.1 and Table 24.1, a formal scheme has been devised to classify each breath. The appropriate variable X value and its SD value are used to classify each breath as either normal (N) or in the other categories given in Table 24.1 and Fig. 24.1. For each animal, a file is created by TABLEVT containing the number of breaths in each category, i.e., N, S, A, etc., occurring during each 15-s collection period. Time-response plots are then prepared by TABLEVT and MLEGCV by plotting each breath classification, as a percentage of the total number of breaths collected during each 15-s period. The maximum or plateau response during exposure to a chemical or mixture of chemicals for each breath classification is then obtained from these plots. It should be noted that when the classification P1 is arrived at, as shown in Fig. 24.1, no combination of effect as with S, A, or P is possible. The P1 effect is the first phase of pulmonary irritation, preceding the P effect. It is characterized by rapid, shallow breathing (RSB) recognized by decrease in VT, a shorter TI, and shorter TE as given in Fig. 24.1 and Table 24.1. The P1 effect is usually not very pronounced in mice, while it is prominent in guinea pigs (Schaper et al. 1989).

24.6 LIMIT OF DETECTION OR JUST-DETECTABLE EFFECT (JDE)

Any assay has a limit of detection. For this bioassay, a just-detectable effect (JDE) was established for each variable and each breath classification, as given in Table 24.1. The JDE

Terpenes and ozone; BALB/c mice	Wolkoff et al. (2000)
Emissions from fabric softener; Swiss-Webster mice	Anderson and Anderson (2000)

values were obtained from sham exposures of eight groups of four mice by processing these data with the MLEGCV program (Boylstein et al. 1996, Alarie 1998). For the breath classifications, a recurrence filter of 3 was selected when processing the data in order to avoid misclassifications due to body movements of the animals held in body plethysmographs (Boylstein et al. 1996, Alarie 1998).

24.7 TYPICAL RESULTS

The computerized method has been used to investigate single chemicals or mixtures as listed in Table 24.2, and several are relevant to IAQ.

Single Chemicals

A recent report can be consulted for the details of how this computerized bioassay will perform and how the results should be presented and analyzed (Alarie 1998). In this report, *o*-chlorobenzylchloride (CBC) was used as a sensory irritating vapor in a total of 16 exposure concentrations. Several low exposure concentrations were used to explore the variation to be expected and to demonstrate the reliability or robustness of the bioassay. Figure 24.7

FIGURE 24.7 Concentration-response relationship for the breathing frequency (BPM) variable during exposures to the sensory irritant *o*-chlorobenzylchloride at different concentrations. The regression line (solid), 95% confidence interval (dotted lines), and 95% prediction interval (dashed lines) are presented. Open circles indicate data points omitted from regression analysis. The regression equation is: % BPM = $-59.41 + (64.99 \times \log \text{exposure concentration})$, $r^2 = 0.96$. The horizontal dotted line drawn at 12% BPM indicates the limit of detection or just-detectable effect (JDE). [From Alarie (1998). Reprinted with permission of Springer-Verlag.]

FIGURE 24.8 Concentration-response relationship for the duration of braking (TB) variable during exposure to the sensory irritant *o*-chlorobenzylchloride at different concentrations. The regression line (solid), 95% confidence interval (dotted lines), and 95% prediction interval (dashed lines) are presented. Open circles indicate data points omitted from regression analysis. The regression equation is: % TB = $-824.9 + (715 \times \log \text{exposure concentration})$, $r^2 = 0.93$. The horizontal dotted line drawn at 20% TB indicates the limit of detection or just detectable effect (JDE). [From Alarie (1998). Reprinted with permission from Springer-Verlag.]

presents the concentration-response relationship for BPM. BPM was calculated by the computer program in the exact same way as in the original bioassay, from which a decrease in respiratory rate by 50 percent (RD50) was then calculated (Alarie 1966, ASTM 1984). Thus RD50 results (an expression of potency) obtained with this computerized method can be directly incorporated with previous results collected in the database of RD50 values published by Schaper (1993). As shown in Fig. 24.7, three of the low exposure concentrations failed to elicit a level of response above the JDE and are excluded from the regression analysis. Similarly the data point at the highest concentration was omitted since the maximum response was reached. The results for the increase in TB are presented in Fig. 24.8; the results for the four lowest concentrations are omitted in the regression analysis since they are below the JDE. The data point at the highest concentration is omitted since TB no longer increased because effects other than S were present. This is illustrated in Fig. 24.9, with the S effect increasing rapidly until 41 mg/m^3 was reached. Above this concentration the S effect was still present but S + A, S + P, and S + P + A occurred. This reduced the percentage of breaths with S only, but if all breaths with S or combinations with S are counted as S, the values for these data points would be 95 to 98 percent space S.

Comparing the results for BPM and TB, the calculated potency is similar ($\text{RD50} = 48.4$ and $\text{TB50} = 43.8 \text{ mg/m}^3$) but S50 (22.0 mg/m^3) is lower by a factor of 2. Since, as shown in Fig. 24.4, an increase in TB directly reduces BPM, the two should be correlated. The linear relationship obtained between the percentage decrease in BPM and percentage increase

FIGURE 24.9 Concentration-response relationship for the S classification during exposure to the sensory irritant *o*-chlorobenzylchloride. The regression line (solid), 95% confidence interval (dotted lines) and 95% prediction interval (dashed lines) are presented. Open circles indicate data points omitted from regression analysis. The regression equation is: $\% S = -149.4 + (148.4 \times \log \text{exposure concentration})$, $r^2 = 0.89$. The horizontal dotted line drawn at 2% indicates the limit of detection or just-detectable effect (JDE). [From Alarie (1998). Reprinted with permission from Springer-Verlag.]

in TB for the results presented in Figs. 24.7 and 24.8 was found to be: $\% \text{ increase in TB} = -112.4 + (9.46 \times \% \text{ decrease in BPM})$, $r^2 = 0.90$ (Alarie 1998). Thus TB50, which is specific for the S effect, can be substituted for RD50.

Comparing the S classification, TB and BPM results, the regression line intercept to the JDE line for each is about the same. The advantage in using the S classification is a steeper slope, not a greater sensitivity. This is useful when high exposure concentrations are difficult to obtain, particularly for mixtures. The steeper slope is due to the fact that each breath is classified and held in that classification as a percentage of total breaths occurring for each 15-s measurement period; there is no dilution from averaging multiple breath values as when TB is just beginning to increase at low concentrations.

Mixtures

Metalworking fluids (MWFs) (or machining fluids, metal removing fluids) are widely used in industrial operations such as cutting, drilling, and grinding. In the older literature, these fluids were described as “cutting oils.” During their use, aerosols and vapors are formed and industrial workers are exposed. A list of components used in synthetic and semisynthetic MWFs is presented in Table 24.3. Some of these components have been investigated and

FIGURE 24.10 Time-response analysis by the MLEGCV program for a group of four animals exposed to a mixture of aerosolized chemicals from a metalworking fluid (MWF). The data are shown for the S and P effects, as determined by the increase in the TB and the TP variables, respectively. The smoothed polynomial spline curves (with 95% confidence interval) are presented for the breath classifications and the variables. [From Boylstein *et al.* (1995). Reprinted with permission of Springer-Verlag.]

identified as capable of inducing sensory irritation alone, pulmonary irritation alone, or both effects (Schaper and Detwiler 1991, Schaper and Detwiler-Okabayashi 1995, Krystofiak and Schaper 1996, Detwiler-Okabayashi and Schaper 1996). Thus, in evaluating these MWFs, a variety of effects are to be expected. An example of the dual S and P effects obtained with an

MWF is presented in Fig. 24.10. Such complex effects were also obtained with mixtures of VOCs emitted from consumer products such as: fragrances, air fresheners, disposable diapers, and synthetic mattress covers [Anderson and Anderson (1997, 1998, 1999a, 1999b)]. Volatile emissions from these products were produced as described in Chap. 23. and introduced in the exposure chamber to evaluate their effects in mice.

24.8 ADVANTAGES OF THE COMPUTERIZED METHOD

1. At low exposure concentration, it is difficult to accurately recognize the presence of S or P from examination of chart recordings as done with the original bioassay (Alarie 1966, ASTM 1984). This is particularly so when the S or P effects are not sustained but occur at different time intervals during exposure. The computer programs, however, classify each breath according to defined criteria and the graphical presentation of the results makes it easy to recognize any type of effect of any magnitude and at any time interval. The computer programs also calculate the intensity of the effect for each breath, which is impossible to do manually. They also diagnose the A and P1 effects as well as combinations of effects. This was impossible to obtain with the original bioassay (Alarie 1966, ASTM 1984).

2. The MAKEVDVT computer program produces a binary file of the collected data. The file contains the time and date on which each experiment was performed, as well as all the calibration information and details of the experiment entered by the investigator. It thus becomes a primary file under good laboratory practice (GLP) according to U.S. governmental regulations. The file can be copied (but is impossible to modify) and used with the described processing programs by any investigator for verification of the reported results. This also permits exchange of files for collaborative studies.

3. The results are displayed continuously during each experiment. This permits the investigator to change the exposure concentration once a given level of effect is reached and to extend the recovery period if needed to observe the persistence of an effect.

4. The computer programs include well-defined statistical procedures so that presentation of the results will be consistent and interchangeable among laboratories.

TABLE 24.3 Some Components of Metalworking Fluids (MWFs)

These components have been found to induce sensory or pulmonary irritation or both, depending on exposure concentration and duration of exposure. These components were evaluated in the vapor or aerosol form or both.

Alkanolamide	Potassium hydroxide
Boramide	Potassium soap
Boric acid	Propanediol
Catalytic dewaxed light paraffinic oil	Propanol amines
Isononanoic acid	Siloxane
Microcrystalline wax	Sodium sulfonate
Naphtenic oil	Tall oil fatty acids
Oxybispropanol	Tolutriazole
Petroleum oil	Triazine

Source: Schaper and Detwiler (1991), Schaper and Detwiler-Okabayashi (1995), Krystofiak and Schaper (1996), Detwiler-Okabayashi and Schaper (1996).

5. Limits of detection have been established for each variable and breath classification using well-defined statistical procedures. These prevent false positive findings and provide for obtaining reliable concentration-response relationships.

6. The original bioassay relied on a decrease in BPM caused by an increase in TP to quantitate the degree of the P effect. However, the P1 effect may occur first with TP simply added to it (see Fig. 24.4, parts E and F). If so, BPM will first increase above normal, then return to normal and finally decrease as TP increases further. The measurement of TP is more direct and is more sensitive than a change in BPM. It is specific for the P effect.

24.9 GUIDELINES FOR INVESTIGATORS USING THE COMPUTERIZED METHOD

Concentration-Response Analysis

That the original bioassay (Alarie 1966) was adopted as ASTM E 981 standard method (ASTM 1984) greatly helped the creation of a reliable database on the sensory irritation potency (RD50) of a large number of chemicals and mixtures, as published by Schaper (1993). It is the largest published database available in inhalation toxicology. Several investigators have now implemented the computerized version of this bioassay as presented in Table 24.2. This can lead to an even more reliable database and eventually a review and adoption of the computerized bioassay as a new ASTM standard method. It will greatly help in preventing or solving IAQ problems related to irritation of the respiratory tract. A few simple rules should be followed to arrive at these goals.

1. A baseline period of 15 min should be used. This will yield approximately 3500 breaths for each animal when mice are used (1300 breaths when guinea pigs are used), which will provide for a reliable control $\bar{X}$ value. Each investigator should provide the actual $\bar{X}$ control and SD values for the variables of interest when publishing results, not only the percentage change during exposure. Such values are a basis to evaluate the competency of the laboratory performing the experiments.

2. The exposure period should be long enough that a maximum response or a plateau response is obtained, which is used in establishing concentration-response relationships and the calculation of potency via linear regression analysis. In publishing the results, it may be impossible to provide the time-response plots because of journal limitation. Nevertheless investigators should provide a written description of their time-response results.

3. From the time-response results obtained, investigators should provide a concentration-response relationship by plotting a minimum of four exposure concentrations producing an effect above the JDE. The linear least-squares regression analysis plot should be provided, along with the regression equation and r^2 value. If possible the 95% prediction interval (PI) and 95% confidence interval (CI) as shown in Fig. 24.7 should be presented. Data points below the JDE and after reaching the maximal effect should be excluded from regression analysis to calculate potency, particularly if the low exposure concentrations are far below the first concentration eliciting a positive effect. However all data points should be shown on the plot (see Fig. 24.7). They provide important additional information.

Time-Response Analysis

General Problems. With volatile emissions from products that may create IAQ problems, adequate concentration-response relationships as shown in Figs. 24.7, 24.8, and 24.9

may not be achieved for a variety of reasons. It may be impossible to generate several exposure concentrations for complex mixtures as required to obtain concentration-response relationships. In such cases, the investigators should provide time-response profiles that are representative of the results obtained. The example presented (Figure 24.10) and other published examples (Anderson and Anderson 1997, 1998, 1999a, 1999b) should be followed. It is important to note that several types of effects have been obtained when complex mixtures were investigated. The variation observed between animals can be quite large in comparison with the results obtained when evaluating single chemicals. With some mixtures, different animals have responded very differently (Boylstein et al. 1995, 1996). Reporting such differences when they exist is of importance if we are to begin to understand, explain, or probe further the fact that in the human population we often find such differences. Summarizing time-response results for mixtures is difficult. The computer programs provided for data processing will help the presentation of such results to produce reliable databases.

Negative and Low Level Positive Findings in Single Experiments. Levels of responses below the JDE values given in Table 24.1, when time-response plots are inspected, should be entered as negative findings. Levels of response just above these JDE values should be reproduced twice by the investigator to avoid declaring spurious positive results (Boylstein et al. 1996) when a concentration-response relationship cannot be obtained.

24.10 PROBLEMS TO BE EXPECTED WITH THE COMPUTERIZED METHOD AND THEIR SOLUTIONS

Computer programs are a set of rules that can be implemented on a machine. An understanding of the rules will prevent erroneous conclusions. A list of expected "errors," their causes, and solutions is given below to guide investigators in arriving at appropriate conclusions. Also, guidelines are provided in Table 24.4 for inspecting the results obtained for all the respiratory variables.

1. During normal breathing there is always some body movements of the animals in the body plethysmographs. This will create some erroneous TB and TP values, because of the way TB and TP are measured using a sine wave as a model (see Figs. 24.4 and 24.5). When a VT wave becomes severely distorted, smaller than normal and even negative values for TB can be obtained. Investigators can expect a few of these errors and will recognize them when they inspect the output files for individual breaths, when the program HISTVAR is used. They are few and will not influence the $\bar{X}$ control value, which is calculated from about 3500 breaths. They will increase the SD value only slightly. Since an increase in TB is used to classify the breath as S, erroneous negative values will not influence the breath classification, which is based on the $>\bar{X} + 2 \text{ SD}$ of TB as given in Fig. 24.1 and Table 24.1. An investigator may easily remove these few small negative values by writing a short program to read the ASCII file, find the negative values, and replace them with the next positive value. We have not found this to be necessary. During an A effect, TB values will decrease because the slope of the line (line 2 in Fig. 24.4, part D and segment $T_3 - T_4$ in Fig. 24.5) during expiration will be less steep than under normal breathing, because of an increase in TE. This decrease in TB is irrelevant since the diagnosis of the A effect is based on VD. However, an S effect will appear less pronounced (i.e., a lower TB) if induced with the A effect. Body movements of the animals will create higher than normal values for VD. Since the breath classification A is based on the $<\bar{X} - 1.5 \text{ SD}$ these higher values will not influence the diagnosis of an A effect.

TABLE 24.4 Guidelines for Inspecting the Results Obtained with the Computer Programs

Effect on the respiratory tract	Variables used for classification of each type of effect	Changes expected and remarks
S	TB	Increase. TB will never increase during other effects. It can decrease and even reach a negative value during severe A or P or during body movements. There will be a slight decrease in TB during P1.
A	VD	Decrease. VD will never decrease during S but it may decrease during P1 or P because of a decrease in VT. The decrease in VD must be due primarily to an increase in TE without a substantial increase in TP to accept the A effect.
P	TP	Increase. TP will never increase during other effects but there will be a slight decrease in TP during P1.
P1	VT	Decrease. Will also decrease during P but not significantly during S or A.
P1	TI and TE	Decrease. TI will increase slightly during S and A and decrease during P. TE will increase during S and A. TE will increase during P when TP is high enough.
—	BPM (not used for breath classification)	BPM always decreases during S and A. The decrease in BPM during S is proportional to the increase in TB. It always increases during P1. During P, three different phases will be observed. First there is an increase in BPM because the P effect can be simply the addition of a longer TP to P1. As the effect increases, TP becomes longer and BPM will be in the "normal" range. With further increase in TP, BPM will decrease. If P occurs directly without the P1 effect, BPM decreases in proportion with the increase in TP.

2. When severe S occurs, particularly with combinations such as S + A, S + P, or S + P + A, the VT wave becomes severely distorted from a sine wave. The calculation of TB by the computer program may yield a value lower than the actual value for TB, again because of the rules used by the program to calculate TB. An investigator can easily observe this when processing the files with the DRAWVDVT program. No attempt has been made to correct this lower than actual TB value. At this level of response (an increase in TB of more than 800 percent above control) it is clear that each breath will be classified as S and that the maximal response has been achieved. Furthermore, this error does not influence BPM in any way. This variable is obtained independently as a count of VT waves regardless of the distortion, as in the original bioassay (Alarie 1966) and the ASTM E 981 standard method (ASTM 1984).

3. To prevent counting as a breath a small VT wave caused by noise or body movement of the animal, the investigator is requested to enter a value below which a small VT wave will be eliminated as a breath by the MAKEVDVT program. For mice, a value of 0.04 mL has been used, while a value of 0.4 mL has been used for guinea pigs to prevent such errors. If the P1 effect (rapid, shallow breathing) begins to develop, it may be necessary to reduce these values. This is not a major problem. The above values can be changed during an experiment when this effect is observed. However an investigator must be aware that this

change has to be made *during* the experiment, when this effect begins to be displayed on the video terminal by the MAKEVDVT program.

4. In working at low exposure concentrations and low levels of effect, it is best to use the recurrence filtering option in analyzing the time series data set for breath classifications with the TABLEVT and MLEGCV programs (Boylstein et al. 1995). This recurrence filtering option requires that a minimum of 3 (this value can be changed) abnormal breaths of the *same* abnormal classification occur in a row. Otherwise a breath classified in any of the abnormal categories is reclassified as N. This filtering reduces false abnormal breath classifications due to body movement of the animals in the body plethysmograph. However, in evaluating mixtures of chemicals a variety of effects may occur. Even for single chemicals as shown for *o*-chlorobenzylchloride (see Fig. 24.9), a variety of effects may occur. For example, three consecutive abnormal breaths may be S, A, and S + A. These breaths will be replaced by N since although they are classified as abnormal they are not in the same abnormal category, occurring three times in a row. This filtering option should be used only after inspection of the results with no filtering, otherwise there is a danger of declaring that no effect occurred. The recurrence filtering option does not affect in any way the values for the variables used to arrive at breath classifications. Insofar as an investigator inspects the results for these variables to select the most appropriate recurrence filtering option, appropriate results will be obtained for the breath classifications and no false negative will be declared.

5. The A classification is based on a decrease in VD. This decrease in VD does not occur during the S or P effects, as shown in Fig. 24.4. During A, VT is maintained at close to its normal value or is even slightly higher than normal. The reason for the decrease in VD is a longer TE, not a lower VT (Vijayaraghavan et al. 1993, 1994; Neuhaus-Steinmetz et al. 2000). A longer TE (segment $T_4 - T_3$ in Fig. 24.5) occurs to compensate for the increase in resistance to airflow along the conducting airways of the lung (Vijayaraghavan et al. 1993, 1994). However, during the P1 effect (a decrease in VT, TI, and TE) a decrease in VD *may* occur because of the decrease in VT, typically when VT decreases by more than 50 percent, which seldom occurs in mice but easily occurs in guinea pigs. When this occurs, the investigator should process the data with the P1 option first. This will eliminate the possibility of an erroneous conclusion that an A effect occurred when a P1 effect was evident. Clearly, to classify a breath as A, a decrease in VD is necessary but it must be due to an increase in TE, not a decrease in VT. Another option is to analyze the data using VD/VT ratios after inspecting each variable (Larsen and Nielsen 2000).

6. Depression of the central nervous system (CNS) by asphyxiants (e.g., CO, HCN) and general anesthetics will also induce a pause (TP) at the end of expiration and a decrease in BPM (Alarie 1981, Mutoh et al. 1998). Many VOCs with sensory irritating properties also have general anesthetic properties at high concentrations (Kasanen et al. 1998, 1999). During exposure to airborne chemicals or simply room air, incidental escape attempts (body movement in the plethysmograph) are always observed. They decrease or are absent with sedation, anesthesia, or asphyxiation. If such occurs, TP can no longer be used to evaluate pulmonary irritation.

24.11 CONCLUSIONS

The computerized bioassay is a tool well suited to investigate the effects of airborne chemicals at three major portions of the respiratory tract. It recognizes and quantifies important effects related to irritation (sensory irritation or inflammatory reaction) of the respiratory tract that correspond to frequent complaints by occupants in homes or buildings with IAQ problems. It is particularly well suited to investigate complex airborne mixtures, regardless

of their chemical compositions. The method requires simple laboratory equipment, calibration is easy, and the system can be implemented quickly. It is relevant for preventing or solving IAQ problems, since the results obtained can be directly extrapolated to humans regardless of the chemical composition of the mixtures or its physical form, i.e., vapor phase or aerosol, in which the chemicals are present. It is impossible to do so with analytical chemistry results, unless only nonreactive airborne volatile chemicals are present in the mixtures and the chemicals are only in the vapor phase (Alarie et al. 1996), which is an obvious limitation. Finally, the computerized method provides well-defined statistical procedures for the analysis of complex effects, which was impossible to do with the original bioassay and is impossible to do with analytical chemistry results.

CHAPTER 25

SENSORY IRRITATION IN HUMANS CAUSED BY VOLATILE ORGANIC COMPOUNDS (VOCs) AS INDOOR AIR POLLUTANTS: A SUMMARY OF 12 EXPOSURE EXPERIMENTS

Lars Mølhave, D.M.Sc., Ph.D.

*Department of Environmental and Occupational Medicine
The University of Aarhus
Aarhus, Denmark*

25.1 INTRODUCTION

During the years from 1984 to 1996 several controlled experiments were performed in laboratories around the world in which human responses to volatile organic compounds (VOCs) known to be indoor air pollutants were investigated.

In view of the number of volatile organic compounds found indoors these compounds have for practical reasons been divided into classes defined by boiling point ranges. The class of VOCs has been defined as organic compounds with boiling points between 50 to 100°C and 240 to 260°C with reference to the sampling and analysis techniques mostly used for these compounds indoors (WHO 1989, Berglund et al. 1997, Mølhave et al. 1997). From a toxicologic point of view all compounds present as air pollutants are relevant. Toxicologists therefore request a wider analytical window to be used. In consequence, a Scandinavian working group has recommended that investigations are planned to include the entire range of organic compounds in indoor air (OCIA) (Andersson et al. 1997).

The experiments reviewed here were initiated because field investigations in buildings where the occupants complained about reduced indoor air quality and discomfort often failed to demonstrate the reason for these symptoms. However, the symptoms were similar

to those known to follow from low-level exposure to VOCs in occupational environments. Controlled experiments, therefore, were initiated to test to what extent low-level exposures to such VOCs might contribute to the prevalence of complaints in nonindustrial buildings. This chapter summarizes some of the findings of these controlled experiments.

In most indoor environments the exposure is described as *low level*. This phrase is generally used to imply that irreversible adverse effects as known in the occupational environment are not expected. The concentrations are low in comparison to occupational or threshold limit values (TLV) levels and so low that the relevant effects are only expected to be reversible and nonspecific reactions. e.g., those caused by stimulations of the common chemical sense. Most, if not all, indoor air pollutants are expected to some degree to cause these nonspecific effects at low exposure levels, and at low exposure levels the unspecific effects generally are expected to be dominating for the majority of normally occurring air pollutants in indoor environments (Berglund et al. 1991, 1992; Bluyssen et al. 1997).

Generally, the effects or symptoms observed after exposures to low-level VOCs do not identify a specific causality or a particular compound. Symptoms may result from several causes, such as thermal stresses, mental strains, or from any number of diseases. The mere complexity of such covariates is a likely reason why many uncontrolled field investigations often fail to demonstrate clear associations between environmental exposures and symptoms reported with building occupancy.

Several biologic models for these nonspecific responses have been discussed in the literature (e.g., Mølhave 1991). Table 25.1 summarizes one of the classifications, or general categories of effects, suggested in the literature. They include: perceptions of non-VOC-related environmental exposures (such as lighting or thermal environment); perceptions of odors; perceptions of irritation of nose, eyes, and upper airways; and general discomfort, or neurologic symptoms, such as mental fatigue or headache. The main emphasis is on sensory irritation and related effects. In the literature the term *irritation* is used for two different types of sensory irritation. One is the perceived sensory irritation caused by an environmental exposure to substances, e.g., pollutants that stimulate the senses (normally the trigeminal or general chemical sense). The other is often called *inflammatory irritation* and refers to stimulation of the senses through mediators released in the body, e.g., after exposure of tissue to biologically potent pollutants.

This classification will be used in this summary. However, it should be noted that no unambiguous scientific classification is possible because of the complexity of the responses. The table merely offers a vocabulary used in this chapter that will identify symptoms reported to be significantly related to VOC-exposure in at least two experiments. These are indicated in Table 25.1 in italics. The subjective sensory effects (self-reported) are in focus because they seem to be experienced at lower exposure doses (time and concentration) than the objectively measurable effects.

It has been found that perceived indoor air quality and general well-being are strongly related to both irritation and odor (Hudnell et al. 1993, Mølhave et al. 1986, Otto et al. 1990b). Therefore, general evaluations such as perceived IAQ, general well-being, and need more ventilation are reported outcomes also included in this summary.

In the literature, different types of questionnaires were used to register subjective evaluations. They are all self-administered. Some are paper and pencil questionnaires (Andersson 1998, Mølhave et al. 1986, Fanger 1988) and some are administered by personal computers, one for each subject (Kjærgaard et al. 1993, Otto et al. 1992). The rating scale differs, as some are visual analog scales in which the rating is reported by making a mark on a line anchored between two extremes while other scales use fixed phrases (categorical scales) between which the subject has to choose. Despite differences in type of scale and phrasing, the questions and symptoms are grouped here in the general categories shown in Table 25.1.

TABLE 25.1 Ad Hoc Classification of Effects

Class of symptom	Rating of	General classes of perceptions	Examples*
Perceptions of non-VOC exposures from the environment	Annoyance or intensity	Auditorial Visual	• Air temperature • Noise
Perceptions related to VOC exposures	Annoyance, intensity, hedonic mode or strength	Olfaction Stimulation of the chemical sense	• <i>Odors</i>† • <i>Perceived indoor air quality</i>† • <i>Perceived irritation of mucosal membranes in eyes, nose or throat</i>† • <i>Dryness of eyes, nose or throat</i>† • <i>Dryness or humidity of skin</i>† • <i>Facial skin irritation</i> • <i>Erythema</i>‡‡
General evaluations	Annoyance, intensity, or strength		• <i>General well-being</i> • <i>Need more ventilation</i> • <i>Perceived overall air quality</i> • <i>Unspecific hypersensitivity</i>†
Perceptions of body symptoms	Annoyance or intensity	Symptoms predominantly of inflammatory origin Symptoms predominantly of neurologic or stress origin Predominantly other types of symptoms	• <i>Feeling of watering or runny eyes</i> • <i>Feeling of blocked or of watering or runny nose</i> • <i>Feeling of cough</i>† • <i>Concentration difficulties</i> • <i>Sleepiness, tiredness or fatigue</i>† • <i>Headache, sluggishness, or heavy head</i>† • Skin temperature • Sweating • Nausea† • Hoarseness† • Facial skin temperature and humidity

*Italics mark the symptoms dealt with in this chapter. General irritation = irritation in eyes, nose or throat.
†Included in WHO definition of SBS (WHO 1982, 1986).
‡Erythema is the name applied to redness of the skin produced by congestion of the capillaries, which may result from a variety of causes.

Some symptoms have been reported more frequently than others. One group of such frequent symptoms has been identified as a syndrome of coexisting symptoms related to indoor air quality. The syndrome is often called the *sick building syndrome* (SBS) and includes, according to its first definition by WHO working groups (WHO 1982, 1986), the symptoms mentioned above and in Table 25.1. The syndrome has been further discussed by Mølhave (1991) and is considered in Chaps. 3 and 28 in this volume. Presently, it is not clear if this SBS syndrome consists of truly correlated symptoms related to one exposure type indoors or reflects an accumulation of effects of several unrelated exposures indoors.

In this chapter, no distinction will be made between immediate acute responses appearing, e.g., within the first 10 or 15 minutes after the onset of exposure, and responses appearing later, even after the exposure has stopped. This is often taken to correspond to the visitors' and the occupants' responses, respectively, and may indicate different time cause of effects.

Table 25.2 summarizes the 12 exposure experiments reviewed. The experiments dealt with exposures to mixtures of selected VOCs, individual VOC compounds, and emissions from building materials and office machines. One specific mixture of VOCs has been frequently used. The composition of this mixture of 22 VOCs has changed only slightly since it was first introduced in 1984 (Mølhave et al. 1984, 1985, 1986). The constituents of the most recently used version are shown in Table 25.3, taken from Mølhave et al. (1991a). In the experiments, the relative concentrations of the constituents were constant as indicated in the table. Only the total concentration varied in the experiments based on this type of exposure. Exposure to a mixture of 22 VOCs is identified as M22.

This M22 mixture originally was introduced in the experiments to average out the effects of individual compounds and to include the possibility of interactions between these compounds. The debate about use of individual compounds or mixtures and the criteria to be used in selection of components for the mixture is still ongoing. However, as long as the biologic mechanisms and the interactions between compounds are unknown, both exposures to single compounds and mixtures will be needed in research. Until now only few tests have been made with individual compounds at exposure levels relevant to indoor air.

As a reference, clean air was used in most experiments. This refers to air as clean as technically and practically possible. A certain level of VOCs is inevitably present because of offgassing of previously adsorbed pollutants from chamber walls, persons, etc. Generally, this level was between 0.02 and 0.4 mg/m³ (TVOC), depending on the flushing time between pollutant and clean air exposures.

After the first experiment with low-level exposures to a mixture of VOCs had demonstrated that unexpected health and comfort effects may follow from low-level exposures (Mølhave et al. 1986), the concept of total volatile organic compounds (TVOCs) was suggested as a measure of a mixture's potency to cause effects. The concept was recently revised (Mølhave and Nielsen 1992, Andersson et al. 1997, Mølhave et al. 1997, Seifert 1999). This TVOC concept is still debated. Undoubtedly, it is based on several not yet justified assumptions and its general usefulness for prediction of effects of mixtures other than the M22 mixture is undocumented. The appealing aspect of the indicator is that it is easy to measure and use in pollution control and regulation.

As the M22 mixture is the type of mixture mostly dealt within this review, the TVOC indicator will be adapted here as a general exposure measure in the form of the sum of individual compound concentrations in mg/m³. For some studies only toluene-equivalent TVOC concentrations were reported.

Olf and decipol are other units for indoor pollution. The olf is a unit for emission rate of bioeffluents and other indoor air pollutants. It reflects the perceived air pollution caused by emissions from a standard person in thermal comfort. The decipol is a unit for perceived air pollution, and 1 decipol is the pollution caused by one standard person ventilated by 10 L/s unpolluted air (Fanger 1988).

Attempts will be made to estimate NOEL and LOEL for the effects that were found to be significantly related to VOC exposures in at least two experiments. NOEL is the no observed effect level, which is the highest exposure level that did not show significant effects of exposure. LOEL is correspondingly the lowest exposure level showing such an effect. The interest in LOEL and NOEL is derived from their use as estimates for the threshold of the effect and exposure in question. The estimated threshold therefore refers to a specific population exposed under specified conditions to specified compounds. Not all experiments can supply estimates of both NOEL and LOEL or even one of these toxico-

TABLE 25.2 Summary of the 12 VOC Exposure Experiments

Study no.	References	Subjects and type	Exposure type	Exposure, mg/m ³	Exposure duration	Notes

logical key data. If only one exposure level is used, only one of the estimates can be made. Even if two exposure concentrations are used, the resulting data may turn out to be too few or the variance too big to allow a detailed statistical analyses. In such cases only differences in relation to exposure or nonexposure can be tested, and often only positive findings are reported. Therefore it is not possible to estimate NOEL in such cases.

If M22 is considered a best case in relation to VOC indoors, this leads to the conclusion that the experimental thresholds for VOC effects based on TVOC are upper limits for the real-life thresholds (when other factors are absent). A corresponding worst case would be that all VOCs present are as potent as, for example, formaldehyde, in which case a 0.1 mg/m³ threshold would be expected.

25.2 STUDY SUMMARIES

Study 1. The aim of this study was to test whether VOCs at low levels have an effect on humans and to bring forward the first indications of the nature of any such effects (Mølhave et al. 1984, 1985, 1986; Bach et al. 1984; Pedersen et al. 1984; Thygesen et al. 1987). In the controlled exposure experiment subjects were exposed to M22 at 0, 5, and 25 mg/m³ (TVOC toluene equivalents). The exposure duration was 2.75 hours. The climate factors were kept constant in the climate chamber. The study design was balanced and the subjects were used as their own controls.

The 62 volunteering subjects were selected for the study in a prestudy of a group of 286 potential subjects. The subjects were aged 18 to 64 years. They had all previously experienced SBS symptoms, but were otherwise healthy and without asthma, allergy, or chronic bronchitis. Forty percent were smokers. Measurements included subjective and objective effects both acutely, subacutely, and after the exposure stopped as a hangover effect from the exposure. The measures included several objective effects not included in this summary and questionnaire ratings of exposure and air quality-related symptoms.

Study 2. The study aim was to determine a dose-response relation for VOC and general symptoms and discomfort (Mølhave et al. 1988, 1991a). Human subjects were exposed in a climate chamber at normal indoor climate conditions to M22 at 0, 1, 3, 8, and 25 mg/m³. Each exposure had a duration of 50 min preceded by a 20 min acclimatization and baseline period in clean air conditions. The design was balanced and controlled. Subjects were their own controls. The 25 subjects came from the general population and were healthy, aged 16 to 64 years, and equally distributed between the two genders and between smokers and nonsmokers. The preexperimental investigations of the subjects included subjective reactions using several questionnaires and rating procedures. The odor threshold for *n*-butanol was measured before and after each exposure to indicate any changed threshold following the exposures.

Study 3. This study was run in the United States at the Environmental Protection Agency (EPA) facilities in Research Triangle Park, North Carolina, and was focused on neurobehavioral and sensory irritant effects. The purpose was to confirm previous findings of study 1, to identify sensitive measures for use in subsequent studies of the sick building syndrome, and to study the time course of any observed effects (Hudnell et al. 1990, 1992; Otto et al. 1990a, 1990b, 1992). The exposures, during separate sessions, were to clean air and 25 mg/m³ of the M22 mixture (TVOC concentration). Exposure duration was 2.75 hours. The exposures took place in a climate chamber at normal but constant climatic conditions.

A contrabalanced design was used in which each subject was his own control. Seventy-six young adult males, aged 18–39 years, with no history of chemical sensitivity, were exposed. Subjects rated the intensity of perceived irritation, odor, and other variables before, and twice during, the exposure periods. In addition numerous neurobehavioral tests were made.

Study 4. The purpose of this study was to test if asthmatics respond to emissions from four building materials (Johnsen et al. 1991, Wolkoff et al. 1991). The exposure duration was 6 hours, during which the subjects were exposed to the emissions from four different building materials, one at a time. Exposures ranged from 1.1 mg/m³ to 2.0 mg/m³ TVOC and from 11 to 743 µg/m³ formaldehyde. Clean air was used as the baseline. The study was single-blinded and randomized and took place in two twin chambers. The design was not balanced with respect to VOC exposure, therefore conclusions on VOC causalities were only indicative. The 20 asthmatics were selected among hospital patients and five nonasthmatic voluntary subjects were selected among the university staff. The subjective ratings of symptoms were made by using a questionnaire, and an additional panel rated the air quality (olfs).

Study 5. This study investigated the isolated effects of office machines in a simulated office on mucous membrane irritation, odor, and the personal perceptions of these effects under controlled conditions (Wolkoff et al. 1992). The 30 healthy females were either white collar workers or nurses and were exposed under normal indoor air conditions in a climate chamber during simulation of office work and with office machines in operation. An additional empty chamber with clean air was used for control exposures. The exposure duration was 6 hours. The exposures included VOC (TVOC, mean 87 µg/m³ corrected for perfumes etc. in the exposure chamber and 71 µg/m³ in control chamber), formaldehyde (average 95 ± 11 µg/m³, 3 times that of empty control chamber), ozone (below 52 µg/m³), carbon dioxide (3100 ppm, same in both chambers), TSP (50 ± 43 µg/m³, background: 29 ± 16), respirable particulate matter (44 ± 27 µg/m³). Noise levels were also measured. The design was not balanced with respect to VOC exposure, therefore conclusions on VOC causalities were only indicative. The subjective effects measures were symptoms reported in a questionnaire and air quality ratings (olfs) by an additional panel.

Study 6. The purpose of the study was to investigate whether VOC exposure causes increased symptom ratings or impaired neurobehavioral performance, and whether men and women respond differently (Otto et al. 1993). The study was made in a climate chamber under controlled climatic conditions. The 4-hour exposures were to clean air and 25 mg/m³ M22 (FID/toluene equivalents). A repeated measures design was used. The 41 subjects, 26 male and 15 females, were normal, healthy, nonsmoking subjects aged 26 to 39 years. They were selected after advertising in newspapers. The subjective measures included symptoms reports in questionnaires and several neurobehavioral tests.

Study 7. The purpose of this study was to investigate if VOC exposures affect respiration (Prah et al. 1993). The subjects were exposed to the M22 mixture of VOC for 4 hours at 0, 12, and 24 mg/m³. The study design was a contrabalanced pretest-posttest design using randomized exposures. This human exposure experiment included 20 subjects (healthy, aged 18–35 males). Hourly, the subjects rated perceived irritation and filled in a symptoms questionnaire prior to and 4 times during exposures. For comparison, a standard mouse assay was used to measure the same effects on mice.

Study 8. The purpose of the study was to investigate the use of the TVOC indicator as a predictor of health or comfort effects. The health and comfort effects caused by expo-

tures of humans in a climate chamber to three different mixtures of VOC at three different TVOC levels were compared. The dose-response relations found were compared by using TVOC expressed in mg/m³, in PPM, and as thermodynamic activity to test which gave the best correlations (Mølhave et al. 1991b, 1993b; Kjærgaard and Mølhave 1994). The exposure levels were 15, 5, and 1.7 mg/m³ (TVOC) for 60 min. The VOCs were three different subsets of M22 and this mixture itself. Table 25.4 shows the composition of the mixtures used for the experiment. The selection of subsets was based on (1) lowest vapor pressure, (2) highest vapor pressure, and (3) chemicals with reactive radicals etc. Clean air was used as a control. The design was double-blinded and contrabalanced; subjects served as their own controls. The 30 subjects were university employees, students, and others who responded to advertisements. They were of age 19 to 60 years, with an equal number of males and females. All were healthy. The measured effects were questionnaire ratings of 25 symptoms and discomfort, continuous rating of irritation in eyes, nose, or throat.

Study 9. The aims of this study were to identify differences between normal healthy subjects and SBS-sensitive subjects and to confirm previously found responses among normal subjects to VOC exposures (Kjærgaard et al. 1990, 1991). The exposures were to a mixture M22 at 25 mg/m³ for 2 hours and to clean air. The exposures took place in a climate chamber. The design was a double-blinded, split-plot Latin square design. The 21 healthy subjects were selected at random from the general population and 14 SBS sufferers selected from participants of previous experiments. Effects measures included subjective ratings of odor, indoor air quality, and irritation of mucus membranes, etc.

Study 10. The purpose of this study was to investigate the influence of air temperature on human responses to air pollutants (Mølhave et al. 1993a, Zunyong et al. 1994, Kjærgaard et al. 1993). The subjects were exposed to clean air and 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour in a climate chamber in a balanced Latin square design. The 10 subjects were healthy and were selected among participants in previous experiments. The effects measures included several objective measures, questionnaires, and visual analog rating scale (VAS) ratings of irritation in eyes, nose, or throat.

Study 11. The aims of the study were to investigate whether VOCs cause effects and whether asthmatics respond differently than healthy subjects (Kjærgaard et al. 1995a,

TABLE 25.4 The Three VOC Mixtures Used for Exposures in Study 8

1995b). The subjects were exposed to M22 at 20 mg/m³ or to clean air for 4 hours. The design was a blinded Latin square design. This experimental exposure included 18 hay fever patients and 18 healthy subjects who were selected among respondents to a local advertisement. All were nonsmokers. The effects measures included several objective measurements and a symptoms questionnaire and a VAS rating of irritation in eyes, nose, or throat.

Study 12. The purpose of this study was to investigate exposure effects and the time course of these effects in humans (Hudnell et al. 1993). The experimental treatments were exposures to VOC (M22 mixture) for 4 hours and to clean air. The VOC concentrations were (TVOC) 6, 12, and 24 mg/m³. The design was contrabalanced. For this experimental exposure in a climate chamber, 46 male subjects were selected as normal and healthy from the general population. The effects measures were symptom ratings in questionnaires.

25.3 DOMINATING SUBJECTIVE SYMPTOMS OF VOC EXPOSURES

Perceived Air Quality

Findings of the 12 relevant studies on effects of VOCs on perceived air quality are summarized in Table 25.5.

In study 1 ratings of air quality were reduced at 25 mg/m³ of M22 but not at 5 mg/m³. In study 2 ratings of air quality during 50-min exposures to M22 were affected at 8 mg/m³ but not at 3 mg/m³. Exposures to 25 mg/m³ of M22 for 2.75 hours in study 3 caused degraded air quality. Study 4 showed that a trained panel registered reduced air quality (decipol) at 1.1 mg/m³ but not at 0.06 mg/m³. Exposed subjects rated lower IAQ during exposures for 6 hours to 0.071 to 0.087 mg/m³ of VOCs from office machines in study 5. Several differences were seen between the responses to the two exposures but the design was not balanced with respect to VOC, and several coexisting exposures may have been present. Therefore, the VOC causality cannot be definitively concluded. Exposure in study 6 for 4 hours to clean air and 25 mg/m³ of M22 caused reduced perceived air quality. Degradation of air quality followed the exposures in study 7 to the M22 mixture at 0, 12, and 24 mg/m³ for 4 hours. The analyses tested only for differences between exposure and nonexposure. Exposure in study 8 to four different VOC mixtures, each at three TVOC levels 15, 5, and 1.7 mg/m³ for 60 min, caused decreased air quality at 1.7 mg/m³. The VOCs were M22 and three different subsets of the M22 mixture (see Table 25.4). All caused effects at 1.7 mg/m³. Indoor air quality decreased during exposure in study 9 to M22 at 25 mg/m³ for 2 hours. Air quality decreased in study 10 during exposure to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour. Perceived air quality decreased in study 11 during exposures to M22 at 20 mg/m³ for 5 hours. Perceived air quality was worse at exposure to 6 mg/m³ in study 12.

The air quality was affected in all 12 studies. The lowest LOEL found is 1.7 mg/m³ for a selected mixture of VOC. The highest NOEL reported is 5 mg/m³ for M22. However, in 9 of the 12 studies no reliable estimate of NOEL could be made. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on perceived air quality is between 1.7 and 5 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

Odor Intensity or Strength

Table 25.6 summarizes the results reported in the 12 studies of effects of VOCs on odor intensity or strength.

() = no conclusive evidence.

NE = no estimate.

M22 = mixture of 22 VOCs (see Table 25.3).

LOEL = lowest observed effect level.

NOEL = no observed effect level.

Ratings of increased odor intensity were found in study 1 at 5 mg/m³ exposures to M22 for 2.75 hours. In study 2 VAS ratings of odor intensity increased during 50-min exposures to M22 at 3 mg/m³ but not at 1 mg/m³. Increased intensity of odor was seen in study 3 at 25 mg/m³ of M22 for 2.75 h. Comfort and symptoms questionnaires in study 4 showed increased odor intensity of mixtures of materials emissions (TVOC from 1.1 to 2.0 mg/m³) for 6 hours but not at 0.06 mg/m³. Exposure for 4 hours to clean air and 25 mg/m³ M22 in study 6 caused increased odor intensity. Exposures to M22 up to 24 mg/m³ for 4 hours caused increased odor strength in study 7. Exposure in study 8 to four different VOC mixtures each at three TVOC levels (15, 5, and 1.7 mg/m³) for 60 min caused decreased odor intensity at 1.7 mg/m³. The VOCs were three different subsets of M22 and this mixture itself (Tables 25.3 and 25.4 show the mixtures). Increased odor intensity was seen in study 9 during exposure to M22 at 25 mg/m³ for 2 hours. Odor intensity increased in study 10 during exposure to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour. The odor intensity increased during exposures to M22 at 20 mg/m³ for 5 hours in study 11. Odor intensity increased at all exposure levels in study 12 and decreased with increasing exposure time. The exposure duration was 4 hours to M22 mixture at (TVOC) 6, 12, and 24 mg/m³.

The odor intensity was affected in all 12 studies. The lowest LOEL found is 1.7 mg/m³ for a selected mixture of VOCs. The highest NOEL found is 1 mg/m³ for M22. However, only two studies allowed estimates of NOEL to be made. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on perceived odor intensity is between 1.0 and 1.7 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

Perceived Irritation of Mucous Membranes of Eyes, Nose, or Throat

This summary on perceived irritation is based on pooled responses reported as eye, nose, or throat, mucosal, or general irritation. All these symptoms are in the following, called *irritation of mucosal membranes*. Table 25.7 summarizes the reported results.

Irritation in throat, irritation in nose, and general irritation were indicated and rating of mucous membrane irritation increased during exposure to M22 at 5 mg/m³ for 2.75 hours in study 1. Ratings of irritation of eye and nose increased during 50-min exposures in study 2 to M22 at 8 mg/m³; no irritation at 3 mg/m³, no throat irritation at 25 mg/m³ in study 2. Increased intensity of eye irritation was found during exposures to M22 at 25 mg/m³ for 2.75 hours in study 3. The comfort or symptoms questionnaire in study 4 showed effects on perceived eye irritation of mixtures to materials emissions (TVOC from 1.1 to 2.0 mg/m³). Exposed subjects in their questionnaires rated increased mucous irritation, dry eyes, nose, and throat in study 5. Several differences were seen between the two exposure groups. Exposure for 4 hours to 25 mg/m³ of M22 cause increased eye, nose, and throat irritation in study 6. Exposures to M22 at 0, 12, and 24 mg/m³ for 4 hours in study 7 caused increased eye irritation. Exposure in study 8 to four different VOC mixtures each at three TVOC levels (15, 5, and 1.7 mg/m³) for 60 min caused ratings of acceptability of irritation to increase during exposures. The VOCs were three different subsets of M22 and this mixture itself. Threshold of effects of exposure for nose irritation was 1.7 mg/m³, for acceptability of eye irritation 15 mg/m³, and for acceptability of throat irritation 5 mg/m³. Increased irritation of eyes and throat was seen in study 9 during exposure to M22 at 25 mg/m³ for 2 hours. Eye and nose irritation and general irritation increased in study 10 during exposure to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour. Nose irritation and general irritation showed an acute increase during exposures to M22 at 20 mg/m³ for 5 hours in study 11. Both eye and nose irritation increased in study 12 at 6 mg/m³ for an exposure duration of 4 hours to M22. Throat irritation showed a tendency to increase at 24 mg/m³.

All 12 studies reported perceived mucosal irritation. The lowest LOEL found is 8 mg/m³ for eye irritation, 1.7 for nose irritation, and 5 for throat irritation. The highest NOEL found

was 5 for nose irritation, 3 mg/m³ for eye irritation, and 25 mg/m³ for throat irritation. Assuming that M22 is a best case the upper estimate of the threshold of VOC, effect on perceived irritation of eyes, nose, or throat is between 2 and 8 mg/m³ for eye or nose irritation and 5 and 25 mg/m³ for throat irritation, but lower thresholds are likely to appear for other mixtures and air temperatures.

Feeling of Dryness of Eyes, Nose, or Throat

Table 25.8 summarizes the findings in the 12 studies on the effects of VOC exposures on the feeling of dryness of eyes, nose, or throat.

In study 1 dry nose was not found even at exposure to 25 mg/m³ of M22 for 2.75 hours. In study 5 exposed subjects rated increased dryness of eyes, nose, and throat. Exposure duration was 6 hours. Several differences were reported between the two exposures but the study design was not balanced with respect to VOCs and the VOC causality cannot be inferred. No LOEL was found. The highest NOEL found is 25 mg/m³. However, only one study showed a conclusive effect. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on perceived dryness of eyes, nose, or throat is above 25 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

Feeling of Skin Humidity, Dryness, or Irritation

Table 25.9 summarizes the findings in the reported studies of the effects of VOC exposures on the feeling of skin humidity, dryness, or irritation.

Exposed subjects rated more dry facial skin during VOC exposures in study 5. The exposure duration was 6 hours. The design was not balanced with respect to VOC and causality cannot be inferred. Perceived facial skin dryness increased in study 10 during exposures to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour. Facial skin irritation in study 11 showed no effects of exposure to a mixture of VOCs (M22) at 20 mg/m³ for 5 hours.

Only three studies reported dryness as an effect of VOC exposures. The lowest LOEL found is 10 mg/m³. The highest NOEL found is 20 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on perceived skin humidity, dry-

ness, or irritation is between 10 and 20 mg/m³, but lower thresholds are likely to appear for other mixtures and exposure conditions.

Feeling of Watering or Runny Eyes

Table 25.10 summarizes the findings of the reported studies of the effects of VOC exposures on watering or runny eyes.

Feeling of watery eyes increased during exposure to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour in study 10. The feeling of runny eyes/watering eyes increased in study 11 during acute exposure and postexposure to a mixture of M22 at 20 mg/m³ for 5 hours.

The lowest LOEL found is 10 mg/m³. The NOEL was not reported. Assuming that M22 represents a best case and that negative findings were not reported, an estimate of NOEL is 24 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on perceived watering or runny eyes is between 10 and 24 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

Feeling of Blocked, Watering, or Runny Nose

Table 25.11 summarizes the findings of the 12 studies on the effects of VOC exposures on the feeling of blocked, watering, or runny nose.

The feeling of watering or runny nose increased in study 11 among hay fever patients and decreased among the healthy during exposures to M22 at 20 mg/m³ for 5 hours.

The lowest LOEL found is 20 mg/m³. The highest NOEL cannot be estimated. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on perceived air quality is below 20 mg/m³.

Feeling That Additional Ventilation Is Needed

Table 25.12 summarizes the findings of the reported studies of the effects of VOC exposures on the feeling that additional ventilation is needed.

In study 1 subjects reported needing more ventilation at 5 mg/m³ during exposure to M22 for 2.75 hours. Need for additional ventilation increased during 50-min exposures to 8 mg/m³ of M22 but not to 3 mg/m³ in study 2. In study 8 exposure to four different VOC mixtures each at three TVOC levels (15, 5, and 1.7 mg/m³) for 60 min caused increased need for ventilation (see Table 25.4). Need for more ventilation increased during exposure in study 10 to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour. Need of more ventilation increased during exposures in study 11 to M22 at 20 mg/m³ for 5 hours.

The lowest LOEL found is 1.7 mg/m³. The highest NOEL found is 3 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on additional ventilation needed is between 1.7 and 3 mg/m³, but lower thresholds are likely to appear for other mixtures at other air temperatures.

Feeling of Cough

Table 25.13 summarizes the findings in the reported studies of the effects of VOC exposures on the feeling of need to cough.

In study 3 no increased feeling of cough was seen during exposure to 25 mg/m³ of M22 for 2.75 hours. Exposure in study 8 to four different VOC mixtures, each at three TVOC

LOEL = lowest observed effect level.
NOEL = no observed effect level.

levels (15, 5, and 1.7 mg/m³) for 60 min, caused indications for increased feeling of cough, depending on mixture type. The exposures used were three different subsets of M22 and this mixture itself. The feeling of cough increased in study 11 among hay fever patients during exposure to M22 at 20 mg/m³ for 5 hours.

The lowest LOEL found is 1.7 mg/m³. The highest NOEL found is 25 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on cough needed is between 1.7 and 25 mg/m³, but lower thresholds are likely to appear for other mixtures at other temperatures.

General Well-Being or Discomfort

Table 25.14 summarizes the findings in the reported studies of the effects of VOC exposures on the feeling of general well-being.

Ratings of general well-being decreased during 50-min exposures in study 2 to M22 at 25 mg/m³. Ratings of general discomfort increased during exposures to M22 at 25 mg/m³

11	Kjærgaard et al. 1995a, 1995b	20	NE	M22	

NE = no estimate.
M22 = mixture of 22 VOCs (see Table 25.3).
LOEL = lowest observed effect level.
NOEL = no observed effect level.

for 2.75 hours in study 3. The general well-being was reduced in an interaction between exposure and temperature during exposures to 10 mg/m³ of M22 at three different temperatures (18, 22, and 26°C) for 1 hour in study 10. The general well-being decreased acutely during exposures to M22 at 20 mg/m³ for 5 hours in study 11.

The lowest LOEL found is 10 mg/m³. The highest NOEL found is 8 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on general well-being is between 8 and 10 mg/m³, but lower thresholds are likely to appear for other mixtures and temperatures.

Headache and Feeling of Heavy Head

Table 25.15 summarizes the findings in the reported studies of the effects of VOC exposures on headache and feeling of heavy head (lethargy).

In study 3, headache increased during exposure to 25 mg/m³ of M22 for 2.75 hours. In study 4 increased headache and heavy head was reported during exposures to all four of the material emissions. The concentrations ranged from 1.1 to 2.0 mg/m³. Exposure to emissions from office machines at TVOC 0.071 to 0.087 mg/m³ for 6 hours in study 5 caused increased headache. Subjects exposed to 25 mg/m³ of M22 for 4 hours in study 6 had increased headache. In study 11 heavy head and headache were reported after exposures to 20 mg/m³ of M22.

The lowest conclusive LOEL found is 20 mg/m³. The highest NOEL could not be estimated. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on headache is below 20 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

() = no conclusive evidence.
NE = no estimate.
M22 = mixture of 22 VOCs (see Table 25.3).
LOEL = lowest observed effect Level.
NOEL = no observed effect level.

Concentration Difficulties

Table 25.16 summarizes the findings in the reported studies of the effects of VOC exposures on concentration difficulties.

In study 1 no difficulties in concentration or short-term memory were observed even at 25 mg/m³ of M22 for 2.75 hours. In study 4 emissions from one material caused concentration difficulties at 1.2 mg/m³; other mixtures at 2.0 mg/m³ did not provoke effects. Exposure to 25 mg/m³ of M22 for 2.75 hours caused difficulties in study 6. Allergic persons reported concentration difficulties in study 11 during exposures to 20 mg/m³ of M22. In study 12 difficulties were reported during exposures to 24 mg/m³ but not at 12 mg/m³.

The lowest conclusive LOEL found is 20 mg/m³. The highest NOEL was 12 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on concentration is between 20 and 12 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

Feeling of Sleepiness or Tiredness

Table 25.17 summarizes the findings in the relevant studies of the effects of VOC exposures on the feeling of sleepiness.

In study 3 increased sleepiness was reported during exposures to 25 mg/m³ of M22 for 2.75 hours. In study 4 emissions from three materials caused feeling of tiredness after exposure to 1.2 to 2.0 mg/m³ (TVOC). No effects were reported in study 6 during exposures to 25 mg/m³ of M22.

The lowest LOEL found is 25 mg/m³. The highest NOEL is 25 mg/m³. Assuming that M22 is a best case, the upper estimate of the threshold of VOC effect on tiredness is about 25 mg/m³, but lower thresholds are likely to appear for other mixtures and air temperatures.

Effect of Type of Exposure

One study addressed the differences in potency of different VOC exposures (8). The study is not conclusive on this matter. It indicates differences in potency but the relative size of the differences is not presented.

The exposure TVOC levels in study 8 were 15, 5, and 1.7 mg/m³ for 60 min. The VOCs were three different subsets of M22 and this mixture itself. The dose response relations found were tested by using TVOC expressed in mg/m³, in PPM, and as thermodynamic activity to determine which gave best correlations. The selection of subsets (see Tables 25.3 and 25.4) was based on (1) lowest vapor pressure, (2) highest vapor pressure, and (3) chemicals with reactive radicals, etc. The best effect predictor was TVOC based on sum of mg/m³. Most potent for sensory effects was the mix with low vapor pressure. Most potent for objective physiological effects was the mixture with reactive compounds. The thresholds of effects were shown to be a TVOC level of 1.7 mg/m³.

25.4 DISCUSSION AND CONCLUSIONS

Principles for Interpreting Experiments

The following interpretation is based on results of experimental exposures of humans to low levels of VOCs at or just above the threshold for effects. In most cases one of the aims of the studies was to establish the dose-response relation between exposure to VOCs and effects, or at least the threshold. The low exposure levels mean that the investigations are made at unfavorably high noise-to-signal ratios for most of the measuring methods used for effects measurements. Such experiments are seldom sensitive enough to be conclusive and definitive. The sensitivity of chamber experiments may be improved by increasing the number of subjects, increasing control of the relevant covariables, and improving the sensitivity and accuracy of the measures of effects used in the investigations. The interpretation of controlled experiments, therefore, must consider how the relevant covariables were handled in the experimental design and analyses.

Effect modifiers are often inadequately addressed, in part because of limited sample size, and in part because the relevant factors have not yet been identified. In many studies the statistical analyses have examined the possible effects of response-modifying variables such as age, gender, and education. Most of the studies reviewed here were, however, not conclusive in these matters.

Epidemiologic studies and experimental laboratory studies do not always agree in type of effects seen or the thresholds found. The main reasons may be differences in:

- Definition or measurements of effects are not always the same (e.g., acceptability in home is different from that at work).
- Dose (e.g., concentration and exposure time) can be estimated in clinical studies but not epidemiologic studies).
- Chronic or repeated exposures may be more relevant than a single acute chamber exposure.
- Chamber studies have small sample sizes so between-subject differences sensitivity is critical.
- Response-modifying variables such as temperature and humidity are not controlled in epidemiologic studies.
- Other VOCs than those detected may be present in real situations.

Generally odor perceptions are considered to be the most sensitive responses to normal indoor exposures. It follows that odors normally will be obvious to the subjects in an experiment when they are exposed to VOCs. Although adaptation and careful step-wise administration of exposure may reduce this bias, the issue of odor detection makes it difficult to conduct truly unbiased studies of this type. For example, in study 2 ratings of general well-being were related to irritation, odor perceptions, air quality, and the need for more ventilation. Therefore, not only odor evaluations but also all related symptoms may be biased by odor detection.

Such bias was not found in study 1 where sensory irritation was related to air quality, eye irritation, and nose irritation, but not to odor intensity. Similar indications have been found in other studies and show that this odor bias may not affect ratings of irritation (Mølhave et al. 2000) However, definitive investigations of this matter are lacking.

The biological models that the researchers, in retrospective, appear to have used to interpret the observed human responses differ, but they often involve a chain of mechanisms in the human organism. Mechanisms may include the presence of pollutants in the air, penetration of the pollutant through the barrier between air and the mucosa or skin, transportation in the tissues, metabolic or other types of biochemical transformation of the compounds, release of messenger compounds, receptor activation, neural transmission, processing in the central nervous system, symptom reporting, or psychic reactions. Each air pollutant may, depending on concentration and exposure duration, activate several of these mechanisms to different degrees. Furthermore, mixtures of compounds may interact in unpredictable ways. It follows that no simple dose-response relation can be expected for the relation between exposure and observed effects. This is especially true for the sensory effects dealt with here.

As a consequence, no simple dose-response relation is expected and traditional toxicological evaluations are difficult to perform. In addition, the published studies refer to different exposures, populations, and end-point effects and seldom supplement each other in establishing a dose-response relation. This situation will probably not change dramatically in the future. Instead, less refined toxicological evaluations must be developed (e.g., Andersson et al. 1997, Mølhave et al. 1997) under the condition that compounds causing severe risks or adverse effects have been otherwise excluded. For irritation and other effects with a threshold, LOEL- or NOEL-type data can be the starting point.

The VOC Relevant Symptoms

Table 25.18 summarizes the findings of the 12 studies. The table refers to SBS symptoms related to VOC exposures that have been observed in at least two of the reported studies. The studies cover exposure ranges from 0.087 mg/m³ to 25 mg/m³. However, only those in the range from 1 to 25 mg/m³ are conclusive with respect to the effects of VOC exposures indoors. The non-conclusive studies illustrate the importance of cofactors and underline that the following can be used only as estimates of the upper level of thresholds of the effects of mixtures of VOC.

TABLE 25.18 Summary of LOEL and NOEL of Effects Observed More Than Once in the 12 VOC Experiments

Effect	Lowest LOEL, mg/m ³	Highest NOEL, mg/m ³	Number of observations	Remarks
Perceived air quality	1.7	5	12	Depending on VOC mixture and temperature
Odor intensity	1.7	1	12	
Irritation of:			12	
• Eye	8	3		
• Nose	1.7	5		
• Throat	5	25		
Feeling of dryness of eye, nose, throat	No data	25	1	
Feeling of skin humidity, dryness, or irritation	10	20	3	
Perceived watering or runny eyes	10	(24)	2	Assuming no report = no effect at highest exposure
Blocked, watering, or runny nose	20	No data	1	
Additional ventilation needed	1.7	3	5	
Feeling of cough	1.7	25	3	
General well-being	10	8	4	
Headache or heavy head	20	No data	5	
Concentration difficulties	20	12	5	
Feeling of sleepiness or tiredness	25	25	3	

() = no conclusive evidence.

It should be remembered that most papers do not give the entire list of questions or symptoms addressed and only the positive findings are reported. However, most of the studies used the same basic set of symptoms, although the phrasing may differ. Therefore, missing information about the more well-known SBS symptoms may indicate a NOEL at the highest exposure used in the experiment.

As stated by several groups, no common dose-response relation is expected to exist for all possible mixtures of VOC. However, to the extent that the M22 mixture referred to in most of the studies reviewed here can be assumed to be a best case, then the estimates may represent the upper limit of the threshold of different mixtures.

Considering that at least two studies should have shown effects and that the thresholds should be relevant for the low-level indoor exposure range (e.g., below 10 mg/m³), then the list of important symptoms and thresholds (mg/m³) in relation to M22 in Table 25.19 is suggested.

Assuming that M22 is a best case, then at exposures below about 2 mg/m³ (TVOC), perceived air quality, odor intensity, irritation of eyes or nose, additional ventilation needed, and cough are expected to be the most sensitive indicators of VOC exposures. However, it must be kept in mind that these symptoms are unspecific and may have many other possible causes. Therefore the presence or absence of these symptoms cannot infer that VOC concentrations indoors are the responsible agent, but only indicates the possibility. In addition, studies 4 and 5 show that the presence of additional non-VOC exposure, air temperature, etc. may change these estimates.

Effect of Exposure Types

Study 8 showed that the thresholds of effects were shown to be above a TVOC level of 1.7 mg/m³. Thus the findings in studies 4 and 5 of effects during exposures at much lower VOC exposure levels clearly demonstrates the difficulties in using TVOC as an exposure indicator in relation to VOC indoors. This observation is in line with the recommendations of several international consensus groups (Andersson et al. 1997, Bluyssen et al. 1997, Mølhave et al. 1997, Seifert 1999).

One study has specifically addressed the differences in potency of different VOC exposures (8). The study is not conclusive on this matter. It indicates differences in potency, but the relative size of the differences is not presented. However, the authors state that for prac-

TABLE 25.19 Symptoms Following VOC Exposures at Low Levels in Two or More of the Reviewed Papers

Symptom	Range of thresholds indicated, mg/m ³	Number of reported cases
Perceived air quality	1.7–5	12
Odor intensity	1.0–1.7	12
Irritation of eyes or nose	1.7–8	12
Additional ventilation needed	1.7–3	5
Feeling of cough	1.7–25	3
Irritation of throat	5–25	12
General well-being	8–10	4
Feeling of skin humidity	10–25	3
Headache	≥ 20	5
Concentration difficulties	12–20	5
Feeling of sleepiness	≥ 25	3

tical purposes, where the exposure can be expected to exceed the thresholds of effects, the differences between different types of exposures at the same TVOC level seem to be small.

CHAPTER 26

METHODS FOR ASSESSING IRRITATION EFFECTS IN IAQ FIELD AND LABORATORY STUDIES

Annette C. Rohr, M.A.Sc.

*Harvard University School of Public Health
Boston, Massachusetts*

Over the past decade or so, air quality concerns related to buildings and other indoor environments have been raised, due in large part to increased reporting of building-related symptoms such as sick building syndrome (SBS). Many of these symptoms originate with sensory irritation, including stinging, itchy, or dry eyes, burning nasal passages, throat irritation, or perception of offensive odors. The emergence of such irritation symptoms has prompted research to identify the airborne substances of concern and to establish methods to quantify the effect in humans. Subjective human reactions have been used to determine relative irritant potencies of various substances; however, in an attempt to find objective measures of irritant effects, much research has been focused on biologic markers of irritation. A standard test method has been developed in mice (ASTM 1996) whereby compounds and mixtures of substances can be evaluated for their irritant abilities in a standardized manner. This method is described in detail in Chaps. 23 and 24 of this handbook. Reliable, reproducible, and standardizable methods of such assessment in humans would be useful in helping to elucidate the etiologies of IAQ-based health effects like SBS.

This chapter of the handbook briefly describes the sensory irritation response, discusses the use of biologic markers, and then outlines various objective measures that have been used to assess irritation in either experimental or observational settings. The chapter focuses on markers of eye and upper respiratory tract irritation, since these effects are sensory irritant responses mediated by the trigeminal nerve. Other effects such as neurobehavioral symptoms, dermal complaints, and lower respiratory system problems are not covered. The chapter concludes with an analysis of the utility of each marker on the basis of selected characteristics to arrive at a general measure of its overall usefulness in IAQ investigations.

26.1 THE SENSORY IRRITANT RESPONSE

The irritation response is mediated by the “common chemical sense” (CCS), which, along with the olfactory system and the gustatory system, mediate responses to the environment. However, in contrast to the two last senses, which essentially provide the organism with information about their immediate surroundings, CCS is believed to be a direct warning system (Nielsen 1991).

Sensory irritants are believed to interact with receptors on trigeminal nerve (cranial nerve V) endings in the nasal and ocular mucosa (Alarie 1973). Stimulation of trigeminal nerve endings results in a stinging sensation, which can increase to a sensation of pain.

There are believed to be two distinct modes of receptor activation (Cain and Cometto-Muñoz, 1995). The *physical* mechanism of irritancy is based on the equilibrium between the ambient concentration and the internal concentration (receptor-bound) of the molecule. These compounds tend to be weak irritants. For volatile organic compounds (VOCs), strong relationships have been observed between physicochemical properties, such as vapor pressure and molecular weight, and irritancy. Specifically, increasing irritancy tends to be associated with increasing carbon number and decreasing vapor pressure, within a given chemical class. In contrast, some chemicals evoke an irritancy response via a *chemical* mechanism in which the molecule and receptor form a chemical bond, and clearance is via systemic mechanisms. Formaldehyde is an example of this type of compound. These compounds tend to be stronger irritants and produce a response at lower concentrations than their nonreactive analogs. Both in terms of the number of compounds and concentration, nonreactive substances acting via the former physical mechanism tend to predominate in indoor air (Cain and Cometto-Muñoz 1995).

26.2 USE OF BIOLOGIC MARKERS IN HUMANS

Biologic markers are indicators signaling events in biological systems or samples (National Research Council 1987). More specifically, biomarkers serve as hallmarks of changes along the continuum from causal *exposure* to resultant *disease*. This continuum has been well characterized by a number of researchers and scientific committees (Schulte 1989). Four types of biomarkers have been proposed to lie between exposure and disease. A biomarker of *internal dose* is the amount of a xenobiotic material in a biological medium, while a marker of *biologically effective dose* is the amount of this substance interacting with subcellular, cellular, and tissue targets. A marker of *early biological effect* is an event correlated with, and possibly predictive of, health impairment, and biomarkers of *altered structure/function* indicate a biologic change more closely related to disease development. Table 26.1 provides examples of these four categories of markers. Using lead as an example, internal dose is represented by blood lead levels, since these are indicative of the amount of lead present in body tissues and capable of interacting with key tissue components. Lead level in bone marrow cells reflects biologically effective dose, as bone marrow is a target organ for lead toxicity. An early biological effect is characterized by inhibition of δ -aminolevulinic acid dehydratase, a key enzyme in the heme biosynthesis pathway. Finally, a marker of altered structure or function is represented by an accumulation of zinc protoporphyrin, since zinc is preferentially incorporated into the porphyrin structure in hemoglobin when heme synthesis is impaired.

One objective of using biologic markers is to recognize or identify a pathological condition so that intervention can occur to prevent further damage or disease. For a marker of irritation, it would be desirable that the biomarker be associated with subjective symptoms of irritation, or that it precede such symptoms in a predictable fashion. A useful biomarker

TABLE 26.1 Selected Examples of Biologic Markers*

Exposure	Internal dose	Biologically effective dose	Early biological effect	Altered structure/function
Lead	Blood lead levels	Lead level in bone marrow cells	Inhibition of δ -aminolevulinic acid dehydratase	Accumulation of Zn protoporphyrin
Ionizing radiation	Inhaled radionucleotides	HPRT [†] mutation	Chromosomal micronuclei	Hyperplasia
Fatty food	Serum cholesterol	HDL/LDL [‡]	Chylomicrons in blood	Serum enzymes

*The order of specific components in each continuum may be speculative and subject to other interpretations.
[†]HPRT: hypoxanthineguanine phosphoribosyl transferase.
[‡]HDL/LDL: high-density lipoprotein/low-density lipoprotein.

is also highly reproducible with respect to laboratory procedures and has low variability within an individual. A biomarker that has high specificity for a given exposure or type of effect is more useful than one that occurs with a number of different exposure conditions or is indicative of a variety of effects. Since this information may not be known, this issue should be kept in mind in conducting studies involving biomarkers.

26.3 METHODS FOR ASSESSING EYE IRRITATION

A number of potentially useful biological markers of eye irritation have been used to evaluate the association between objective eye manifestations and subjective symptoms, as well as to assess the effects of a variety of exposures under both controlled conditions and in field settings. The following subsections summarize various methods that have been used to assess eye irritation to date, including examples of their application, where applicable. The subsection “Symptom Validation” at the end of this section provides a discussion of the validity of these methods, where it has been evaluated.

Eye Redness

Eye redness, or inflammation, can be assessed by photography. Two general approaches to subsequent photographic evaluation have been used. First, photographs taken before and after a controlled or occupational exposure can be compared (Kjaergaard and Pedersen 1989). A more standardized photographic method of assessing eye redness was described by Kjaergaard (1992). The eye is photographed while the subject looks outward and slightly upward, and a cross set in a square is then used to count the number of vessels crossing or just touching the figure. This method may be more repeatable and potentially less subject to bias. Also, inflammatory changes can be measured over time, as in epidemiological studies.

The reproducibility of the former method was evaluated by Kjaergaard et al. (1990a); reproducibility of the latter quantitative method has not been assessed. Photographs of the eyes following exposure to birch pollen in hayfever sufferers were compared by a five-person panel using a 5-point scale and a double-blind design. Reasonable reproducibility was

found, with correlation coefficients within panel members for two different series of evaluation ranging from 0.70 to 0.78, and correlation coefficients between panel members ranging from 0.61 to 0.81. The sensitivity of the method was measured as the likelihood of detecting an increase in redness if irritation was suggested by simple clinical observation. Sensitivity was determined to be either 0.72 or 0.88, depending on which classification/ranking scheme was used. The study also noted that the time-consuming nature of the photograph comparisons could be avoided or minimized by computerized video methods, which focus on a single blood vessel under high magnification and are therefore able to detect changes in ocular vasculature occurring over shorter time periods.

Goldstein et al. (1993) differentiated between two methods of measuring eye redness (hyperemia). *Background redness*, an even change in scleric appearance from white to some shade of red, can be estimated by photographing the eye, digitizing the slides, and assigning a gray level (0 to 225) to the sclera. *Conjunctival injection* refers to an increase in the size and number of the conjunctival vasculature. This parameter is assessed by separating the blood vessel area (foreground) from the total image area via a two-step shading compensation algorithm.

Experimental studies incorporating eye redness have not generally found an association between eye redness and exposure conditions. Kjaergaard et al. (1989) assessed eye redness in healthy subjects exposed to *n*-decane at concentrations of 0, 10, 35, or 100 $\mu\text{L/L}$ for 6 hours. Pre- and postexposure photographs were compared in a double-blind manner, and the number of blood vessels in an arbitrary unit area were counted. Redness was found to decrease during the exposure period; however, this was unrelated to *n*-decane exposure.

Kjaergaard et al. (1990a) instilled birch pollen into the eyes of hayfever sufferers, and photographs taken before and after exposure were compared. Surprisingly, the authors initially found decreased redness after pollen exposure, although objective findings correlated more strongly at higher pollen exposures. The authors hypothesized that the expectance of a hayfever attack may have precipitated peripheral vasoconstriction, or that the reduction in redness may have been the equivalent of the "white response" observed in skin, where mechanical force causes a white line or area to appear.

Irgren et al. (1993) made close-up slides of the eyes of subjects exposed to *n*-butyl acetate both before and immediately after exposure. Slides were projected in pairs on a screen, and redness differences before and after exposure were judged without knowledge of the order of the slides or exposure concentration. Each eye was judged to be more, equally, or less red than the other eye. No significant differences between the proportions of increased eye redness were observed in any of the exposure conditions, which ranged from 70 mg/m^3 in 4-hour sessions to 1400 mg/m^3 in 20-minute sessions.

Ocular response to methyl tertiary butyl ether (MTBE) exposure was assessed by Prah et al. (1994). Study subjects were each exposed for 1 hour to 1.39 ppm MTBE and clean air in separate sessions separated by at least 1 week. The order of the sessions was randomly selected, with both the subjects and technicians blinded to exposure status. The degree of eye redness was measured as the ratio of foreground redness to background whiteness by digitizing pre- and postexposure color slides by a densitometer. No effect of MTBE exposure on eye redness was observed.

A study by Rasmussen et al. (1995) evaluated changes in eye redness following exposure to nitrous acid. Subjects were exposed to either clean air, 77 parts per billion (ppb), or 395 ppb nitrous acid for 3.5 hours in a double-blind, balanced protocol. A 1-hour baseline measurement period preceded each exposure, and exposures were separated by 1 week. Photographs taken before and during exposure were compared by a panel comprising four trained technicians and one investigator. Results indicated a trend toward more redness with increasing concentrations; however, repeated measures ANOVA could not verify this trend.

Epidemiological studies have reported mixed results in terms of associations between eye redness and exposure conditions. Kjaergaard and Pedersen (1989) assessed changes in

eye redness in tobacco workers by randomized, double-blind evaluation of pairs of pictures taken before and after a workshift, by a five-person panel. A 5-point scale was used to describe redness differences between the photographs, as well as the level of certainty associated with the panel members' judgments. Statistically significant differences in the prevalences of increased redness were associated with increasing personal tobacco dust exposure.

In contrast to this occupational setting, several studies conducted in complaint office settings failed to identify a significant increase in eye redness in these offices compared with reference buildings. Kjaergaard and Brandt (1993) conducted an observational study over 2 years that examined eye redness and other objective eye parameters in workers in four offices having sick building syndrome problems and in one reference office. Dust sedimentation rate and temperature were also measured, and time spent at video display terminals was assessed by using questionnaires. Eye redness was graded on a scale of 1 to 5 by a panel of four trained technicians and the investigator. No significant differences were identified between the two types of buildings, nor was any correlation observed with any of the three exposure parameters investigated. Similarly, eye redness was measured by Kjaergaard et al. (1993) in 53 staff members at a library characterized as a sick building and compared with a group of randomly selected individuals from another study. No significant difference in eye redness, which was measured using the technique of Kjaergaard (1992), was observed between the two groups of subjects.

Blinking Frequency

The blinking reflex is mediated by the trigeminal nerve endings on the ocular epithelium and would thus be expected to serve as an objective measure of irritant exposure. This measure may not be completely objective, however, since it can be cortically influenced. Ideally, therefore, studies evaluating blinking frequency should be blinded such that the subject is unaware of the monitoring of blinking activity. No information on reproducibility or population variability of blinking frequency has been reported.

For the most part, controlled exposure studies evaluating blinking frequency have reported exposure effects. Increased blinking frequency was reported by Weber-Tschopp et al. (1977) when they exposed healthy volunteers to formaldehyde concentrations ranging from 0.3 to 4 ppm. Blinking rate was observed to increase as a function of exposure concentration.

Similarly, Prah et al. (1993) exposed young, healthy males to a mixture of volatile organic compounds at 0, 12, and 24 ppm and measured blinking frequency using electrodes. Frequency increased with exposure and showed a significant interaction between exposure level and duration of exposure.

Iregren et al. (1993) videotaped subjects before and after exposure to *n*-butyl acetate and counted the number of blinks for one minute during playback. Subjects were also exposed to control conditions using balanced designs, with control exposures being a low solvent concentration of 70 mg/m³. Baseline values were obtained 2 minutes prior to exposure, during seated and relaxed conditions. Blinking frequency during the control exposure was not significantly different from the baseline values; however, a significant increase in blinking frequency was noted at the last recording (15 minutes) at exposure to 1400 mg/m³.

An observational study completed by Carrer et al. (1996) measured blinking frequency in 34 office workers and conducted personal monitoring for total VOC (TVOC), formaldehyde, and particulate matter simultaneously. Blinking frequency was measured by a piezoelectric transducer fixed near to the eye lateral canthus. No correlation between increased blinking frequency and levels of the exposure parameters was observed. However, frequency was higher, although not statistically significant, for those workers with a high

environmental score, which comprised total VOC (TVOC), formaldehyde, particulate, microclimate parameters, lighting conditions, and visual load.

The use of electrodes and transducers might introduce error into the evaluation of blinking frequency, since blinking activity may be influenced by both the presence of apparatus near the eye, and, as mentioned, the fact that blinking is being monitored.

Tear Film Stability

Tear film stability, represented by the breakup time (BUT), has commonly been measured in irritation studies because of the film's protective function in moistening the corneal surface (Kjaergaard 1992). Under normal circumstances, the precorneal tear film is stable, continuous, approximately 6 μm in thickness, and composed of three strata, including the lipid, aqueous, and mucous layers (Basu et al. 1978). Two mechanisms serve to maintain the film's integrity between blinks. First, goblet cells of the conjunctiva secrete mucous, which lowers surface tension and allows the tear film to spread over the corneal epithelium. Second, the outer lipid layer, secreted by the meibomian glands, reduces evaporation from the aqueous phase of the film.

Breakup time is typically measured by using a slit lamp in cobalt-filtered light after instillation of a sodium fluorescein solution into the lower conjunctival sac and cessation of blinking. BUT is the time from the last blink to the breakup of the tear film, i.e., the appearance of the first randomly distributed dry spot. According to Basu et al. (1978), BUT in normal eyes ranges from approximately 25 to 30 seconds.

More recently, Goldstein et al. (1993) used a noninvasive method to measure BUT. Tear-film stability was determined by using a photokeratoscope, an instrument that continuously views the reflected image of a concentric circular pattern from the surface of the cornea. The subject focuses on a green light target in the center of a placido disk, and the keratoscope projects white concentric rings onto the cornea. When the tear film breaks up, the keratoscope image becomes distorted. The image is recorded by a closed-circuit camera, allowing later examination and determination of the moment of distortion. The time from blinking to the distortion is thus the breakup time. Using this technique, a mean BUT of 22 seconds was determined on 24 subjects, with a range of 0 to 120 seconds.

The reproducibility of BUT has been evaluated. Shapiro and Merin (1979) found a correlation coefficient of 0.66 between the same test in the two eyes. Lemp and Hamill (1973) retested the same eye and concluded that the BUT in a given individual is reproducible. Vanly et al. (1977) reported high autocorrelation in a given individual's BUT for breakup times greater than 10 seconds and less than 5 seconds, although a great variation was observed in the individual eye from one patient visit to the next.

Franck (1986) evaluated the validity of BUT as a measure of irritation by assessing a reduction in this measure with subjective symptoms of eye discomfort. The study population consisted of 169 office workers in four Danish town halls who had complained of poor indoor air quality. A statistically significant association was found between self-reports of eye irritation and reduced BUT, as well as a significant rank correlation for increasing discomfort and decreasing BUT.

The BUT parameter has been used to assess irritation in a number of experimental settings. Basu et al. (1978) used a corneal microscope to measure BUT in subjects exposed to cigarette smoke. The study included the collection of four sets of measurements for each subject: baseline BUTs on exposure and control days, and BUTs following exposure for 10 minutes to either air or cigarette smoke. Breakup times after smoke exposure were significantly shorter (around 13 seconds) than for the other three conditions (around 21 seconds). The authors suggested that this outcome may reflect a change in the relative proportions of the three precorneal film components, and hypothesized that changes in the mucous or lipid layers may have a more significant effect on BUT than decreases in the aqueous layer.

Kjaergaard et al. (1989) measured BUT in healthy subjects exposed to varying concentrations of *n*-decane, and found that tear film stability decreased during the day in all exposure groups, but did so in a dose-related manner. BUT values did not change in subjects exposed to clean air.

A controlled study of VOC exposure from four different building materials was conducted on 20 asthmatic subjects and 5 healthy controls (Johnsen et al. 1991). All four of the materials, painted gypsum board, rubber floor, nylon carpet, and particle board with acid curing paint, significantly reduced the tear film quality index at TVOC concentrations of at least 1.3 mg/m^3 . The index was composed of measurements of foam at eyelid and corners of the eyes, thickness of the corneal lipid layer, BUT, and epithelial damage. The rubber floor produced the lowest tear film quality index, while the weakest effect was observed with exposure to particle board. There was a trend for a higher tear film quality index for nonasthmatics; however, this was not statistically significant.

Exposure effects have not been reported for all substances evaluated in experimental settings. Tear film stability in a group of healthy subjects exposed to a 22-component mixture of VOCs was evaluated and compared with individuals who had complained of SBS symptoms (Kjaergaard et al. 1990b). Three exposure groups were used, and exposures were conducted in both morning and afternoon sessions. One exposure group was exposed to 0 mg/m^3 in both sessions. The other two groups were exposed either to 0 mg/m^3 in the morning session and 25 mg/m^3 in the afternoon session, or vice versa. BUT was found to be unaffected by VOC exposure. Similarly, Prah et al. (1993) found no effect on BUT in subjects exposed to 1.39 ppm MTBE for 1 hour. Iregren et al. (1993) used this technique in their assessment of the irritation effects of *n*-butyl acetate. Baseline values were obtained 1 week prior to exposure. No significant effects on BUT were noted in any of the exposure conditions. Mølhave et al. (1993a) did not report an exposure effect of four different mixtures of VOCs at 1.7, 5, and 15 mg/m^3 on healthy adult Danish volunteers; nor did Mølhave et al. (1993b) identify an effect on BUT of exposure to a mixture of 22 VOCs at 10 mg/m^3 and varying air temperatures (18, 22, and 26°C). However, in the last study, although no difference in response to VOCs or air temperature was noted, there was a significant interaction between tear film stability, VOC exposure, and temperature, suggesting that VOC exposure and air temperature may not be independent variables for IAQ evaluations.

Tear film stability has been used most often in the context of observational studies conducted in complaint buildings, and positive associations have often been reported. In Franck et al.'s study (1993) a BUT of less than 5 seconds after a blink was considered abnormal, one occurring between 5 and 10 seconds as borderline, and one occurring more than 10 seconds as normal. Using this index, they determined that office workers in buildings with a high prevalence of sick building syndrome had shorter BUTs than either those in buildings with lower prevalences of SBS or those in the general population. In addition, the odds ratio for the occurrence of subjective eye symptoms when a decreased BUT was present was calculated to be 2.28 (95% CI 1.19–4.36) in office workers, but only 0.76 (95% CI 0.24–2.37) in controls. The authors postulated that insufficient meibomian fat might be an important etiologic factor in decreased BUT, as well as in other objective eye manifestations to be discussed in later sections. They further hypothesized that the irritancy mechanism in this case may be the direct exposure of trigeminal nerve endings to the environment.

Franck and Boge (1993) completed a follow-up study to an original investigation on Danish office workers, focusing on the chronic nature of "office eye syndrome," a term coined to describe dry eye conditions when no etiologic factor could be identified. The study reported that dry eyes in office workers is not a transient phenomenon, as evidenced by a premature breakup time 6 months and 1 year following the initial assessment. In addition, no seasonal variation was noted in the two follow-ups in both summer and winter. Similarly, in the "sick library" investigation of Kjaergaard et al. (1993) mentioned earlier, BUT

was found to be significantly shorter in library staff than in a group of randomly selected individuals from other studies conducted by the authors in Denmark. Positive findings were also reported by Muzi et al. (1998) in their assessment of a variety of objective ocular and respiratory alterations in employees in both a “sick” building and noncomplaint control buildings. Evaluation of BUT revealed that tear film stability was significantly reduced in employees in the sick building compared to controls. Specifically, the frequency of BUT values from 5 to 9 seconds was higher among workers in the complaint building (24.3 percent) than in control workers (5.4 percent). Although low BUT values were noted more often in those reporting subjective complaints than those without symptoms, this trend was not statistically significant.

A study by Carrer et al. (1996) revealed an insignificant decrease in BUT in workers with higher exposure to VOCs, as measured by personal monitoring. However, BUT reduction was more frequent, although not statistically significant, in subjects with high “environmental scores,” which encompassed total VOC (TVOC), formaldehyde, particulate, microclimate parameters, lighting conditions, and visual load.

A negative exposure effect was also noted by Kjaergaard and Brandt (1993) in their study of the four SBS problem buildings, with increased BUT in workers associated with increasing dust sedimentation rate in the workers’ immediate areas.

Foam Formation

Foam is an agglomeration of gas bubbles separated by thin liquid films. Decreased foam in the outer canthus of the eye has been associated with self-reports of subjective eye irritation (Frank and Skov 1989, Franck et al. 1993), and has been postulated to be due to fatty substances or oils in the eye or increased blinking frequency caused by irritation. Foam can be measured by using diffuse light produced by a wide open slit and maximum magnification (Franck and Skov 1989). Measurement can be conducted immediately before or after BUT, and the result can be expressed either as a dichotomous variable (presence or absence) or a continuous variable, by measuring the number of bubbles present. Frank and Skov (1989) determined that foam was present if three or more bubbles were observed. No information on reproducibility or population variability of foam formation has been reported.

Mølhave et al. (1993b) assessed foam formation in healthy adult subjects exposed to four different mixtures of VOCs at 1.7, 5, and 15 mg/m³. Foam formation was reduced during exposure to all mixtures; however, differences in the thresholds of the mixtures to affect foam were not significant. Moreover, concentration-response relationships were not observed. The strongest effect on foam formation was observed with a mixture composed of compounds with both high vapor pressures and high thermodynamic activities.

Foam has also been assessed in several epidemiological studies conducted in office buildings. Franck and Skov (1989) assessed the presence of foam in the eyes of Danish office workers and in controls from the general population in the same area. They reported a significant association between foam and increasing age in controls, with females tending to have less foam than males in both groups. After controlling for possible confounders including age, gender, and use of eye makeup, the prevalence of foam was significantly lower in the office workers than in the general population. Similarly, Frank et al. (1993) reported that foam was absent (less than 3 bubbles) more often in office workers in both high and low SBS areas than in the general population. Also, an odds ratio (OR) of 2.94 (CI 1.08–7.96) was calculated for the occurrence of subjective eye symptoms in office workers when foam was absent (less than 3 bubbles); the OR was only 1.09 (CI 0.46–2.62) in controls.

In contrast to these findings, however, Kjaergaard and Brandt (1993) found that increased foam formation in workers was associated with an increased dust sedimentation rate, a somewhat unexpected result.

Epithelial Damage

Assessment of epithelial damage can be conducted by counting the number of green dots on the epithelium after instillation of lissamine green B dye in the lower conjunctival sac (Kjaergaard 1992). A blinking period lengthy enough to eliminate surplus dye is permitted, and the number of dots is counted for four different areas of the eye. Franck et al. (1993) counted dots 1 minute after instillation, and considered more than 50 dots in a cluster to be abnormal, between 10 and 50 to be borderline, and less than 10 to be normal. Increased numbers of dots is indicative of conjunctival and corneal epithelial proliferation and may indicate a change to more highly keratinized cells (Kjaergaard 1992). No information on reproducibility or population variability of epithelial damage has been reported.

Iregren et al. (1993) assessed epithelial damage in an experimental study of *n*-butyl acetate exposure. Rose bengal solution was used instead of lissamine green. If a minimum of 10 red-stained conjunctival cells were noted, they were counted; however, isolated and widely dispersed single red-stained cells were not counted. Baseline values were obtained 1 week prior to exposure. No significant differences in the proportion of subjects with stained cells were found following the different exposure conditions to butyl acetate.

Several observational studies have incorporated this biomarker. Franck (1986) assessed epithelial damage in office workers in Danish town halls who had complained of poor indoor air quality. A significant association was found between subjective symptoms and objective manifestations in the form of lissamine green staining. Also, a significant rank correlation was observed for increasing irritation and increasing epithelial damage.

Epithelial damage was higher in "sick" library staff than in a group of randomly selected individuals from other studies conducted by the authors in Denmark (Kjaergaard et al. 1993). Similarly, in their follow-up study of office eye syndrome, Franck and Boge (1993) reported that, as with BUT, epithelial damage as measured by lissamine green staining was significantly correlated at the initial investigations and again at 6 months and 1 year. They concluded that this is indicative of the chronic nature of dry eyes in office workers. Increased epithelial damage was also noted with increased dust sedimentation rate in workers in problem buildings (Kjaergaard and Brandt 1993).

Franck et al. (1993) evaluated epithelial damage along with BUT and foam formation in office workers and controls. Epithelial damage was not significantly elevated in office workers relative to the general population. Furthermore, the calculated odds ratio of 1.89 (95% CI 0.91–3.92) for the occurrence of subjective eye complaints when epithelium damage was present was not statistically significant.

Tear Fluid Cytology

Tear fluid cell content can be determined by the removal of a small amount of tear fluid from the conjunctival sac by withdrawal by a pipette, placement on a slide, fixation, and staining. Cell content is analyzed and counted by microscopy (Kjaergaard 1992). No information on reproducibility or population variability of cell counts in tear fluid has been reported.

This method of assessing irritation has been used in several experimental settings. Kjaergaard et al. (1989) exposed subjects to *n*-decane at 0, 10, 35, and 100 $\mu\text{L/L}$ and measured polymorphonuclear neutrophils (PMNs) and cuboidal epithelial cells in conjunctival fluid. PMN counts in control subjects exposed to clean air decreased during the exposure period, while counts in exposed individuals increased in a significant concentration-dependent manner. Epithelial cells were only significantly higher than controls in the group exposed to

35 $\mu\text{L/L}$. Kjaergaard et al. (1990b) exposed healthy subjects and individuals who had complained of SBS symptoms to a mixture of 22 VOCs at 25 mg/m^3 , as well as clean air. Conjunctival secretions were collected from beneath the lower lid and total PMNs, lymphocytes, and squamous, cuboidal, and cylindrical epithelial cells were counted. PMNs are markers of inflammation. PMN counts were higher in subjects exposed to VOCs compared with those exposed to clean air; however, no difference in counts between healthy subjects and those who had complained of SBS symptoms was evident. Also, no differences in epithelial cell counts were noted. When Mølhave et al. (1993a) exposed healthy subjects to the same VOC mixture at 10 mg/m^3 , no significant changes in median PMN counts following exposure were observed.

In Rasmussen et al.'s study (1995) of nitrous acid exposure, tear fluid cytology results indicated statistically significant dose-response effects with regard to increases in both squamous epithelial cells and PMNs. The number of squamous cells increased by 20, 67, and 80 percent after exposure to clean air, 77 ppb, and 395 ppb nitrous acid (HONO), respectively. Cuboidal epithelial cells showed significant effects for the highest nitrous acid level only. No subjective sensations of mucous membrane irritation were reported during either the low or high HONO exposure levels.

Tear fluid cytology has also been evaluated in observational settings. Kjaergaard and Pedersen (1989) used this technique to evaluate the potential irritant effects of tobacco dust, and used both workers in the tobacco industry and a matched control group employed by a telephone company. Results indicated that, with the exception of lymphocytes, tobacco workers had higher cell counts than controls both before and after a work-shift. Also, counts of cuboidal and columnar epithelial cells in tobacco workers increased during the day, especially in the workers at the highest tobacco dust exposure level of 1.26 mg/m^3 . A dose-response relationship for cuboidal epithelium changes was found, with the highest exposed having higher prevalences of increasing cuboidal cell counts than the lowest exposed. Columnar epithelium changes were not dose related.

Tear fluid cytology was assessed in an observational study in office workers in four problem buildings and one reference building. Increased numbers of PMNs in tear fluid were associated with both increased dust sedimentation rate and increasing video display terminal work (Kjaergaard and Brandt 1993).

Impression Cytology

Impression cytology was used by Prah et al. (1994) to remove small numbers of epithelial and other cells from the surface of the conjunctiva to determine if MTBE exposure resulted in ocular inflammation. The technique involved placing a cellulose acetate filter at six different ocular sites, gently pressing the filter with a glass rod to ensure contact with the conjunctiva, peeling back, and placing in a tube. Filters were processed for light microscopy and cells were counted. In addition, quantitative polymerase chain reaction (PCR) methods were used to assess the presence of messenger RNA (mRNA) coding for the proinflammatory cytokines interleukin-6 (IL-6) and interleukin-8 (IL-8). No information on the reproducibility or population variability of cell counts using impression cytology was reported.

Each subject was exposed for 1 hour to 1.39 ppm MTBE and clean air in separate sessions at least one week apart. The order of the sessions was randomly selected, with both the subjects and technicians blinded to exposure status. No PMNs were observed in either the air- or MTBE-exposed samples, though numerous squamous epithelial cells of normal appearance were present. Furthermore, although mRNA coding for IL-6 and IL-8 was detected in all samples, there was no difference in amount between exposure conditions.

Corneal Lipid Layer Thickness

A reduction in the thickness of the fatty layer of the precorneal film may be associated with irritant effects (Franck 1991). Film thickness is measured by the semiquantitative interference method, which involves focusing diffuse light from a slit lamp exactly onto the anterior surface of the precorneal film. If red hydrocarbon-like patterns appear on the film immediately, the fatty layer is of maximal thickness and is recorded as >200 nm. If the fatty layer is colorless, the lower lid is slowly moved upward by $1/4$ eye opening increments until red interference occurs. If the interference is observed at $1/4$ closed, $1/2$ closed, and $3/4$ closed, thickness is considered 150 nm, 100 nm, and 50 nm, respectively, since as the eyelid is moved upward, the lipid layer is pushed together on the exposed portion of the cornea. Thickness is considered 0 nm if interference is not observed. No information on the reproducibility or population variability of corneal film thickness has been reported.

This method was used in an experimental setting by Iregren et al. (1993) who quantified the thickness of the precorneal lipid layer before and after exposure to *n*-butyl acetate. Baseline values were obtained 1 week prior to exposure. Results indicated that the eyelid positions at interference were significantly higher after 4 hours of exposure to control and exposure conditions than to baseline values; however, the differences between exposure and control conditions could not be tested because of the presence of less than 6 nonzero differences in the Wilcoxon signed-rank test.

In an observational setting, Franck (1991) assessed lipid layer thickness in Danish office workers and controls from the general population, and reported that the fatty layer was significantly reduced in the office population, even after controlling for confounding by the use of eye makeup, which generally reduced film thickness, and an investigation time prior to noon, which resulted in a thicker film.

CO₂ Eye-Provocation Test

The CO₂ exposure method has been proposed to be of value in the prediction of individual sensitivity to airborne pollutants (Kjaergaard et al. 1992). The method involves evaluation of the irritation threshold induced by CO₂, since this threshold may change, depending on ocular condition and sensitivity resulting from other environmental exposures. No information on the reproducibility or population variability of this biomarker has been reported.

In experimental settings, this marker of irritation has not shown an exposure effect. Kjaergaard et al. (1990b) assessed the CO₂ threshold following exposure to 0 and 25 mg/m³ of a mixture of 22 VOCs, and somewhat unexpectedly found that the threshold increased with VOC exposure. The method was also used by Rasmussen et al. (1995) to evaluate nitrous acid exposure effects. In this study, the provocation test was performed both before and after exposure to clear air, 77 ppb HONO, or 395 ppb HONO. A single eye was exposed to CO₂, with the subject blinded to which eye was being exposed. Following exposure, the subject scored each eye separately with respect to sensory irritation. An exposure effect was observed for the 16% CO₂ exposure; however, the effect was significant only for females in the group. A dose-dependent decrease in CO₂ threshold with HONO exposure was suggested but did not reach statistical significance.

In an observational setting (Kjaergaard et al. 1992), healthy subjects and individuals reporting sick building symptoms were exposed to progressive concentrations of CO₂ (10, 20, 40, 80, and 160 mL/L). Each exposure lasted 2 minutes, and exposures were continued until an irritant reaction was reported by the subject. Findings indicated that the individuals with SBS complaints had lower CO₂ thresholds than healthy subjects. Additionally, CO₂ thresholds appeared to be related to skin irritation sensitivity, which was evaluated by response to dermal application of lactic acid.

Schirmer I Tear Test

The Schirmer tear test (Williamson and Allison 1967) assesses the extent of eye wetness by using a strip placed in the lower conjunctival sac of the open eye. The extent of wetting, expressed in millimeters, is an indicator of the amount of lachrymal secretions. Williamson and Allison determined that a positive Schirmer test was indicated by less than 15 mm of wetting. No information on the reproducibility or population variability of the Schirmer test has been reported.

Williamson and Allison (1967) used this technique to assess the effects of temperature and humidity on eye wetness. In their evaluation of patients in a rheumatic hospital (mean temperature over the study period 72.3°F, humidity 40.5%) and an eye hospital (mean temperature 57.4°F, humidity 48%), the Schirmer test was consistently lower in the drier and warmer rheumatic hospital setting.

The Schirmer test was also used by Muzi et al. (1998) for the assessment of objective ocular and respiratory changes in complaint building employees. Average values of Schirmer tests were not significantly different in workers in a building with a high prevalence of sick building complaints compared with workers in three non-complaint office buildings (21.13 ± 8.71 mm versus 21.02 ± 7.36 mm).

Symptom Validation

An objective measure of eye irritation would be most useful if it correlates with subjective sensations of discomfort, unless it can be shown to consistently precede subjective symptoms and thus serve as a preclinical marker, allowing intervention.

Several studies described in the preceding sections have evaluated the association between subjective symptoms and selected biomarkers. The findings of these studies are summarized in Table 26.2. One must keep in mind that all the studies are cross-sectional in nature, and thus proving a cause-and-effect relationship is not possible.

Eye redness did not correlate with subjective sensations of discomfort in studies by Kjaergaard and Pedersen (1989), Kjaergaard et al. (1993), or Kjaergaard and Brandt (1993). Moreover, symptoms preceded redness in the pollen study (Kjaergaard et al. 1990a), suggesting that the marker's usefulness may be limited. Similarly, the one study that assessed the correlation of self-reported irritation with the Schirmer I tear test (Muzi et al. 1998) failed to find such a positive association.

Other eye-irritation biomarkers showed somewhat mixed results. A decrease in tear film stability, measured as shortened BUT, was positively correlated with subjective sensations of discomfort in studies by Franck (1986), Kjaergaard et al. (1993), and Franck et al. (1993); however, no association was observed by Kjaergaard and Brandt (1993) or Muzi et al. (1998). Findings are also inconsistent with regard to the correlation between epithelial damage and symptoms. Franck (1986) and Kjaergaard et al. (1993) found a strong correlation, but the odds ratio reported by Franck et al. (1993) of 1.89 (95% CI 0.91–3.92) for the occurrence of subjective eye complaints when epithelium damage was present was not statistically significant. Moreover, Kjaergaard and Brandt (1993) did not find an association between objective assessment of epithelial damage and symptoms. Decreased foam in the outer canthus of the eye was found by Franck and Skov (1989) and Franck et al. (1993) to be associated with self-reported symptoms; however, no such association was observed by Kjaergaard and Brandt (1993). With regard to tear fluid cytology, increased PMN count was found to be a significant covariate to subjective eye irritation when stepwise covariate selection was performed in regression analysis (Kjaergaard and Pedersen 1989), but no correlation was observed in work conducted by Kjaergaard and Brandt (1993). Furthermore, although Rasmussen et al. (1995) observed significant exposure-related changes in tear

TABLE 26.2 Correlation of Eye Irritation Markers with Subjective Sensations

Study	Biomarkers	Symptom correlation?	Comment
Franck 1986	Tear film stability, epithelial damage	Yes	Both markers independently and significantly associated with self-reports
Franck and Skov 1989	Foam formation	Yes	Low foam formation significantly associated with symptoms in office population, not in control population
Kjaergaard and Pedersen 1989	Eye redness, tear fluid cytology	Partial	Association with symptoms for PMNs in tear fluid; no association observed for eye redness
Kjaergaard et al. 1990a	Eye redness	Partial	No association at lower pollen doses; subjective irritation occurred before eye redness
Kjaergaard et al. 1993	Eye redness, tear film stability, epithelial damage	Partial	No association for eye redness; positive correlation for combined score of BUT and epithelial damage; model with only BUT was also significant
Kjaergaard and Brandt 1993	Eye redness, tear fluid cytology, tear film stability, foam formation, epithelial damage	No	No associations found for any of the objective measures and subjective reports
Franck et al. 1993	Foam formation, tear film stability, epithelial damage	Yes	Objective measures were intercorrelated, but were independently and significantly associated with self-reported complaints
Rasmussen et al. 1995	Eye redness, tear fluid cytology, CO ₂ eye-provocation test	No	Neutral subjective sensations reported, although definite exposure-related changes in tear fluid cytology observed
Muzi et al. 1998	Tear film stability, Schirmer I tear test	No	No strong relationships between subjective reports and objective measures

fluid cytology, no adverse subjective sensations were reported. Some markers have not been assessed for validity, such as blinking frequency, impression cytology, and corneal lipid layer thickness. The CO₂ eye-provocation test cannot be validated against symptoms, since the procedure itself involves the induction of irritation.

From the preceding discussion, it would appear that from a validity standpoint, tear film stability, epithelial damage, foam formation, and tear fluid cytology show promise as useful objective measures of irritation.

26.4 METHODS FOR ASSESSING UPPER RESPIRATORY TRACT IRRITATION

A given chemical can have three different immediate effects on the respiratory tract (Vijayaraghavan et al. 1993). The chemical may act as a sensory irritant and thus affect the upper respiratory tract. In mice, this effect is characterized by a reflex pause prior to expiration, as discussed in more detail in Chap. 24. A chemical may also act on the conducting airways to cause bronchoconstriction, an effect quantified in mice by an increase in expiratory airflow at the midpoint of tidal volume. Effects at the alveolar level are manifested as an increase in the length of pause at the end of expiration.

Although lower respiratory tract responses have tended to dominate research on health effects from air pollution, there has recently been increased attention on the upper regions of the respiratory tract, including the nose and sinuses. This is largely due to the fact that the upper airway serves as an initial clearance site for inhaled pollutants, and that certain chemicals are deposited or absorbed to a greater degree in the nose than other substances. Thus, it would appear that upper respiratory responses may serve as the earliest adverse health effects resulting from exposure to some airborne chemicals (Cho et al. 1997).

Since sensory irritation is trigeminal nerve-mediated, pulmonary irritation, which is mediated by stimulation of vagal nerve endings, will not be considered here. As a result, methods to assess pulmonary function, such as spirometry or techniques to evaluate inflammatory processes occurring at the alveolar level, such as bronchoalveolar lavage, are not discussed. Methods for the assessment of upper respiratory tract irritation that will be considered in the following subsections include respiratory frequency; methods for assessment of nasal patency (degree of “stiffness”) including nasal volume, nasal resistance, nasal peak inspiratory flow, and rhinostereometry; nasal lavage; and alternative methods for assessment of nasal mucosa, including biopsies, smears, scrapings, secretion analysis, imprints, and brush samples. Where applicable, examples of the application of each method in controlled or observational settings are provided. “Symptom Validation,” near the end of Sec. 26.4, provides a discussion of the validity of these methods, where it has been evaluated.

Respiratory Frequency

As mentioned earlier, the characteristic change in respiratory frequency and pattern in mice has been used to develop an ASTM method for the assessment of the irritant response. In humans, respiratory frequency can be measured by using a mercury strain gauge strapped around the chest (Iregren et al. 1993). Resistance alterations are measured as oscillations on a graphic plotter. No information on the reproducibility or population variability of respiratory frequency has been reported; however, this parameter is expected to have high individual and population variability. Furthermore, its usefulness as a marker of irritation is somewhat questionable because of the level of cortical control with which humans can influence their respiration activity.

Perhaps because of these underlying limitations, this technique has not commonly been used in irritation studies. Iregren et al. (1993) reported no significant increase in respiratory frequency from the baseline condition of about 20 cycles per minute to that measured during exposure to 70 to 1400 mg/m³ *n*-butyl acetate. Similarly, Prah et al. (1993) exposed young, healthy males to a mixture of VOCs at 0, 12, and 24 ppm, and found that not only was frequency unaffected by exposure to VOCs, but it also increased with time in the chamber for both the exposed and the controls.

Methods of Assessment of Nasal Patency

Nasal patency, or the degree of “stuffiness” or mucosal swelling, can be expected to be relevant in the context of sensory irritation. Patency has been objectively assessed by a number of techniques; however, its use has largely been in clinical settings and its application to studies of sensory irritation has not been widespread.

Nasal patency can be objectively assessed through the evaluation of nasal airway resistance, nasal peak inspiratory flow, and nasal volume. These three parameters are of interest in the context of irritation because of their partial regulation by the expansion and constriction of nasal blood vessels, mediated by both sympathetic and parasympathetic nerves as well as by circulating adrenaline (Lundqvist et al. 1992). During neurogenic inflammation, there is an acute increase in vascular permeability, vasodilatation, and increase in blood flow (Nielsen 1991). In addition, changes in the thickness of the nasal mucosa could lead to changes in nasal volume, resistance, and peak inspiratory flow. Filtration of pollutants is mediated by changing nasal geometry, and thus changes in nasal airway resistance at specific locations may alter the ability of the nose to modify inspired air (Willes et al. 1992).

Specific techniques used to evaluate the physiological parameters of nasal airway resistance and peak inspiratory flow, and the anatomical parameters of nasal volume and mucosal swelling, are discussed below.

Nasal Airway Resistance. Nasal airway resistance (NAR) can be assessed through rhinomanometry or whole-body plethysmography. The former technique involves the measurement of the pressure drop across the nasal cavity and airflow through the nose, with calculation of nasal resistance as pressure divided by flow. More specifically, in posterior rhinomanometry, pressure values are obtained by placing probes in the mouth, while in anterior rhinomanometry, the device is situated in the nasal vestibule (Gleeson et al. 1986). A shortcoming of both rhinomanometric techniques is a failure to result in a satisfactory correlation with subjective perception of stuffiness. In addition, the technique is technically somewhat difficult to apply, and some subjects are not able to carry out the necessary maneuvers (Hilberg et al. 1989). In the plethysmographic method, box pressure and differential pressures are measured while the subject pants through a pneumotachograph (Rasmussen et al. 1995). No information on the reproducibility or population variability of NAR has been reported.

Rhinomanometry has been used in several controlled exposure studies. Willes et al. (1992) used posterior rhinomanometry to assess the effect of exposure to sidestream tobacco smoke containing 45 ppm carbon monoxide for 15 minutes. Sidestream tobacco smoke is that portion of tobacco smoke that is produced by the burning end of a cigarette while not actively puffed. The mean postexposure NAR value for the 18 exposed subjects was 4.49 ± 0.6 cmH₂O/(L·s) versus a baseline value of 2.86 ± 0.2 cmH₂O/(L·s) ($p < 0.05$), indicating a significant increase in resistance in response to tobacco smoke exposure.

Anterior rhinomanometry was used by Lundqvist et al. (1992) to evaluate the effect of a 15-minute exposure to 75 mg/m³ diethylamine on acute nasal responses. Results indicated no significant difference in nasal resistance following exposure.

Rasmussen et al. (1995) used the plethysmographic method to measure airway resistance during exposures to nitrous acid. No difference was observed between exposure levels; however, 11 percent and 12.8 percent increases in resistance were noted following exercise at 77 and 395 ppb nitrous acid, respectively. Clean air exposure resulted in a 2 percent increase in resistance following exercise.

Nasal Peak Inspiratory Flow. Nasal peak inspiratory flow (PIF) is an easily performed, nontraumatic, and inexpensive method to assess changes in airflow (Cho et al. 1997). Peak inspiratory flow measurements have been compared with other parameters of airflow, including rhinomanometry and peak expiratory flow, and strong correlations have consistently been demonstrated (Jones et al. 1991, Gleeson et al. 1986). In addition, a strong relationship was shown for nasal peak inspiratory flow and subjective sensations of nasal patency (Fairley et al. 1993).

The measurement of nasal PIF is conducted by using a portable microspirometer (Cho et al. 1997) or a peak nasal inspiratory flow meter (Gleeson et al. 1986; Jones et al. 1991, Fairley et al. 1993). For both methods, the subject inhaled as hard and fast as possible through the flow meter or nasal mask, and a maximum of three separate measurements was taken to minimize the effort-dependent variation in this parameter.

Cho et al. (1997) performed serial measurements of nasal peak inspiratory flow to assess the reproducibility of this method, and found intraclass correlation coefficients of 0.78 and 0.89, depending on the measurement method. These coefficients refer to the proportion of between-subject variability among the total variability; thus, a higher coefficient indicates that the measurement on a given individual is similar at each measurement occasion. The authors concluded that good reproducibility existed and that nasal peak inspiratory flow could be used in epidemiologic studies evaluating the effects of air pollutant exposure on the upper airways.

The only irritation study incorporating this marker was conducted by Willes et al. (1992) to evaluate sidestream tobacco smoke exposure. A significant decrease in peak flow was noted, with a preexposure mean value of 2.74 ± 0.3 L/s and a postexposure value of 2.14 ± 0.3 L/s.

Nasal Volume. Nasal volume can be assessed through the instillation of saline solution into the nasal cavities of subjects and subsequent collection of drained fluid (Gleeson et al. 1986). Rhinomanometry can also be used to evaluate nasal volume; however, more recently the technique of acoustic rhinometry has been used to evaluate this parameter (Hilberg et al. 1989). This method is based on acoustic reflection and evaluates nasal cavity cross-sectional area as a function of distance from the nostril. The volume of the nasal cavity can then be calculated following integration. Advantages of this method over rhinomanometry include the low level of cooperation required from the subject and its usefulness during conditions of complete nasal occlusion. In the study by Hilberg et al. (1989), the nasal cavity volumes of human cadavers, normal subjects, and patients with nasal cavity afflictions were determined by acoustic rhinometry, anterior rhinomanometry, computerized tomography (CT) scans, and a specially developed water displacement method. Results indicated that the acoustic rhinometric measurements were highly correlated with those from CT scanning ($r = 0.94$) and water displacement ($r = 0.96$). No information on the reproducibility or population variability of nasal volume has been reported.

A number of controlled exposure studies have incorporated acoustic rhinometry. The method was used by Lundqvist et al. (1992) to assess the effects of diethylamine exposure; however, there was no difference in nasal volume between baseline and postexposure measurements. Similarly, the use of acoustic rhinometry by Rasmussen et al. (1995) to assess nitric acid exposure revealed no statistical evidence of an exposure effect. Mølhave et al. (1993a) reported no effect on nasal volume following exposure to 1.7, 5, and 15 mg/m³ of four different mixtures of VOCs.

Exposure to a mixture of 22 VOCs in conjunction with varied air temperature was carried out by Mølhave et al. (1993b) and nasal cross-sectional area was assessed by acoustic rhinometry. VOC exposure decreased the minimum cross-sectional area by about 8 percent ($p < 0.05$), although nasal volume differences between control (0 mg/m³ VOC) and exposure conditions were not significant. Warm air exposures increased both cross-sectional area and nasal volume, while colder air decreased these parameters. In addition, interactions between VOC exposure and temperature were observed that would predict a lower volume during combined thermal and VOC exposure than during either of these exposures alone.

An observational study was conducted by Walinder et al. (1998) to assess the effect of ventilation type and rates in schools on objective nasal measures, including nasal volume, which was measured by acoustic rhinometry. A lower air exchange ratio was associated with reduced nasal volume in a multivariate analysis with room temperature and ventilation type. In a similar fashion, a bivariate analysis as well as a multivariate analysis controlling for possible confounders revealed that subjects in schools with mechanical ventilation had lower nasal volumes.

Nasal Mucosal Swelling. A technique known as rhinostereometry has been used to evaluate mucosal swelling (Falk et al. 1993) in individuals exposed to formaldehyde. Rhinostereometry is an optical method of measurement which utilizes a microscope mounted on a table and fixed to a frame. The microscope is movable in three perpendicular directions, and a horizontally located scale is inserted in the ocular. The person to be examined is placed in a reproducible position with an individually adapted tooth splint that is fixed to the frame, and the position of the medial surface of the inferior turbinate is measured through the ocular. Falk et al. reported that the accuracy of the method is 0.18 mm; however, no information on the reproducibility or population variability of mucosal swelling has been reported.

Falk et al.'s study consisted of exposing seven nonallergic individuals with a history of nasal distress in their homes to formaldehyde concentrations of 0.021, 0.028, 0.073, and 0.174 mg/m³. Six controls reporting no nasal complaints were exposed to similar concentrations. Results indicated that the symptomatic individuals showed a significant increase in mucosal swelling at the two highest formaldehyde concentrations; however, controls failed to show any increase.

Nasal Lavage

Nasal lavage (NAL) is an inexpensive and relatively noninvasive procedure which is performed by instilling warm physiologic saline fluid into each nasal cavity, holding for 10 seconds, and then either forcibly expelling or passively draining into a sterile collection cup (Koren and Devlin 1992). Collected fluid can then be centrifuged to separate cells, which can then be counted, and various biochemical assessments can be performed on the supernatant. Cell viability can be ascertained by staining, and neutrophils can be determined from differential counts obtained from stained cytospin preparations.

Advantages of nasal lavage include the easy accessibility of the mucosal surface for challenge and sampling, the repeatability of the test, the demonstration of measurable mediators in cases where symptoms have occurred, the ability to measure effects with a substantially varying time course, the importance of the nose in sick building syndrome, and the ability to perform the test in other species and extrapolate to humans (Koren and Devlin 1992).

Nasal lavage fluid contains numerous biomarkers, both cellular and soluble, of inflammation and allergy (Koren and Devlin 1992). Polymorphonuclear neutrophils serve as the predominant cell in the acute inflammatory response and thus have been applied extensively to investigations of air pollution-induced acute inflammation.

Eosinophils and mast cells indicate an allergic response. Protein and albumin indicate increased permeability of vasculature and thus an inflammatory response. Histamine, tryptase, *N*- α -*p*-tosyl-*L*-arginine methyl ester (TAME) esterase activity, serotonin, kinins, and prostaglandin D₂ (PGD₂) are indicators of mast cell degranulation and allergic response. The presence of IgE also indicates an allergic response. Inflammatory responses are indicated by the presence of eicosanoids, C5a, C3a, antioxidants (e.g., uric acid), kallikrein, kinins, substance P, and cytokines. Urokinase-type plasminogen activator (U-PA) activity, prostaglandin E₂, and leukotrienes C₄, D₄, and E₄ have also been measured (Graham and Koren 1990).

Both interindividual (Graham et al. 1988) and intraindividual variability (Hauser et al. 1994) of PMN counts in nasal lavage have been evaluated on unexposed subjects. Assessment of interindividual variability over a period of 2 years demonstrated a large range of cell counts, ranging from zero PMNs to over 100,000 cells/mL of recovered lavage fluid. Intraindividual variability was smaller, with correlation coefficients of reliability *R* of 0.88 and 0.67 for trials completed 72 hours and 48 hours after a baseline lavage, respectively. The lower *R* obtained after 48 hours was hypothesized to be a result of more washout of cells.

Nasal lavage has been used in a number of settings to assess the response to air pollutants. Experimental studies, in particular, have utilized this method to compare baseline values with postexposure measurements. Graham et al. (1988) collected background neutrophil counts from 200 unexposed subjects and then documented the inflammatory response in PMN counts following exposure to rhinovirus. To determine if ozone could induce a similar response, subjects were exposed to either filtered air or 0.5 ppm ozone for 4 hours on 2 consecutive days. PMN counts in the ozone-exposed group were increased 3.5-, 6.5-, and 3.9-fold compared with the control group at the end of the first day's exposure, prior to the second day of exposure, and following the second day of exposure, respectively, indicating that ozone exposure can induce an inflammatory response. Response to ozone was later assessed by Koren et al. (1990), who measured PMNs in nasal lavage fluid from volunteers exposed to 0.4 ppm ozone for 2 hours. Almost 8-fold increases in PMN counts were reported immediately postexposure (*p* < 0.05). These increases were still detectable 18 hours postexposure. The study also showed an increase in tryptase, released by mast cells, immediately after exposure, and albumin levels 18 hours later. Other markers of acute inflammation, including PGE₂, C3a, and U-PA, as well as uric acid, were not significantly elevated in nasal lavage fluid following exposure.

Koren et al. (1992) assessed nasal responses to exposure to a mixture of 25 VOCs in "normal" subjects, i.e., those without a history of allergies. A total VOC concentration of 25 mg/m³ was used, and the VOCs selected were deemed to be representative of those present in synthetic materials typical of homes and offices. Results indicated a statistically significant increase in PMN influx into the nasal passages both immediately following a 4-hour exposure and 18 hours later. However, Prah et al. (1994) conducted nasal lavage on volunteers exposed to 1.39 ppm MTBE and clean air in separate sessions, and did not observe any evidence of inflammation either immediately postexposure or 20 hours later. Biomarkers measured in lavage fluid included neutrophils, interleukin-8 (IL-8), albumin, and prostaglandin D₂. Similarly, Rasmussen et al. (1995) reported no effect of nitrous acid exposure on PMN counts.

Nasal lavage has been used in several occupational settings. Ahman et al. (1995) measured a variety of inflammatory markers, including PMNs, albumin, tryptase, and eosinophil cationic protein (ECP), in lavage fluid from industrial arts teachers exposed to wood dust and other irritants. Although none were elevated in the teachers as compared with controls, albumin concentrations were higher in subjects reporting nasal stuffiness. Also, a relationship between the proportion of PMNs and the number of classes per week was reported, indicating that wood dust may have inflammatory effects on the nasal mucosa.

The irritancy of fuel-oil ash, and in particular, vanadium dust, was evaluated by using nasal lavage on boilermakers and utility workers (Hauser et al. 1995). A baseline lavage was conducted after a lengthy period away from work (average of 114 days). After 3 days of work, the lavage was repeated, and the PMN counts for the two samples were compared. In smokers, an increased PMN count was not observed, while in nonsmokers, a significant increase was noted. High variability in cell counts was observed in both groups, and the study was unable to identify a significant dose-response relationship between cell counts and either particulate or vanadium dust exposure.

The one observational study using nasal lavage in a nonindustrial setting was conducted by Walinder et al. (1998) to investigate the effect of ventilation type and rate in schools on a variety of inflammatory indicators, including eosinophil cationic protein, myeloperoxidase (MPO), lysozyme, and albumin. In multivariate analyses controlling for possible confounders as well as type/rate of ventilation and room temperature, increased levels of ECP, and lysozyme in nasal lavage fluid were associated with lower air exchange rates and with the use of mechanical ventilation based on dilution. Lower levels of inflammatory markers were noted in subjects working in a school with mechanical displacement ventilation than in personnel in naturally ventilated schools.

Alternative Methods for Assessment of Airway Mucosa

Several other methods for cellular and biochemical analysis of airway cells have been developed. Although many of these methods have been applied mainly in the context of clinical hypersensitivity conditions such as asthma, it is possible that they could be used to assess irritation resulting from chemical stimuli.

Mucosal biopsy specimens have been studied (Gomez et al. 1986); however, biopsies can be repeated only a limited number of times, and the biopsy procedure itself can introduce an inflammatory reaction. Bleeding is also a potential risk, particularly if the mucosa is already inflamed. Topical or submucosal anaesthesia is required, which may introduce artifacts. Furthermore, since the nasal epithelial lining changes from squamous epithelium in the anterior parts to ciliated, columnar, respiratory epithelium in the posterior parts of the nasal cavities, it is important to select the biopsy site carefully when attempting to make either intra- or interindividual comparisons (Pipkorn and Karlsson 1988).

A smear technique, involving the movement of a cotton wool swab over the nasal mucosa from the anterior to the posterior part of the nasal cavity, has been used for morphological assessments (Hansel 1953). The method apparently has shortcomings related to the very small sample of cells usually obtained and to procedure standardization (Pipkorn and Karlsson 1988); however, it can be used successfully to determine the presence or absence of particular cell types despite its limitations for quantitative use.

A sharp curette has been used to obtain mucosal scrapings (Okuda and Otsuka 1977), which has the significant advantage of being able to directly investigate specific sites on the mucosa. The cell harvest typically contains mainly chunks of epithelial lining which permit differential counting of epithelial cells and evaluation of other cell populations (Pipkorn and Karlsson 1988). The scraping can be repeated several times and anesthesia is not required.

Secretions obtained through blowing of the nose can be analyzed following fixation on glass slides (Hastie et al. 1979). Since the cells are only those contained within the secretions themselves, they reflect a different cell population than that collected in either the smear or scraping techniques described above. Disadvantages are that the area from which the collected cells originate is unknown; the cell yield is highly variable and may contain only discarded epithelial cells; and sometimes any yield at all is not possible (Pipkorn and Karlsson 1988).

Mucosal imprints have been used in an effort to standardize the area from which the cytological specimen is collected (Pipkorn and Karlsson 1988). Small, thin, plastic strips coated

with 1 percent albumin to produce a sticky surface are introduced into the nose and gently pressed onto the mucosal surface (Pipkorn and Enerback 1984). The strip is then stained and examined. This has been shown to be a useful method in the evaluation of less numerous cells; however, a disadvantage is that a significant amount of mucous in nasal secretions remains on the slide.

Another method involves obtaining mucosal samples through the rotation of a small nylon brush over the epithelium and then soaking and shaking the brush in a balanced saline solution (Pipkorn et al. 1988). This method appears to result in a higher proportion of epithelial cells and monocytes than through nasal lavage. Since, in contrast to nasal lavage, the brush method obtains cells from the deeper epithelial layers, it likely more accurately represents intraepithelial inflammatory events. Pipkorn et al. also report a strong correlation between histamine concentrations and mast cell counts from harvested cells with this method.

Symptom Validation

As with the eye irritation markers discussed previously, a useful biomarker of upper respiratory tract effects should correlate well with subjective sensations of irritation or nasal patency. The few studies attempting to determine the correlation of subjective respiratory tract irritation and objective measures are summarized in Table 26.3. Of the four studies, two (Willes et al. 1992 and Lundqvist et al. 1992) were controlled chamber exposures in which assessment of the association between symptoms and objective manifestations of irritation/patency was secondary to that of the exposure effect. Even in these controlled settings, a positive association does not prove that the objective measures are related to the symptoms, although the evidence is certainly more convincing than in a cross-sectional study.

Since so few validation studies have been completed, there is little opportunity for corroboration of results. Willes et al. measured changes in nasal airway resistance in response to tobacco smoke exposure via rhinomanometry. They reported that rhinitis symptoms were correlated with this objective measure for most subjects. However, work by Lundqvist et al. (1993) indicated that although diethylamine exposure produced sensory effects, no increase in nasal airway resistance was observed. Furthermore, exposure-related changes in NAR were observed in Rasmussen et al.'s (1995) nitrous acid study, but no subjective irritation was reported.

Nasal peak inspiratory flow rates were found to be strongly correlated both with nasal patency score in a longitudinal study conducted by Fairley et al. (1993) and with rhinitis symptoms in the tobacco exposure study by Willes et al. (1992). Lundqvist et al. (1992) did not find a correlation between nasal volume, as measured by acoustic rhinometry, and sensory effects. Only one study attempted to relate nasal lavage findings with nasal patency self-reports (Ahman et al. 1995). The study reported that subjects reporting nasal stuffiness had higher albumin concentrations in nasal lavage fluid; however, levels of other inflammatory markers, including PMNs, tryptase, and eosinophil cationic protein (ECP) were uncorrelated with symptoms. Other methods such as respiratory frequency, nasal mucosal swelling, and mucosal alterations, have not been assessed with respect to their correlation with subjective effects.

26.5 APPLICATION TO IAQ FIELD STUDIES

Tables 26.4 and 26.5 provide summaries of experimental and epidemiological studies, respectively, that have incorporated biomarkers of eye or upper respiratory tract irritation.

TABLE 26.3 Correlation of Upper Respiratory Tract Irritation Markers with Subjective Sensations

Study	Biomarkers	Symptom correlation?	Comments
Willes et al. 1992	Nasal airway resistance via rhinomanometry, nasal peak inspiratory flow	Yes	Rhinitis symptoms correlated with objective measures for most subjects
Lundqvist et al. 1992	Nasal airway resistance via rhinomanometry, nasal volume via acoustic rhinometry	No	Sensory effects noted on exposure to diethylamine, but no objective manifestations
Fairley et al. 1993	Nasal peak inspiratory flow	Yes	Longitudinal study, with strong correlation between nasal patency score and inspiratory flow rates
Rasmussen et al. 1995	Nasal airway resistance via plethysmography, nasal volume via acoustic rhinometry, nasal lavage	No	Neutral subjective sensations reported, although exposure-related changes in nasal airway resistance observed
Ahman et al. 1995	Nasal lavage, with analysis of PMNs and several inflammatory markers	Partial	Higher albumin concentrations in subjects reporting nasal stuffiness; no association with symptoms for other markers

The studies in these tables have been described previously in the text, and do not include those investigations conducted for development or validation purposes only. The majority of the epidemiological studies were conducted in nonindustrial IAQ settings, with several carried out in occupational settings. In general, many of the objective measures used to assess IAQ in office buildings have shown positive associations between the biomarker and certain environmental conditions, including complaint building status, temperature, and humidity.

Some discussion of the overall usefulness of each biomarker examined would be helpful for designing IAQ field studies. A rating scheme was developed (Table 26.6) that considered a total of six attributes believed to be important factors in the selection of specific methods for field settings. The factors included: (1) symptom validation, discussed in Secs. 26.3 and 26.4; (2) reproducibility; (3) invasiveness/discomfort; (4) technical difficulty; (5) equipment; and (6) use in the literature. Each of these factors was scored on a scale of 1 to 3. Factors 3, 4, and 5 were combined by arithmetic averaging to produce a “field feasibility index.”

For symptom validation, a score of 1 indicated that the method was either as yet not validated, or that no association between symptoms and the marker had largely been reported in the literature. A score of 2 was indicative of mixed results, while 3 was given when validation studies had on the whole found correlations between symptoms and the marker. For reproducibility, a biomarker received a score of 1 if no information regarding this attribute was available, and 2 if some information had been reported. The maximum score of 3 was given if reproducibility had been assessed, and was found to be reasonable.

TABLE 26.4 Summary of Epidemiological Studies of Irritation Incorporating Biomarkers

Study	Setting	Exposures	Biomarkers	Summary of findings
Ahmen et al. 1995	Occupational	Wood dust and other irritants	Nasal lavage	No exposure effect noted for PMNs and other inflammatory markers; albumin concentrations higher in persons reporting nasal stuffiness; PMN counts associated with length of time of exposure
Carrer et al. 1996	IAQ (office)	VOCs	Blinking frequency Tear film stability	No correlation for volatile organic compounds (VOCs) No significant reduction in workers with higher VOC exposure.
Franck 1986	IAQ (office buildings)	Indoor air	Tear film stability Epithelial damage	Significant association between subjective eye irritation and unstable tear film Significant association between subjective eye irritation and epithelial damage
Franck and Skov 1989	IAQ (office buildings)	Indoor air	Foam formation	Foam prevalence lower in office workers compared to controls
Franck 1991	IAQ (office buildings)	Indoor air	Corneal lipid layer thickness	Lipid layer thinner in office workers compared with controls
Franck et al. 1993	IAQ (complaint office buildings)	Indoor air	Tear film stability Foam formation Epithelial damage	Shorter BUT in workers in buildings with high SBS prevalence compared with buildings with lower prevalences or the general population Less foam in office workers (from both high and low SBS buildings) compared with general population More damage in office workers (from both high and low SBS buildings) compared with general population
Franck and Boge 1993	IAQ (office buildings)	Indoor air	Tear film stability Epithelial damage	Significant correlations between BUT at initial investigation and again at two later investigations Significant correlations between degree of damage at initial investigation and again at two later investigations
Hauser et al. 1995	Occupational	Fuel-oil ash	Nasal lavage	No dose-response relationship identified for PMN counts

Kjaergaard and Pedersen 1989	Occupational	Tobacco dust	Eye redness Tear fluid cytology	Increased prevalence of redness with increasing exposure Workers had higher cell counts before and after exposure compared with controls; in workers, some cell types increased during the work day; dose-response relationship observed for cuboidal epithelial cells
Kjaergaard and Brandt 1993	IAQ (complaint offices)	Dust sedimentation rate (DSR), temperature, time spent at VDT	Eye redness Tear fluid cytology Tear film stability Foam formation Epithelial damage	No difference between complaint and reference buildings; no correlation with exposure parameters Increased PMNs associated with increased DSR and increased VDT work Increased BUT associated with increasing DSR Increased foam associated with increased DSR Increased damage associated with increasing DSR
Kjaergaard et al. 1993	IAQ (complaint library)	Indoor air	Eye redness Tear film stability Epithelial damage	No difference between library staff members and controls BUT reduced in library staff More damage in library staff
Muzi et al. 1998	IAQ (complaint office building)	Indoor air	Tear film stability Schirmer I tear test	BUT reduced in employees in complaint building compared with controls No difference between complaint and control buildings
Walinder et al. 1998	IAQ (schools)	Ventilation rate	Nasal volume via acoustic rhinometry Nasal lavage	Reduced nasal volumes in schools with lower air exchange rates and those with mechanical ventilation Higher levels of eosinophil cationic protein (ECP) and lysozyme in lavage fluid from persons in schools with lower air exchange rates and those with mechanical ventilation
Williamson and Allison 1967	IAQ (hospitals)	Temperature, humidity	Schirmer I tear test	Lower test in drier and warmer rheumatic hospital setting compared with eye hospital

TABLE 26.5 Summary of Experimental Studies of Irritation Incorporating Biomarkers

Study	Exposures*	Biomarkers	Summary of findings
Basu et al. 1978	Cigarette smoke	Tear film stability	BUT shorter after smoke exposures
Falk et al. 1993	Formaldehyde	Nasal mucosal swelling via rhinostereometry	Increased swelling in persons with history of nasal distress at two highest concentrations; no such increase in control (asymptomatic) persons
Graham et al. 1988	Ozone	Nasal lavage	Increased PMN counts in exposed group compared to controls
Iregren et al. 1993	<i>n</i> -butyl acetate	Eye redness Blinking frequency Tear film stability Epithelial damage Corneal lipid layer thickness Respiratory frequency	No exposure effect observed Increased at highest exposure level near the end of the exposure time No exposure effect observed No exposure effect observed No exposure effect observed No exposure effect observed
Johnsen et al. 1991	4 building materials	Tear film quality index (comprising foam, corneal lipid layer thickness, tear film stability, and epithelial damage)	Tear film quality index lower for exposure to building materials compared to clean air
Kjaergaard et al. 1989	<i>n</i> -decane	Eye redness Tear film stability Tear fluid cytology	No exposure effect observed Decreased BUT with increasing exposure Dose-related increase in PMNs
Kjaergaard et al. 1990a	Pollen in hayfever sufferers	Eye redness	Good correlation of redness with reports of irritation at high pollen doses but decreased redness at lower doses; reports of irritation occurred before redness appeared
Koren et al. 1990	Ozone	Nasal lavage	Increased PMN counts postexposure; also increased tryptase and albumin; other inflammatory markers unaffected by exposure

Koren et al. 1992	VOC mixture	Nasal lavage	Increased PMN counts immediately postexposure and 18 hours later
Lundqvist et al. 1992	Diethylamine	Nasal airway resistance Nasal volume via acoustic rhinometry	No exposure effect observed No exposure effect observed
Mølhave et al. 1993a	VOC mixture, temperature	Tear film stability Tear fluid cytology Nasal volume and cross-sectional area via acoustic rhinometry	No exposure effect observed No exposure effect observed Decreased with decreasing temperature and increasing VOC exposure
Prah et al. 1993	VOC mixture	Respiratory frequency Blinking frequency	Unaffected by exposure Increased with exposure
Prah et al. 1994	Methyl <i>n</i> -butyl ether	Eye redness Tear film stability Impression cytology Nasal lavage	No exposure effect observed No exposure effect observed No exposure effect observed No exposure effect observed
Rasmussen et al. 1995	Nitrous acid	Eye redness Tear fluid cytology CO ₂ -eye provocation Nasal airway resistance	Dose-dependent increase in redness suggested but not significant Dose-related increases in PMNs and squamous epithelial cells Dose-dependent decrease in CO ₂ threshold suggested but not significant Increased resistance following exercise during exposure
Weber-Tschopp et al. 1977	Formaldehyde	Nasal volume Nasal lavage Blinking frequency	No exposure effect observed No exposure effect observed Increased with increasing exposure concentration
Willes et al. 1992	Tobacco smoke	Nasal airway resistance Nasal peak inspiratory flow	Increased with exposure Decreased with exposure

*All studies completed in exposure chambers, with the exception of Kjærgaard et al. 1990, which was conducted with eye instillation.

TABLE 26.6 Biologic Marker Evaluation Scheme*

Biomarker	A Symptom validation	B Reproducibility	C Invasiveness/ discomfort	D Technical difficulty	E Equipment	F Field feasibility index†	G Use in literature	H Total score
Eye redness	1	3	3	2	2	2.3	3	9.3
Blinking frequency	1	1	2-3‡	2-3‡	2-3‡	2-3‡	2	6-7‡
Tear film stability	3	3	2	2	2	2	3	11
Foam formation	2	1	3	2	2	2.3	3	8.3
Epithelium damage	3	1	2	2	2	2	3	9
Tear fluid cytology	2	1	3	3	3	3	3	9
Impression cytology	1	1	2	2	2	2	1	5
Corneal lipid layer thickness	1	1	3	2	2	2.3	2	6.3
CO ₂ eye-provocation test	1	1	1	2	1	1.3	2	5.3
Schirmer I tear test	1	1	3	3	3	3	1	6
Respiratory frequency	1	1	3	3	3	3	1	6
Nasal airway resistance	2	1	1	1	1	1	2	6
Nasal peak inspiratory flow	3	3	3	2	2	2.3	2	10.3
Nasal volume	1	1	2	2	2	2	2	6
Nasal mucosal swelling	1	1	2	2	2	2	2	6
Nasal lavage	2	3	2	3	3	2.7	3	10.7
Mucosal assessment	1	1	1	2	2	1.7	1	4.7

*Scoring:

Symptom validation: 1 = not validated, or negative correlations with symptoms and marker reported; 2 = mixed results in validation studies; 3 = largely positive correlations with symptoms and marker reported.

Reproducibility: 1 = reproducibility not evaluated; 2 = some assessment completed; 3 = reproducibility well characterized.

Invasiveness/discomfort: 1 = invasive or uncomfortable; 2 = somewhat invasive; 3 = minimally invasive with no discomfort.

Technical difficulty: 1 = technically difficult; 2 = somewhat difficult; 3 = simple.

Equipment: 1 = extensive, bulky, or specialized equipment required in the field; 2 = moderate equipment requirements; 3 = little/simple equipment required.

Use in literature: 1 = rarely appears in literature, not used in irritation studies; 2 = used on occasion; 3 = method appears often in literature.

†Field feasibility index = (C + D + E)/3

‡Depends on method.

The field feasibility index was calculated as the average of three separate scores, each on a scale of 1 to 3. The *invasiveness/discomfort* factor was scored as 1 if the procedure was invasive and/or uncomfortable, 2 if the procedure was slightly invasive and/or uncomfortable, and 3 if the procedure was noninvasive and associated with no discomfort. The *technical difficulty* factor reflects the degree of difficulty the procedure poses to the subject and/or the technician, either in terms of the subject carrying out the necessary maneuvers, or the technician operating the instrumentation. This factor was scored as 1 for difficult procedures, 2 for somewhat difficult procedures, and 3 for simple procedures. Finally, the *equipment* factor indicates the equipment intensiveness of the procedure. Methods requiring specialized, extensive, or bulky equipment were scored as 1, while those with moderate equipment requirements were scored as 2. Procedures that require only minimal or simple equipment to carry out received a score of 3.

Finally, the amount of use the method had received in the literature was considered in the total biomarker score. If a procedure was minimally developed and rarely appeared in the literature, it received a score of 1. A somewhat developed method was scored as 2, while a method that was relatively common was scored as 3.

From this scoring scheme, the most appropriate markers of eye irritation for use in field studies appear to be tear film stability (11), epithelium damage (9), tear fluid cytology (9), and foam formation (8.3). Although eye redness received a score of 9.3, its usefulness is questionable because of the consistent lack of symptom validation. For assessment of upper respiratory tract irritation, nasal peak inspiratory flow (10.3) and nasal lavage (10.7) received the highest scores. Note that the respiratory tract biomarkers generally scored below the eye irritation markers, largely because of their low symptom validation and field feasibility scores.

26.6 SUMMARY

The development of reliable, objective measures of irritation in humans would complement the current animal bioassay method and provide a useful epidemiological tool in both indoor and occupational settings. Several markers appear to show promise as indicators of sensory irritation, particularly in the case of eye irritation assessment. The objective ocular manifestations of irritation have generally been more thoroughly studied than those of the upper respiratory tract, and have in some cases been validated with symptoms. Some markers of respiratory tract irritation have also been studied extensively; however, validation with irritation symptoms has on the whole not been conducted.

Further research is needed to ensure that objective measures represent physiological manifestations of sensory irritation. Also, additional evaluation of the reproducibility and both intra- and interindividual variability of these methods is warranted. Controlled chamber experiments with concurrent subjective ratings and measurement of objective parameters would allow a clearer determination of biomarker validity. And finally, although cross-sectional investigations provide useful information, causal relationships are difficult to prove in such settings, and therefore longitudinal studies should be conducted wherever possible.

27.1 INTRODUCTION

In the setting of a sick building, sometimes sporadically, there are some occupants who report extreme sensitivity to a host of exposures, ranging from new carpet and paint odors to cleaning agents and offgassing from office equipment. Because these persons are in the minority, their complaints tend to be ignored. They suffer from an enigmatic condition known as multiple chemical sensitivity, or multiple chemical intolerance.

These individuals report multiple symptoms, including severe headaches, fatigue, muscle pain, memory and concentration difficulties, various skin conditions, shortness of breath, and a variety of gastrointestinal problems, which they report being triggered by common, low-level chemical exposures and various foods and drugs. Some have been diagnosed with chronic fatigue syndrome or fibromyalgia. There is growing concern among scientists that indoor air contaminants may not only trigger their symptoms, but may cause the illness itself. These individuals are not to be ignored. They are often the key to understanding indoor air problems in a building.

Susceptibility to indoor air contaminants varies greatly from person to person, perhaps by several orders of magnitude. Building managers and indoor air quality (IAQ) specialists need to be on the lookout for these “canaries,” individuals who may be more susceptible to low-level air pollutants, for a variety of reasons. First, their health concerns tend to drive the building investigation process. Until they feel better or until the building is ruled out as a cause for their symptoms, air quality concerns will fester, as other occupants tend to regard these individuals as barometers for the building’s health. Second, these individuals

can often help locate problem sources that are not identifiable by air sampling or other testing methods. Third, addressing sensitive individuals' concerns openly and honestly makes good risk management sense and will help prevent compensation claims, disability disputes, and litigation.

These chemically intolerant individuals report disabling symptoms when exposed to myriad substances, e.g., fragrances, tobacco smoke, diesel exhaust, as well as particular foods, medications, alcoholic beverages, and caffeine—intolerances that sometimes, but not always, predate their difficulties in the building by years, even decades. The chemically intolerant are showing up in increasing numbers in the waiting rooms of occupational/environmental medicine doctors and allergists, yet little is currently known about the underlying disease that afflicts them.

One thing we do know is that chemically intolerant people appear in a variety of settings, ranging from manufacturing plants, offices, schools, and farms, to hospitals, court-houses, and casinos. Those affected report multisystem symptoms and new-onset chemical, food, and drug intolerances that never bothered them before their “initiating” exposure event. Scientists have described this breakdown in tolerance, referred to by some as *toxicant-induced loss of tolerance* (TILT), among different demographic groups in more than a dozen countries. Research in this area is in its infancy. Nevertheless, there remains the potential for liability if, in the future, indoor air exposures are shown to initiate TILT, resulting in long-term disability.

Investigators responding to IAQ complaints must consider all possible etiologies, weighing the relative contributions of contaminant sources, HVAC system deficiencies, occupant load, and physical factors (temperature, humidity, etc.), and, no less importantly, the susceptibility of the occupants themselves. Chemically intolerant individuals represent an estimated 2 to 6 percent of the population. They spend time in office buildings, schools, homes, and public buildings. To a great extent, their needs will dictate the design, construction, and operation of twenty-first century indoor environments. This has already begun. The Canada Mortgage and Housing Corporation (CMHC) has sponsored several prototype residential housing units for the chemically intolerant, educating and encouraging Canadian builders to adopt practical approaches to protect this subset of the population.

27.2 HISTORICAL BACKGROUND

In the 1950s, an allergist named Theron Randolph described a phenomenon he called *chemical susceptibility* in a cosmetic saleswoman suffering from asthma, fatigue, irritability, depression, and intermittent loss of consciousness. Her symptoms seemed to flare whenever she was exposed to “man-made combustion products and derivatives of gas, oil, and coal” (Randolph 1962, Randolph and Moss 1980). Other physicians, noting similar problems in their patients and even themselves, allied with Randolph. In 1965, Randolph and his adherents broke away from the allergists' organizations and founded the Society for Clinical Ecology (renamed the American Academy of Environmental Medicine in 1984). Many clinical ecologists adopted various unorthodox diagnostic and treatment approaches, going well beyond Randolph's original teachings. Most, however, continued to employ his central diagnostic/therapeutic approach, i.e., trial avoidance of potential chemical and food incitants followed by judicious reexposure to determine which ones trigger symptoms. Position papers by several influential medical societies (American Academy of Allergy and Immunology 1981, 1986; American College of Physicians 1989; American Medical Association 1992) challenged the ecologists' claims. Over the past decade, there has been an outpouring of technical reports, concept papers, and hypotheses about this illness. People on all sides of the issue seem to think its prevalence is on the rise. Some physicians

and researchers attribute this surge of patients and interest to (1) increased synthetic organic chemical production and use since World War II (including pesticides), coupled with (2) decreased fresh air exchange indoors due to energy conservation efforts following the oil embargo of the mid-1970s. Others attribute it to increased media attention and public awareness of environmental exposures.

Recently, there has been a softening of positions taken against the illness (Ashford and Miller 1998, ACOEM 1999). Although concerns about unproved diagnostic and treatment practices continue, affected individuals are turning to board-certified occupational and environmental medicine physicians and toxicologists in universities. In 1987, Mark Cullen of Yale edited a collection of papers entitled *Workers With Multiple Chemical Sensitivities: An Overview*, offering a spectrum of authors' opinions on the illness (Cullen 1987). He recommended the name *multiple chemical sensitivity* (MCS), and offered the first of several proposed case definitions for it: "Multiple chemical sensitivity (MCS) is an acquired disorder characterized by recurrent symptoms, referable to multiple organ systems, occurring in response to demonstrable exposure to many chemically unrelated compounds at doses far below those established in the general population to cause harmful effects. No single widely accepted test of physiologic function can be shown to correlate with symptoms." The terms *multiple chemical sensitivity* and *environmental illness* now appear on the National Library of Medicine's bibliographical database, MEDLINE. While there is general agreement that an illness exists, and that these patients suffer, medical opinion concerning the nature and origin of the phenomenon remains polarized. At the debate's core is the question, "Is MCS the result of chemical exposures, psychological factors or some mix of these?" The mix might also vary from person to person. If chemical exposures can cause MCS, the repercussions for environmental policy, product liability, compensation, and medical treatment, will be monumental.

Canada was the first nation to examine this problem through its 1985 Thomson Report (Thomson 1985) and subsequent sponsorship of clinical studies. In the United States, the issue has been examined by several states (New Jersey, Maryland, and California) (Ashford and Miller 1989, Bascom 1989, Kreutzer et al. 1999), federal environmental agencies (ATSDR 1994, Fiedler and Kipen 1997a), the National Academy of Sciences (NRC 1992), and various professional organizations (AOEC 1992, ACS 1999). Proposed research strategies have evolved from these meetings (summarized in Ashford and Miller 1998), but few comprehensive or illuminating studies have been funded. Amid the confusion of opinion swirling around the problem, affected individuals and those who wish to help them are in need of safe, rational, interim approaches that might help alleviate the condition. Of equal importance, there is a need for practical strategies (e.g., integrated pest management, reducing VOC levels in new construction) to prevent the illness from developing in other people.

27.3 DEFINING SENSITIVITY AND INTOLERANCE

The different meanings ascribed to the term *sensitivity* may have added to the confusion surrounding this illness. "Sensitivity" is used in three relatively distinct ways (Ashford et al. 1995):

1. The heightened responses of certain individuals to *known* toxicants or allergens, e.g., the responses of susceptible persons to toxic substances like mercury and carbon monoxide, or allergic reactions to antigens like housedust mites and animal dander.
2. The responses of certain individuals to identifiable exposures that at this time cannot be explained by generally accepted disease mechanisms. This category includes:

- a. Sick building syndrome (SBS) involving individuals who respond to one or several air contaminants that may or may not be identifiable. The fact that affected individuals' symptoms resolve when they leave the building provides evidence for SBS.
- b. Sensitivity, such as that induced by toluene di-isocyanate (TDI), that starts out as specific hypersensitivity to a single substance (or one chemical class), but evolves into nonspecific hyperresponsiveness (described further in category 3 below).
3. The heightened, extraordinary, or unusual responses of certain individuals to structurally diverse chemicals at exposure levels orders of magnitude below those producing symptoms in most people (cf. Cullen 1987).

Patients with MCS appear to exhibit this third type of sensitivity. Synonyms and related terms include environmental illness (EI), chemical intolerance, ecological illness, idiopathic environmental intolerance (IEI), universal allergy, and toxicant-induced loss of tolerance (TILT). Proposed underlying mechanisms range from entirely psychogenic to entirely toxigenic, and everything in between (Ashford and Miller 1998, ACS 1999, NRC 1992, AOEC 1992, ATSDR 1994). Odor conditioning is one example of a possible dual toxigenic-psychogenic mechanism (Doty et al. 1988). A bright line should be drawn between this third type of sensitivity and antibody-mediated sensitivities, or allergies. Allergists prefer the term *chemical intolerance* over *chemical sensitivity* in order to distinguish this condition from true allergies. We also prefer the term *chemical intolerance* because it describes these individuals' responses without presuming any specific mechanism, allowing time for the science to unfold. *Sensitivity*, on the other hand, implies an underlying sensitization process, when, in fact, the loss of tolerance these individuals describe may result from something entirely different, e.g., cell membrane disruption or gene activation. For the remainder of this chapter, we will therefore use the term *chemical intolerance* or *multiple chemical intolerance* in preference to *chemical sensitivity* or *multiple chemical sensitivity*. Tolerance is defined as the ability to withstand an insult. Affected individuals appear to lose their prior natural or innate tolerance for a wide spectrum of substances.

Researchers have observed multiple chemical intolerances occurring in a minority of sick building occupants (type 2a), with some people developing profound illness marked by multisystem symptoms and multiple intolerances. Many of these people ultimately adopt constricted lifestyles that transform their careers, families, social life, ability to travel, and recreational pursuits. Even their selection of home furnishings and clothing is dictated by their striving to avoid problem exposures.

27.4 PHENOMENOLOGY

Chemically intolerant individuals often say their illness began following specific exposure events, referred to as *initiating* events, e.g., a chemical spill, repeated exposure to solvents,

Case Study 1. Multiple Chemical Intolerance Following Pesticide Use

A "mystery illness" involving some 250 people broke out at a major casino resort hotel following repeated application of propoxur, a carbamate insecticide, used for cockroach control. Affected individuals reported dizziness, weakness, nausea, sore throat, fainting, sweating, headaches, racing heartbeat, shaking and trembling, lip and facial tingling, and red, splotchy rashes. While most recovered, 19 people experienced persistent symptoms. When these individuals were seen in an occupational medicine clinic 9 to 15 months after the initial episode, 12 of the 19 (63 percent) reported intolerances to perfume, gasoline, newsprint, cleaning materials, pesticides, and various other solvents that had not bothered them before the casino exposure (Cone and Sult 1992).

Case Study 2. Multiple Chemical Intolerance at the Environmental Protection Agency's Headquarters

EPA's Washington, D.C., headquarters building became a "sick building" during an extensive renovation, which included painting, moving walls, and the installation of 27,000 square yards of new carpeting. Even before the renovation, some occupants had reported symptoms suggestive of a potential indoor air quality problem in the building.

The EPA Waterside Mall headquarters building was originally a housing complex, consisting of two residential towers with a mall between. Residential space was converted to office space for the agency's use. During the remodeling, more than 100 individuals, including agency scientists, reported symptoms. Most who were affected improved when corrective measures were taken. Some office areas were found to have as little as 0.2 air changes per hour. About 2 dozen employees experienced persistent symptoms, long after the building had outgassed, including malaise, "spacey" feelings, difficulty thinking, respiratory problems, nausea, headaches, and dizziness. Symptoms were triggered by various common foods and chemicals, including perfumes, auto exhaust, and tobacco smoke (Welch and Sokas 1992, Ashford and Miller 1998, EPA 1989, Hirzy and Morison 1989). Even 10 years later, some of these individuals continue to experience disabling symptoms triggered by common exposures.

Case Study 3. Multiple Chemical Intolerance in a Manufacturing Facility

Some 50 to 75 aerospace manufacturing workers became acutely ill when a new composite plastic material was introduced into their workplace. Symptoms included headaches, fatigue, dizziness, nausea, breathing difficulties, and cognitive disturbances. Industrial hygienists identified phenol, formaldehyde, and methyl ethyl ketone as principal components, although airborne concentrations were within established safety limits. Thirty-seven workers filed compensation claims. A panel of medical specialists found no medical diagnosis or immunological abnormalities that could explain most workers' symptoms. More than a dozen of the claimants reported persistent, disabling symptoms triggered by common environmental exposures (Simon et al. 1990).

a pesticide application, indoor air contaminants associated with new construction, combustion products, etc. (Miller 1994) (see Case Studies 1 to 3). A subset of those exposed in these situations appear to evolve to a chronic condition that can persist many years, even decades, beyond the initial exposure. At first, individuals describe "flu-like" symptoms that will not go away, or feeling as though they are in a "perpetual fog." Next to develop are multisystem symptoms that seem to wax and wane unpredictably and a dawning awareness of a few new intolerances or adverse reactions, e.g., to alcohol or medications. Over time, these intolerances spread to a wide variety of everyday exposures—chemicals, foods, drugs, caffeine, alcoholic beverages, and skin contactants. The intolerances may appear within weeks of an acute, high-level exposure, or, in the case of lower-level, chronic exposures as in a sick office building, develop insidiously over months or years. Food intolerances may not be recognized as such initially; instead, every sort of digestive difficulty, feeling ill after meals, or extreme irritability if a meal is missed or delayed may be noted. Symptoms may occur following inhalation, ingestion, mucosal contact, or injection (e.g., drugs). Different exposures (Table 27.1)—fragrances, chemicals outgassing from new furnishings or carpeting, traffic exhaust, cleaning agents, etc.—may trigger different constellations of symptoms in different individuals. Even the same individual may experience different symptom patterns with different exposures. There is consistency, however: A *particular* exposure, e.g., diesel exhaust or a certain fragrance, in a *particular* person, reportedly elicits a characteristic constellation of symptoms—a signature response for that person having that exposure. Responses may occur at below-olfactory-threshold concentrations. Symptoms develop seconds to hours following a triggering exposure, and may persist minutes to days. Responses

are diverse and highly individual, ranging in intensity from mild (nasal congestion, nausea, or slight headache) to severe (mental confusion, depression or seizures) (Table 27.2). Hyperresponsiveness to physical stimuli, including light, noise and touch, is commonly reported (Miller and Prihoda 1999a, 1999b). People with no sense of smell (anosmic) still may report chemical intolerances.

The chemically intolerant appear to constitute a distinct subset of the population. The fact that normal people do not experience these same symptoms, even when exposed to much higher concentrations of the same chemicals, has led some doctors to conclude the problem must be psychogenic. These intolerances to structurally unrelated substances violate fundamental tenets of toxicology and allergy, and the symptoms can be almost anything. The condition simply cannot be explained by existing disease paradigms. What *is* compelling about the condition is the fact that researchers have described identical patterns of multisystem symptoms and new-onset intolerances developing in demographically diverse *groups* in more than a dozen countries following well-documented chemical exposures. This, more than anything else, has fueled scientists' search for a new disease paradigm that would explain these observations. Recently proposed animal models for the condition (Sorg 1999, Overstreet et al. 1996, Rogers et al. 1999) may offer a new window into the underlying mechanism. Building managers and IAQ professionals need to bear in mind that medicine may be in the early observational stages of uncovering a new disease process.

People with multiple chemical intolerances report that avoiding triggering exposures provides some relief (Lax 1995). Comprehensive avoidance is challenging, as well as socially isolating; low VOC exposure levels (parts per billion or trillion) are near-ubiquitous. Symptom-exposure relationships may be difficult to discern for several reasons (Ashford and Miller 1998): *habituation* with chronic exposures, e.g., VOCs in a sick office building, and *apposition*, i.e., overlapping symptoms resulting from common exposures (chemicals, foods, drugs), both can hide or "mask" the effects of particular exposures. Many individuals quit their jobs in order to minimize exposures to fragrances, carbonless copy paper, cleaning agents, etc., while others switch employers, occupations, and residences, searching for a safer environment.

TABLE 27.1 Triggering Exposures

Reported by at least 80 percent of 112 people who developed multiple chemical intolerance following an exposure to pesticides (n = 37) or indoor air contaminants (n = 75)

New carpeting	Enclosed mall
New automobile interior	Oil-based paint
Poorly ventilated meeting rooms	Particle board
Perfume	Gas engine exhaust
Detergent aisle in grocery	Hotel rooms
Newspaper/printed materials	Phenolic disinfectants
Fresh asphalt/tar	Dry-cleaned clothes
Diesel exhaust	Insecticides
Felt-tip markers	Gasoline
Nail polish/remover	Potpourri
Restroom deodorizers	New tires
Fabric stores	Cigar smoke
Heavy traffic	Cigarette smoke
New plastic shower curtain	Incense
Hairspray	Insect repellent

Source: Miller and Mitzel (1995).

TABLE 27.2 Symptoms Commonly Reported by Chemically Intolerant Individuals

Major categories were derived via factor analysis of symptoms reported by 112 self-identified chemically intolerant people who reported becoming ill following exposure to indoor air contaminants (n = 75) or cholinesterase-inhibiting pesticides (n = 37).

Neuromuscular	Weak arms	Trembling hands
Loss of consciousness	General stiffness	Insomnia
Stumbling/dragging foot	Cramps in toes/legs	Airway
Seizures	Painful trigger points	Cough
Print moving/vibrating on page	Gastrointestinal	Bronchitis
Feeling off balance	Abdominal gas	Asthma or wheezing
Tingling in fingers/toes	Foul gas	Postnasal drainage
Double vision	Problems digesting food	Excessive mucus production
Muscle jerking	Abdominal swelling/	Shortness of breath
Fainting	bloating	Eye burning/irritation
Numbness in fingers/toes	Foul burping	Susceptible to infections
Clumsiness	Diarrhea	Dry eyes
Problems focusing eyes	Abdominal pain/cramping	Enlarged/tender lymph
Cold or blue nails/fingers	Constipation	nodes
Uncontrollable sleepiness	Cardiac	Hoarseness
Head-related	Heart pounding	Cognitive
Head fullness/pressure	Rapid heart rate	Memory difficulties
Tender face/sinuses	Irregular heart rate	Problems with spelling
Sinus infections	Chest discomfort	Slowed responses
Tightness in face/scalp	Affective	Problems with arithmetic
Brain feels swollen	Feeling tense/nervous	Problems with handwriting
Ringling in ears	Uncontrollable crying	Difficult concentration
Headache	Feeling irritable/edgy	Difficulty making decisions
Feeling groggy	Depressed feelings	Speech difficulty
Musculoskeletal	Thoughts of suicide	Feelings of unreality/spacey
Joint pain	Nerves feel like vibrating	Other
Muscle aches	Sudden rage	Feeling tired/lethargic
Weak legs	Loss of motivation	Dizziness/lightheadedness

Source: From Miller and Mitzel (1995).

27.5 PREVALENCE AND DEMOGRAPHICS

Between 15 and 30 percent of the U.S. population report being “especially” or “unusually” sensitive to certain chemicals (Table 27.3). Population-based surveys show that approximately 2 to 6 percent of the general population report physician-diagnosed “multiple chemical sensitivity,” “environmental illness,” or significant daily impairment from chemical exposures (Kreutzer et al. 1999, Meggs et al. 1996, Voorhees 1998). Questions used in these surveys varied, but their findings are strikingly similar.

The largest and best designed of these studies was a 1995 California Department of Health Services state-wide, randomized telephone interview survey involving more than 4000 people (Kreutzer et al. 1999). The researchers found that 15.9 percent of participants reported being “allergic or unusually sensitive to everyday chemicals”; 11.9 percent described sensitivities to more than one type of chemical; and 6.3 percent reported doctor-diagnosed “environmental illness” or “multiple chemical sensitivity.” Female gender and Hispanic ethnicity were associated with increased self-reporting of sensitivity (adjusted odds ratios of 1.63 and 1.82, respectively). In contrast with most published clinical studies,

employment and education were not associated with chemical sensitivity or doctor-diagnosed MCS, nor were there any associations with marital status, geographic location, and income. The California study concludes: "Surprising numbers of people believed they were sensitive to chemicals and made sick by common chemical exposures. The homogeneity of responses across race-ethnicity, geography, education, and marital status is compatible with physiologic response or with widespread societal apprehensions in regard to chemical exposure."

Results of several state surveys (California, New Mexico, North Carolina) suggest that multiple chemical intolerance could be one of the most prevalent, *if not the most* prevalent, chemically related illnesses in the United States (Kreutzer et al. 1999, Voorhees 1998, Meggs et al. 1996). A U.S. EPA survey found that nearly one-third of federal office workers in mechanically ventilated federal office buildings considered themselves "especially sensitive" to one or more common chemical exposures (Table 27.3) (Wallace et al. 1993). Notably, rates were similar for complaint and non-complaint buildings.

On average, 80 percent of self-identified MCS patients enrolled in clinical studies have been women with an average age in the fourth decade and an average educational level of at least 2 years of college (Fiedler and Kipen 1997b). In contrast, among military and industrial populations, the vast majority of those reporting chemical intolerances are males, likely reflecting underlying gender ratios (Simon et al. 1990; Miller and Prihoda 1999a, 1999b). In office building situations, the condition is more commonly reported by college-educated white females of middle to upper-middle socioeconomic status who are in the midage range (30 to 50 years) (Ashford and Miller 1998). It is not known why more chemically intolerant patients report working in office buildings and service industries, rather than in heavy industry where exposures to chemicals are more common, nor why more women than men appear to be sick (Lax and Henneberger 1995, Miller and Mitzel 1995, Black et al. 1990). The skewed gender ratios may stem from male/female differences in willingness to report symptoms; something unique about the mixture of indoor air pollutants in a sick building, a setting in which women may be relatively more confined, e.g., as secretaries; or gender-based biological response differences. The apparent paradox that fewer multiple chemical intolerance cases arise in heavy industries versus service industries may be due to: "The healthy worker" selection effect, i.e., workers bothered by chemical exposures tend to migrate to nonchemical jobs; the fact that women, who may be biologically more vulnerable, are less apt to work in heavy industry, mining, construction, etc.; or some unknown, but unusually insidious effect of indoor air chemical mixtures.

TABLE 27.3 Frequency of Self-Reported Chemical Intolerance from Several Large Surveys

Population	Number of people studied	Those considering themselves especially or unusually sensitive to certain chemicals, %	Those reporting physician-diagnosed multiple chemical intolerance or daily symptoms triggered by chemicals, %
EPA office workers (Wallace et al. 1993)	3948	31	Not evaluated
Rural North Carolinians* (Meggs et al. 1996)	1027	33	3.9
California residents* (Kreutzer et al. 1999)	4046	15.9	6.3
New Mexico residents* (Voorhees 1998)	1814	17	1.9

*Randomly sampled.

27.6 SYMPTOMS

The vast majority of chemically intolerant individuals report multisystem symptoms (Table 27.2). Fatigue is the most prevalent complaint. Their symptoms greatly overlap those of chronic fatigue syndrome and fibromyalgia (Ashford and Miller 1998, Miller and Mitzel 1995, Chester and Levine 1994, Buchwald and Garrity 1994). Mood changes (irritability, anxiety, depression) are commonly reported. Exposure-related memory and concentration difficulties have led teachers, attorneys, executives, nurses, and other professionals to abandon their cognitively demanding careers.

Different groups with different “initiating” exposures describe strikingly similar symptoms: Among 75 chemically intolerant individuals who became ill following building remodeling and 37 who became ill following exposure to a cholinesterase-inhibiting pesticide, symptoms, ranked in order by severity, were nearly identical (Table 27.2). Central nervous system symptoms led the list. The most common gastrointestinal complaint was “problems digesting food.” The most frequent respiratory complaint was “shortness of breath or being unable to get enough air.”

Individuals’ symptoms are often exposure-specific, e.g., “spaciness” or an upset stomach around diesel exhaust, irritability in the detergent aisle of a grocery store, or confusion with a particular fragrance. Some patients say the nature of their symptoms helps them identify a particular trigger (e.g., a pesticide), even when no odor is evident. Individuals who shared the same initial exposure event (e.g., remodeling of the EPA’s headquarters building—see Case Study 2) may report very different symptoms.

Illness often begins with “flu-like” symptoms, resembling “chronic fatigue syndrome,” a diagnosis many eventually acquire (Buchwald and Garrity 1994). Awareness of chemical or food intolerances develops gradually, sometimes accidentally, e.g., following a work holiday or vacation trip (especially to a relatively clean environment such as the mountains or seashore). In these situations, the chemically intolerant may become “unmasked.” Then when they return to their workplace or home, their symptoms flare up. After this happens several times, they begin to suspect environmental causes.

27.7 THE INTERNATIONAL EXPERIENCE WITH MULTIPLE CHEMICAL INTOLERANCE

Researchers have described this phenomenon—groups of individuals developing multi-system symptoms and new-onset intolerances following an initial chemical exposure event—in more than a dozen countries, including the United States, Canada, Australia, New Zealand, and nine European nations. These groups include: radiology workers from New Zealand and other nations exposed to x-ray developer solution containing glutaraldehyde and other solvents (Genton 1998); federal employees in the EPA headquarters building in Washington, D.C., exposed to volatile organic chemicals outgassing from new carpet and construction materials (Hirzy and Morison 1989, EPA 1989); homeowners in Germany exposed to pentachlorophenol wood preservative used in log homes (Ashford et al. 1995); sheep dippers in Great Britain exposed to organophosphate pesticides (Ashford and Miller 1998, Monk 1996, Stephens et al. 1995); hospital workers in Nova Scotia exposed to building air contaminants (Ashford and Miller 1998); casino card dealers in Lake Tahoe, California, exposed to solvents and pesticides (Cone and Sult 1992); and Gulf War veterans exposed to various chemicals and drugs during military service (Miller and Prihoda 1999a, 1999b; Ashford and Miller 1998; Fiedler et al. 1996b; Miller 1996).

A study comparing European and U.S. experiences with the condition revealed that “initiating” exposures involving pesticides and solvents were commonly reported on both

continents (Ashford et al. 1995, Ashford and Miller 1998). There were notable differences between countries that may inform future studies. For example, pesticides were not implicated in Sweden, Finland, and the Netherlands, where cooler temperatures help control insects. Organophosphate and carbamate pesticides are frequently cited initiators in the United States. Those who first become sick after organophosphate or carbamate pesticide exposures tend to report more severe symptoms, on average, than those exposed to building air contaminants, suggesting that pesticides in these classes might be especially potent initiators (Miller and Mitzel 1995).

Organic solvent initiating exposures were reported in all nine European countries surveyed and in North America. Most of these exposures were chronic, involving repeated solvent use, rather than a one-time chemical spill or release. A so-called wood preservative syndrome, attributed to pentachlorophenol used to preserve logs for homes, appeared only in Germany (Schimmelpfennig 1994). Notably, sick building syndrome, which is widely recognized in Scandinavia, has not been associated with cases of multiple chemical intolerance there. Perhaps the fact that Scandinavians tend not to use pentachlorophenol or pesticides indoors might explain this. Onset with new carpeting installation has been noted there, however.

Environmental activism may influence prevalence rates in some countries; however, similar illnesses appeared in every European country studied (Ashford et al. 1995). The practice of clinical ecology (Sections 27.2 and 27.11), which began in the United States and spread to Canada and the United Kingdom, may explain the apparent higher prevalence in those countries, but it fails to explain the illness' presence in Germany and Holland. Differences in cultural practices may play a role. In Europe, people tend to spend more time out of doors, walking to work and shopping, and windows in homes and offices are frequently left open, while in the United States, 90 percent of people spend their day indoors, often in tightly sealed schools, homes, and office buildings.

Building construction materials and furnishings vary greatly between countries, e.g., wall-to-wall carpeting versus washable throw rugs, or no floor covering at all; solid hardwood furnishings versus particle board, veneered or pressed wood; varying use of paint, wallpaper, and adhesive constituents; and office equipment, including photocopiers, computers, and laser printers. Ventilation practices also differ between countries and cultures. In North America, tightly constructed office buildings and schools with little or no provision for fresh outside air have become increasingly common over the past 2 decades. Chemical use indoors, e.g., pesticides, cleaners, personal care products, fragrances, etc., also varies greatly between nations.

27.8 RELATIONSHIP BETWEEN MULTIPLE CHEMICAL INTOLERANCE AND INDOOR AIR POLLUTANTS

Indoor air pollutants are among the most frequently cited initiators *and* triggers for multiple chemical intolerance. Over the past 2 decades, the condition has become widely known among indoor air professionals. Proposed explanations for the condition's apparent increase include:

1. The exponential rise since World War II in synthetic organic chemical production and use (including pesticides), indoors and out, resulting in widespread exposure to novel chemical species never encountered during human evolution
2. The construction of tighter, more energy-efficient housing, offices, and commercial buildings, together with decreased fresh outside air supply resulting from energy conservation measures during the oil embargo of the mid-1970s

3. The fact that today more people spend the majority of their day indoors, in buildings or vehicles, inhaling myriad, low-level volatile organic chemicals

Indoor air pollutants not only appear to set off symptoms in the chemically intolerant, but several studies suggest that some pollutants or pollutant mixtures may also initiate the condition (Miller and Mitzel 1995; Cone and Sult 1992; Miller and Prihoda 1999a, 1999b). Indoor air VOC levels tend to be much higher during or soon after remodeling or new construction, by as much as several orders of magnitude, than those later said to trigger symptoms. Differentiating between exposures that initiate the process and those that trigger the first robust symptoms is not always possible. For example, a person might become ill following a pesticide application at home (initiation), but notice the most pronounced symptoms with workplace exposures to fragrances, new carpet, paint, particle board, furnishings, etc., at work (triggering). The former may cause subtle and gradual loss of tolerance; the latter, robust and immediate symptoms. About 40 percent of chemically intolerant individuals are unable to recall any initiating events (Fiedler et al. 1996a); others describe a series of exposures they feel caused stepwise deterioration in their health; and still others report lifelong health problems and intolerances that are exacerbated by indoor air contaminants.

27.9 CASE DEFINITIONS

By definition, a syndrome is “a *group* of symptoms or signs typical of a disease” (Webster’s 1986). Technically, therefore, MCS is not a syndrome: The symptoms patients report are too heterogeneous. Different organ systems are affected in different individuals. This feature, more than any other, has encumbered the development of a case definition for the condition. Nevertheless, several consensus case definitions have been proposed that may have utility for research or medical evaluation purposes, e.g., for compensation (Bartha et al. 1999, NRC 1992, AOEC 1992, Nethercott et al. 1993). Some researchers fear that restricting the illness’ definition to a limited number of symptoms, as has been done for chronic fatigue syndrome and “Gulf War syndrome,” could prematurely constrict the field of view, thereby excluding from study cases that do not fit preordained criteria. For example, some proposed MCS case definitions exclude asthma or depression on the grounds that these are “diagnosable” conditions (Cullen 1987), even though low-level chemical exposures might cause asthma and depression. There is a consensus that scientifically conducted human exposure challenge studies (double-blinded, placebo-controlled) are needed to determine whether chemically intolerant individuals do in fact respond adversely to very low level environmental exposures, at concentrations well below those affecting most people (NRC 1992, AOEC 1992, Miller et al. 1997).

It appears that other medical conditions may share the same two-step mechanism (initiation and triggering) involved in multiple chemical intolerance (see Sec. 27.10). For example, reactive airways dysfunction syndrome (RADS), an asthma-like condition, begins after a specific, acute chemical exposure; subsequently, bronchoconstriction is triggered by diverse chemical inhalant exposures. Some researchers think RADS may be multiple chemical intolerance manifesting in single organ systems, e.g., the lungs (Meggs 1994). Conceivably, some cases of depression (Rosenthal and Cameron 1991, Bell 1994, Bell et al. 1992), migraine headaches, attention deficit disorder, panic attacks, seizures, etc., might be initiated by acute or chronic chemical exposure and thereafter perpetuated by everyday, low-level exposures (Ashford and Miller 1998).

Most case definitions proposed for MCS (summarized in Ashford and Miller 1998) echo the same central observations: chronic, multisystem symptoms triggered by diverse, low-level chemical exposures, with symptoms resolving when those exposures are avoided.

A recent paper (Bartha et al. 1999) proposed six “consensus criteria” for MCS, based primarily on an earlier survey of 89 clinicians and researchers familiar with, but having divergent views of, the illness (Nethercott et al. 1993). The consensus paper defines MCS as (1) a chronic condition (2) with symptoms that recur reproducibly (3) in response to low levels of exposure (4) to multiple unrelated chemicals and (5) improve or resolve when incitants are removed (6) with symptoms that occur in multiple organ systems. These same criteria are encompassed by most proposed research case definitions for MCS. The authors recommend that MCS be formally diagnosed *in addition to* any other diagnosable disorders (e.g., migraine, asthma, depression) in all patients in whom the above six criteria are met and “no single other organic disorder...can account for all the signs and symptoms associated with chemical exposure.”

Miller and Mitzel (1995) compared symptoms reported by 112 self-identified MCS patients, 37 who traced their illness to a cholinesterase-inhibiting pesticide exposure and 75 to remodeling of a building. *Individual symptom patterns* varied, yet, overall, the two exposure groups exhibited statistically similar ordering of symptoms, ranked by intensity. These findings suggest a shared underlying mechanism or final common pathway for the illness despite different initiating exposures. A second comparative study of persons with MCS, Gulf War veterans, and individuals with implants (mostly breast implants) again showed similar distributions of multisystem symptoms and new chemical, food, and drug intolerances, despite differences in reported initiating exposures (Miller and Prihoda 1999a, 1999b). These studies imply that a wide variety of chemical exposures, whether exogenous (e.g., chemical spill, pesticide application, indoor air contaminants) or endogenous (e.g., implants), might initiate multiple chemical intolerance.

27.10 PROPOSED MECHANISMS

The underlying dynamic remains a mystery. Some physicians and researchers view multiple chemical intolerance as a psychogenic phenomenon resembling depression, somatoform disorder, or posttraumatic stress disorder. Others see it as a chemically caused medical illness and propose various physiological explanations (Table 27.4) (for details see Ashford and Miller 1998, Bell et al. 1992, Bascom 1989, Meggs 1994). To date, surprisingly little research has been done looking into possible immunological, neurological, inflammatory, or psychological underpinnings for the condition. Funding for such studies has been scant.

TABLE 27.4 Theories/Mechanisms Proposed to Explain Multiple Chemical Intolerance

Immune dysfunction or sensitization
Neurological damage or sensitization
Impaired detoxification pathways
Inflammation
Vasoconstriction/vasculitis
Psychiatric or psychological disorders:
An erroneous belief that chemicals are causing illness
Posttraumatic stress disorder
Conditioned behavior (odor conditioning)
Somatoform disorder
Depression
Combinations of the above mechanisms

As discussed above, researchers have surveyed more than a dozen countries and in each one have found people who report developing multisystem symptoms and new-onset chemical, food, drug, alcohol, and caffeine intolerances following well-documented exposures, e.g., to pesticides, indoor air contaminants, or solvents. *The fact that these groups, who share little in common save some initial chemical exposure, all report the same new-onset chemical, food, and drug intolerances, is a compelling anomaly.* Compelling anomalies in science expose the limitations of old paradigms and drive the search for new ones. Although the symptoms associated with multiple chemical intolerance are too diverse for it to be a *single* syndrome, it is possible that what we are dealing with is an entirely new *class* of diseases. The germ theory and the immune theory of disease also arose out of a need to explain certain anomalous observations. These theories took seemingly unrelated illnesses involving different organ systems, myriad causal agents, and different *specific* mechanisms and collapsed them into a single general mechanism that fit the observations of reliable observers and just made sense. Fever, the hallmark symptom for infectious diseases, may have its parallel in the new-onset chemical intolerances that mark these illnesses, all of which appear to share the same general mechanism, here referred to as toxicant-induced loss of tolerance (TILT) (Miller 1997, Ashford and Miller 1998, Newlin 1997). Exposures causing TILT, e.g., pesticides, solvents, or combustion products, may be acting via different *specific* mechanisms and affecting different target organs (Fig. 27.1), as is the case for different infectious diseases, e.g., cholera, AIDS, and shingles.

TILT appears to involve two steps (Fig. 27.2) (Ashford and Miller 1998, Miller 1997): (1) First, a single high-level exposure or repeated lower-level exposures to pesticides, solvents, indoor air contaminants, etc. cause loss of tolerance in a subset of those exposed (initiation); (2) thereafter, low levels of common substances—chemicals, foods, medications, alcoholic beverages, and caffeine—set off multisystem symptoms, thus perpetuating illness (triggering).

FIGURE 27.1 Conditions that may result from toxicant-induced loss of tolerance. Illnesses like depression, migraine, arthritis, and chronic fatigue may have various underlying mechanisms, one of which might be TILT.

FIGURE 27.2 Phenomenology of toxicant-induced loss of tolerance (TILT). Illness appears to develop in two stages: (1) initiation, i.e., loss of prior, natural tolerance resulting from an acute or chronic exposure (pesticides, solvents, indoor air contaminants, etc.), followed by (2) triggering of symptoms by small quantities of previously tolerated chemicals (traffic exhaust, fragrances), foods, drugs, and food/drug combinations (alcohol, caffeine). The physician sees only the tip of the iceberg—the patient’s symptoms—and formulates a diagnosis based on them (e.g., asthma, chronic fatigue, migraine headaches). Masking hides the relationship between symptoms and triggers. The initial exposure event causing breakdown in tolerance also may go unnoticed. (©UTHSCSA 1996.)

Which inhalants, foods and drugs trigger symptoms varies from case to case. Many affected individuals say that continued exposure expands their circle of intolerances, a phenomenon referred to as “spreading.” Symptoms are exposure-specific and highly individual. For example, one person might experience headaches with diesel exhaust, mental confusion with a certain fragrance, or nausea with cashews. The effects of a single exposure may last for hours. Thus, a person who uses hairspray or fragrances in the morning, cooks breakfast on a gas stove, and then drives through heavy traffic to work in a sick building may experience near-continuous symptoms that overlap in time, creating a kind of background symptom noise that hides or “masks” the effects of single exposures (Miller 1996, 1997). Repeated daily exposure to the *same* trigger, whether office air contaminants or caffeine, appears to result in *habituation*, with symptoms becoming chronic in nature. Masking and habituation tend to blur the symptom-exposure relationship so that physicians, and even the patients themselves, may fail to recognize triggers. “Withdrawal-like” symptoms may occur when exposures are interrupted (e.g., over a weekend) with symptoms becoming robust with reexposure following a period of avoidance, e.g., Monday morning on return to work. Masking may explain the day-to-day variations in symptom intensity most affected individuals initially report.

Converging lines of evidence support TILT as a general mechanism underlying this illness:

1. Similar multisystem symptoms and new-onset intolerances reported by researchers among different demographic groups from more than a dozen countries following well-defined exposures to pesticides, solvents, indoor air contaminants, etc.

2. The fact that these new-onset intolerances are not limited to chemical inhalants but also involve foods, caffeine, alcohol, medications, and skin contactants.
3. The striking parallels between this condition and addiction (see below) suggesting related neural mechanisms (Randolph and Moss 1980, Miller 1997).
4. The identification of an anatomical substrate—the nervous system—whose malfunction could explain these problems,
5. Recent animal models replicating features of TILT (Overstreet et al. 1996, Sorg 1996, Rogers et al. 1999).

Randolph was first to describe the striking resemblance between chemical intolerance and drug addiction. Both are characterized by stimulatory and withdrawal symptoms, cravings, and cross-addiction/intolerances to structurally diverse substances. One theory is that both addiction and chemical intolerance (or “abddiction”) might result from loss of tolerance due to repeated exposure to drugs or pollutants, leading to an amplification of stimulatory and withdrawal symptoms. Addicts become addicted, in part, in order to avoid unpleasant withdrawal symptoms. In contrast, chemically intolerant individuals who recognize specific triggers tend to avoid those triggers, but for the same reason addicts remain addicted—in order to avoid unpleasant withdrawal symptoms. Initially, many chemically intolerant individuals consume caffeine and have no idea that it bothers them. In fact, they may experience a brief lift from it, while overlooking the caffeine withdrawal headaches they develop several days later. These apparent polar opposites—addiction and abddiction—thus could be mirror-image strategies for avoiding withdrawal symptoms resulting from TILT (Newlin 1997, Miller 1996, 1999).

Specific physiological mechanisms that might explain TILT and multiple chemical intolerance include olfactory-limbic kindling (sensitization of the nerve pathways that lead from nose to brain) (Bell et al. 1992), other neural sensitization processes (Sorg 1999), neurogenic inflammation (Bascom 1991, Meggs and Cleveland 1993), genetically based or chemically induced cholinergic supersensitivity (Overstreet et al. 1996), and metabolic differences, e.g., decreased sulfation capacity (McFadden 1996), abnormal porphyrin metabolism (Morton 1995), or paraoxonase deficiency (organophosphate detoxifying enzyme) (Costa et al. 1999, Haley et al. 1999).

Proposed psychological mechanisms include odor conditioning, physician-induced (iatrogenic) beliefs, panic disorder, toxic agoraphobia, posttraumatic stress disorder (e.g., illness resulting from a traumatic chemical spill or childhood sexual abuse), somatoform disorder, and depression (Binkley and Kutcher 1997; Göthe et al. 1995; Gots 1995; Guglielmi et al. 1994; Kurt 1995; Pennebaker 1994; Simon 1994; Sparks et al. 1994a, 1994b; Spyker 1995; Staudenmayer et al. 1993; Staudenmayer and Selner 1987; Staudenmayer 1999). Carefully conducted studies are needed to untangle this confusion of competing hypotheses.

Persons who develop chemical intolerances following an “initiating” exposure sometimes suffer from health problems that preceded the “initial” exposure event. Aerospace workers whose chemical intolerances began after a new composite plastic was introduced in a workplace process averaged 6.2 unexplained physical symptoms which *preceded* the change in process, versus 2.9 unexplained symptoms in unaffected coworker controls (Simon et al. 1990) (see Case Study 3). Fifty-four percent of the chemically intolerant workers had a history of anxiety or depression that preceded their exposure, versus 4 percent of controls. Other researchers find that past psychiatric illness does not explain the illness (Fiedler et al. 1992). Even for chemically intolerant individuals who have a history of depression predating their “initiating” exposure, the question remains whether their intolerances are due to depression, whether they may be more vulnerable to developing intolerances because of preexisting depression (altered brain neurochemistry), or whether their

preexposure depression was itself due to prior, unidentified intolerances (Davidoff and Fogarty 1994).

Some researchers have concluded the condition must be psychogenic because it runs counter to accepted disease mechanisms. Davidoff and Fogarty (1994) examined 10 published studies that explored possible psychogenic theories for chemical intolerance. All were found wanting: In these studies, scientifically unsupportable conclusions concerning cause-and-effect were drawn, and psychological symptoms were erroneously assumed to be psychogenic when chemical exposures might also explain them. The study designs failed to exclude physiological mechanisms. Future studies need to be designed to distinguish between competing hypotheses.

27.11 MEDICAL EVALUATION AND TREATMENT

“Clinical ecologists,” who today call themselves “environmental physicians,” are the physician group historically most sympathetic to this illness. Some worked earlier as allergists, otolaryngologists, etc. before joining the ecologists. Various professional medical societies, especially the allergists, have been critical of the ecologists’ claims, and have published position papers critical of their theories and practices, citing the anecdotal nature of their studies, an overreliance on self-reported symptoms, and their “unproven” diagnostic and treatment practices, such as sauna therapy, vitamin and mineral supplements, and provocation/neutralization (subcutaneous injection or under-the-tongue administration of dilute foods and chemicals for testing and treatment). Clinical ecology has been labeled “junk science,” and a “medical subculture,” the patients as “true believers,” and the whole phenomenon as “An unnecessary burden perpetrated on society...tantamount to organized crime” (Staudenmayer 1999, Brodsky 1987, Staudenmayer and Selner 1987, Huber et al. 1992). Some see these attacks on the ecologists as “killing the messenger,” using the lack of evidence of therapeutic effectiveness not only to reject their unorthodox approaches, but also to reject the legitimacy of the condition.

There is no established or even widely accepted *medical* treatment for multiple chemical intolerance at this time. A multifaceted approach, components of which include the identification and avoidance of chemicals and foods that trigger symptoms, low- or no-cost alterations of patients’ physical environments, and psychological support, as appropriate, has the potential to alleviate suffering and prevent worsening of the condition.

In the United States, affected individuals must chart their own course to recovery. Obtaining balanced information and medical help from informed and receptive physicians is difficult. Patients’ memory and concentration problems interfere with care seeking, making lifestyle changes, obtaining social support services, etc. difficult, especially in the absence of good family support. Many individuals seek assistance from federal agencies. However, the Environmental Protection Agency (EPA), the Agency for Toxic Substances and Disease Registry (ATSDR), the National Institute of Environmental Health Sciences (NIEHS), the National Institute for Occupational Safety and Health (NIOSH), and various state agencies provide no clear path for obtaining answers or assistance. Canada alone has two government-sponsored clinics devoted to chemical intolerance research and patient evaluation. Comparable facilities are not available in the United States or elsewhere (Ashford and Miller 1998).

Chemically intolerant patients often deplete their financial resources and energies consulting dozens of specialists and trying a host of unproved treatments. In one study, 40 percent had consulted at least 10 medical practitioners (Miller and Mitzel 1995). The average patient makes 23 health care provider visits per year (Buchwald and Garrity 1994). The practitioners they see often have never heard of the condition and little train-

ing is available through medical schools or professional conferences. Various national patient support groups offer counsel free to patients, referring them to sympathetic physicians, attorneys, etc.

Busy doctors seldom take occupational or environmental histories, even when circumstances warrant (IOM 1995). These histories are time-consuming and physicians may be unable to interpret the information they do receive. Potentially important exposures may be missed or dismissed, e.g., recent remodeling, pesticide use. Specialists who focus on single organ systems tend to underestimate the illness' full impact. As a result, chemically intolerant patients migrate from physician to physician accumulating personalized sets of diagnostic labels—organic brain syndrome, chronic fatigue syndrome, psychosomatic disease, migraines, fibromyalgia—unaware of the underlying dynamic. Patients often become angry with and try to avoid doctors they find skeptical or ill-informed, especially since physicians render professional opinions that bear heavily on insurers' determinations, compensation boards, and disability reviewers, as well as the views of employers, friends, and family.

Physicians need to ask about and document chemical, food, drug, alcohol, and caffeine intolerances these individuals may have experienced, both before and since the putative initiating exposure. Self-administered questionnaires, e.g., the 50-item Quick Environmental Exposure and Sensitivity Inventory (QEESI) (see appendix at the end of the chapter), can speed this process (Miller and Prihoda 1999a, 1999b). The QEESI contains five scales that allow patients to self-rate their symptoms, chemical intolerances, other intolerances (foods, drugs, alcohol, caffeine, skin contactants, pollens, dust, molds), life impact, and masking (i.e., ongoing exposures that may hide the symptom-exposure relationship). These scales have been shown to exhibit good reliability, validity (i.e., they correlate well with standard health status and life function measures), sensitivity (92 percent) and specificity (95 percent) (Miller and Prihoda 1999a, 1999b). This screening questionnaire takes only 10 to 15 minutes to complete and can be administered at intervals to monitor progress. The QEESI might also help indoor air consultants identify more vulnerable building occupants and tailor indoor air interventions accordingly. A workplace physician, nurse, or industrial hygienist could also provide the QEESI to individuals who report building-related health problems.

Physicians may be hesitant to diagnose multiple chemical intolerance even when they feel this label best fits the patient's situation. They tend to use "piecemeal," but widely accepted, diagnoses with compensable diagnostic codes, e.g., asthma, toxic encephalopathy, or migraine headache. Workers' compensation boards and insurance companies often challenge a multiple chemical sensitivity diagnosis, undermining physicians' willingness to use it. In contrast, toxicant-induced loss of tolerance, which describes the underlying mechanism—the breakdown in tolerance resulting from exposure that has been reported by reputable scientists in numerous, peer-reviewed medical articles, has not yet been scrutinized or challenged in this manner.

It is the responsibility of health care providers to discuss TILT with their patients *when symptoms and circumstances warrant*. Which symptoms? Fatigue, memory and concentration difficulties, mood changes, and multisystem health problems. The more organ systems are affected, the more practitioners should entertain this possibility (recalling that when the illness begins, only a single organ system may be involved). What circumstances? If symptoms develop in the aftermath of an exposure to solvents, pesticides, a sick building, remodeling, or new construction; if a sudden, major change in an individual's health has occurred; if clinical laboratory abnormalities (e.g., pulmonary function tests) appear after the exposure and/or improve with avoidance and/or worsen with reexposure; if others who share the same initial exposure became ill at about the same time, particularly if they manifest multiple symptoms and intolerances; and if formerly well-tolerated exposures—chemicals, foods (or feeling ill after meals or if a meal is missed), medications, alcohol, or

caffeine—now set off symptoms. New-onset depression, asthma, severe headaches, etc., *in the absence of other clear causes*, should invite inquiry as to whether chemical intolerance might be involved. None of the above factors alone “proves” anything, but the more that fit, the more the practitioner should suspect TILT.

Under circumstances like these, a practitioner needs to help patients understand the divergent opinions about this illness in the medical community, explore available treatment options, including psychological therapies, social support interventions, and avoidance strategies, being mindful that the efficacy of any treatment for this condition remains unproved, and help patients understand that the underlying mechanism remains a mystery and that no test is diagnostic of the problem.

The value of a careful exposure history cannot be overemphasized. Patients can be instructed to draw their own symptom/exposure timelines: Symptoms and medical problems are recorded across the top of the line, and lifetime events (e.g., changes in jobs, residences, military service, surgeries, pregnancies, remodeling, pesticide use, etc.) along the bottom. A clear, concise chronology, preferably in this format, can bring into clearer focus potential contributory exposures.

A comprehensive physical examination is essential, even though findings are frequently negative or not diagnostic. Routine baseline laboratory tests may be helpful, e.g., a complete blood count and chemistry profile, as well as specific tests suggested by symptoms or physical findings, e.g., thyroid function tests, pulmonary function testing, autoimmune markers, neuropsychological testing, etc. (Weaver 1996). Blood tests for environmental chemicals should be ordered only when specific exposures are suspected *and* the substance is not rapidly metabolized or excreted. Biological specimens can confirm exposure to chlorinated pesticides or *recent* exposure to cholinesterase-inhibiting (organophosphate or carbamate) pesticides, but generally are not helpful for exposures to most solvents, indoor air VOCs, or cholinesterase-inhibiting pesticides months after an acute pesticide exposure. To date, no single, consistently abnormal immunological parameter has been demonstrated in these patients.

Various atypical laboratory findings have been reported in these individuals, including abnormal T and B lymphocyte counts; helper/suppressor T cell ratios; immunoglobulin levels; autoimmune antibodies (e.g., antinuclear, antismooth muscle, antithyroid, anti-parietal cell); activated T lymphocytes (TA1 or CD26); quantitative EEGs; evoked potentials; SPECT and other brain scans (Heuser and Mena 1998, Hu 1999, Mayberg 1994, Ross et al. 1999); vitamin, mineral, amino acid, and detoxification enzyme levels; and blood or tissue levels of pesticides, solvents, and other chemicals. Study flaws vary, but include the failure to define the study population (no case definition used); to compare cases with age- and sex-matched controls; to blind specimens so that those performing the analyses are unaware of whether samples came from patients or controls; and to document the test method's accuracy and reproducibility. Some proponents for the illness claim that different immunological abnormalities occur in different patients. However, if enough tests are done, statistically a certain number will be abnormal (e.g., 1 in 20), a fact frequently forgotten.

There is an emerging consensus that “in cases of claimed or suspected MCS, complaints should not be dismissed as psychogenic and a thorough work-up is essential” (EPA 1994). Recognition of chemical intolerance as a disability under the Americans with Disabilities Act (ADA) likewise is growing (see below). Employers who dismiss the condition out-of-hand because of the medical uncertainties surrounding it, or on the basis of their own hunch that it does not exist, leave themselves open to litigation (Winterbauer 1997).

Among treatments patients have tried, the one they most consistently report as helpful is identifying and avoiding their chemical and food triggers (Johnson 1996, LeRoy et al. 1996, Miller 1995). In one study, 97 percent of 112 chemically intolerant individuals reported major food intolerances (Miller and Mitzel 1995). The occupational medicine doc-

tors these patients see are unlikely to attempt food elimination diets. It simply is not part of their training. On the other hand, allergists, who may use elimination diets, often feel ill-prepared to evaluate the patients' chemical exposure concerns. As a result, these patients tend to "fall in the crack" between these two specialties. Inadequate reimbursement for the physicians who see them, the complexities of medical management, and frequent involvement in compensation and litigation have not helped their popularity as patients.

Compounding these difficulties, chemically intolerant patients frequently report adverse reactions to drugs (prescription and over-the-counter) (Miller and Prihoda 1999a). Many either avoid drugs altogether or use reduced doses if possible. Drug side effects, even with standard dosing, and frequent unusual or idiosyncratic reactions frustrate physicians and patients alike (McLellan 1987).

The condition disrupts careers, families, and social lives. Psychological support (to be distinguished from traditional psychotherapy) can be an important therapeutic adjunct irrespective of whether the condition is psychogenic or physical in origin, and may be provided by psychologists, psychiatrists, social workers, or primary care doctors. Some patients have found psychological support "very helpful," although most report that psychological interventions do little to alleviate their responses to chemicals (Miller 1995). Claims that certain psychological and psychiatric interventions are effective are strictly anecdotal (Amundsen et al. 1996, Bolla-Wilson et al. 1988, Guglielmi et al. 1994, Schottenfeld and Cullen 1985, Spyker 1995). No studies comparing the efficacy of exposure avoidance versus psychological/behavioral interventions have been conducted. Some authors have touted psychological interventions as the preferred or only acceptable treatment modality (Sparks et al. 1994b). Given the uncertainties concerning the origins of this condition, these recommendations are at best premature and, at worst, potentially harmful (Miller 1995).

Multiple chemical intolerance is increasingly being recognized as a disability (Winterbauer 1997). Internal memoranda of the Social Security Administration and Department of Housing and Urban Development recognize the illness for purposes of compensation and housing accommodation, respectively. The most recent available statistics from the Equal Employment Opportunity Commission (EEOC) indicate that from November 1, 1993, through September 30, 1998, 465 MCS discrimination-related complaints were filed, 60 percent of which alleged failure of the employer to provide reasonable accommodation and 47 percent of which alleged wrongful discharge (EEOC 2000). MCS complaints have a lower resolution rate (39.9 percent) than other discrimination complaints (81.2 percent) (EEOC 2000).

The courts have struggled over whether the illness should be viewed as a disability, issuing conflicting opinions. Current law would make it difficult for an employer to claim that a condition that so greatly restricts daily activity is not a disability (Winterbauer 1997). The Americans with Disabilities Act obligates employers to seek inexpensive, practical solutions that will reduce troublesome exposures (for a detailed discussion of the ADA and its applicability to MCS, see Winterbauer 1997). It does not require that a chemical-free workplace be provided.

Few affected by this illness report full recoveries, even decades after it develops. There are those rare individuals whose illness was recognized at an early stage, who avoided additional exposure, and who appear to have recovered (see Case Study 4) (Hileman 1991). Early recognition and exposure avoidance thus may have the potential to prevent permanent, disabling illness. Treating the illness once it is entrenched is difficult, underscoring the importance of prompt intervention and exposure avoidance. Physicians and indoor air specialists need to watch for individuals manifesting multiple symptoms and intolerances who may have ongoing exposures to pesticides, remodeling, solvents, etc., and who may be in the initiation phase of the illness. Removal from suspect exposures for 7 to 10 days on a trial basis may be diagnostic, as well as therapeutic. If improvement occurs, and symptoms not so severe as to preclude it, judicious reexposure under a physician's watchful eye may be illuminating.

Case Study 4. Improvement in Chemical Intolerance After Early Intervention

A 50-year old pharmacology professor developed facial itching and eye irritation, which bothered him whenever he worked in his small, windowless university office that was stacked floor-to-ceiling with books, papers, and files. Reading new journals and certain books made his eyes water. He felt better when he worked in the adjoining laboratory, despite its chemicals and solvents, so he moved in there. At home, he took all of his papers and books down to the basement. Despite these measures, his symptoms persisted. He started to notice that the Sunday paper had a pronounced odor and made his eyes water.

Weeks later, he became aware of burning and stinging of his face and inner eyelids when he tried to assemble cardboard file folders or examine freshly developed photographs. A physician suggested to him that he might be suffering from multiple chemical intolerance, and advised him not to touch paper and to air out newly printed materials before reading them. Still, the odor of newspapers became so objectionable that he could not be in the same room with one. Simply walking past a bookshelf full of books set off his symptoms. He resorted to wearing goggles, a face shield, gloves, and a respirator with formaldehyde and VOC absorbent cartridges, and used a desk fan whenever he worked with papers.

His intolerances spread further to include scented soaps, aftershaves, cosmetics, and lotions worn by others. These irritated his upper airway, and caused coughing, chest pain, and difficulty breathing. Carbonless copypaper, new permanent-press pants, automobile interiors, the subway, gasoline, enclosed malls, clothing aisles, his gas stove, felt-tip pens, carpeted areas, and his computer's exhaust also triggered symptoms. He went to see a second physician who recommended that he avoid unnecessary irritant exposures, which he did. Within a month, his symptoms began to improve. Subsequently, he learned that the exhaust vent to his office had been shut off during some repairs and never reopened. Nearly a year after he had first become ill, he was able to return to his laboratory, use solvents, and read new journals with only minor difficulty (Hileman 1991).

Some patients have been able to continue to work, provided they avoid exposures that bother them. Successful workplace accommodations (see Sec. 27.12) have included: increasing fresh air supply and air circulation, removing business machines (fax machines, copiers, laser printers) from the immediate work environment, providing an alternate work space, removing carpeting, selecting odorless and less toxic cleaning agents, adopting integrated pest management, and allowing employees to work from home (Table 27.5).

27.12 ENVIRONMENTAL EVALUATION AND INTERVENTION

Indoor air quality consultants experienced in dealing with multiple chemical intolerance can be helpful in identifying sources and low-cost solutions during an initial walk-through survey. These individuals need to be nonsmokers with an excellent sense of smell, enabling them to track down potential contributory sources, e.g., building materials, furnishings, office equipment, and cleaners. Molds also release VOCs that may trigger symptoms and, conceivably, even initiate the illness. Water leaks, water damage, musty odors or visible mold call for immediate corrective action in any building, no matter how hardy its occupants.

The chemical concentrations that trigger symptoms in these individuals appear to be orders of magnitude below OSHA standards. Unless OSHA limits are exceeded, which will rarely be the case, such standards have no relevance in these situations and should not be invoked nor used as a benchmark for safety. Not infrequently, building owners hire consultants who conduct extensive, expensive air sampling, hoping to assure occupants the

TABLE 27.5 Strategies for Accommodating Chemically Intolerant Individuals

- Adopt a fragrance-free workplace policy, asking that no scented products be worn during work hours. Some organizations have adopted dress codes that discourage fragrance use. Others post signs. Under no circumstances should affected individuals be named in memos or signage. Many people do not realize that shaving lotions, aftershaves, fabric softeners, deodorants, hairspray, and handcreams commonly contain fragrances; they need to know that even the fragrances they most enjoy wearing contain VOCs that may be noxious to others. Fragrances are readily transferable from hands to papers, posing a potential problem for highly susceptible individuals. Hospitals, especially, should be fragrance-free. Patients suffering from asthma, migraine headaches, nausea (e.g., individuals undergoing chemotherapy), not just multiple chemical intolerance, often are bothered by odors. The Mayo Clinic in Scottsdale, Arizona, discourages fragrance use by staff with a statement in its dress and decorum policy and quarterly newsletter reminders to employees: “Perfume Usage—for the consideration of patients and co-workers, please do not use heavily scented perfumes and colognes. Patients as well as employees may be allergic to certain scents, and heavy perfume/cologne usage can cause them discomfort or make them ill.”

Fragrance sprays and dispensers in restrooms, and scents or “air fresheners” dispensed automatically into the air or ventilation system, need to be eliminated. Unscented, nonodorous cleaning agents are preferred for restrooms, floors, and other surfaces. If restrooms are properly cleaned and ventilated, air fresheners should not be needed to mask odors. *Note:* The University of Minnesota’s School of Social Work has a fragrance-free policy for offices and classrooms. Signs alert visitors: “Some persons employed or studying in the School of Social Work report sensitivities to various chemical-based or scented products. We ask for everyone’s cooperation in our efforts to accommodate their health concerns.” Several California cities have adopted fragrance-free resolutions or policies, in order to improve access to public events and facilities for the chemically intolerant.

- Modify or relocate the affected individual’s work space so as to increase fresh air ventilation and reduce troublesome exposures. Other potentially helpful strategies include: Openable windows, fresh air exchangers, and/or adequately sized air filtration units with filter media for particulates and vapors; eliminating odorous furnishings, e.g., carpet, particle board furniture, or odorous veneers, laser printers, copiers, carbonless copypaper (some brands may be better tolerated); and placing personal computers and printers in ventilated enclosures with glass fronts. Metal desks and shelving may be preferable to veneers or particle board. Some employers have assigned an assistant to chemically intolerant employees to help with photocopying, entering problem areas, etc. In a few cases, state disability funds have paid for assistants.
- Provide personal protective equipment, e.g., face masks with appropriate filters, for meetings or other short-term exposures.
- Notify susceptible individuals in advance about maintenance activities that may pose a problem for them. Provide schedules for cleaning, extermination, floor waxing, repair and construction work, landscape chemical applications, or mowing. Alternatively, schedule these activities while affected employees are away from the building. Offer temporary, alternative work arrangements, e.g., during carpet cleaning, painting, or pesticide application, until employees can reenter the space without experiencing symptoms.
- Select the least toxic, most odor-free construction and maintenance supplies. Affected individuals’ advice should be sought when choosing paint brands, cleaning products, whiteboard markers, new furnishings, etc.
- Eliminate, or at least minimize, pesticide use indoors and out. Lawn treatment chemicals, herbicides, etc., can migrate indoors via air intakes, cracks, and crevices (consider how a skunk’s odor seeps indoors even when windows are closed). Use integrated pest management (IPM), applying pesticides only when non- or less-toxic approaches fail. IPM emphasizes improved sanitation, mowing, insect traps, baits, and sealing crevices and openings (for one university’s experience with a pest control policy to protect the chemically intolerant, see Brown 1999). If pesticides are needed, then select the least toxic, least volatile, and least persistent formulation that will still work.

TABLE 27.5 Strategies for Accommodating Chemically Intolerant Individuals (*Continued*)

-
- Allow affected individuals to adopt flexible schedules and even work from home. Certain jobs permit flexible work hours, enabling chemically intolerant individuals to avoid traffic and traffic exhaust, or customers or coworkers wearing fragrances. Telemarketing, writing, or computer assignments may lend themselves to work-at-home arrangements. Employers need to ensure that such off-site employees know their assignments, function as full partners in the workforce, and are eligible for awards and other perquisites.
 - Educate the entire workforce. All coworkers, custodial staff, maintenance personnel, etc. must receive instruction concerning the nature of the disability. This is essential for enlisting coworkers' support (e.g., for fragrance-free policies), and avoiding stigmatization or harassment of those affected. Coworkers need to understand that chemically intolerant individuals may *appear* well and occasionally be seen in restaurants, movie theaters, or hair salons, or working on their car without obvious difficulties, but that their health may be jeopardized by certain exposures. Managers need to show that they take the illness seriously and explain the protective actions being taken. A positive, proactive approach will prevent grumbling or unkind remarks or actions by coworkers. An appropriately phrased memo may preempt inconsiderate behavior by others, e.g., deliberate perfume use or spraying of fragrances on the affected individual's chair or telephone, actions that potentially could expose the employer to a harassment suit.
-

building is safe. The obliging consultant's report finds that exposures in the building are well below OSHA limits—an uninformative and potentially disastrous conclusion. Affected occupants are apt to see this as management's discounting their symptoms or questioning their veracity. Compensation claims and litigation can be the unfortunate result.

Environmental interventions for the chemically intolerant target three building occupant groups: (1) those who are healthy, but if exposed, may be at increased risk for developing the illness; (2) individuals who show early signs of TILT, e.g., those whose symptoms persist hours or days after they leave the building and/or who are beginning to develop new intolerances; and (3) those with the full-blown condition. Protective measures directed at these groups involve: (1) prevention; (2) early intervention; and (3) accommodation, respectively.

Achieving good indoor air quality draws on the entire compendium of strategies in this handbook—the use of nonoutgassing construction materials and furnishings, sufficient fresh makeup air, moisture control, proper HVAC maintenance, etc. Protecting the most vulnerable occupants should provide a margin of safety for others. Intervention during the illness' initiation phase has the potential to halt or even reverse its course (see Case Study 4). Like the proverbial canary in a coal mine, these individuals may be sentinels for building exposures that could be affecting others to varying degrees, e.g., causing eye irritation or lowering productivity. Illness recognition may occur in the workplace or a doctor's office. An employer's industrial hygienists and physicians are best positioned to recognize symptoms associated with workplace exposures. The QEESI (Sec. 27.11 and appendix to the chapter) can help affected individuals understand their condition better, enabling them to recognize triggers at work and at home, e.g., household extermination, hobby exposures, or home remodeling. At the present time, early recognition and prompt removal from exposure offer the most promise for reversing the condition.

Once the illness progresses beyond a certain point, no current medical treatment reliably reverses it. For this reason, it is crucial to respond to complaints immediately and to act quickly to resolve the problems. Frequently, an individual can be moved to another area or allowed to work at home temporarily to prevent worsening illness and disability, while management determines, preferably with the help of the affected individual and perhaps the physician, what actions are needed to remediate the problem. Accommodating chemically

intolerant individuals in the workplace is challenging. There are some low-cost interventions. An ongoing partnership between the affected person(s), management, personal physicians, the company's health professionals, industrial hygienists, building engineers, and maintenance staff should be established. Single interventions rarely are curative. More often, a trial-and-error process over an extended period, e.g., weeks or months, is required. Not every intervention will work. Installing an openable window might bring in exhaust from idling vehicles or buses. Moving the workstation away from copier machines and coworkers' fragrances will not be helpful if the new workstation is next to a restroom or janitor's closet.

People who are chemically intolerant fear being singled out or considered workplace troublemakers. Many simply suffer silently. If they appear well, coworkers may assume incorrectly that things are fine. Continued exposure, however, may jeopardize their health, as well as the health of others. Individuals who have had the condition for years are often the best source of information concerning what corrective measures may be beneficial.

Some patient support and advocacy groups work willingly with employers and employees to help identify cost-effective interventions. The director of one group, the National Center for Environmental Health Strategies, has served on federal advisory committees for housing and employment accommodations under the Fair Housing Act and the Americans with Disabilities Act (Lamielle 1999). Employers tend to steer clear of these groups for fear they may demand chemical-free workspaces. Reportedly, this is not the case. Neither is it incumbent on an employer to adopt these groups' recommendations. Rather, "to some degree, the employer's choice is between learning what these sources have to say at the outset of the accommodation process or in the middle of a trial" (Winterbauer 1997). Seeking advice from support groups demonstrates both a good faith effort and that the employer considers the employee inherently reasonable. Many employers have successfully accommodated chemically intolerant individuals, thereby retaining productive, loyal, and grateful employees (Miller et al. 1999, Brown 1999) (see Case Study 5).

Case Study Number 5. Workplace Accommodation for Multiple Chemical Intolerance

Three women with multiple chemical intolerances learned that the government agency they worked for was about to move to a new office building. In response to their concerns, an industrial hygienist conducted baseline air sampling just prior to move-in. Total VOC concentrations of 200 $\mu\text{g}/\text{m}^3$ (toluene equivalent units with chemical constituents) were found (Miller et al. 1999). Soon after the move, all three women reported worsening of their symptoms, including severe asthma, seizure-like activity, headaches, irregular heart beat, feelings of drunkenness, unsteadiness, light-headedness, cognitive difficulties, irritability, fatigue, and skin burning and redness, and worsening and/or spreading of their intolerances to chemicals associated with new construction, vapors from copier machines and fax machines, perfumes, and insecticides.

One woman who experienced balance problems and light-headedness in the new office building, ended up transferring to an older building and finally had to work from home. Another who became ill also left the building, but was able to return when an air cleaner equipped with charcoal/high-efficiency particulate filters was installed in her office. The third woman was able to work normally in the building, but only after it had outgassed for a year. One year postconstruction, a fourth chemically intolerant woman came to work in the same building. She experienced no major difficulties in the building, however, outside of work she noticed having reactions to perfumes, vehicle exhaust, petroleum and paint vapors, tire stores, carpeting, pet supplies, and insecticides.

One of the women reported having been chemically intolerant all her life. The others said they became sick after staying in a new motel room, working with laboratory solvents, or during new home construction. Workplace accommodations included scheduling maintenance activities while the women were away and providing respirators as needed (Miller et al. 1999). None of the other building occupants reported developing chemical intolerances, suggesting that VOC levels in the building were below those that might initiate TILT.

APPENDIX: THE QEESI^{®1}

The Quick Environmental Exposure and Sensitivity Inventory (QEESI[®]) was developed as a screening questionnaire for multiple chemical intolerances (MCI). (See Miller and Prihoda 1999a, 1999b.) The instrument has four scales: symptom severity, chemical intolerances, other intolerances, and life impact. Each scale contains 10 items, scored from 0 = “not a problem” to 10 = “severe or disabling problem.” A 10-item masking index gauges ongoing exposures that may affect individuals’ awareness of their intolerances as well as the intensity of their responses to environmental exposures. Potential uses for the QEESI include:

1. *Research*—to characterize and compare study populations, and to select subjects and controls.
2. *Clinical evaluations*—to obtain a profile of patients’ self-reported symptoms and intolerances. The QEESI can be administered at intervals to follow symptoms over time or to document responses to treatment or exposure avoidance.
3. *Workplace or community investigations*—to identify and assist those who may be more chemically susceptible or who report new intolerances. Affected individuals should have the option of discussing results with investigators or their personal physicians.

Individuals whose symptoms began or intensified following a particular exposure event can fill out the QEESI using two different ink colors, one showing how they were before the event, and the second how they have been since the event. On the cover of the QEESI is a “symptom star” (Figure 27.3), which provides a graphical representation of patients’ responses on the symptom severity scale.

Interpreting the QEESI[®]

In a study of 421 individuals, including four exposure groups and a control group, the QEESI provided sensitivity of 92 percent and specificity of 95 percent in differentiating between persons with multiple chemical intolerances and the general population (Miller and Prihoda 1999a, 1999b).

Cronbach’s alpha reliability coefficients for the QEESI’s four scales—symptom severity, chemical intolerances, other intolerances, and life impact—were high (0.76 to 0.97) for each of the groups, as well as over all subjects, indicating that the questions on the QEESI form scales showing good internal consistency. Pearson correlations for each of the four scales with validity items of interest, i.e., life quality, health status, energy level, body pain, ability to work, and employment status, were all significant and in the expected direction, thus supporting good construct validity.

Information on the development of this instrument, its interpretation, and results for several populations have been published (Miller and Prihoda 1999a, 1999b). Proposed ranges for the QEESI’s scales and guidelines for their interpretation appear in Tables 27.6 and 27.7.

Miller, John Wiley & Sons, 1998 (1-800-225-5945).

OTHER EXPOSURES

The following items ask about your responses to a variety of other exposures. As indicated, please indicate whether these exposures would make you feel sick. Rate the severity of your symptoms on a 0-10 scale. Do not leave any items blank.

0 = not at all a problem
5 = moderate symptoms
10 = disabling symptoms

For each item, circle one number only:

1. Chlorinated tap water	0 1 2 3 4 5 6 7 8 9 10
2. Particular foods, such as candy, pizza, milk, fatty foods, meats, barbecue, onions, garlic, spicy foods, or food additives such as MSG	0 1 2 3 4 5 6 7 8 9 10
3. Unusual cravings, or eating any foods as though you were addicted to them; or feeling ill if you miss a meal	0 1 2 3 4 5 6 7 8 9 10
4. Feeling ill after meals	0 1 2 3 4 5 6 7 8 9 10
5. Caffeine, such as coffee, tea, Snapple, cola drinks, Big Red, Dr. Pepper or Mountain Dew, or chocolate	0 1 2 3 4 5 6 7 8 9 10
6. Feeling ill if you drink or eat less than your usual amount of coffee, tea, caffeinated soda or chocolate, or miss it altogether	0 1 2 3 4 5 6 7 8 9 10
7. Alcoholic beverages in small amounts such as one beer or a glass of wine	0 1 2 3 4 5 6 7 8 9 10
8. Fabrics, metal jewelry, creams, cosmetics, or other items that touch your skin	0 1 2 3 4 5 6 7 8 9 10
9. Being unable to tolerate or having adverse or allergic reactions to any drugs or medications (such as antibiotics, anesthetics, pain relievers, x-ray contrast dye, vaccines or birth control pills), or to an implant, prosthesis, orthodontic appliance or device, or orthopedic surgical or dental material or procedure	0 1 2 3 4 5 6 7 8 9 10
10. Problems with any classical allergic reactions (asthma, nasal symptoms, hives, anaphylaxis or eczema) when exposed to allergens such as: tree, grass or weed pollen, dust, mold, animal dander, insect stings or particular foods	0 1 2 3 4 5 6 7 8 9 10

Total Other Intolerance Score (0-100):

CHEMICAL EXPOSURES

The following items ask about your responses to various odors or chemical exposures. Please indicate whether or not these odors or exposures would make you feel sick, for example, you would get a headache, have difficulty thinking, feel weak, have trouble breathing, get an upset stomach, feel dizzy, or something like that. For any exposure that makes you feel sick, on a 0-10 scale rate the severity of your symptoms with that exposure. For exposures that do not bother you, answer "0." Do not leave any items blank.

0 = not at all a problem
5 = moderate symptoms
10 = disabling symptoms

For each item, circle one number only:

1. Diesel or gas engine exhaust	0 1 2 3 4 5 6 7 8 9 10
2. Tobacco smoke	0 1 2 3 4 5 6 7 8 9 10
3. Insecticide	0 1 2 3 4 5 6 7 8 9 10
4. Gasoline, for example at a service station while filling the gas tank	0 1 2 3 4 5 6 7 8 9 10
5. Paint or paint thinner	0 1 2 3 4 5 6 7 8 9 10
6. Cleaning products such as disinfectants, bleach, bathroom cleansers or floor cleaners	0 1 2 3 4 5 6 7 8 9 10
7. Certain perfumes, air fresheners or other fragrances	0 1 2 3 4 5 6 7 8 9 10
8. Fresh tar or asphalt	0 1 2 3 4 5 6 7 8 9 10
9. Nailpolish, nailpolish remover, or hairspray	0 1 2 3 4 5 6 7 8 9 10
10. New furnishings such as new carpeting, a new soft plastic shower curtain or the interior of a new car	0 1 2 3 4 5 6 7 8 9 10

Total Chemical Intolerance Score (0-100):

Name any additional chemical exposures that make you feel ill and score them from 0 to 10:

QUICK ENVIRONMENTAL EXPOSURE AND SENSITIVITY INVENTORY V-1 (QEESI)®

The purpose of this questionnaire is to help identify health problems you may be having and to understand your responses to various exposures. If your health problems began suddenly or became much worse after a particular exposure event, such as a pesticide exposure or moving to a new home or office building, complete pages 1-3 describing how you are now, then go back through these same questions a second time, and identify how you were before the exposure event. After you have completed all of the items on pages 1-5, fill in the "target" diagram below.

SYMPTOM STAR

Instructions: After completing pages 1 through 5, unfold page 3 so that it lies just to the right of this page. Place a small dot on the corresponding spoke for each symptom item on page 3. Connect these points. For "before and after" scores (described above), use two different colors.

Symptoms

The following questions ask about symptoms you may have experienced commonly. Rate the severity of your symptoms on a 0-10 scale. Do not leave any items blank.

0 = not at all a problem
5 = moderate symptoms
10 = disabling symptoms

For each item, circle one number only:

1	Problems with your muscles or joints, such as pain, aching, cramping, stiffness or weakness?	ms 0 1 2 3 4 5 6 7 8 9 10
2	Problems with burning or irritation of your eyes, or problems with your airway or breathing, such as feeling short of breath, coughing, or having a lot of phlegm, postnasal drainage, or respiratory infections?	airway 0 1 2 3 4 5 6 7 8 9 10
3	Problems with your heart or chest, such as a fast or irregular heart rate, skipped beats, your heart pounding, or chest discomfort?	cor 0 1 2 3 4 5 6 7 8 9 10
4	Problems with your stomach or digestive tract, such as abdominal pain or cramping, abdominal swelling or bloating, nausea, diarrhea, or constipation?	gi 0 1 2 3 4 5 6 7 8 9 10
5	Problems with your ability to think, such as difficulty concentrating or remembering things, feeling spaced out, or having trouble making decisions?	cog 0 1 2 3 4 5 6 7 8 9 10
6	Problems with your mood, such as feeling tense or nervous, irritable, depressed, having spells of crying or anger, or feeling unable to do things that used to interest you?	aff 0 1 2 3 4 5 6 7 8 9 10
7	Problems with balance or coordination, with numbness or tingling in your extremities, or with focusing your eyes?	bal 0 1 2 3 4 5 6 7 8 9 10
8	Problems with your head, such as headaches or a feeling of pressure or fullness in your face or head?	head 0 1 2 3 4 5 6 7 8 9 10
9	Problems with your skin, such as a rash, hives or dry skin?	skin 0 1 2 3 4 5 6 7 8 9 10
10	Problems with your urinary tract or genitals, such as pelvic pain or frequent or urgent urination? (for women: or discomfort or other problems with your menstrual period?)	gu 0 1 2 3 4 5 6 7 8 9 10

Masking Index

The following items refer to ongoing exposures you may be having. Circle "0" if the answer is NO, or if you don't know whether you have the exposure. Circle "1" if the answer is YES, you do have the exposure. Do not leave any items blank.

Circle "0" or "1" only:

1.	Do you smoke or dip tobacco once a week or more often?	NO=0 YES=1
2.	Do you drink any alcoholic beverages, beer, or wine once a week or more often?	NO=0 YES=1
3.	Do you consume any caffeinated beverages once a week or more often?	NO=0 YES=1
4.	Do you routinely (once a week or more) use perfume, hairspray, or other scented personal care products?	NO=0 YES=1
5.	Has either your home or your workplace been sprayed for insects or fumigated in the past year?	NO=0 YES=1
6.	In your current job or hobby, are you routinely (once a week or more) exposed to any chemicals, smoke or fumes?	NO=0 YES=1
7.	Other than yourself, does anyone routinely smoke inside your home?	NO=0 YES=1
8.	Is either a gas or propane stove used for cooking in your home?	NO=0 YES=1
9.	Is a scented fabric softener (liquid or dryer sheet) routinely used in laundering your clothes or bedding?	NO=0 YES=1
10.	Do you routinely (once a week or more) take any of the following: steroid pills, such as prednisone; pain medications requiring a prescription; medications for depression, anxiety, or mood disorders; medications for sleep; or recreational or street drugs?	NO=0 YES=1

Masking Index (0-10):
(Total number of YES answers)

4

Impact of Sensitivities

If you are sensitive to certain chemicals or foods, on a scale of 0-10 rate the degree to which your sensitivities have affected various aspects of your life. If you are not sensitive or if your sensitivities do not affect these aspects of your life, answer "0." Do not leave any items blank.

0 = not at all
5 = moderately
10 = severely

1.	Your diet	0 1 2 3 4 5 6 7 8 9 10
2.	Your ability to work or go to school	0 1 2 3 4 5 6 7 8 9 10
3.	How you furnish your home	0 1 2 3 4 5 6 7 8 9 10
4.	Your choice of clothing	0 1 2 3 4 5 6 7 8 9 10
5.	Your ability to travel to other cities or drive a car	0 1 2 3 4 5 6 7 8 9 10
6.	Your choice of personal care products, such as deodorants or makeup	0 1 2 3 4 5 6 7 8 9 10
7.	Your ability to be around others and enjoy social activities, for example, going to meetings, church, restaurants, etc.	0 1 2 3 4 5 6 7 8 9 10
8.	Your choice of hobbies or recreation	0 1 2 3 4 5 6 7 8 9 10
9.	Your relationship with your spouse or family	0 1 2 3 4 5 6 7 8 9 10
10.	Your ability to clean your home, iron, mow the lawn, or perform other routine chores	0 1 2 3 4 5 6 7 8 9 10

Uses “high” cutoff points for symptom severity (≥ 40) and chemical intolerances (≥ 40), with masking low or not low (<4 or ≥ 4)

Degree to which MCI is suggested†	Risk criteria*			Percentage of each group meeting risk criteria				
	Symptom severity score	Chemical intolerance score	Masking score	Controls <i>n</i> = 76	MCS—no event <i>n</i> = 90	MCS—event <i>n</i> = 96	Implant <i>n</i> = 87	Gulf War veterans <i>n</i> = 72
Very suggestive	≥ 40	≥ 40	≥ 4	7	16	23	39	45
Very suggestive	≥ 40	≥ 40	<4	0	65	66	36	4
Somewhat suggestive	≥ 40	<40	≥ 4	3	1	2	16	26
Not suggestive	≥ 40	<40	<4	0	0	2	3	6
Problematic	<40	≥ 40	≥ 4	7	3	1	1	0
Problematic	<40	≥ 40	<4	3	13	4	2	0
Not suggestive	<40	<40	≥ 4	68	1	0	2	18
Not suggestive	<40	<40	<4	12	1	2	1	1
				100	100	100	100	100

*Subjects must meet all three criteria, i.e., symptom severity, chemical intolerance, and masking scores, as indicated in each row of this table.

†“Very suggestive” = high symptom and chemical intolerance scores.

“Somewhat suggestive” = high symptom score but possibly masked chemical intolerance.

“Not suggestive” = either (1) high symptom score but low chemical intolerance score with low masking, or (2) low symptom and chemical intolerance scores.

“Problematic” = low symptom score but high chemical intolerance score. Persons in this category with low masking (<4) may be sensitive individuals who have been avoiding chemical exposures for an extended period (months or years).

Technical University Munich, Germany*

28.1 OVERVIEW

The skin, as a critical barrier organ, is constantly exposed to a broad range of environmental agents, including contaminants in indoor air, and a variety of types of injury and illness may result from these exposures. Thus, environment physical forces (ionizing and nonionizing radiation, temperature, and mechanical energy), chemical substances (water, organic and inorganic chemicals) and biological agents (plants, animals, and insects) may injure the skin through radiation, direct contact or injection, and the media of food and air (Fig. 28.1). Risk of injury and disease, as for other organs, is variable with dose and dose rate, and for some agents, with sensitivity or susceptibility to the agent. The underlying mechanisms of injury can be classified into direct toxicity or hypersensitivity reactions which may be immunologically mediated ("allergies") or non-immunologically mediated (idiosyncrasy or pseudo-allergy).

This chapter provides an introduction to dermatological health consequences of indoor environments. The relevant biomedical literature is limited, referring largely to various types of dermatitis associated with indoor irritants and allergens. However, complaints related to the skin are frequently elements of two complex syndromes associated with indoor air quality: sick building syndrome and multiple chemical sensitivity. These topics are covered in detail in other chapters and their dermatologic manifestations receive a brief treatment here. In addition, complaints related to the skin, particularly dryness and itching, may reflect air that is too dry. Dermal effects thus merit consideration as part of assuring that building occupants are comfortable.

FIGURE 28.1 Environment: substances, forces, sources, ways.

The chapter also provides a broader perspective on the environment and dermatological conditions, considering physical factors and the broader psychosocial environment and stress, an aspect of indoor air quality that may influence responses to indoor pollutants affecting the skin. The skin, of course, is a complex organ, distinguished by its surface area and barrier function. For those seeking background information on skin diseases, including the normal structure and functioning of the skin, there are a number of textbooks available, including those edited by Champion, Burton, and Ebling (1992), and by Fitzpatrick, Eisen, Wolff, Freedberg, and Austen (1993).

These books or a basic medical text could be consulted to gain an introduction to and explanation of the structure and function of the skin. In brief, the skin is crucial to human health and survival; it is made up of many tissues, cell types, and specialized structures serving many functions. As one of the largest and most dynamic human organs, it serves as the boundary between the human body and the environment. Among its functions crucial to survival are protection against such elements as ultraviolet light (UV), mechanical and chemical injury, invasion by infectious agents, dehydration, and others; it is key to regulating the body's temperature. By monitoring various environmental stimuli, the skin acts as a sensory receptor for the body. It is active in immunologic surveillance and often reflects internal disease processes (Parker 2000). Skin abnormalities requiring dermatological treatment are common: almost one in three Americans seeks professional care for skin conditions (Parker 2000), although the contribution of indoor air quality to this total burden is likely to be minor.

The skin's structure mirrors its barrier, thermoregulatory, and other roles. The epidermis is the skin's outer layer; both the epidermis and the dermis—the inner layer—are cushioned on the fat-containing subcutaneous tissue, the panniculus adiposus. The epidermis

TABLE 28.1 Effect of Nitrogen Dioxide (0.1 ppm) or Formaldehyde (0.08 ppm) on Transepidermal Water Loss ($\text{g/h}\cdot\text{m}^2$) in Controls ($n = 7$) and Atopic Eczema Patients ($n = 7$).

continuously renews and differentiates its cells; the latter process involves the formation of fibrous proteins known as keratin. The epidermis itself is made up of two main layers of cells: an inner region of viable cells known as the *stratum germinativum*, and an outer region of anucleate cells known as the *stratum corneum*, or horny layer. The dermis, or inner layer, composes the principal mass of the skin. It is tough and flexible, with viscoelastic properties, and consists of loose connective tissue composed of fibrous proteins (collagen and elastin) in a nebulous substance (glycosaminoglycans). This network of tissue provides the infrastructure for intertwining blood vessels, nerves, and lymphatics. The eccrine sweat glands, of which 2 to 3 million are distributed over the body surface and play major roles in thermoregulation, are also located in the dermis (Parker 2000).

There has been little research on mechanisms by which air pollutants may affect the skin. An experimental study carried out by Eberlein-König et al. (1998) illustrates the potential for airborne pollutants to affect the skin's barrier function. In this experimental study involving persons with atopic eczema and controls, short-term exposures, up to 4 hours, to low concentrations of nitrogen dioxide or formaldehyde disturbed the epidermal barrier function, as measured by transepidermal water loss. These effects were more pronounced in persons with atopic eczema (Table 28.1).

We now review physical factors that affect the skin, then chemical and biological factors.

28.2 PHYSICAL FACTORS AFFECTING THE SKIN

Electromagnetic Radiation

We are exposed to light in both indoor and outdoor environments. Light is part of the spectrum of electromagnetic radiation; the solar spectrum is made up of visible light (about 50 percent), ultraviolet radiation (about 10 percent), and infrared radiation (about 40 percent). Both visible light and UV are photobiologically active on the skin, causing a number of specific and nonspecific diseases (Table 28.2). The frequencies of these conditions vary with latitude, the seasonal position of the sun, and the population.

UV radiation is divided into three spectral bands by wavelength. The biological effects of the three bands differ. The shortwave UV-C radiation (200 to 280 nm) emitted from the sun is absorbed by the atmosphere's ozone layer and does not reach the earth's surface. UV-C radiation, however, is also emitted from artificial radiation sources and exposure leads to erythema (redness) of the skin after 6 hours, followed by the appearance of dermatitis.

UV-B radiation (280 to 320 nm), coming from the sun and reaching the earth's surface, is the most photobiologically effective band of radiation on the skin. It induces sunburn (der-

TABLE 28.2 UV-Induced Skin Diseases

Photoallergic reactions:	Questionable photoallergic reactions:
Photoallergic contact dermatitis	Solar urticaria
Chronic actinic dermatitis	Polymorphous light eruption
(persistent light reaction,	("sun allergy")
actinic reticuloid)	Sun-provoked dermatoses:
Phototoxic reactions:	Lupus erythematosus
Acute and chronic solar damage	Darier's disease
Phototoxic dermatitis	Porokeratosis
Metabolic disorders	Lichen planus
(porphyrrias, Hartnup's	Psoriasis
disease, etc.)	Atopic eczema
[Questionable: Hydroa vacciniforme,	Herpes simplex
Acne aestivalis (Mallorca)]	

matitis solaris), which starts about 4 to 6 hours after exposure, reaching its maximum intensity 12 to 24 hours later and fading away after 72 hours. In parallel, 48 to 72 hours after the radiation exposure a delayed tanning (suntan) of the skin becomes visible. The degree of the sunburn reaction (slight erythema, edema, or blisters) depends on different environmental factors. For example, UV radiation is particularly intensive at the sea and in high mountains because of missing UV-absorbing dust or haze particles as well as reflection by snow, water or sand.

UV-A radiation (320 to 400 nm) has an approximately 1000 times weaker effect than UV-B radiation. However, the energy of UV-A radiation reaching the earth's surface is 10 to 100 times greater than that of UV-B radiation. UV-A radiation induces an immediate pigment darkening and delayed tanning by synthesis of melanin. At high doses an immediate erythema appears. It has been assumed that UV-A radiation has a cumulative or synergistic effect with respect to the effects of UV-B radiation. With regard to indoor exposure, UV-A can pass through glass windows.

The acute responses of the skin to UV radiation can be aggravated by photosensitizing substances applied topically or given systemically. These reactions can be based on a toxic or allergic mechanism (phototoxic or photoallergic reactions, respectively). In several metabolic disorders (e.g., the porphyrias) photosensitizing agents are formed endogenously. In these diseases, typical skin lesions appear in sun-exposed body areas. The common symptoms of the polymorphic light eruption (PLE), often described as "sun allergy," seem to be caused by photosensitization by so far unknown agents (Table 28.2).

These skin disorders developing immediately after sun exposure need to be separated from reactions with a latency of years or decades that lead to aging of the skin. Sunlight exposure over the life course not only leads to aging of the skin but to the development of skin cancer and to precancerous lesions. Typical UV-induced precancerous skin lesions include solar keratoses of various types (erythematous type, keratotic type, cornu-cutaneum type, lichen planus-like type, pigmented type). Approximately 10 to 20 percent of these lesions progress to formation of a squamous cell carcinoma at temperate latitudes.

Solar radiation also plays a major etiologic role in the development of basal cell carcinomas, which occur largely in sun-exposed areas of the body, primarily in older persons, and very rarely in dark-skinned peoples. The frequency of basal cell carcinomas increases in light-skinned peoples in relation to proximity of residence to the equator. In several heritable syndromes with increased UV sensitivity (xeroderma pigmentosum, albinism) (Armstrong and English 1996) skin cancers develop more frequently.

Sun exposure also has been identified as a risk factor for malignant melanoma [5]. UV radiation exposure is considered to underlie this risk, but its effect on risk seems to vary for

different types of melanoma. The direct cumulative effect of chronic sun radiation seems to be relevant only for the lentigo maligna melanoma that develops usually at older ages from a lentigo preexisting for decades. In addition to other risk factors (e.g., familial melanoma and number of acquired melanocytic nevi), UV exposure plays a more indirect role for other types of melanoma (superficial spreading melanoma, nodular melanoma, acral lentiginous melanoma). Severe sunburns in childhood, a photosensitive skin type with fair skin color, with blue or green eyes, red or sandy hair, and freckles, as well as an intermittent, intense UV exposure seem to contribute to an increased risk for the development of malignant melanoma.

It has been hypothesized that fluorescent lighting, common in indoor environments, may increase risk for malignant melanoma. In 1982, Beral and colleagues (1982) reported a case-control study of malignant melanoma; they found that risk for this important cutaneous malignancy increased with duration of exposure to fluorescent lighting. They noted that the emissions from fluorescent lighting may extend into a range of wavelengths possibly associated with cancer. However, not all studies have replicated this association, which remains under investigation (Armstrong and English 1996).

The damaging effect of ionizing radiation on the skin has long been known. Acutely, sufficient exposure causes acute radiation dermatitis, while long-term, chronic effects include chronic radiation dermatitis, radiation ulcers, radiation keratoses, and radiation-induced skin cancer. The severity of the acute radiation response depends on the dose received and ranges from erythema at the mildest to radiation necrosis; there may be chronic and permanent changes as a consequence of receiving a sufficiently high skin dose.

Effects of Temperature and Air Humidity

Exposure to extremes of heat or cold can lead to skin changes or skin diseases, although these extremes are unlikely to be encountered in indoor environments. Frostbite occurs in individuals exposed to extreme cold. The response depends on the exposure temperature and duration. At the mildest, there is ischemic vasoconstriction with white and insensitive skin (grade 1) or serous or hemorrhagic blisters (grade 2). The most severe form, grade 3, is characterized by tissue necrosis and then mumification or gangrene. Chilblains (perniosis) are caused by exposure to temperatures above 0°C and dampness (chilly and damp weather in the spring and in the fall). Cold urticaria (hives), one of the most frequent forms of physical urticaria, occurs after direct cold exposure as an itching erythema with wheals.

High-temperature exposures, of course, cause burning or scalding. The reaction is classified by the intensity of the response, which can range from painful erythema with swelling to actual necrosis. Cancers may eventually develop in burn scars.

Of course, such extremes of temperature are not of concern in indoor environments, but skin complaints may be made that appear to have their basis in the temperature and humidity of the indoor environment. Skin complaints are often claimed in relation to indoor air quality problems, with particularly high rates from persons working at video display terminals (VDTs) (Stenberg 1992). However, only recently has the objective basis for office-related skin complaints been evaluated. In an extensive investigation of sick building syndrome, German investigators have correlated questionnaire-reported subjective symptoms of skin problems with medical observations and measurements of skin sebum content and the hydration of the stratum corneum (Brashe et al. 2000). Persons characterized by low sebaceous secretion and/or low stratum hydration reported significantly more skin complaints. For complaints of “quite” or “very annoying” dry skin in the workplace, the prevalence was 35 percent compared to 18 percent among those with low (<25 percent) sebum content.

This study, while helping to differentiate responders within a population, does not provide insight as to the possible causes for such complaints. Møhlave and coworkers (1993)

exposed healthy adults in a climate-controlled chamber to various concentrations of VOCs at different temperatures. They reported both temperature and pollutant effects on perception of feeling of dryness of facial skin as well as measured skin humidity of the forehead. Both significant independent and interactive effects were found. While the temperatures used reflect a typical range found in office spaces, the concentration of mixed VOCs was either zero or 10 mg/m³, the latter level being more typically found during renovations or new construction. Nevertheless, the findings suggest that pollutants together with environmental conditions can induce the sensation of skin dryness [9].

Sundell and Lindvall (1993) examined the relationship of indoor air humidity with the sensation of dryness in a large survey of almost 5000 Swedish office workers. They surveyed the literature to that time and found inconclusive evidence on the benefits and risks of humidification. In one study by Reinikainen et al. (1991), increasing the humidity to 30 to 40 percent RH in an office building reduced the complaints of dryness of the skin and eyes as well as the sensation of dryness, as compared to periods when the building RH was between 20 and 30 percent. In an earlier English study by Rycroft and Smith (1980), the term “low humidity occupational dermatosis” was used to describe an outbreak of skin symptoms. An association was not found between perception of “dry air” and humidity in a Swedish study. This study did find, however, a strong association for both men and women between the sensation of dryness, both for work and at home, and the symptoms of skin irritation. Lowering air humidity under controlled conditions in a climate chamber increased skin roughness in patients with atopic eczema (Eberlein-König et al. 1996).

In light of the findings from the more recent German studies and the earlier chamber study of Møhlhede et al. (1993), there is a substantial possibility that interactive effects and between-subject variability in sensitivity to skin dryness make it difficult to directly observe strong associations in observational studies. These factors, along with the lower range of RH (10 to 40 percent) experienced in the Swedish building study, suggest that there are complex interactions among indoor pollutants and humidity in determining symptoms related to the skin. Research on skin symptoms in buildings is complicated by the interactions among these factors, and observational data may be difficult to interpret as a result.

28.3 CHEMICAL AGENTS

Many chemicals have toxic-irritative effects on the skin that occur in a dose-dependent fashion. Their effects have been identified through case studies of patients, studies of workers, and follow-up of persons exposed inadvertently through accidents. Furthermore, some chemicals are associated with alterations of the connective tissue, preneoplastic skin lesions and skin cancer (Table 28.3). The range of diseases caused by chemicals includes contact dermatitis, which is particularly relevant to indoor air pollution, cancer, and other conditions. Dioxins, for example, are potent inducers of chloracne (Tindall 1985). Combustion sources produce dioxins; incinerators are major contributors to atmospheric dioxins but they are not prominent indoor sources. Chloracne has been reported in persons exposed through industrial accidents, as well as documented historically and by such episodes as the industrial catastrophe of Seveso in 1976, where trichlorophenols were released. Contact with polychlorinated biphenyls (PCBs) in high doses induces chloracne, hair loss, hyperpigmentation, thickening of fingernails and toenails, and lichenification of the skin.

Chemical agents may also induce other types of skin diseases, including scleroderma-like disorders and cancers. Scleroderma-like skin disorders have been associated with long-term exposure to silica and also to exposure to polyvinyl chloride, the contaminated rapeseed oil that caused “toxic oil syndrome” in Spain, and contaminated L-tryptophan, associated with the eosinophilia-myalgia syndrome (Belongia et al. 1990).

TABLE 28.3 Irritative Skin Reactions and Skin Disorders by Chemicals

Hyperkeratoses	Hyperpigmentation
Blistering	Petechial hemorrhages
Cauterization	Classic eczema
Acneform dermatitis	Urticaria
Scleroderma-like skin disorders	Fasciitis-like disorders
Bowen's disease	Basal cell carcinomas
Squamous cell carcinomas	

Ingestion of arsenic is associated with skin lesions and cancer, and long-term exposure to tar and its by-products is a well-known cause of skin cancer. Percival Pott's description of scrotal cancer in chimney sweeps was the first recognition of an occupational cause of cancer.

Acute irritant contact dermatitis has been associated with chemicals found in indoor environments. An understanding of the barrier function of the skin is relevant to understanding the pathogenesis of this condition. The final product of the highly specialized process of epidermal differentiation is the stratum corneum, which offers a barrier against water loss and penetration of the skin by environmental substances. The horny layer of the stratum corneum can be conceptualized as a two-compartment model ("bricks-and-mortar" model), consisting of protein-enriched corneocytes ("bricks") embedded in lipid-enriched intracellular material ("mortar"). Under normal conditions, these protective functions of the skin are sufficient for protection against environmental agents.

However, even a single exposure to a sufficiently irritating substance can lead to an acute irritant contact dermatitis (Lachappelle 1986). At the extreme, acids or lyes (e.g., nitric acid, sulfuric acid, or soda lye) in high concentrations lead to chemical burns with blisters or tissue necrosis. Other skin-damaging agents include organic solvents and detergents. The combination of photosensitizing substances with UV radiation can lead to the eruption of phototoxic reactions. Contact with noxious agents not primarily damaging the skin can lead to a classic chronic cumulative irritant contact dermatitis after long-lasting repetitive exposure and predisposition. Water is probably the most frequent trigger of these eczemas. Too much contact with water (excessive showers or bathing) leads to dryness of the skin, itching, disturbed barrier function, and finally to a manifest eczema. Soaps and liquid detergents, which remove the lipid layer and water-soluble substances, can be cofactors.

Irritative effects on the skin have been described for some contaminants of indoor air: nitrogen dioxide, pentachlorophenol, pyrethroids, isocyanate, formaldehyde, and other volatile organic compounds. A careful clinical history and examination may reveal the link to indoor air pollution. For airborne contaminants, the problem should involve air-exposed skin, and a temporal relation to specific microenvironments may be identified. Report of similar problems in coworkers is another but not necessary clue.

Dermatitis has been described in persons exposed to artificial fibers released into the air of buildings from construction materials (Lockey and Ross 1994). The dermatitis is thought to represent a direct physical consequence of exposure as the glass fibers directly penetrate the stratum corneum, typically causing itching, particularly of exposed areas. One outbreak was described in a new office building where fibers leaked from improperly installed insulation into the work area (Farkas 1983).

Environmental agents may induce not only classic chronic irritative contact dermatitis but classic allergic contact dermatitis. The latter is characterized by a specific sensitization and activation of T-lymphocytes after antigen presentation to Langerhans cells. Both artificial

and natural allergens may have effects through this mechanism. The most frequent allergens (Table 28.4) are metals (e.g. nickel, chromium, cobalt), rubber accelerating agents (low-molecular-weight chemicals used for vulcanization), natural and artificial resins (e.g., colophony and epoxy resin), substances from cosmetics (e.g., antibiotics like neomycin) as well as plants (e.g., sesquiterpene lactone from Compositae plants). For example, *Primula obconica*, a once-popular house and greenhouse plant for its showy and long-lasting flowers, causes a primula dermatitis by primin, a powerful sensitizer contained in the fine hairs of the plant. The eyelids, face, neck, fingers, hand, and arms are most often affected. *P. obconica* can also induce conjunctivitis and an erythema-multiforme-like eruption.

The symptoms of contact dermatitis from airborne agents correspond to classic contact allergic eczema, but allergen contact takes place through the airborne route. One example of indoor allergens causing airborne contact dermatitis is offered by preservatives, such as isothiazolinones, in wall paints. They are active ingredients in Kathon CG, a preservative often found in cosmetic products and toiletries, increasingly associated with allergic contact dermatitis. Treatment of recently painted rooms with inorganic sulfur salt leads to inactivation of the allergenic properties of Kathon CG.

In hospital environments, there is rising concern about exposure to latex antigen, dispersed from latex powder in gloves used as an infection control barrier (Sussman 1995). Subsequent to the epidemic of infection with the human immunodeficiency virus (HIV) and the acquired immunodeficiency syndrome (AIDS), hospital personnel increasingly used gloves as a barrier against infection. Gloves made from latex rubber contain protein antigens that may lead to allergic reactions that include dermatitis, asthma, and even anaphylaxis (Sussman 1995). These antigens may bind to the starch powder used to facilitate putting on the gloves. The antigen can be measured in the air of hospitals (Bauer et al. 1993; Sussman et al. 1998), although the comparative importance of airborne exposure versus direct contact is uncertain.

A photoallergic contact dermatitis can be induced by interaction of irradiation (in most cases UV-A) and an allergen. Photoallergic reactions can even be triggered by ingredients of sun protective agents, e.g. *p*-aminobenzoic acid, isopropylidibenzoylmethane, or benzophe-

TABLE 28.4 Frequency of Positive Patch Test Reactions
(German Contact Dermatitis Research Group)

Allergen	Frequency, % (<i>n</i> = 4941)
Nickel	17.0
Fragrance mix	14.2
Balsam of Peru	9.9
Thiomersal	9.6
Cobalt chloride	7.0
Wool alcohols	5.1

Euxyl K 400	4.6
<i>p</i> -Phenylendiamine	4.6
Potassium dichromate	3.9
Turpentine	3.5
Mercuric chloride	2.9
Thiuram mix	2.6
Neomycin sulfate	2.2
Kathon CG	2.1
Formaldehyde	2.0

Period: January–June 1999.

TABLE 28.5 Classification for Eczema (Dermatitis)

Classic eczema:
Contact/hematogenous
Allergic/irritant
Atopic eczema:
Extrinsic/intrinsic
Other eczemas:
Seborrheic eczema
Nummular eczema

none derivatives. Such classic eczemas (Table 28.5) cannot only be triggered by skin contact but also by systemic exposure (classic hematogenous eczema). Drugs are also frequently triggers (“iatrogenic sensitization”).

28.4 BIOLOGICAL AGENTS

At its broadest, this category might include not only diseases and conditions resulting from exposures to allergens and irritants but also infectious diseases of the skin induced by viruses, bacteria, fungi, or parasites. However, with regard to indoor air quality problems, exposures to allergens are most relevant. The protein allergens from pollens, animals, house dust mites, and molds are of particular relevance to indoor environments. These aeroallergens have a role not only for allergic respiratory diseases (allergic rhinitis and allergic asthma), but also for the development and maintenance of the extrinsic form of atopic eczema, a disease with inflammatory, chronic, or relapsing skin lesions, intense pruritus, and various skin symptoms and signs. The “atopy-patch test,” in addition to the history of symptoms in relation to exposure (e.g., relapses of eczema after contact with cat hair), gives clinically useful information for the relevance of single environmental agents, with a dose-dependent eczema reaction after epicutaneous application of IgE-inducing allergens. Patients with atopic eczema may show a pattern of lesions on air-exposed, along with positive responses on atopy patch testing (Darsow et al. 1996).

Other routes of exposure to biological agents may also cause allergic responses. Agents may be contained in foods and cause hypersensitivity reactions; these may include components of foods or additives. There may also be pollen-associated food allergy in persons with allergic rhinitis, e.g., cross reactions between birch pollen and kernel fruit, stone fruit as well as nuts, between mugwort pollen and spices (celery seed, dill, anise, paprika, pepper), between grass pollen and flours (soy, grain), and between latex and fruits (banana, avocado, kiwi).

28.5 PSYCHOSOCIAL FACTORS

As addressed in other chapters in this volume, responses to indoor environments are influenced by psychosocial factors, including the frequently complex dynamics among workers, supervisors, and employers. Dissatisfaction with resulting perceptions of stress often arises in workers in buildings where sick building syndrome (SBS) is a problem. Stress may maintain and influence skin disorders (Borelli 1987) particularly atopic eczema, urticaria, psoriasis, and lichen rubber. The potential mechanisms may be neuropsychological or neuroendocrine or possibly related to other hormonal mechanisms. The influence of stress on allergies can occur

in two distinct phases: the sensitization phase and the effector phase. Animal experiments show that stress can lead to a temporary deficiency of the immune system (Syvalahti 1987). An increase of vasoactive mediator release under stress conditions influencing allergic reactions has been shown both for animals and humans (Ring et al. 1991b).

28.6 SICK BUILDING SYNDROME AND MULTIPLE CHEMICAL SENSITIVITY

These two syndromic entities may have multiple symptoms, often including the skin. Each is covered in depth elsewhere in this volume. Sick building syndrome refers to the occurrence of symptoms in building occupants beyond the expected rate and in relation to time spent in the building. As described in Chap. 3, building surveys show that dermal symptoms are common in sick building syndrome, although generally reported by a minority of occupants.

Also of concern are the relations between exposure to environmental agents and the appearance of symptoms of illness among a population seemingly intolerant of levels of exposures acceptable to the majority of those exposed. The term *multiple chemical sensitivity* (see Chap. 27) describes the condition of individuals who appear to suffer from responsiveness to low-level exposure to environmental agents. They complain of various symptoms involving different organ systems, and dermal complaints may be a component. This patient group is best examined by an interdisciplinary team of clinicians and investigators, including a dermatologist if warranted. After evaluation of patient symptoms, one set of investigators found that the complaints from about half the patients in their study lacked a chemical explanation; a third of the patients had not experienced objectively allergic or pseudo-allergic hypersensitivity reactions previously. This study suggests that anxiety reactions to some pollutants can induce psychic illness. However, known physical disorders caused by exposure to environmental agents should not be overlooked (Ring et al. 1991a).

Petersen and colleagues (1999) report on a study examining objective and self-reported allergy. They point out that numerous studies have reported that atopy is an apparent risk factor for SBS. However, the relationship between increased SBS reporting and actual expressing of allergies has not been evaluated. In a sample of over 600 adult women from hospital and office settings, both questionnaire responses and blood samples were obtained. The blood was used for *in vitro* specific IgE analysis, including a mixture of common inhaled allergens (pollens, animal epithelium, house dust mites, and fungi). They report that self-reported allergic rhinitis and/or asthma were positively related to a positive specific IgE test as well as to work-related SBS symptoms from the eye, nose, and throat. There was, however, no correlation between a positive specific IgE test and work-related SBS symptoms. Also of interest was the highest prevalence of work-related SBS symptoms in the group having negative specific IgE test. The authors state that their study findings suggest that individuals may incorrectly interpret SBS symptoms as allergy.

28.7 SUMMARY

The skin represents on the one hand a barrier against influences from the environment; on the other hand it can be the point of entry for such influences. Environmental agents can induce skin disorders via toxic or allergic reactions, such as urticaria, eczema, or exanthematous eruptions. Since skin alterations often precede other disorders, knowledge of the interactions between skin diseases and environmental influences can be essential for early diagnosis.

INDOOR POLLUTANTS

CHAPTER 29

COMBUSTION PRODUCTS

Michael L. Burr, M.D., F.F.P.H.M.

*University of Wales College of Medicine
Cardiff, United Kingdom*

Heating and cooking are universal requirements for the home. The burning of fuel for these purposes produces smoke and fumes, and the irritant properties of these emissions have always created an immediate need for exhaust. In fact, unvented or poorly vented combustion of biomass fuels represents one of the major sources of indoor air pollution throughout the world. Cold, damp climates pose the problem of simultaneously keeping the heat in while exhausting fumes and minimizing the exchange between outdoor and indoor air to conserve energy. Central heating avoids the problem of smoke disposal associated with open fires, but the associated construction practices tend to reduce air exchange and consequently to increase the potential for elevated concentrations of indoor air pollutants. There is a complex interplay between need for combustion sources within homes, their control, and the related consequences for general building design with implications for levels of other pollutants.

29.1 PRINCIPAL COMBUSTION PRODUCTS

Smoke is the most obvious product of combustion, owing to its visible particulate nature and pungent smell (see Chap. 30). Water vapor and carbon dioxide (CO_2) are the two major products always emitted by the burning of organic fuels (solid, liquid, or gaseous). Water vapor contributes to the dampness of a house, which has implications for the health of the occupants, promoting mold growth (see Chap. 45) and infestation with house dust mites (Chap. 43). Carbon dioxide does not usually have important effects on health, except as a result of accidental fires that lead to asphyxiation. Certain other combustion products have health effects at much lower concentrations, and these constitute the main topic of this chapter.

29.2 THE NATURE OF THE EVIDENCE

In evaluating the health effects of combustion products, it is important to understand the nature of the available evidence. This derives from various types of investigation, each with its own limitations. The different kinds of study designs are, therefore, reviewed briefly with particular reference to evidence from epidemiologic surveys.

Clinical Studies Following Acute Exposure

Concern about the health effects of indoor combustion products was first aroused by episodes when people were accidentally exposed to these substances. The acute and chronic toxic effects of carbon monoxide (CO) have long been appreciated, and numerous observations have been made on persons who have been exposed to this gas. Most of the relevant observations relate to the immediate effects of short-term exposure, but follow-up studies show that delayed and chronic effects can occur. These studies are concerned with acute exposure to fairly high concentrations of noxious gases; the findings are not necessarily relevant to long-term exposure to lower concentrations.

Experimental Studies of Volunteers

Knowledge about the acute effects of exposure is supplemented by experimental studies of volunteers exposed on a short-term basis. For reasons of safety, these studies can deal only with short-term exposure under carefully controlled conditions that are not expected to have either lasting or potentially hazardous consequences. These studies have provided useful information about the immediate physiological effects of various gases in healthy persons, the effects of CO on persons with angina, and the actions of nitrogen dioxide (NO₂) and sulfur dioxide (SO₂) on persons with asthma. This evidence is invaluable in showing the results of inhaling different gases in known concentrations, such as can occur indoors. But this line of investigation is not informative about longer-term exposures; additionally, data gathered from volunteers who are not necessarily representative may have uncertain generalizability.

Experimental Studies on Animals

Evidence on the long-term effects of exposure can be provided by experimental studies using animals. Animal models can involve exposures to different concentrations of gases for various periods of time with measurement of various end points while the animals are alive, and then changes attributable to the exposure can be studied in detail by postmortem examination. This approach provides important information about the toxicology of gases such as CO and NO₂. Some caution is needed, however, in extrapolating the results of these experiments to humans, depending on the exposure and the health outcome of concern. It cannot be assumed that humans respond in the same way as the laboratory animal to these substances, particularly if the disease under investigation does not occur naturally in the animal in question, or if the human disease takes longer to develop than is allowed by the lifespan of the animal.

Epidemiologic Evidence

Epidemiologic evidence contributes to the study of this topic in many ways. Epidemiologic research can directly address the frequency of known episodes of indoor toxicity resulting

from combustion products, showing the importance of these episodes in a population context. Epidemiologic evidence also directly addresses the long-term effects of naturally occurring exposures. The various types of epidemiologic evidence will be outlined in turn. The simplest type of epidemiologic study is the cross-sectional survey. A sample of the population is selected, and data are collected about exposure to various potential hazards and their likely effects. The information relating to exposure usually comprises details about possible sources (e.g., cookers and heaters), but it may include measurements of concentrations of specific compounds in the air or of biomarkers in the blood or other biologic materials. The effects may be studied in terms of symptoms or physiological variables, such as forced expiratory volume in one second (FEV_1), forced vital capacity (FVC), peak expiratory flow rate (PEFR), and forced expiratory flow between 25 and 75 percent FVC (FEF_{25-75}). Long-term effects can be related to exposure only if the conditions of exposure have been fairly constant over a period of time or data are available to retrospectively estimate exposure with a reasonable degree of validity. This is often the case, since methods of heating and cooking do not change very frequently.

There are obvious limitations in cross-sectional surveys, in that the observations on exposure and effects are being made simultaneously, whereas it is likely that past exposure is more important than current exposure, particularly if the agents affect the growing child. In addition, a measurement of atmospheric concentration at one point in time does not reveal the occurrence of occasional peaks, which may cause acute or chronic damage. It may be possible to obtain information about short-term fluctuations in exposure by means of continuous monitoring, but it is difficult and expensive to do this for large numbers of people for any length of time. Furthermore, indoor monitoring requires the cooperation of the household, which is not always forthcoming, so that those who participate in a survey may not represent the whole population. There are some subgroups of households about whom very little is known, such as people living in mobile homes or trailers, which are likely to be particularly prone to air pollution because of their small volume and common use of propane for cooking.

Several types of study involve the collection of retrospective data. Questions can be asked about past exposure and past symptoms. Within a cross-sectional survey there is always a retrospective element in the information being sought, insofar as the investigator is interested in the occurrence of intermittent symptoms or illnesses requiring medical attention. This information typically becomes less accurate as the period for retrospective data collection extends further into the past. There is also the opportunity for recall bias to operate, in that the subject's memory will be influenced by what happened during the intervening time. For example, a mother who is repeatedly aware of fumes from the heating system may preferentially remember some instances of exposure after children's illnesses, which she would otherwise have forgotten.

The case-control study usually involves the retrospective collection of information on exposure. Participants are selected who have a particular condition or disease that is believed to be caused by the exposure under investigation; they are matched with a comparison group not having the disease or condition, and both groups are asked about past and present exposure to the suspected agent. This design may be more efficient than the survey but is often subject to the same types of information bias and also to the possibility of selection bias arising from the way that cases and controls are selected.

The prospective cohort design avoids the pitfalls of retrospective classification of exposure. Here, the information about exposure is collected when the subjects are recruited, and it may be updated during the follow-up period. Information about outcomes, such as episodes of illness or lung function level, is also prospectively collected. Some approaches for repeated data collection that are feasible include telephone calls, postal questionnaires, and symptom diaries. Although the prospective cohort design has these attractive features, its application may be limited by feasibility and funding.

29.3 CARBON MONOXIDE

CO is a colorless, odorless gas that is produced by the incomplete combustion of any fuel containing carbon atoms. Since nearly all natural fuels contain carbon, CO is a potential hazard of almost every form of combustion. The gas is exceedingly toxic, and its dangers have long been recognized. Aristotle was aware that fumes from coal fires caused headaches and death; CO poisoning probably affected two Byzantine emperors, fatally in one case (Lascaratos and Marketos 1998). Today, CO is an air pollutant of concern in both indoor and outdoor environments. In many countries, sources of CO that contaminate outdoor air, such as vehicles, are regulated and concentration limits for CO have been promulgated. Indoor environments, however, remain a principal locus of exposure.

Death from acute CO poisoning remains a problem throughout the world, although mortality rates have fallen in some countries with greater recognition of CO toxicity. Mortality from CO poisoning has fallen in Britain since coal gas was replaced by natural gas, but numerous fatalities still occur every year. The deaths among men are mostly suicides (involving car exhaust fumes); among women, the number of CO deaths is much lower, and they are mostly accidental. Most of the fatal cases die before reaching the hospital: in 1985, 1365 people died of CO poisoning in England and Wales, but only 475 admissions and 10 deaths were recorded in hospitals (Meredith and Vane 1988). In Britain, more children die from CO than from any other form of poisoning. A French survey revealed the mean annual incidence of CO poisoning to be at least 17.5 per 100,000 population; 97 percent of the events were accidental, and 5 percent of the cases died (Gajdos et al. 1991). In the United States, the most recent statistics indicate that approximately 600 accidental deaths are due to CO poisoning, with the number of intentional deaths 5 to 10 times higher (Ernst and Zibrak 1998). The difficulties in diagnosis make estimates of incidence uncertain, however; it is suggested that nearly a third of all cases are undiagnosed (Hardy and Thom 1994).

Sources

In England and Wales, the most frequent type of accidental CO poisoning is associated with fire. During 1985–1990 there were 833 male accidental CO deaths, 445 (53.4 percent) of which were accidents caused by fire and flames, the figures for women being 569 and 405 (71.2 percent), respectively (Office of Population Censuses and Surveys 1989–1992). Carbon monoxide poisoning is the most common cause of immediate death in fire victims. In the United States, malfunctioning of combustion sources or operation of improperly ventilated combustion sources remains the most common cause of acute CO poisoning (Ernst and Zibrak 1998).

The usual source of CO in cases of indoor nonfatal poisoning is some form of heater. In the French survey, the fuels concerned were (in descending order of frequency) piped gas, coal, butane, and heating oil; poisoning was attributed to defective devices, poor evacuation of combustion products, and poor ventilation (Gajdos et al. 1991). Accidental fires accounted for 15 percent of all the cases of CO poisoning. A Danish survey of flueless gas water heaters found that 16 percent produced CO in excess of the recommended safety threshold (Michaelsen and Taudorf 1983). Car exhaust fumes are another important source: a harmful concentration of CO can rapidly build up in a poorly ventilated garage, and a house or office attached to a garage may also be affected.

The concentration of CO attributable to a given source depends on a number of factors, including the burner itself and the environment where it is operated. Incomplete combustion has two main causes: inadequate oxygenation and flame chilling, which, in turn, may arise from internal defects, drafts, or deliberate chilling of the boiler flame to suppress NO₂

production. Common defects of burners include blockage of the air inlet or of the flue outlet, both of which reduce the flow of air. Deposits of fluff or soot in the burner or mixing tube impair the availability of oxygen for combustion and increase the output of CO. Appliances sold in Britain must conform to minimum standards of combustion laid down by the British Standards Institution (BS 5258). This specification requires that the ratio of CO:CO₂ in the emissions must not exceed 0.02 under stipulated conditions. Tests are conducted in circumstances that simulate the worst conditions likely to occur in households with regard to sooting, poor combustion, and situations where the speed of the air-gas mixture within the burner is too fast or too slow (either of which can lead to incomplete combustion). In some countries the acceptance standard depends on the rate of production of CO rather than on its ratio to CO₂ (Berry 1990).

A particular problem with ventilation can occur when extract fans are run concurrently with “open flued” devices (i.e., combustion devices that take in room air and then discharge the combustion products through a flue to the outside). When the extract fan is running, it tends to depressurize the room in which it is sited. If the air available to the combustion appliance is limited, the fan may have difficulty in drawing in enough fresh air. Depending on the outside wind speed, the flow rate of the fan and the airtightness of the room, the direction of airflow in the flue can be reversed so that air flows down the chimney into the room. Any such spillage is potentially hazardous, since the room begins to fill with the products of combustion. Research on this topic led to a recommendation that “A suitable spillage test should always be carried out when an air extract fan is being installed in the same dwelling as an open-flued combustion appliance. As a rough guide, for open-flued gas-fired boilers, fan extract rates in excess of 20 l/s are not recommended.”

Concentrations

The CO concentration in the atmosphere is usually expressed as a percentage by volume or as parts per million (ppm), but it is sometimes measured as mg/m³ (1 ppm is approximately 1145 mg/m³). The high affinity of hemoglobin for CO yields another index of exposure—the percentage of total hemoglobin that is in the form of carboxyhemoglobin (COHb). Nonsmokers not exposed to CO have COHb levels of 0.4 to 0.7%, derived from the production of CO within the body. Patients with haemolytic anaemia produce increased amounts of CO, giving COHb levels of 4 to 8% (Ellenhorn and Barceloux 1988). Similarly high concentrations are found in cigarette smokers. The relationship between atmospheric concentration of CO and blood COHb depends on the duration of exposure (Peterson and Stewart 1975). An atmospheric concentration of 229 mg/m³ (0.02%) CO produces little change in COHb within 10 min and a maximum level of about 25 percent with indefinite exposure, while a concentration of 4580 mg/m³ (0.4%) produces 60% COHb within a few minutes, a rapidly fatal scenario of exposure.

The World Health Organization (WHO) recommends the following guidelines, which are designed to prevent COHb levels exceeding 2.5 to 3.0% in nonsmoking populations (including sensitive groups). A maximum permitted exposure of 100 mg/m³ is proposed for periods not exceeding 15 min. For longer periods, a time-weighted average (TWA) exposure should not exceed 60 mg/m³ for 30 min, 30 mg/m³ for 1 h, and 10 mg/m³ for 8 min (WHO 1987a). By comparison, typical indoor air concentrations are in the range of 5 to 60 mg/m³ when emission sources are present (Spengler and Sexton 1983). In a normal kitchen in London with a gas cooker and natural ventilation, maximum mean concentrations of 18 and 184 mg/m³ have been measured over periods of 24 h and 15 min, respectively (Royal Commission on Environmental Pollution 1984). Short-term CO concentrations of 57.5 mg/m³ (50 ppm) or more were found in 17 percent of Dutch houses (WHO 1987a). In an American study, 6 out of 14 homes containing kerosene heaters had CO concentrations that

exceeded the maximal 8-h levels specified by ambient air quality standards (9 ppm) (Cooper and Alberti 1984). The residents had significantly higher COHb concentrations when the heaters were operating than when they were not. Thus it is likely that there are many homes in which the preceding guidelines are exceeded.

Toxicology

Carbon monoxide is rapidly absorbed by the lungs, where it combines with hemoglobin with about 250 times the affinity of oxygen. The COHb concentration rises very rapidly in the coronary and cerebral arteries, and more slowly in the peripheral vessels (WHO 1987a). Carbon monoxide is eliminated only through the lungs; the half-life of COHb in ordinary conditions is 5 to 6 h (Winter and Miller 1976). The toxicity of CO arises from the resultant limitation of oxygen delivery to the tissues, exacerbated by the effect of CO on the remaining oxyhemoglobin; it impedes the unloading of oxygen from blood. There may also be some inhibition of cellular respiration by CO (Meredith and Vane 1988). The effects on blood vessels seem to be mediated by the release of nitric oxide from vascular endothelial cells, causing oxidative injury to perivascular tissues (Thom et al. 1997). The fetus is particularly susceptible, owing to its lower initial blood oxygen level, an even greater affinity of fetal hemoglobin for CO, and a greater tissue hypoxia produced by the same COHb level as in the adult (Ellenhorn and Barceloux 1988).

The various organs of the body are affected by CO poisoning to different degrees. Brain function is profoundly affected, and severe poisoning produces permanent pathological changes similar to those occurring with other types of asphyxia. The heart is also specifically vulnerable because of its high oxygen consumption and the very high affinity of myoglobin for CO: about 3 times that of hemoglobin (Astrup 1972). Patients with ischemic or coronary heart disease are at particularly high risk because of their inability to increase coronary perfusion, and they may suffer myocardial infarction or sudden death with exposure to CO. Retinal hemorrhage commonly occurs, and was found in all 12 patients in one series of exposures lasting more than 12 h (Kelley and Sophocleus 1978). Other organs that may be affected include the skin (where massive blisters may appear), the lungs (pulmonary edema), and skeletal muscle (breakdown of muscle cells and massive tissue death).

Acute Effects

There is a considerable body of evidence on the acute effects of CO poisoning, which have been recognized for many years. Table 29.1 summarizes the approximate relationship between CO exposure, COHb concentrations, and symptoms (Peterson and Stewart 1975, Winter and Miller 1976). The degree of risk for a given exposure is increased by various factors, including duration, altitude, activity level, a high metabolic rate, childhood (the neonate is especially vulnerable as it possesses some fetal hemoglobin), anemia, and cerebrovascular or coronary disease. The first symptoms are usually headache, fatigue, and impaired exercise tolerance, which occur at about 10 to 20% COHb, but more subtle effects are detectable at lower concentrations if suitable tests are employed. For example, the ability to discriminate small differences of light intensity and to estimate time intervals is impaired at a COHb level of 5% or even lower (Astrup 1972), and driving skills may be affected while the subject is unaware that anything is amiss (WHO 1987a).

Higher concentrations produce a wide range of symptoms that are easily mistaken for other disorders, including gastroenteritis, influenza, cerebrovascular disease, alcoholism, and acute psychosis. The combination of mental and physical effects is particularly lethal: judgment is impaired, so that a person can be on the verge of collapse without realizing that

TABLE 29.1 Acute Effects of Carbon Monoxide Poisoning

Duration of exposure		COHb, %	Effects
229 mg/m ³	1145 mg/m ³		
2 h	20 min	10	Exercise tolerance reduced
7 h	45 min	20	Breathlessness on exertion, headache
—	75 min	30	Severe headache, weakness, dizziness, dimness of vision, disturbed judgment, nausea, vomiting, diarrhea, fast pulse rate
—	2 h	40–50	Confusion, collapse on exertion, coma, convulsions
—	5 h	60–70	Coma, convulsions, slow pulse rate, low blood pressure, respiratory failure, death

anything is wrong. Any sudden exertion then causes immediate collapse and an inability to escape from the situation (Berry 1990). Coma, convulsions, and death are likely to occur if the COHb level exceeds 60%.

Several investigators have examined the acute effects of low concentrations of CO on susceptible subjects in carefully controlled experiments. For example, Aronow (1981a) conducted a controlled exposure study of persons with angina pectoris and found that a rise in COHb from 1 to 2% aggravated their symptoms. Another study showed a dose-response effect of CO at 2 and 3.9% COHb on the duration of exercise needed to cause symptoms or electrocardiographic changes in angina patients (Allred et al. 1989). Animal experiments suggest that CO reduces the threshold for ventricular fibrillation during an episode of myocardial ischemia (Aronow 1981b).

Subacute and Chronic Effects

Exposure to CO can cause longer-term damage in two distinct ways: the subacute and chronic effects of acute severe poisoning, and the insidious consequences of prolonged or repeated exposure to low concentrations. Neurological and psychiatric changes can develop after recovery from acute poisoning, and may include apathy, amnesia, irritability, personality changes, incontinence, disturbance of gait, and mutism. In one large series of patients with CO poisoning, delayed neurological effects appeared in 12% of the cases who had been admitted to the hospital, usually in deep coma (Choi 1983). The symptoms and signs ensued after a lucid interval of 2 to 40 days, and affected only the patients over 30 years of age. Most of those who were followed up had recovered 12 months later, but some had residual loss of memory and disturbance of gait.

In another study, patients who had been admitted to the hospital with CO poisoning were followed up 3 years later (Smith and Brandon 1973). Of the survivors, 11 percent had gross neuropsychiatric sequelae (cognitive change, personality change, or frank neurological abnormality) which were “directly and unequivocally the result of CO poisoning.” All of these patients had been comatose before admission to the hospital. Lesser degrees of brain damage had occurred in other patients, so that 33 percent altogether had some deterioration of personality (irritability, aggression, and violence), and 43 percent had impairment of memory. The outcome was similar in those deliberately and accidentally poisoned by CO, but different in attempted suicides using CO and barbiturates. The memory and personality changes observed after CO intoxication are, therefore, unlikely to be attributable to a propensity for self-poisoning.

The effects of chronic or recurrent low-dose exposure are easily overlooked or misdiagnosed. The symptoms include headache, fatigue, difficulty in thinking, dizziness, abnormal sensations, chest pain, visual disturbances, nausea, diarrhea, and abdominal pain (Meredith and Vane 1988). Performance at school or work is likely to deteriorate. Exposure of pregnant women to low concentrations of CO may impair fetal development; it is well known that smokers tend to have lighterweight babies, and animal experiments suggest that this could be due to fetal sensitivity to CO (Astrup 1972).

Long-Term Cardiovascular Effects

The question has also been raised as to whether CO is the atherogenic agent in cigarette smoke. Experimental studies in rabbits and other animals have shown conflicting results as to whether CO promotes atherogenesis (Astrup 1972, Weir and Fabiano 1982). Exposure to CO causes release of the free radical nitric oxide from platelets and vascular endothelial cells, likely to produce chronic arterial damage (Hardy and Thom 1994, Thom et al. 1997).

A cross-sectional study showed that the presence of atherosclerotic heart disease correlated much better with COHb than with smoking history (Wald et al. 1973). This finding may imply a causative role for CO; alternatively, COHb may be merely a marker for increased inhalation and absorption of the various ingredients of tobacco smoke, some other element of which is the atherogenic agent. A report from Japan suggested that morbidity and mortality from heart disease were raised among villagers whose COHb concentrations often reached 20 to 30% as a result of exposure to charcoal fires (Goldsmith 1970). A study in Finland found that the prevalence of angina was highest in foundry workers with definite CO exposure, and lowest in those with no CO exposure (Hernberg et al. 1976). Two studies reported an increased mortality from ischemic heart disease among men (foundry workers, engineers, and firefighters) who were occupationally exposed to CO (Decoufle et al. 1977, Andjelkovich et al. 1992). On the other hand, a survey of blast furnace workers revealed no association between cardiovascular disease and CO exposure (Jones and Sinclair 1975).

It is difficult to assess the strength of this evidence; there are numerous confounding variables, including smoking, exposure to other hazards (e.g., heat), and selection of workers by state of health. If a causative role for CO in atherosclerosis were to be established, then chronic exposure to CO would carry serious public health implications.

29.4 OXIDES OF NITROGEN

Nitrogen forms a range of oxides, some of which are present in the atmosphere to a measurable extent. Nitrous oxide (N_2O) is a normal constituent of air, at a concentration of about $940 \mu\text{g}/\text{m}^3$ (500 ppb) (Tewari and Shukla 1989). Nitrogen dioxide (NO_2) and nitrogen pentoxide (N_2O_5) are also formed naturally and participate in the nitrate cycle, which is important for organic growth. Various human activities produce nitric oxide (NO) and NO_2 in concentrations that constitute atmospheric pollution. Indoor fuel combustion employs air as the oxidant, and a small percentage of the atmospheric nitrogen is converted into NO and NO_2 . Most of the NO reacts spontaneously with atmospheric oxygen to form NO_2 , which is therefore usually measured as the index of air pollution by the oxides of nitrogen.

Sources

The major indoor sources of NO_2 are gas-fueled cookers, fires, water heaters and space heaters, and oil-fired space heaters. The rate of production is governed by three main fac-

tors: the amount of oxygen, the flame temperature, and the rate of cooling of the combustion products (since NO formation and conversion proceed more rapidly at higher temperatures). Low-heat domestic burners yield 18,800 to 188,000 $\mu\text{g}/\text{m}^3$ (10,000 to 100,000 ppb) oxides of nitrogen in their emissions (Tewari and Shukla 1989). Pollution of the indoor air occurs if the emissions are not externally vented, either because there is no venting system (as with many gas cookers and portable oil stove), or because the venting system is malfunctioning or inadequate.

In British houses, high levels of NO_2 are associated with gas pilot lights, gas fires, paraffin heaters, and the use of gas cookers for drying clothes and heating (Goldstein et al. 1979, Melia et al. 1982a). Concentrations tend to be much higher in Dutch kitchens containing unvented geysers (hot water heaters at the tap) than in those with no geysers, and intermediate in kitchens containing vented geysers (Dijkstra et al. 1990). Car exhaust containing NO_2 may enter a house from an attached garage, although the oxides of nitrogen are produced in only small amounts while the engine is idling rather than accelerating (Tewari and Shukla 1989). Tobacco smoke also contains small amounts of NO_2 .

A British study investigated NO_2 concentrations in the kitchens, bedrooms, and living rooms of 174 houses in Bristol (Coward and Raw 1996). Concentrations were always highest in the kitchen and were usually lowest in the bedroom. Indoor levels were strongly affected by outdoor levels, but in the absence of indoor sources they tended to be lower indoors. The main indoor source was gas cooking; the effects of heating and tobacco smoking were negligible by comparison. In homes with gas cooking, other important factors were household size and occupant density; presumably more cooking occurs in larger households, and for any size of household, there is less opportunity for pollutants to disperse in smaller homes. The only nonventilation removal mechanism to be identified was green plants.

Concentrations

Concentrations of NO_2 in air are expressed as parts per million, parts per billion, or $\mu\text{g}/\text{m}^3$ (1 ppb = 1.88 $\mu\text{g}/\text{m}^3$). Measurements can take the form of spot checks, integrated average concentrations over time, and continuous monitoring. An individual's total exposure can be recorded by means of a personal NO_2 monitor worn over a period of time. Short peak concentrations can occur in kitchens during cooking with, for example, concentrations of 500 $\mu\text{g}/\text{m}^3$ being recorded when a single gas burner was lit and over 1100 $\mu\text{g}/\text{m}^3$ when an oven was in use (Speizer et al. 1980). In the Bristol survey, mean concentrations in kitchens (averaged over the year) were 28.1 $\mu\text{g}/\text{m}^3$ where the main cooking fuel was natural gas, and 14.9 $\mu\text{g}/\text{m}^3$, where it was electricity (Berry et al. 1996). Two homes had at least one 14-day mean above the 150- $\mu\text{g}/\text{m}^3$ WHO guideline for 24 h, so that more homes would probably have exceeded this value during a single day (Coward and Raw 1996). An earlier British survey reported much higher mean weekly concentrations: 211 $\mu\text{g}/\text{m}^3$ in kitchens using gas, and 34 $\mu\text{g}/\text{m}^3$ in those using electricity (Goldstein et al. 1979). In this survey the outside NO_2 concentrations were also substantially higher.

In an American study the number of sources (gas cookers and oil heaters) was correlated with the mean NO_2 value and with the proportion that exceeded the United States Environmental Protection Agency (USEPA) annual average ambient health standard of 100 $\mu\text{g}/\text{m}^3$ (Leaderer et al. 1986). In the houses that contained gas stoves, the NO_2 concentrations were somewhat higher in the kitchens than in living rooms or bedrooms, but the differences were not very great, showing that NO_2 diffuses readily throughout the house. The average 2-week NO_2 concentrations were highly correlated with peak NO_2 exposures derived from continuous monitors and with total personal NO_2 exposures of residents who wore personal monitors for the same period. In houses containing no known NO_2 source, the mean NO_2 level in the living room was slightly but significantly higher (by 1.1 $\mu\text{g}/\text{m}^3$) if the household contained a smoker than if it did not.

These findings suggest that NO_2 exposure can be estimated with a reasonable degree of accuracy by questionnaire methods that characterize sources and their use. On the other hand, a Dutch survey suggested that NO_2 exposure cannot be estimated indirectly with sufficient accuracy for epidemiologic studies, and that actual measurements are unavoidable (Remijn et al. 1985). The disparity between these two surveys is probably explained by the fact that nearly half the American homes contained no sources of NO_2 at all, whereas in the Dutch survey only 3 percent of the houses had no gas appliances; gas was in almost universal use in the Netherlands. Thus questionnaire methods distinguish houses with NO_2 sources from those that have none, but they do not estimate the degree of exposure where sources are universally present.

In another British survey, personal exposure was found to relate most strongly to the mean of the NO_2 levels in the living room and bedroom (Raw and Coward 1992). Although levels were usually higher in the kitchen, less time was spent there.

On the basis of the lowest concentration known to affect asthmatics (see discussion below), the World Health Organization recommends that exposure not exceed $400 \mu\text{g}/\text{m}^3$ (210 ppb) for 24 h (WHO 1987b). These limits are probably exceeded in many British homes.

The COST report on indoor pollution by NO_2 states that existing ventilation requirements in countries where measurements have been conducted do not give sufficient protection against high exposures (COST 1989). This report recommends local exhaust with hoods and flues rather than increasing general ventilation as the best way of preventing high exposure. This must not be done in such a way as to cause spillage of combustion products from appliances with balanced flues. In the longer term, the method of choice is reduction of source emissions by applying clean combustion techniques. In the United States, the burning of pilot lights on stoves and ovens is a substantial contributor to indoor NO_2 . This source is removed by newer appliances with electronic ignition.

Toxicology

Toxicological studies of NO_2 in humans relate largely to industrial exposures to doses that are very unlikely to occur in homes or offices. The effects are mostly on the respiratory system, causing damage to the lining of the smaller airways. Oxidant injury seems to be the principal mechanism of action (Samet and Utell 1990). Experiments on animals show a reduction in the efficacy of the lung defense mechanisms, including effects on mucociliary clearance, particle removal by alveolar macrophages, and immunologic function (Dawson and Schenker 1979, Samet and Utell 1990). In consequence, there is a reduced clearance of respiratory pathogens and greater susceptibility to bacterial infections. Concentration is more important than duration of exposure in increasing susceptibility to infection (WHO 1987b). Changes resembling emphysema have been observed in mice exposed to $940 \mu\text{g}/\text{m}^3$ (500 ppb) for 12 months; exposure of dogs to NO_2 and NO for more than 5 years seems to induce emphysematous changes that continue to progress during a postexposure period in clean air (Gillespie et al. 1980).

In general, a few hours' exposure to low concentrations of NO_2 does not seem to have adverse effects in animals, whereas exposure lasting weeks, months, or years is liable to cause lung damage (WHO 1987b). However, short-term exposure to high concentrations ("spikes") may be important in determining the health risks of NO_2 . In one study, mice were exposed to a background NO_2 level on which spikes were superimposed (Miller et al. 1987). The NO_2 levels used were similar to those found in homes. One conclusion was that the peaks of NO_2 exposure rather than the background levels were the primary determinants of the effects on lung antibacterial defenses. The duration of the spike was unimportant; it was the peak concentration that mattered. The authors suggested that the risk to humans from NO_2 may also depend on the pattern of exposure, especially the pattern of the spikes.

Interpretation of the animal (experimental) evidence is complicated by the fact that different species vary widely in their sensitivity to NO_2 . Exposure of guinea pigs to 500 ppb for several days produces certain minor biochemical effects (e.g., changes in red blood cell enzymes and in alveolar proteins and phospholipids); hamsters, however, are far less sensitive, and it is not at all clear where humans fall in the spectrum of sensitivity (Dawson and Schenker 1979).

Health Effects

Although NO_2 concentrations in houses are low compared with those known to be acutely toxic, it has been suggested that indoor exposure to NO_2 could cause minor degrees of ill health, including respiratory symptoms, susceptibility to respiratory infections, and some impairment of lung function; it may also adversely affect persons with asthma. It might reasonably be expected that infants and children, because of their narrower airways and growing lungs, would be particularly vulnerable to prolonged exposure to NO_2 and the intermittent peak concentrations associated with gas cookers. Since there are no specific symptoms or signs attributable to low-level exposures to NO_2 , the evidence for an effect must be obtained from large epidemiologic surveys that relate the occurrence of symptoms, illnesses, or other effects to the presence of a source of NO_2 or raised concentrations of the gas.

Table 29.2 summarizes the findings of various cross-sectional and cohort studies of children. Only a few studies recorded symptoms continuously, by means of medical records (Ogston et al. 1985), repeat telephone calls (Keller et al. 1979a, Berwick et al. 1989, Samet et al. 1993), diaries (Braun-Fahrländer et al. 1992, Samet et al. 1993, Pilotto et al. 1997), or home visits (Keller et al. 1979b). In most of these studies, the presence of a gas cooker was taken as a surrogate of NO_2 exposure, but in some this was actually measured (Florey et al. 1979, Melia et al. 1982b, Farrow et al. 1997, Dijkstra et al. 1990, Braun-Fahrländer 1992, Berwick et al. 1989, Neas et al. 1991, Samet et al. 1993, Pilotto et al. 1997). Studies that followed up children over time suggested that any effect of NO_2 exposure tends to wane over time and that NO_2 exposure does not reduce lung growth (Melia et al. 1979, Dijkstra et al. 1990, Dodge 1982, Ware et al. 1984, Berkey et al. 1986).

A meta-analysis was conducted on the results of 11 of these studies (Hasselblad et al. 1992). Using several different approaches for pooling the results, the authors found remarkably similar results: an odds ratio of 1.2 for respiratory illness in children exposed to NO_2 , with 95 percent confidence limits of 1.1 to 1.3. This implies a 20 percent increase in the risk of respiratory illness corresponding to an increase of $30 \mu\text{g}/\text{m}^3$ in NO_2 level. This meta-analysis can be criticized, however, for the heterogeneity of the outcomes in the pooling. The results of several subsequent large epidemiologic studies of infants have not been consistent with the finding of the meta-analysis (Samet et al. 1993, Farrow et al. 1997).

Several investigators have used a case-control approach. A Canadian study compared newly diagnosed asthmatic children aged 3 to 4 years with nonasthmatics of the same age, in regard to NO_2 exposure as measured by a personal badge (Infante-Rivard 1993). A dose-response relation was found between 24-h NO_2 exposure and asthma. This finding was surprising in view of the brief measurement protocol and needs replication. A Swedish study revealed that wheezing bronchitis was associated with a gas cooker in the home (and with outdoor NO_2) in girls but not in boys aged 4 months to 4 years (Pershagen et al. 1995).

Fewer surveys have examined effects of NO_2 in adults. Table 29.3 summarizes some of the studies that have been published. Jarvis et al. (1996) examined symptom prevalence and lung function in a random sample of adults aged 20 to 44 years, as part of the European Community Respiratory Health Survey (ECRHS). The use of gas cookers and other unvented gas appliances was associated with respiratory symptoms and impaired lung function in women but not

TABLE 29.2 Respiratory Effects of Gas Cooking or NO₂ in Children

First author	Country	Number of children	Age, years	Association with symptoms	Association with changes in lung function
Melia (1977)	U.K.	15,758	6-11	Yes; declines over time	
Melia (1979)	U.K.	7,235	5-11

Comstock (1981)	U.S.	1,724	20+	In male nonsmokers	In male nonsmokers
Jones (1983)	U.S.	205	20–39	—	? Yes
Ostro (1993)	U.S.	321 nonsmokers	36.6 (mean)	Yes	
Jarvis (1998)	11 countries	11,590	20–44	In women	? No

? denotes some uncertainty or inconsistency in the relationship.

in men. The same survey in France showed a similar association between gas cooking and symptoms in women but not in men (Leynaert et al. 1996); in Belgium, the results were less consistent (Wieringa et al. 1996). When all the ECRHS results from 11 countries were analyzed together, gas cooking was associated with respiratory symptoms in women but not in men; there was no consistent significant relationship with lung function (Jarvis et al. 1998).

The Dutch survey by Fischer et al. (1985) was a prospective study of 97 nonsmoking women. Several spirometric measures of lung function, including FEV₁ and FVC, were negatively associated with current NO₂ exposure in a cross-sectional analysis, but at follow-up there was no evidence of an association between NO₂ and decline in lung function. The survey by Jones et al. (1983) used a different study design analogous to the case-control approach. Nonsmoking women in the highest quartile of FEV₁ were compared with nonsmoking women in the lowest quartile with respect to their current use of gas stoves. The women in the lowest quartile were slightly less likely to use gas cookers, but the association fell short of statistical significance.

Experimental investigations of the possible effects of low concentrations of NO₂ in persons with asthma have produced conflicting results. Bauer et al. (1986) reported that NO₂ potentiated the bronchoconstrictive actions of exercise and cold air although it had no direct effect on lung function level. A study of asthmatic subjects reported changes in sensitivity to carbachol after exposure to 100 ppb NO₂, although most of the subjects showed no change in specific airway resistance (Orehek et al. 1976). Other studies have failed to confirm this finding. For example, Linn et al. (1986) found no potentiating effect of NO₂ in concentrations up to 3000 ppb. It is possible that some asthmatics are more susceptible than others to NO₂. Goldstein et al. (1988) monitored the lung function of 11 asthmatics and 12 nonasthmatics during the cooking of meals over a gas cooker. With NO₂ concentrations below 300 ppb, FVC and PEFR were as likely to increase as to decrease with exposure; above this level there was a suggestion of a slight decline among the asthmatics but not among the nonasthmatics. Another study suggested that 400 ppb NO₂ potentiates the effect of house dust mite antigen in asthmatic airways, although the effect was small (Tunnicliffe et al. 1994).

A review of experimental studies revealed that 300 ppb (560 µg/m³) is the lowest observed level that has been reported in more than one laboratory as to affect the pulmonary function of asthmatics with intermittent exercise and without a bronchoconstrictor (WHO 1987b). Unlike asthmatics, patients with chronic bronchitis do not seem to be more responsive to NO₂ than are healthy subjects. Concentrations above 2000 ppb (3760 µg/m³) raise the airway resistance of normal subjects, while lower levels have had effects in some studies but not in others.

29.5 SULFUR DIOXIDE, COAL SMOKE, AND OIL FUMES

Sulfur dioxide (SO₂) is a colorless gas with a characteristic pungent smell. It is produced by the combustion of fossil fuels, and as a pollutant of the external air it has been carefully monitored because of the damage it causes to the environment. As it is a combustion product of coal and oil, it tends to be associated with other components of coal and oil smoke, and these topics are considered together here.

Sources

In Britain the traditional domestic open coal fire (now much less common) was a potential source of SO₂. A Dutch survey revealed that an anthracite heater was a source of high SO₂ levels (Biersteker et al. 1965). In an American survey, indoor SO₂ levels were related to the use of oil heaters and to the sulfur content of the fuel (Leaderer et al. 1986). Fuels currently

available for use in flueless heaters in Britain have a low sulfur content, so they are not an important source of SO_2 .

Concentrations

Concentrations of SO_2 are expressed as ppm or $\mu\text{g}/\text{m}^3$; 1 ppm is approximately equal to $2660 \mu\text{g}/\text{m}^3$ at 20°C . The concentration indoors is usually substantially lower than the external level, probably because SO_2 is adsorbed onto the room surfaces (Andersen 1972). In the Netherlands a small proportion of homes were found to have higher concentrations inside than outside, either intermittently or continuously, as a result of a faulty heater (giving daily concentrations up to $1250 \mu\text{g}/\text{m}^3$) or a malfunctioning chimney (Biersteker et al. 1965). An American study found concentrations up to 1 ppm ($2660 \mu\text{g}/\text{m}^3$) in houses containing unvented kerosene heaters (Cooper and Alberti 1984); half the houses exceeded the 24-hour standard for SO_2 . Another American study found two-weekly average SO_2 levels to be less than $2 \mu\text{g}/\text{m}^3$ in the absence of a kerosene heater, but up to $150 \mu\text{g}/\text{m}^3$ in homes containing a kerosene heater (Leaderer et al. 1986).

The limit for the annual average SO_2 concentration set by the European Community is $80 \mu\text{g}/\text{m}^3$ if smoke is present, and $120 \mu\text{g}/\text{m}^3$ if it is not (Royal Commission on Environmental Pollution 1984); the American limit is also $80 \mu\text{g}/\text{m}^3$ (Leaderer et al. 1986). The maximum permissible daily concentration is $350 \mu\text{g}/\text{m}^3$. These limits were devised primarily for external air, and are very unlikely to be breached in British homes except in unusual circumstances (e.g., a solid fuel heater with a leaking flue), although American kerosene can produce high concentrations.

Toxicology

As SO_2 is highly soluble in water, exposure to about $26,600 \mu\text{g}/\text{m}^3$ tends to irritate the moist mucous membranes of the eyes, nose, and throat. It may be carried by carbon particles and water droplets into the terminal bronchioles. At $53,200 \mu\text{g}/\text{m}^3$ (20 ppm), it is very irritating to the eyes and causes chronic respiratory symptoms if exposure continues. Coal and oil produce a wide range of other substances on combustion, some of which are toxic or mutagenic in vitro, and emissions from small domestic heaters seem to be more mutagenic than those from large coal power plants (Holmberg and Ahlborg 1983).

Health Effects

Pollution of external air by SO_2 and coal smoke is known to aggravate respiratory disease (Lawther 1987), so it might be expected that similar effects would follow exposure indoors. There has been very little work on this topic, and the evidence is largely indirect. A study in 14 American homes containing kerosene heaters showed SO_2 concentrations capable of inducing bronchospasm in some asthmatics, although the lung function of the (nonasthmatic) residents was not obviously affected (Cooper and Alberti 1984). A survey in South Wales showed that the habitual use of open coal fires was associated with a history of breathlessness and wheezing in young adults (Burr et al. 1981). The decline in open coal fires has reduced this potential source of indoor pollution in Britain. A survey in China revealed that people who used coal for domestic heating had lower values of FEV_1 and FVC (Xu et al. 1991). On the other hand, a survey of Scottish schoolchildren showed no increase in symptoms associated with the use of solid fuel for heating (Austin and Russell 1997), while a German study found that bronchial hyperresponsiveness was actually less in children whose homes were heated by coal or wood (von Mutius et al. 1996).

The chronic effects of SO_2 have repeatedly been investigated with relation to industrial exposure. Among workers in a copper smelter, significant reductions in FEV_1 and FVC were associated with chronic exposure to SO_2 (Archer and Gillam 1978), but a follow-up study in the same smelter found that decline in lung function over time was small and unrelated to SO_2 exposure (Rom et al. 1986). Other studies of workers chronically exposed to high levels of SO_2 have failed to show impairment of FEV_1 or FVC, or any excess of respiratory symptoms (Broder et al. 1989). Interpretation of the evidence is not entirely simple; the investigators may not always have allowed for confounding factors such as age, smoking habit, and other industrial toxins. There is, moreover, some evidence of a “healthy worker effect”—i.e., a tendency for more healthy people to be employed selectively. Thus it cannot be assumed that the SO_2 levels encountered in certain industries, where $2660 \mu\text{g}/\text{m}^3$ is not unusual, would be harmless to everybody over long periods of time.

Experimental studies have investigated the acute effects of SO_2 in patients with asthma. Jorres and Magnussen (1990) found no effect of $1330 \mu\text{g}/\text{m}^3$ (0.5 ppm) on clinical asthma, but this concentration may potentiate the bronchoconstrictive action of exercise (Linn et al. 1990). Patients with a high degree of bronchial reactivity are potentially at risk of experiencing asthma attacks provoked by peaks of SO_2 from indoor sources.

Coal smoke contains a wide variety of organic compounds, some of which have mutagenic activity in vitro and cause tumors in animals. A study in China showed that lung cancer was much more common in an area that used smoky coal for domestic heating than in areas that used wood or smokeless coal, and the differences were particularly great for women, who seldom used tobacco (Mumford et al. 1987). Air samples taken in the different areas showed much higher concentrations of particulate matter and of certain carcinogens (polycyclic aromatic hydrocarbons and nitrogen heterocyclic compounds) within homes using smoky coal than in those using other fuels.

The combustion products of oil similarly include various organic compounds, some of which could have carcinogenic properties. A case-control study in Hong Kong showed a highly significant association between lung cancer in women and the use of kerosene stoves for cooking (Leung 1977). A study in Singapore, however, showed no such association (MacLennan et al. 1977). There are obvious possibilities for confounding with other relevant variables in such studies, and the risk may vary with the type of oil, the type of stove, and the degree of ventilation.

29.6 WOOD SMOKE

Toxicology

The burning of wood produces a wide range of substances, some of which are known to have harmful effects. In addition to CO, the emissions include respirable particulates, formaldehyde, acrolein, benzo(a)pyrene, and a variety of polycyclic aromatic hydrocarbons. Some of these substances are carcinogenic when inhaled by animals in experimental conditions. Impairment of the antibacterial properties of pulmonary macrophages has been demonstrated in rabbits after exposure to wood smoke (Fick et al. 1984). There are therefore grounds for suspecting that people who are repeatedly exposed to wood smoke might suffer some respiratory damage.

Health Effects

Two American surveys, with conflicting results, examined the relationship between wood burning and respiratory symptoms in children. Honicky et al. (1985) selected 31 children

from homes that contained a wood-burning stove and 31 from homes without such a stove. The parents were questioned about their children's respiratory symptoms during the previous winter; severe symptoms were reported for 84 percent in the wood-burning homes but for only 3 percent in those in the other homes. By contrast, a survey by Tuthill (1984) of 399 children found no association between wood-burning and respiratory symptoms. Furthermore, in a large Australian survey the use of wood for heating was significantly associated with a lower prevalence of dry cough and ever having wheezed, in children aged 4 to 5 years (Volkmer et al. 1995). The disparity between these studies may reflect differences in the kind of wood or type of stove, and different confounding variables in the different situations.

A study in Japan drew attention to a possible carcinogenic effect (Sobue 1990). A case-control study of lung cancer was conducted in nonsmoking women; 144 cases were compared with 713 hospital controls. The cases were significantly more likely than the controls to have used wood or straw as cooking fuel when they were 30 years old. It would obviously be foolish to assume that wood burning in different circumstances carries a similar risk, but in view of the known carcinogenic properties of some constituents of wood smoke, the association should be sought in other countries where wood is used as fuel.

29.7 SUMMARY

Although most people in industrialized countries spend most of their time indoors, interest in air pollutants has been directed largely to the outdoor environment, probably because pollutants are more easily measured there. In consequence, we have less information about the indoor concentrations of combustion products, and their likely effects on human health. Table 29.4 summarizes the values that have been reported for three major gases, together with recommended limits. These limits were set for the outdoor air; indoor limits should probably be lower, since people typically spend more time indoors, especially those in poor health, who are likely to be more vulnerable to these substances.

Carbon monoxide is a very dangerous gas—acute poisoning is often misdiagnosed, and can cause serious illness and death. Even if immediate treatment is successful, major neurological defects are liable to appear after an initial period of recovery, and some permanent damage may occur. There is some uncertainty about the danger of long-term low-level exposure; angina is aggravated, and research on animals suggests the possibility of cardiovascular damage. Regular maintenance of heating and cooking appliances and appropriate ventilation can remove most of the hazard.

Nitrogen dioxide is produced by gas burners and cookers, and indoor concentrations can exceed the WHO recommendations. The balance of evidence suggests that gas cooking is associated with an increased incidence of respiratory symptoms in childhood (though probably not in infancy); the effect does not seem to persist as the children grow older. There also appears to be an increased risk of respiratory symptoms in women. Regulations and guidance should ensure good ventilation where gas is burning, and avoid drawing combustion products back into the house from flues.

Sulfur dioxide does not seem to be a major indoor problem in countries such as Britain, where the fuel has a low sulfur content, although it is produced by American kerosene. Smoke and fumes from coal, oil, and wood have been suspected of causing lung cancer, but not in circumstances that commonly occur in most Western countries.

Interpretation of the evidence is difficult; people who are exposed to indoor pollutants are likely to differ from other people in various ways that have health implications, and the various sociological and environmental confounding factors may not have been adequately allowed for. A given concentration of a pollutant may have health effects in some

TABLE 29.4 Indoor Concentrations of Gases and Recommended Maximum Levels

Gas	Circumstances	Typical indoor concentrations, $\mu\text{g}/\text{m}^3$	Limits,* $\mu\text{g}/\text{m}^3$
CO	In presence of sources	5–60 [1]	8 h at 10 [2]
	Short peaks	Up to 200 [4]	1 h at 30 [2]
NO ₂	Annual average (U.S.)	—	Annual average 100 [5]
	Weekly average, kitchen with gas cooker (U.K.)	10–600 [6]	24 h at 150 [3]
	Short peaks, kitchen with gas cooker	>1000 [7]	1 h at 400 [3]
SO ₂	No specific source	0.2 [5]	Annual average 80–120 [4]
	Kerosene heaters 2 week average (U.S.)	100–150 [5]	Max daily average 350 [4]
	During use of kerosene heaters (U.S.)	0–2660 [8]	

*Nearest equivalent to circumstances in second column.

circumstances but not in others. More research is needed to clarify the effects of these substances in a wide range of households. Meanwhile, action should be taken to prevent, as far as possible, the recommended levels being breached. This action will relate to the design of buildings, the construction and maintenance of appliances, and public education.

30.1 INTRODUCTION

Extensive toxicological, experimental, and epidemiologic data, collected largely since the 1950s, have established that active cigarette smoking is the major preventable cause of morbidity and mortality in the United States (USDHEW 1979; USDHHS 1989). More recently, since the 1960s, involuntary exposure to tobacco smoke has been investigated as a risk factor for disease and also found to be a cause of preventable morbidity and mortality in nonsmokers. This chapter summarizes the converging and now extensive evidence on the health effects of involuntary exposure to tobacco smoke. The initial research on involuntary smoking addressed respiratory effects primarily; more recent investigations have examined associations with diverse health effects including nonrespiratory cancers, ischemic heart disease, age at menopause, sudden infant death syndrome (SIDS), and birth weight. The evidence on involuntary exposure to tobacco smoke is now voluminous; consequently, this chapter is selective in its citations. The most recent compilation of the evidence can be found in a 1997 report of the California Environmental Protection Agency (Cal EPA 1997). Prior key reviews include the 1986 reports of the U.S. Surgeon General (USDHHS 1986), the National Research Council (NRC 1986), and the 1992 report of the U.S. Environmental Protection Agency (USEPA 1992).

Respiratory effects of passive smoking have also been covered in a series of systematic reviews published in *Thorax* (Strachan and Cook 1997; Anderson and Cook 1997; Cook and Strachan 1997; Strachan and Cook 1998*a*, 1998*b*) and in the *British Medical Journal* (Hackshaw et al. 1997, Law and Hackshaw 1997). These reviews provide the

basis for conclusions on passive smoking in a 1998 report from the United Kingdom (Scientific Committee on Tobacco and Health, HSMO 1998).

30.2 EXPOSURE TO ENVIRONMENTAL TOBACCO SMOKE

Characteristics of Environmental Tobacco Smoke (ETS)

Nonsmokers inhale ETS, the combination of the sidestream smoke that is released from the cigarette's burning end and the mainstream smoke exhaled by the active smoker (First 1985). The inhalation of ETS is generally referred to as *passive* or *involuntary* smoking. The exposures of involuntary and active smoking differ quantitatively and, to some extent, qualitatively (USDHHS 1984, 1986; NRC 1981, 1986; USEPA 1992; Guerin et al. 1992). Because of the lower temperature in the burning cone of the smoldering cigarette, most partial-pyrolysis products are enriched in sidestream as compared to mainstream smoke. Consequently, sidestream smoke has higher concentrations of some toxic and carcinogenic substances than does mainstream smoke; however, dilution by room air markedly reduces the concentrations inhaled by the involuntary smoker in comparison to those inhaled by the active smoker. Nevertheless, involuntary smoking is accompanied by exposure to toxic agents generated by tobacco combustion (USDHHS 1984, 1986; NRC 1981, 1986; USEPA 1992).

Environmental Tobacco Smoke Concentrations

Tobacco smoke is a complex mixture of gases and particles that contains myriad chemical species (USDHEW 1979, USDHHS 1984, Guerin et al. 1992). Not surprisingly, tobacco smoking in indoor environments increases levels of respirable particles, nicotine, polycyclic aromatic hydrocarbons, carbon monoxide (CO), acrolein, nitrogen dioxide (NO₂), and many other substances; concentrations of some of these have been measured as ETS markers. Recent data from work environments (Table 30.1) and homes (Table 30.2) show that nicotine can be detected in locations with smoking. The extent of the increase in concentrations of these markers varies with the number of smokers, the intensity of smoking, the rate of exchange between the indoor airspace and with the outdoor air, and the use of air-cleaning devices. Ott (1999) has used mass-balance models to characterize factors influencing concentrations of tobacco smoke indoors, confirming the roles of these factors in determining ETS concentrations and offering an approach to predict concentrations.

Several components of cigarette smoke have been measured in indoor environments as markers of the contribution of tobacco combustion to indoor air pollution. Particles have been measured most often because both sidestream and mainstream smoke contain high concentrations of particles in the respirable size range (USDHHS 1986, NRC 1986). Particles are a nonspecific marker of tobacco smoke contamination, however, because numerous sources other than tobacco combustion add particles to indoor air. Other, more specific markers have also been measured, including nicotine, solanesol, and ultraviolet light (UV) absorption of particulate matter (Guerin et al. 1992). Nicotine, a highly specific marker present in the vapor phase of ETS, can be measured with active sampling methods and also using passive diffusion badges (Guerin et al. 1992, Leaderer and Hammond 1991). Studies of levels of ETS components have been conducted largely in public buildings; fewer studies have been conducted in homes and offices (USDHHS 1986, NRC 1986).

The contribution of various environments to personal exposure to tobacco smoke varies with the time-activity pattern. Time-activity patterns may heavily influence exposures in

TABLE 30.1 Occupational ETS Exposures in Non-Office Settings (Nonsmokers only)

particular environments for certain groups of individuals. For example, exposure in the home predominates for infants who do not attend day care (Harlos et al. 1987). For adults residing with nonsmokers, the workplace may be the principal location where exposure takes place (Cal EPA 1997). A recent nationwide study assessed exposures of nonsmokers in 16 metropolitan areas of the United States (Jenkins et al. 1996). This study, involving 100 persons in each location, was directed at workplace exposure and included measurements of respirable particulate matter and other markers. The results showed that in 1993/94 average exposures to ETS in the home were generally much greater than those in workplaces where smoking took place.

The contribution of smoking in the home to indoor air pollution has been demonstrated by studies using personal monitoring and monitoring of homes for respirable particles. In one of the early studies, Spengler et al. (1981) monitored homes in six U.S. cities for respirable particle concentrations over several years and found that an individual who smoked one pack of cigarettes daily contributed about $20 \mu\text{g}/\text{m}^3$ to 24-h indoor particle concentrations. Because cigarettes are not smoked uniformly over the day, higher peak concentrations must occur when cigarettes are actually smoked. Spengler et al. (1985) measured the personal exposures to respirable particles sustained by nonsmoking adults in two rural Tennessee communities. The mean 24-h exposures were substantially higher for those exposed to smoke at home: $64 \mu\text{g}/\text{m}^3$ for those exposed versus $36 \mu\text{g}/\text{m}^3$ for those not exposed.

In several studies, small numbers of homes have been monitored for nicotine (Table 30.2). In a study of ETS exposure of daycare children, average nicotine concentration during the time that the ETS-exposed children were at home was $3.7 \mu\text{g}/\text{m}^3$; in homes without smoking, the average was $0.3 \mu\text{g}/\text{m}^3$ (Henderson et al. 1989). Coultas and colleagues (1990) measured 24-h nicotine and respirable particle concentrations in 10 homes on alternate days for a week and then on 5 more days during alternate weeks. The mean levels of nicotine were comparable to those in the study by Henderson et al. (1989), but some 24-h values were as high as $20 \mu\text{g}/\text{m}^3$. Nicotine and respirable particle concentrations varied widely in the homes.

The Total Exposure Assessment Methodology (TEAM) study conducted by the U.S. Environmental Protection Agency, provided extensive data on concentrations of 20 volatile organic compounds in a sample of homes in several communities (Wallace and Pellizzari 1987). Indoor monitoring showed increased concentrations of benzene, xylenes, ethylbenzene, and styrene in homes with smokers compared to homes without smokers. This study indicated that cigarette smoking is a substantial contributor to benzene exposure for the population.

More extensive information is available on levels of ETS components in public buildings and workplaces of various types (Guerin et al. 1992, Hammond et al. 1995) (Table 30.1). Monitoring in locations where smoking may be intense, such as bars and restaurants, has generally revealed elevations of particles and other markers of smoke pollution where smoking is taking place (USDHHS 1986, NRC 1986). For example, Repace and Lowrey (1980) used a portable piezobalance to sample aerosols in restaurants, bars, and other locations. In the places sampled, respirable particulate levels ranged up to $700 \mu\text{g}/\text{m}^3$, and the levels varied with the intensity of smoking. Similar data have been reported for the office environment (Cal EPA 1997, USDHHS 1986, NRC 1986, Guerin et al. 1992). More recent studies indicate low concentrations in many workplace settings, reflecting declining smoking prevalence and changing practices of smoking in the workplace. Using passive nicotine samplers, Hammond and colleagues (Hammond et al. 1995) showed that worksite smoking policies can sharply reduce ETS exposure. Transportation environments may also be polluted by cigarette smoking, although smoking is now banned in all domestic air flights and many international flights.

Biological Markers of Exposure

Biological markers, measurements of exposure indicators made in biologic materials, can be used to describe the prevalence of exposure to environmental tobacco smoke, to investigate the dosimetry of involuntary smoking, and to validate questionnaire-based measures of exposure. In both active and involuntary smokers, detection of tobacco smoke components or their metabolites in body fluids or alveolar air provides evidence of exposure to tobacco smoke, and levels of these markers can be used to gauge the intensity of exposure and to estimate risk.

At present, the most sensitive and specific markers for tobacco smoke exposure are nicotine and its metabolite, cotinine (NRC 1986, Jarvis and Russell 1984, USDHHS 1988). Nicotine or cotinine is seldom present in body fluids in the absence of exposure to tobacco smoke, although unusually large intakes of some foods could produce measurable levels of nicotine and cotinine (Idle 1990). Cotinine, formed by oxidation of nicotine, is one of several primary metabolites of nicotine (USDHHS 1988). Cotinine itself is extensively metabolized, and only about 17 percent of cotinine is excreted unchanged in the urine.

Because the circulating half-life of nicotine is generally shorter than 2 h (Rosenberg et al. 1980), nicotine concentrations in body fluids reflect very recent exposures. In contrast, cotinine has a half-life in the blood or plasma of nonsmokers of about 20 h (USDHHS 1988, Kyerematen et al. 1982, Benowitz et al. 1983); hence, cotinine levels provide information about more chronic exposure to tobacco smoke in involuntary smokers. Cotinine can be measured in plasma, saliva, and urine using either radioimmunoassay or chromatography. Concerns about nonspecificity of cotinine, arising from eating nicotine-containing foods, have been set aside (Benowitz 1996). Thiocyanate concentration in body fluids, concentration of carbon monoxide in expired air, and carboxyhemoglobin level distinguish active smokers from nonsmokers but are not as sensitive and specific as cotinine for assessing involuntary exposure to tobacco smoke (Jarvis and Russell 1984, Hoffman et al. 1984).

Cotinine levels have been measured in adult nonsmokers and children (Table 30.3) (Benowitz 1996). In the studies of adult nonsmokers, exposures at home, in the workplace, and in other settings determined cotinine concentrations in urine and saliva. The cotinine levels in involuntary smokers ranged from less than 1 percent to about 8 percent of cotinine levels measured in active smokers. Smoking by parents was the predominant determinant of the cotinine levels in their children. For example, Greenberg et al. (1984) found significantly higher concentrations of cotinine in the urine and saliva of infants exposed to cigarette smoke in their homes than in unexposed controls. Urinary cotinine levels in the infants increased with the number of cigarettes smoked during the previous 24 h by the mother. In a study of schoolchildren in England, salivary cotinine levels rose with the number of smoking parents in the home (Jarvis et al. 1985). In a study of a national sample of participants in the Third National Health and Nutrition Examination Survey, 1988–1991, 88 percent of nonsmokers had a detectable level of serum cotinine using liquid chromatography–mass spectrometry as the assay method (Pirkle et al. 1996). Cotinine levels in this national sample increased with the number of smokers in the household and the hours exposed in the workplace.

The results of studies on biological markers add to the biological plausibility of associations between involuntary smoking and disease documented in epidemiologic studies (Benowitz 1996). The data on marker levels provide ample evidence that involuntary exposure leads to absorption, circulation, and excretion of tobacco smoke components. The studies of biological markers also confirm the high prevalence of involuntary smoking, as ascertained by questionnaire (Pirkle et al. 1996, Coultas et al. 1987). Comparisons of levels of biological markers in smokers and nonsmokers have been made to estimate the relative intensities of active and involuntary smoking and thereby infer risk of ETS exposure. However, proportionality cannot be assumed between the ratio of the levels of markers in passive and active smokers and the relative doses of other tobacco smoke components.

TABLE 30.3 Cotinine Concentrations in Nonsmokers and Smokers (Selected Studies)

Study	Year	Subjects, <i>N</i>	Smoking status	Exposure level	Plasma or serum cotinine, ng/mL	Urine cotinine, ng/mL	Salivary
Jarvis and Russell	1984	46 54	Nonsmokers Nonsmokers	No exposure Exposed	0.8 2.0	1.5 7.7

30.3 HEALTH EFFECTS OF INVOLUNTARY SMOKING IN CHILDREN

Fetal Effects

Researchers have demonstrated that active smoking by mothers results in a variety of adverse health effects in children. Some of the health effects result predominantly from transplacental exposure of the fetus to tobacco smoke components. Studies have also investigated and demonstrated associations between adverse health effects in children and maternal exposure to ETS. For example, paternal smoking in the presence of a pregnant mother may lead to perinatal health effects manifested on birth of the baby, and either maternal or paternal smoking in the presence of a newborn child may lead to postnatal health effects in the developing child.

Health effects on the fetus resulting from maternal smoking during pregnancy include fetal growth effects (decreased birthweight, growth retardation, or prematurity), fetal loss (spontaneous abortion and perinatal mortality), and congenital malformations. ETS exposure of nonsmoking mothers is associated with reduced birthweight as well, although the extent of the reduction is far less than for active maternal smoking during pregnancy. Health effects on the child postnatally, resulting from either ETS exposure to the fetus or to the newborn child, include sudden infant death syndrome and adverse effects on neuropsychological development and physical growth. Possible longer-term health effects of fetal ETS exposure include childhood cancers of the brain, leukemia, and lymphomas, among others.

There are a number of components of ETS that may produce these effects. Fetal exposure to carbon monoxide and nicotine due to ETS may increase risk for perinatal health effects. Carbon monoxide in ETS may contribute to increased concentrations of carbon monoxide and carboxyhemoglobin in the fetus, thereby reducing oxygen delivery, and the fetus may not be able to physiologically compensate (USDHHS 1980), leading to fetal hypoxia. Exposure to nicotine found in ETS can also alter an infant's catecholamine metabolism and response to hypoxia (Milerad and Sundell 1993). Furthermore, nicotine crossing the placenta may lead to decreased in utero placental perfusion, affecting the fetal cardiovascular system, gastrointestinal system, and central nervous system (Stillman et al. 1986). Other constituents of cigarette smoke have also been demonstrated to adversely affect fetal growth (Office of Environmental Health Hazard Assessment 1996). Association between ETS and childhood cancers is biologically plausible in the presence of carcinogenic tobacco smoke components or metabolites, such as benzene, nitrosamines, urethane, and radioactive compounds, at organ sites of the cancers.

Perinatal Health Effects

Fetal Growth. These health effects include reduced fetal growth, growth retardation, and congenital abnormalities. In most studies, paternal smoking has been used as the exposure measure to assess the association between ETS exposure and these nonfatal perinatal health effects. Low birthweight was first reported in 1957 to be associated with maternal smoking (USDHHS 1980) and maternal cigarette smoking during pregnancy is considered to be causally associated with low birthweight (USDHHS 1989). Other studies report lower birthweight for infants of nonsmoking women passively exposed to tobacco smoke during pregnancy (Martin and Bracken 1986, Rubin et al. 1986). For example, Haddow and colleagues (1988) used cotinine as a biomarker to measure exposure to ETS and found a decrease of 100 g in birthweight for fetuses exposed to ETS, defined as a cotinine level of

1.1 to 9.9 ng/mL in the fetus. The most recent biomarker studies (Eskenazi and Bergmann 1995, Eskenazi and Trupin 1995, Rebagliato et al. 1995) support the findings of Haddow et al. (1988). Other epidemiologic studies assessed ETS exposure from multiple sources through questionnaire (Mainous and Hueston 1994, Roquer et al. 1995, Rebagliato et al. 1995) and still demonstrated decreases of 20 to 40 g in mean birthweights after adjustment for potential confounding factors.

Other nonfatal perinatal health effects possibly associated with ETS exposure are growth retardation and congenital malformations. Martin and Bracken (1986) demonstrated a strong association with growth retardation in their 1986 study, and several more recent studies provide support (Mainous and Hueston 1994, Roquer et al. 1995). The few studies (Zhang et al. 1992, Savitz et al. 1991, Seidman et al. 1990) conducted to assess the association between paternal smoking and congenital malformations have demonstrated risks ranging from 1.2 to 2.6 for exposed compared to nonexposed.

ETS exposure to the fetus during its development has been associated in some studies with fatal perinatal health effects such as spontaneous abortion and perinatal mortality. Very few studies have examined the association between ETS exposure and perinatal death, with a few supporting an increase in risk (Comstock and Lundin 1967, Mau and Netter 1974, Lindbohm et al. 1991, Ahlborg and Bodin 1991).

Postnatal Health Effects

ETS exposure due to maternal or paternal smoking may lead to postnatal health effects including increased risk for SIDS, reduced physical development, decrements in cognition and behavior, and increased risk for childhood cancers. For cognition and behavior, evidence is limited and is not considered in this chapter.

SIDS. *Sudden infant death syndrome* refers to the sudden death of seemingly healthy infants while asleep. To date 10 studies have been directed at the association between SIDS and postnatal ETS exposure; six studies have addressed the association between paternal smoking and SIDS, and four studies have assessed household smoke exposure and SIDS (Table 30.4). While maternal smoking during pregnancy has been associated with SIDS, these studies measured maternal smoking after pregnancy, along with paternal smoking and household smoking generally.

Mitchell and colleagues (1993) demonstrated a significant association [odds ratio (OR) = 1.7] between postnatal maternal smoking and SIDS; this association remained significant after adjustment for potential confounders. In an updated study, Mitchell and colleagues (1995) concluded that the elimination of postnatal maternal smoking did not reduce the risk of SIDS and that prenatal exposure was still the more important risk factor. In a larger study, Klonoff-Cohen and colleagues (1995) found an adjusted odds ratio of 2.3 for SIDS and postnatal ETS exposure. Three more studies assessing maternal smoking after pregnancy (Bergman and Wiesner 1976, McGlashan 1989, Mitchell et al. 1991) could not assess a possible independent relationship between postnatal smoking and SIDS due to extensive overlap between maternal smoking during and after pregnancy.

Of the six studies conducted to assess the association between paternal smoking and SIDS, four (Mitchell et al. 1993, Klonoff-Cohen et al. 1995, Nicholl 1992, Blair et al. 1996) demonstrated elevated risks for SIDS while accounting for maternal smoking either by study design or through analyses, with odds ratios of 1.6, 1.4, 3.5, and 2.5, respectively. Two other studies (Bergman and Wiesner 1976, McGlashan 1989) demonstrated elevated risks but did not adjust for maternal smoking. Four studies assessed general household smoke exposure and SIDS. Dose-response relationships were observed by Blair and colleagues (1996), Mitchell and colleagues (1993), and Klonoff-Cohen and colleagues (1995).

TABLE 30.4 Studies Investigating the Association between ETS and SIDS**TABLE 30.4** Studies Investigating the Association between ETS and SIDS

Study	Location	Outcome assessed	Exposure	Exposure ascertainment	Participants	Odds ratio	Odds ratio adjusted for:
Berman and Wiesner (1976)	United States (King County, Washington)	SIDS	Maternal smoking after pregnancy	Mailed questionnaire	56 cases 86 controls	2.4 (1.2, 4.8)	Matched on date of birth, sex, and race Not adjusted for maternal smoking
McClashan (1989)	Tasmania	SIDS	Paternal smoking			1.5 (0.7, 3.2)	
			Maternal smoking during and after pregnancy	Interviewed parents	167 cases 334 controls	1.9 (1.2, 2.9)	Matched on sex
			Paternal smoking			"significantly increased"	
Mitchell et al. (1991)	New Zealand	SIDS	Maternal smoking after pregnancy	Interview with parents or from medical records	128 cases 503 controls	1.8 (1.0, 3.3)	Demographic factors, social factors, breastfeeding, season, sleeping position
Nicholl and O'Cathain (1992)	United Kingdom	SIDS	Paternal smoking		242 cases 251 controls	1.4 (0.8, 2.4)	Spousal smoking matched for date and place of birth
Schoendorf and Kiely (1992)	United States (U.S. National Maternal and Infant Health Survey)	SIDS	Maternal smoking after pregnancy	Interview	435 cases 6000 controls	Whites 1.8 (1.0, 3.0); blacks 2.3 (1.5, 3.7)	Maternal age, education, marital status
Mitchell et al. (1993)	New Zealand	SIDS	Maternal smoking after pregnancy	Interview with parents or from medical records	485 cases 1800 controls	1.7 (1.2, 2.3)	Region Season Breastfeeding Bed sharing Mother's marital status SES
			Paternal smoking			1.4 (1.0, 1.8)	Age Smoking during pregnancy Infant's age Sex Birthweight Race Sleeping position Smoking by mother Smoking by father Smoking by other household members

Klonoff-Cohen et al. (1995)	United States (southern California)	SIDS	Maternal smoking after pregnancy	200 cases 200 controls	2.3 (1.0, 5.0)	Birthweight Routine sleep position Medical conditions at birth Prenatal care Breastfeeding Maternal smoking during pregnancy
			Same-room maternal smoking after pregnancy			
			Paternal smoking			
			Same-room paternal smoking			
Blair et al. (1996)	United Kingdom	SIDS	Paternal smoking	195 cases 780 controls	2.5 (1.5, 4.2)	Marital Status Maternal age SES Maternal smoking Drug and alcohol use Gestational age Sleeping position Breastfeeding Matched by age and region
			Maternal smoking			

Klonoff-Cohen and colleagues (1995) reported adjusted odds ratios for 1 to 10, 11 to 20, and ≥ 21 cigarettes/day of 2.4, 3.6, and 22.7, respectively. Schoendorf and Kiely (1992) demonstrated increased risk of SIDS only in white infants.

Cancers

ETS exposure has been evaluated as a risk factor for the major childhood cancers. The evidence is limited and does not yet support conclusions as to the causal nature of the observed associations. Four studies have shown associations between paternal smoking and risk of brain tumors (Preston-Martin et al. 1982, Howe et al. 1989, John et al. 1991, McCredie et al. 1994), with odds ratios ranging from 1.4 to 2.2, with statistically significant results in two of the studies (McCredie et al. 1994, Preston-Martin et al. 1982). In animal studies, leukemia can be induced by transplacentally acting carcinogens found in tobacco smoke, and benzene, a component of ETS, is a leukemogen. The eight studies (John et al. 1991, Pershagen et al. 1992, van Steensel-Moll et al. 1985, Stjernfeldt et al. 1986, McKinney et al. 1987, Buckley et al. 1986, Magnani et al. 1990, Severson et al. 1993) on parental smoking and the risk of leukemia in children are conflicting. Six studies (John et al. 1991, Pershagen et al. 1992, Stjernfeldt et al. 1986, McKinney et al. 1987, Buckley et al. 1986, Magnani et al. 1990) have been conducted on ETS exposure and the risk of lymphomas and non-Hodgkin's lymphomas. While small increases in risk were observed, the data do not support a conclusion at this time.

ETS exposure has also been assessed as a risk factor for other common childhood cancers including neuroblastoma, germ cell tumors, bone and soft-tissue sarcomas, and Wilm's tumor of the kidney. A small increase in relative risk for neuroblastoma associated with paternal smoking during pregnancy has been demonstrated in one study (Kramer et al. 1987). Several studies have also attempted to assess associations between ETS and germ cell tumors (McKinney et al. 1987), bone and soft-tissue sarcomas (McKinney et al. 1987, Magnani et al. 1990, Grufferman et al. 1982, Hartley et al. 1988). Finally, active smoking is an established risk factor for cancers of the kidney and renal pelvis in adults, and animal studies have suggested that nitrosamines may have an etiologic role in these cancers. However, conclusive studies associating ETS with Wilm's tumor of the kidney in children have not yet been conducted.

Lower Respiratory Tract Illnesses in Childhood

Lower respiratory tract illness are extremely common during childhood. Studies of involuntary smoking and lower respiratory illnesses in childhood, including the more severe episodes of bronchitis and pneumonia, provided some of the earliest evidence on adverse effects of ETS (Harlap and Davies 1974, Colley et al. 1974). Presumably this association represents an increase in frequency or severity of illnesses that are infectious in etiology and not a direct response of the lung to toxic components of ETS. Investigations conducted throughout the world have demonstrated an increased risk of lower respiratory tract illness in infants with smoking parents (Strachan and Cook 1997). These studies indicate a significantly increased frequency of bronchitis and pneumonia during the first year of life of children with smoking parents. Strachan and Cook (1997) report a quantitative review of this information, combining data from 39 studies. Overall, there was an approximate 50 percent increase in illness risk if either parent smoked; the odds ratio for maternal smoking was somewhat higher at 1.72 [95% confidence interval (CI) = 1.55, 1.91]. Although the health outcome measures have varied somewhat among the studies, the relative risks associated with involuntary smoking were similar, and dose-response relationships with extent of parental smoking were demonstrable. Although most of the studies have shown that maternal smoking rather than paternal

smoking underlies the increased risk of parental smoking, studies from China show that paternal smoking alone can increase incidence of lower respiratory illness (Strachan and Cook 1997, Yue Chen et al. 1986). In these studies, an effect of passive smoking has not been readily identified after the first year of life. During the first year of life, the strength of its effect may reflect higher exposures consequent to the time-activity patterns of young infants, which place them in close proximity to cigarettes smoked by their mothers.

Respiratory Symptoms and Illness in Children

Data from numerous surveys demonstrate a greater frequency of the most common respiratory symptoms: cough, phlegm, and wheeze in the children of smokers (Cal EPA 1997, USDHHS 1986, Cook and Strachan 1997). In these studies the subjects have generally been schoolchildren, and the effects of parental smoking have been examined. Thus, the less prominent effects of passive smoking, in comparison with the studies of lower respiratory illness in infants, may reflect lower exposures to ETS by older children who spend less time with their parents.

By the mid-1980s, results from several large studies provided convincing evidence that involuntary exposure to ETS increases the occurrence of cough and phlegm in the children of smokers, although earlier data from smaller studies had been ambiguous. For example, in a study of 10,000 schoolchildren in six U.S. communities, smoking by parents increased the frequency of persistent cough in their children by about 30 percent (Gold et al. 1994). The effect of parental smoking was derived primarily from smoking by the mother. For the symptom of chronic wheeze, the preponderance of the early evidence also indicated an excess associated with involuntary smoking. In a survey of 650 schoolchildren in Boston, one of the first studies on this association, persistent wheezing, was the most frequent symptom (Weiss et al. 1980); the prevalence of persistent wheezing increased significantly as the number of smoking parents increased. In the large study of children in six U.S. communities, the prevalence of persistent wheezing during the previous year was significantly increased if the mother smoked (Gold et al. 1994).

Cook and Strachan (1997) conducted a quantitative summary of the relevant studies, including 41 of wheeze, 34 of chronic cough, 7 of chronic phlegm, and 6 of breathlessness. Overall, this synthesis indicates increased risk for respiratory symptoms for children whose parents smoke (Cook and Strachan 1997). There was even increased risk for breathlessness (OR = 1.31, 95 percent CI = 1.08, 1.59). Having both parents smoke was associated with the highest levels of risk.

Childhood Asthma

Exposure to ETS might cause asthma as a long-term consequence of the increased occurrence of lower respiratory infection in early childhood or through other pathophysiological mechanisms including inflammation of the respiratory epithelium (Samet et al. 1983, Tager 1988). The effect of ETS may also reflect, in part, the consequences of in utero exposure. Assessment of airways responsiveness shortly after birth has shown that infants whose mothers smoke during pregnancy have increased airways responsiveness, a characteristic of asthma, compared with those whose mothers do not smoke (Young et al. 1991). Maternal smoking during pregnancy also reduced ventilatory function measured shortly after birth (Hanrahan et al. 1992). These observations suggest that in utero exposures from maternal smoking may affect lung development, and increased risk for asthma.

While the underlying mechanisms remain to be identified, the epidemiologic evidence linking ETS exposure and childhood asthma is mounting (Cal EPA 1997, Cook and

Strachan 1997). The synthesis by Cook and Strachan (1997) shows a significant excess of childhood asthma if both parents or the mother smoke.

Evidence also indicates that involuntary smoking worsens the status of those with asthma. For example, Murray and Morrison (1986, 1989) evaluated asthmatic children followed in a clinic. Level of lung function, symptom frequency, and responsiveness to inhaled histamines were adversely affected by maternal smoking. Population studies have also shown increased airway responsiveness for ETS-exposed children with asthma (O'Connor et al. 1987, Martinez et al. 1988). The increased level of airway responsiveness associated with ETS exposure would be expected to increase the clinical severity of asthma. In this regard, exposure to smoking in the home has been shown to increase the number of emergency room visits made by asthmatic children (Evans et al. 1987). Asthmatic children with smoking mothers are more likely to use asthma medications (Weitzman et al. 1990), a finding that confirms the clinically significant effects of ETS on children with asthma. Guidelines for the management of asthma all urge reduction of ETS exposure at home (USDHHS 1997).

Lung Growth and Development

During childhood, measures of lung function increase, more or less parallel to the increase in height. On the basis of the primarily cross-sectional data available at the time, the 1984 report of the Surgeon General (USDHHS 1984) concluded that the children of smoking parents in comparison with those of nonsmokers had small reductions of lung function, but the long-term consequences of these changes were regarded as unknown. In the 2 years between the 1984 and the 1986 reports, sufficient longitudinal evidence accumulated to support the conclusion in the 1986 report (USDHHS 1986) that involuntary smoking reduces the rate of lung function growth during childhood. Further cross-sectional studies have also been consistent with this conclusion (Samet and Wang 2000).

The effects of involuntary smoking on lung growth have been demonstrated in several longitudinal studies (Samet and Lange 1996). On the basis of cross-sectional data from a study of children in East Boston, Massachusetts, Tager and coworkers (1979) reported that the level of FEF_{25-75} , a spirometric forced expiratory flow rate sensitive to subtle effects on airways and parenchymal function, declined with an increasing number of smoking parents in the household. In 1983 in the first set of longitudinal data, this investigative group reported the results obtained on follow-up of these children over a 7-year period (Tager et al. 1983). Using a multivariate statistical technique, the investigators showed that both maternal smoking and active smoking by the child reduced the growth rate of the FEV_1 . Lifelong exposure of a child to a smoking mother was estimated to reduce growth of the FEV_1 by 10.7, 9.5, and 7.0 percent after 1, 2, and 5 years of follow-up, respectively. Findings with additional follow-up were similar (Tager et al. 1985).

Longitudinal data from the study of air pollution in six U.S. cities also showed reduced growth of the FEV_1 in children whose mothers smoked cigarettes (Gold et al. 1996). The growth rate of the FEV_1 from ages 6 through 10 years was calculated for 7834 white children. The findings of a statistical analysis were that from ages 6 through 10 years, FEV_1 growth rate was reduced by 0.17 percent per pack of cigarettes smoked daily by the mother. This effect was somewhat smaller than that reported by Tager et al. (1983), although if it is extrapolated to age 20 years, a cumulative effect of 2.8 percent is predicted. In the most recent analysis of these data, Wang and colleagues (1994) modeled exposures in a time-dependent fashion, classifying exposure during the first 5 years of life and cumulative exposure up to the year before follow-up. Current maternal smoking was found to affect lung growth. Findings from other studies are consistent (Samet and Lange 1996).

ETS and Middle-Ear Disease in Children

Otitis media is one of the most frequent diseases diagnosed in children at outpatient facilities; forms of otitis media include acute, persistent, or recurrent disease as well as effusion or fluid within the middle ear. There are now many reported studies on the association between ETS exposure and otitis media in children. ETS exposure in these studies is assessed mostly by questionnaire or interview of the parents, but two studies assessed ETS exposure objectively through the use of biomarkers (serum or salivary cotinine measurements in the children). Outcomes assessed in the studies vary from acute, persistent, and recurrent otitis media or middle-ear effusion, to consequences of otitis media such as hearing loss and ear surgery.

Positive associations between ETS and otitis media have been consistently demonstrated in studies of the cohort or prospective design, but not as consistently in the case-control studies. This difference may have arisen because the cohort studies include children from birth to age 2 years, the peak age of risk for middle-ear disease. Case-control studies, on the other hand, have been directed at older children who are not at peak risk for otitis media. Regardless of study type, however, increase in risk for middle-ear disease is demonstrated when the outcome assessed is recurring episodes of middle-ear effusion or otitis media, versus incident or single episodes of otitis media. In a 1997 metaanalysis, Strachan and Cook (1997) found a pooled odds ratio of 1.48 (95 percent CI: 1.08, 2.04) for recurrent otitis media if either parent smoked, 1.38 (95 percent CI: 1.23, 1.55) for middle-ear effusions, and 1.21 (95 percent CI: 0.95, 1.53) for outpatient or inpatient care for chronic otitis media or "glue ear."

The California EPA (Cal EPA 1997) and the United Kingdom Committee (Scientific Committee on Tobacco and Health, HSMO 1998) have reviewed the literature on ETS and middle-ear disease and concluded that there is a causal association with ETS exposure and otitis.

30.4 HEALTH EFFECTS OF INVOLUNTARY SMOKING IN ADULTS

Lung Cancer

In 1981, reports were published from Japan (Hirayama 1981) and Greece (Trichopoulos et al. 1981) that indicated increased lung cancer risk in nonsmoking women married to cigarette smokers. Subsequently, this controversial association has been examined in investigations conducted in the United States and other countries. The association of involuntary smoking with lung cancer derives biological plausibility from the presence of carcinogens in sidestream smoke and the lack of a documented threshold dose for respiratory carcinogens in active smokers (USDHHS 1982, IARC 1986). Moreover, genotoxic activity, the ability to damage DNA, has been demonstrated for many components of ETS (Lofroth 1989, Claxton et al. 1989, Weiss 1989), although several small studies have not found cytogenetic effects in passive smokers (Sorsa et al. 1985, 1989; Husgafvel-Pursiainen et al. 1987). Experimental exposure of non-smokers to ETS leads to their excreting NNAL, a tobacco-specific carcinogen, in their urine (Hecht et al. 1993). Nonsmokers exposed to ETS also have increased concentrations of adducts of tobacco-related carcinogens (Maclure et al. 1989, Crawford et al. 1994).

Epidemiologists have directly tested the association between lung cancer and involuntary smoking utilizing conventional designs: the case-control and cohort studies. In a *case-*

control study, the exposures of nonsmoking persons with lung cancer to ETS are compared to those of an appropriate control group. In a *cohort study*, the occurrence of lung cancer over time in nonsmokers is assessed in relation to involuntary tobacco smoke exposure. The results of both study designs may be affected by inaccurate assessment of exposure to ETS, inaccurate information on personal smoking habits that leads to classification of smokers as nonsmokers, failure to assess and control for potential confounding factors, and the misdiagnosis of a cancer at another site as a primary cancer of the lung. The potential implications of these methodologic issues have been repetitively considered and refuted as a satisfactory explanation for the ETS–lung cancer association (USDHHS 1986; Scientific Committee on Tobacco and Health, HSMO 1998; Samet and Wang 2000).

The first major studies on ETS and lung cancer were reported in 1981. Hirayama's (1981) early report was based on a prospective cohort study of 91,540 nonsmoking women in Japan. Standardized mortality ratios (SMRs) for lung cancer increased significantly with the amount smoked by the husbands. The findings could not be explained by confounding factors and were unchanged when follow-up of the study group was extended (Hirayama 1984). On the basis of the same cohort, Hirayama (1984) also reported significantly increased risk for nonsmoking men married to wives smoking 1 to 19 cigarettes and 20 or more cigarettes daily. In 1981, Trichopoulos et al. (1981) also reported increased lung cancer risk in nonsmoking women married to cigarette smokers. These investigators conducted a case-control study in Athens, Greece, which included cases with a diagnosis other than for orthopedic disorders. The positive findings reported in 1981 were unchanged with subsequent expansion of the study population (Trichopoulos et al. 1983).

By 1986, the evidence had mounted, and three reports published in that year concluded that ETS was a cause of lung cancer. The International Agency for Research on Cancer of the World Health Organization (IARC 1986) concluded that "passive smoking gives rise to some risk of cancer." In its monograph on tobacco smoking, the agency supported this conclusion on the basis of the characteristics of sidestream and mainstream smoke, the absorption of tobacco smoke materials during involuntary smoking, and the nature of dose-response relationships for carcinogenesis. In the same year, The U.S. Surgeon General (USDHHS 1986) and the National Research Council (NRC 1986) also concluded that involuntary smoking increases the incidence of lung cancer in nonsmokers. In reaching this conclusion, the National Research Council (NRC 1986) cited the biological plausibility of the association between exposure to ETS and lung cancer and the supporting epidemiologic evidence. On the basis of a pooled analysis of the epidemiologic data adjusted for bias, the report concluded that the best estimate for the excess risk of lung cancer in nonsmokers married to smokers was 25 percent. The 1986 report of the Surgeon General (USDHHS 1986) characterized involuntary smoking as a cause of lung cancer in nonsmokers. This conclusion was based on the extensive information already available on the carcinogenicity of active smoking, on the qualitative similarities between ETS and mainstream smoke, and on the epidemiologic data on involuntary smoking.

In 1992 the U.S. Environmental Protection Agency (USEPA 1992) published its risk assessment of ETS as a carcinogen. The agency's evaluation drew on the toxicologic evidence on ETS and the extensive literature on active smoking. A metaanalysis of the 31 studies published to that time was central in the decision to classify ETS as a class A carcinogen—specifically, a known human carcinogen. The metaanalysis considered the data from the epidemiologic studies by tiers of study quality and location and used an adjustment method for misclassification of smokers as never smokers. Overall, the analysis found a significantly increased risk of lung cancer in never-smoking women married to smoking men; for the studies conducted in the United States, the estimated relative risk was 1.19 (90 percent CI 1.04, 1.35). Critics of the report have raised a number of concerns including the use of metaanalysis, reliance on 90 rather than 95 percent confidence inter-

vals, uncontrolled confounding, and information bias. The report, however, was endorsed by the USEPA Science Advisory Board, and its conclusion is fully consistent with the 1986 reports. In spite of this review by the Science Advisory Board, Judge Osteen vacated portions of the report concerned with lung cancer in a 1998 decision that was based on procedural grounds and the judge's own evaluation of the scientific approach followed by the USEPA (Osteen 1997).

Subsequent to the 1992 risk assessment, several additional studies in the United States have been reported (Fontham et al. 1994, Kabat et al. 1995, Cardenas et al. 1997). The multicenter study of Fontham and colleagues (Fontham et al. 1994) is the largest report to date with 651 cases and 1253 controls. It showed a significant increase in overall relative risk (OR = 1.26, 95 percent CI = 1.04, 1.54). There was also a significant risk associated with occupational exposure to ETS.

Findings of an autopsy study conducted in Greece also strengthened the plausibility of the lung cancer/ETS association. Trichopoulos and colleagues (1992) examined autopsy lung specimens from 400 persons 35 years of age and older, assessing airway changes. Epithelial lesions were more common in nonsmokers married to smokers than in nonsmokers married to nonsmokers.

The most recent metaanalysis (Hackshaw et al. 1997) included 37 published studies. The excess risk of lung cancer for smokers married to nonsmokers was estimated as 24 percent (95 percent CI 13, 36 percent). Adjustment for potential bias and confounding by diet did not alter the estimate. This metaanalysis supported the conclusion of the U.K. Scientific Committee on Tobacco and Health (Scientific Committee on Tobacco and Health, HSMO 1998) that ETS is a cause of lung cancer.

The extent of the lung cancer hazard associated with involuntary smoking in the United States and in other countries remains subject to some uncertainty, however (USDHHS 1986, Weiss 1986). Repace and Lowrey (1990) reviewed the risk assessments of lung cancer and passive smoking and estimated the numbers of lung cancer cases in U.S. nonsmokers attributable to passive smoking. The range of the nine estimates, covering both never smokers and former smokers, provided by Repace and Lowrey was from 58 to 8124 lung cancer deaths for the year 1988, with an overall mean of 4500 or 5000 excluding the lowest estimate of 58. The bases for the individual estimates included the comparative dosimetry of tobacco smoke in smokers and nonsmokers using presumed inhaled dose or levels of nicotine or cotinine, the epidemiologic evidence, and modeling approaches. The 1992 estimate of the U.S. Environmental Protection Agency, based on the epidemiologic data was about 3000, including 1500 and 500 deaths in never-smoking women and men, respectively, and about 100 in long-term former smokers of both sexes. These calculations illustrate that passive smoking must be considered an important cause of lung cancer death from a public health perspective; exposure is involuntary and not subject to control.

ETS and Coronary Heart Disease

Introduction. Causal associations between active smoking and fatal and nonfatal coronary heart disease (CHD) outcomes have long been demonstrated (USDHHS 1989). This increased risk of CHD morbidity and mortality has been demonstrated for younger persons and the elderly, in men and women, and in ethnically and racially diverse populations. The risk of CHD in active smokers increases with amount and duration of cigarette smoking and decreases quickly with cessation. Active cigarette smoking is considered to increase the risk of cardiovascular disease by promoting atherosclerosis, increasing the tendency to thrombosis, causing spasm of the coronary arteries, increasing the likelihood of cardiac arrhythmias, and decreasing the oxygen-carrying capacity of the blood (USDHHS 1990). Glantz and Parmley (1991) have summarized the pathophysiological mechanisms by which

passive smoking might increase the risk of heart disease. It is biologically plausible that passive smoking could also be associated with increased risk for CHD through the same mechanisms considered relevant for active smoking, although the lower exposures to smoke components of the passive smoker have raised questions regarding the relevance of the mechanisms cited for active smoking.

Epidemiologic Studies. Epidemiologic data first raised concern that passive smoking may increase risk for CHD with the 1985 report of Garland and colleagues (1985) based on a cohort study in southern California. There are now more than 20 studies on the association between environmental tobacco smoke and cardiovascular disease. These studies assessed both fatal and nonfatal cardiovascular heart disease outcomes, and most used self-administered questionnaires to assess ETS exposure. They cover a wide range of populations, both geographically and racially. While many of the studies were conducted within the United States; studies were also conducted in Europe (Scotland, Italy, United Kingdom), Asia (Japan and China), South America (Argentina), and the South Pacific (Australia and New Zealand). The majority of the studies measured the effect of ETS exposure due to spousal smoking; however, some studies also assessed exposures from smoking by other household members or occurring at work or in transit. Only one study included measurement of biomarkers.

As the evidence has subsequently mounted since the 1985 report, it has been systematically reviewed by the American Heart Association (Taylor et al. 1992) and the California Environmental Protection Agency (Cal EPA 1997), and also in a metaanalysis done for the Scientific Committee on Tobacco and Health in the United Kingdom (Hackshaw et al. 1997). The topic was not addressed in either the 1986 Surgeon General's report or the 1992 EPA risk assessment of ETS, because of the limited data available when these reports were prepared.

Although the risk estimates for ETS and CHD outcomes vary in these studies, they range mostly from null to modestly significant increases in risk, with the risk for fatal outcomes generally higher and more significant. In a 1997 metaanalysis, Law et al. (1997) estimated the excess risk from ETS exposure as 30 percent (95 percent CI 22, 38 percent) at age 65 years. The California Environmental Protection Agency (Cal EPA 1997) concluded that there is "an overall risk of 30 percent" for CHD due to exposure from ETS. The American Heart Association's Council on Cardiopulmonary and Critical Care has also concluded that environmental tobacco smoke both increases the risk of heart disease and is "a major preventable cause of cardiovascular disease and death" (Taylor et al. 1992). This conclusion was echoed in 1998 by the Scientific Committee on Tobacco and Health in the United Kingdom (Scientific Committee on Tobacco and Health, HSMO 1998).

Respiratory Symptoms and Illnesses in Adults

Only a few cross-sectional investigations provide information on the association between respiratory symptoms in nonsmokers and involuntary exposure to tobacco smoke. These studies have primarily considered exposure outside the home. Consistent evidence of an effect of passive smoking on chronic respiratory symptoms in adults has not been found (Kauffmann et al 1989, Lebowitz and Burrows 1976, Schilling et al. 1977, Comstock et al. 1981, Schenker et al. 1982, Euler et al. 1987, Hole et al. 1989).

Several studies suggest that passive smoking may cause acute respiratory morbidity, specifically, illnesses and symptoms. Analysis of National Health Interview Survey data showed that a pack-a-day smoker increases respiratory restricted days by about 20 percent for a nonsmoking spouse (Ostro 1989). In a study of determinants of daily respiratory symptoms in Los Angeles student nurses, with a smoking roommate significantly increased

the risk of an episode of phlegm, after controlling for personal smoking (Schwartz and Zeger 1990). Leuenberger and colleagues (1994) describe associations between passive exposure to tobacco smoke at home and in the workplace and respiratory symptoms in 4197 randomly selected never-smoking adults in the Swiss Study on Air Pollution and Lung Diseases in Adults, a multicenter study in eight areas of the country. Involuntary smoke exposure was associated with asthma, dyspnea, bronchitis and chronic bronchitis symptoms, and allergic rhinitis. The increments in risk were substantial, ranging from approximately 40 to 80 percent for the different respiratory outcome measures. Other studies have also shown adverse effects of involuntary smoking on adults. Robbins and colleagues (1993) examined predictors of new symptoms compatible with "airway obstructive disease" in a cohort study of 3914 nonsmoking participants in the Adventist Health Study. Significantly increased risk was identified in association with exposure during both childhood and adulthood. In a cross-sectional study, Dayal and colleagues (1994) found that never-smoking Philadelphia residents with a reported diagnosis of asthma, chronic bronchitis, or emphysema had sustained significantly greater exposure to tobacco smoke than did unaffected controls. Blanc and colleagues (Eisner et al. 1998) showed that restaurant and bar workers in northern California had reduced symptoms after implementation of regulations that completely prohibited smoking in those venues.

Neither epidemiologic nor experimental studies have established the role of ETS in exacerbating asthma in adults. The acute responses of asthmatics to ETS have been assessed by exposing persons with asthma to tobacco smoke in a chamber. This experimental approach cannot be readily controlled because of the impossibility of blinding subjects to exposure to ETS. However, suggestibility does not appear to underlie physiological responses of asthmatics of ETS (Urch et al. 1988). Of three studies involving exposure of unselected asthmatics to ETS, only one showed a definite adverse effect (Shephard et al. 1979, Dahms et al. 1981, Murray and Morrison 1986). Stankus et al. (1988) recruited 21 asthmatics who reported exacerbation with exposure to ETS. With challenge in an exposure chamber at concentrations much greater than typically encountered in indoor environments, seven of the subjects experienced a more than 20 percent decline in FEV_1 .

Lung Function in Adults. With regard to involuntary smoking and lung function in adults, exposure to passive smoking has been associated in cross-sectional investigations with reduction of several lung function measures (Cal EPA 1997). However, the findings have not been consistent, and methodological issues constrain interpretation of the findings. A conclusion cannot yet be reached on the effects of ETS exposure on lung function in adults. However, further research is warranted because of widespread exposure in workplaces and homes.

Odor and Irritation

Tobacco smoke contains numerous irritants, including particulate material and gases (USDHHS 1986). Both questionnaire surveys and laboratory studies involving exposure to ETS have shown annoyance and irritation of the eyes and upper and lower airways from involuntary smoking. In several surveys of nonsmokers, complaints about tobacco smoke at work and in public places were common (USDHHS 1986); about 50 percent of respondents complained about tobacco smoke at work, and a majority were disturbed by tobacco smoke in restaurants. The experimental studies show that the rate of eye blinking is increased by ETS, as are complaints of nose and throat irritation (USDHHS 1986). In the study of passive smoking on commercial airline flights reported by Mattson and colleagues (1989), changes in nose and eye symptoms were associated with nicotine exposure. The odor and irritation associated with ETS merit special consideration because a high propor-

tion of nonsmokers are annoyed by exposure to ETS, and control of concentrations in indoor air poses difficult problems in the management of heating, ventilating, and air-conditioning systems.

Using a challenge protocol, Bascom and colleagues (1991) showed that persons characterizing themselves as ETS-sensitive have greater responses on exposure than do persons considering themselves as nonsensitive.

Total Mortality

Several cohort studies provide information on involuntary smoking and mortality from all causes. In the Scottish cohort study, total mortality was initially reported as increased for women living with a smoker but not for men (Gillis et al. 1984). On further follow-up, all-cause mortality was increased in all passive smokers (relative risk = 1.27; 95 percent confidence limits 0.95 to 1.70). As described previously, total mortality was also increased among nonsmoking participants in MRFIT who lived with smokers (Svensden et al. 1987). In contrast, mortality was not increased for nonsmoking female subjects in a study in Amsterdam (Vandenbroucke et al. 1984). Neither the study in Scotland nor the study in Amsterdam controlled for other factors that influence total mortality. In the cohort study in Washington County, all-cause mortality rates were significantly increased for men [relative risk (RR) = 1.17] and for women (RR = 1.15) after adjustment for housing quality, schooling, and marital status (Sandler et al. 1989). All-cause mortality was also increased for passive smokers in the Evans County cohort (RR = 1.39, 95 percent confidence interval 0.99 to 1.94).

Wells (1988) has made an estimate of the number of adult deaths in the United States attributable to passive smoking. The total is about 46,000, including 3000 from lung cancer, 11,000 from other cancers, and 32,000 from heart disease.

The small excesses of all-cause mortality associated with passive smoking in the epidemiologic studies parallel the findings for cardiovascular disease, the leading cause of death in these cohorts. The increased risk of death associated with passive smoking has public health significance as an indicator of the overall impact of this avoidable exposure.

30.5 CONTROL MEASURES

Potential approaches for reducing or eliminating exposures to ETS include prohibition of smoking within buildings, restriction of smoking to selected areas with separate ventilation systems, ventilation, and air cleaning. Regulations for the control of smoking in public buildings vary by municipality within the United States and from country to country. Exposures to ETS can be fully eliminated by smoking bans, as are now in place in many municipalities in the United States. Increasingly, smoking is prohibited in workplaces as well. As yet, however, the Occupational Safety and Health Administration has not moved to promulgate its 1994 proposed new regulations on indoor air quality that call for either prohibition of smoking within workplaces or the provision of separately ventilated smoking rooms. Of course, the home, now a major locus of ETS exposure in the United States, does not fall under any regulatory jurisdiction. Policies for reducing exposures in the home, particularly to children, will need to involve education and voluntary steps by the public (Samet et al. 1994).

The role of ventilation as a control measure has been controversial, particularly in relation to Standard 62 of the American Society of Heating, Refrigerating, and Air Conditioning Engineers. Standard 62-89 permitted a "moderate amount of smoking" in the presence of the mandated ventilation rate. That standard was challenged and revision is

now in progress. Air cleaning has not been shown to be effective for controlling ETS exposures, and, in fact, many of the devices commercially touted for ETS are ineffective (American Lung Association and the American Thoracic Society 1997).

30.6 SUMMARY

The effects of active smoking and the toxicology of cigarette smoking have been comprehensively examined. The periodic reports of the U.S. Surgeon General and other summary reports have considered the extensive evidence on active smoking; these reports have provided definitive conclusions concerning the adverse effects of active smoking, which have prompted public policies and scientific research directed at prevention and cessation of smoking.

Although the evidence on involuntary smoking is not as extensive as that on active smoking, health risks of involuntary smoking have been identified and causal conclusions reached, beginning in the mid-1980s. The 1986 Report of the U.S. Surgeon General (USDHHS 1986) and the 1986 Report of the National Research Council (NRC 1986) both concluded that involuntary exposure to tobacco smoke causes respiratory infections in children, increases the prevalence of respiratory symptoms in children, reduces the rate of functional growth as the lung matures, and causes lung cancer in nonsmokers. These conclusions have been reaffirmed in subsequent reports (Cal EPA 1997, EPA 1992, Ott 1999) and new conclusions added. Involuntary smoking is now considered as a cause of asthma and a factor exacerbating asthma (Cal EPA 1997, EPA 1992, Ott 1999) and as a cause of heart disease (Cal EPA, Ott 1999). At present, the evidence on passive smoking and cancer at sites other than the lung does not support causal conclusions.

The adverse effects of involuntary exposure to tobacco smoke have provided a strong rationale for policies directed at reducing and eliminating exposure of nonsmokers to ETS (USDHHS 1986). Complete protection of nonsmokers in public locations and the workplace may require the banning of smoking, since the 1986 *Report of the Surgeon General* (USDHHS 1986) concluded that "the simple separation of smokers and nonsmokers within the same air space may reduce, but does not eliminate, the exposure of nonsmokers to environmental tobacco smoke." Fortunately, source control can be readily accomplished by not allowing cigarette smoking indoors.
