CHAPTER 31

VOLATILE ORGANIC COMPOUNDS

W. Gene Tucker, Ph.D.

*James Madison University
Harrisonburg, Virginia*

The term *volatile organic compounds* (VOCs) was originally coined to refer, as a class, to carbon-containing chemicals that participate in photochemical reactions in the ambient (outdoor) air. They are generated by a wide variety of sources including painting operations, petroleum refineries, solvent cleaning, fuel storage and loading operations, printing operations, and motor vehicles. These chemicals are regulated in many countries to control tropospheric ozone and “smog.” The regulatory definition of VOCs used by the United States Environmental Protection Agency (USEPA) (USCFR, a) is:

Any compound of carbon, excluding carbon monoxide, carbon dioxide, carbonic acid, metallic carbides or carbonates, and ammonium carbonate, which participate in atmospheric photochemical reactions. This includes any such compound other than the following, which have been determined to have negligible photochemical reactivity: methane, ethane, acetone, methyl acetate, completely methylated siloxanes...[and numerous listed halogenated hydrocarbons and perfluorocarbon compounds].

The term is further defined by specified sampling and analytical test methods (USCFR, b).

The term VOCs has a distinctly different—and much less rigorously defined—meaning in the indoor air literature. Indoor air quality (IAQ) investigators usually consider all organic vapor-phase compounds measured by their sampling and analysis methods to be “VOCs.” The sum of all measured VOCs is often reported as *total volatile organic compounds* (TVOCs). One consequence of methodological differences is that some compounds that are not covered under ambient VOC definition are commonly reported as VOCs in indoor air studies. Examples include acetone; 1,1,1-trichloroethane; and perchloroethylene. On the other hand, formaldehyde is considered a VOC in the ambient air, but is considered separately from VOCs in most indoor air studies.

Various efforts have been made to categorize indoor vapor-phase organic compounds into classes, most notably by the World Health Organization (WHO). Table 31.1 summarizes the WHO classification system.

TABLE 31.1 WHO Classification System for Organic Indoor Pollutants

Category Description	Acronym	Boiling-point range, °C*	Typical sampling methods
1 Very volatile (gaseous) organic compounds	VVOC	<0 to 50–100	Batch sampling; adsorption on charcoal
2 Volatile organic compounds	VOC	50–100 to 240–260	Adsorption on Tenax, carbon molecular black, or charcoal
3 Semivolatile organic compounds	SVOC	240–260 to 380–400	Adsorption on polyurethane foam or XAD-2
4 Organic compounds associated with particulate matter or particulate organic matter	POM	>380	Collection on filters

*Polar compounds appear at the higher end of the range.

Source: WHO (1989).

Some VOCs can be malodorous pollutants, sensory irritants (primarily to mucous membranes in eyes and nasal passages), or hazardous air pollutants. Table 31.2 lists examples of vapor-phase organic compounds that are listed by the U.S. Environmental Protection Agency as hazardous ambient-air pollutants and that have been measured inside buildings, often at higher concentrations than in the outdoor air near those buildings. However, the measured concentrations of individual compounds are nearly always lower than levels of known concern.

As a class, VOCs are the most prevalent of indoor air pollutants. They are also the most studied [e.g., see Wolkoff (1995) and Levin (1996a)]. There are often dozens—sometimes hundreds—of individual compounds present at concentrations of 1 $\mu\text{g}/\text{m}^3$ [(roughly 1 to 5 parts per billion (ppb))] or more. Total VOC concentrations typically range from 50 to 1000 $\mu\text{g}/\text{m}^3$ over long periods, and can reach hundreds of mg/m^3 for periods of minutes to hours. The long-term concentrations result from the presence of a wide variety of synthetic and natural products, and people and their activities. The high short-term concentrations are most commonly reached when solvent-laden coatings are being applied during building construction or renovation, and when certain personal care products, hobby materials, or cleaning agents are being used.

The most common sampling and analytic techniques include collection of the VOCs on some type of solid sorbent, followed by thermal desorption or solvent extraction and analysis by a gas chromatograph equipped with a mass spectrometer or flame ionization detector. Standards and guidelines have been published by the American Society of Testing and Materials (ASTM 1995, 1997a), the European Communities (CEC 1989), the U.S. Environmental Protection Agency (Winberry et al. 1990), and others. Comparisons of indoor VOC measurement methods have been limited [e.g., see Hodgson (1995)].

31.1 SOURCES

Virtually any material in a building has some potential for containing organic compounds that can evaporate or sublime from its surfaces and get into the air. Even metallic or

TABLE 31.2 Examples of Hazardous VOCs that Have Been Measured in Indoor Air, and Their Potential Indoor Sources

Compound	Categories of indoor sources with reported emissions data (Not all products in the category contain or emit the compound)
Acetaldehyde*	Floor materials, HVAC systems and components, machines, wood products
Benzene*	Furnishings, paints and coatings, wood products
Carbon tetrachloride*	Pesticides
Chloroform*	Furnishings, pesticides
Ethylbenzene	Floor materials, insulation products, machines, paints and coatings
Formaldehyde*	Cabinetry, floor materials, furnishings, HVAC systems and components, indoor air reactions, insulation products, miscellaneous materials, paints and coatings, space heating and cooking equipment, wall and ceiling materials, wood products
Hexane	Floor materials, furnishings, paints and coatings, wood products
Methylene chloride*	Furnishings
Naphthalene	Pesticides (moth crystals)
Paradichlorobenzene*	Pesticides, floor materials
Styrene	Cabinetry, floor materials, insulation products, machines, miscellaneous materials, paints and coatings, wood products
Tetrachloroethylene*	Caulks and sealants, miscellaneous materials
Toluene	Adhesives, caulks and sealants, floor materials, furnishings, machines, paints and coatings, wall and ceiling materials, wood products
Trichloroethylene*	Furnishings
Xylenes (<i>o</i> , <i>m</i> , <i>p</i>)	Floor materials, furnishings, machines, paints and coatings, wall and ceiling materials

*Included in a list of 33 hazardous air pollutants proposed by the U.S. Environmental Protection Agency as *urban air toxics*, which are thought to pose the greatest health threat to people living in urban areas (USEPA 1998a).

vitreous materials that were entirely inorganic when new may have accumulated organic substances on their surfaces through deposition of vapors or particles from the air (through the so-called sink effect).

The types of sources in typical residential and commercial buildings cover a wide variety of building materials and contents. They range from sources with virtually no emissions (which may in fact act as absorbers, or “sinks” for pollutants) to large-surface-area, high-emission-rate materials that can contaminate indoor air and irritate occupants for long periods.

In addition to emission rate, a measure often referred to as *source strength*, sources can also be characterized by the duration of their emissions. Some have an essentially constant emission rate. Examples include moth crystals (which at room temperature emit *paradichlorobenzene* at a nearly constant rate until the crystals are gone) and certain types of aged particleboard (that have emission rate half-lives of a year or more). Other sources have a *slow-decay emission rate*. These have emission rate half-times of weeks or months. Examples include certain types of floor- and wallcoverings and furniture. A third category is *rapid-decay emission-rate sources*, which have emission rate half-times of minutes, hours, or days. Many wet materials such as paints and coatings emit strongly for a relatively short period after they have been applied.

Table 31.3 presents the general categories of sources of indoor VOCs and examples of specific types. Although emissions from these sources are primarily synthetic organic chemicals from manufactured materials, some are products of incomplete combustion,

natural compounds from plant and animal respiration, or products of chemical reactions in the indoor air. Surfaces that adsorb VOCs during periods of high concentrations from high-emitting sources can subsequently become significant sources when they become reemitting sinks, and release substances that they did not originally contain.

31.2 EMISSIONS

Factors that Influence Emissions

The major factors that are now thought to influence emission of vapor-phase organic compounds from surface materials are

TABLE 31.3 Potential Sources of VOCs in Buildings

Source category	Source type (examples)
Adhesives	Carpet adhesive, flooring adhesive, general adhesive
Cabinetry	Kitchen cabinets, other cabinetry
Caulks and sealants	Caulk, sealant, waterproofing
Cleaning agents	Detergent, disinfectant, miscellaneous cleaning agent, solvent-based cleaner
Floor materials	Carpet, carpet cushion, cork flooring, sheet vinyl, vinyl tile, wood flooring
Furnishings	Drapery, drapery lining, office furniture, residential furniture
HVAC systems and components	Air-cleaning device, air-moving equipment, cooling coils, ductwork, heating coils, humidification equipment
Indoor air reactions	Partial oxidation of unsaturated organics to aldehydes, reemission of sorbed compounds from indoor surfaces (reemitting "sinks")
Insulation products	Fibrous insulation, foam insulation
Machines	Air conditioner, office machine, electronic equipment, in-room air cleaner, in-room humidifier
Miscellaneous materials	Clothing, miscellaneous stored material, coated paper products
Occupants and occupant activities	Animals (pets), cleaning, cooking, human bioeffluents, smoking, occupant use of personal-care products
Outdoor sources	Soil gas, infiltrated outdoor air
Paints and coatings	Oil-based finish, solvent-based paint, stain, varnish, water-based finish, water-based paint, wax
Pesticides	Moth repellent, other pesticides
Space heating and cooking equipment	Electric, gas-fueled (vented and unvented), oil-fueled (vented and unvented), solid-fueled
Wall and ceiling materials	Ceiling tile, gypsum board, plaster, wall paneling, wallpaper/wallcovering
Wood products	Particleboard, plywood, veneer, waferboard/chipboard, insulation board, hardboard, solid natural wood product

1. Total amount and volatility of constituents in the materials
2. Distribution of these constituents between the surface and the interior of the material
3. Time (i.e., age of the material)
4. Surface area of the material per volume of the space it is in ("loading")
5. Environmental factors such as temperature, air exchange rate, and relative humidity
6. Chemical reactions in the source (e.g., in conversion varnishes and some adhesives)

Local air velocity near the surface of the material and material surface details undoubtedly have an effect for some materials, but few controlled studies of this effect have been reported in the indoor air quality literature. Sparks et al. (1996) provide data and a model for the effects of velocity on evaporative sources. DeBortoli et al. (1999) discuss emission testing at controlled velocities and report preliminary data that show moderate effects on evaporative sources and little effect on sources where internal diffusion is controlling.

For a given material, research studies of emission rates should account for time (age), temperature, and air exchange rate. Early research studies of formaldehyde emissions from pressed-wood products showed that relative humidity was also an important factor. However, research studies of other pollutants have shown that their emission rates from various materials are not particularly sensitive to relative humidity, at least for the normal range found indoors. Therefore, only materials that are known to emit highly polar compounds need to be tested at different relative humidities.

Other physical and environmental factors affect emission rates and influence how emissions affect indoor concentrations of pollutants. For example, in composite materials that include wood constituents, adhesives, and multiple coatings or in composite assemblies such as subflooring-underlayment-cushion-carpet, initial emissions may be dominated by the surface materials and long-term emissions by the underlying materials. As another example, emissions from materials that are part of a building's envelope (such as insulation) will contribute to indoor concentrations in a way that depends on pressure differences between indoors and outdoors.

Emission Testing Methods

Controlled studies of the rates and compositions of emissions from representative materials help us understand the potential impact of these sources on indoor air quality and the options for controlling their impacts. Such research studies were begun in Europe in the early 1980s and, somewhat more recently, in North American laboratories. Prior to that, the National Aeronautics and Space Administration (NASA) conducted static head-space tests to obtain qualitative information on materials and objects to be used in manned space flights.

The most common approach for emission rate studies has been to put samples of materials in chambers through which controlled amounts of clean air are passed. Concentrations of emitted pollutants in the air exiting from the chambers are measured. In the most detailed studies, emissions are measured as a function of time (age of material), temperature, air-flow rate, area of sample per unit volume of chamber, and relative humidity.

In North America, guidelines on procedures for testing organic compound emissions from indoor sources have been developed by the American Society for Testing and Materials (ASTM 1997b). These guidelines recommend procedures to use in research studies conducted in small chambers, large chambers, and actual buildings. Procedural guidance covers equipment specifications, experimental design, sampling and analysis, data analysis, and quality assurance. Similar guidelines have been published in Europe by the Commission of the European Communities (CEC 1991), based on a 1990 version of the

ASTM guidelines. Manuals of practice, which will contain more specific procedural details than the guidelines, are under development by ASTM committees for small-chamber testing of VOC emissions from the following sources: carpet, pressed-wood panels, architectural coatings, caulks and sealants, adhesives, and rigid polyurethane foam insulation. A guide for large-scale chamber testing is also under development.

Although difficult to conduct and moderately expensive, such chamber studies are less expensive and more controllable than studies in actual buildings. If chamber data are modeled to simulate emissions from materials under a wide range of environmental conditions, and further modeled to predict indoor concentrations and exposures, chamber studies and modeling become valuable tools for design and selection of indoor materials.

Currently Available Emissions Data

Table 31.4 contains emission factors for various compounds from a variety of sources as reported in the literature. Note that these factors—the emission rate per unit of source—vary by a factor of many thousands from one material to another. Emission rates, which depend on how much source is present, can vary over a similar range. Few of these reports address the time course of emissions. Furthermore, different methodologies used to measure emissions may yield different results, making comparisons among reports difficult. As the following section shows, understanding the limitations in the data is essential in modelling human exposures.

Although emission factors and rates are very important in determining the contribution a material makes to indoor air pollution, the duration of the emissions is also important, as it affects a building occupant's exposure (amount inhaled). Therefore, sources with high initial emissions but a rapid decay rate may lead to lower long-term exposures than sources with initially lower but more persistent emissions. Tables 31.5 and 31.6 contain values of emission factors derived from research studies where the effect of time was considered.

Emission Models

Few sources are constant emitters for significant lengths of time. Mathematical models have been developed to represent how emission rates vary with time. These models are based on either statistically fitting experimental measurements of emission rates or predicting rates from mass-transfer theory. Mass-transfer models are more scientifically rigorous, and can be used for predictions of emissions at various conditions or for scaleup applications to estimate IAQ impact and occupant exposure. Fitted decay models are generally easier to use and therefore more practical for applications where emission rate decay data are available. With data that can be fit by first-order decay models, it is easy to calculate half-lives, total emissions over the life of the source, initial emission rates, and peak emission rates.

Over two dozen source emission models have been reported in the literature (Guo 1996). Aside from the trivial model for constant sources $R(t) = R_0$, statistical models have been developed for decaying sources (first-order, including double, exponential; second- and higher-order exponential), short-lived sources, time-varying sources, and infiltrated outdoor air as a source of indoor pollutants. Several models have also been developed from mass-transfer theory based on phenomena such as evaporation and molecular diffusivity. Combinations of these models may give improved predictions of emission rates over different stages of the life of a complex source such as latex paint on a porous surface. Various of these source emission models are included in indoor air quality prediction models (Sparks 1995, Guo 1996, Walton 1997). Additional information on source models is provided in Chap. 58 of this handbook.

TABLE 31.4 Emission Factors for Selected Volatile Organic Compounds
(Rounded values derived from data in the references cited)

Source type	Emission factor, ($\mu\text{g/h}$)/ m^2 , or as noted	Ref.‡
Acetaldehyde*,†		
Carpet, synthetic fiber (nylon)	5–30	12
Cigarette smoking	4000–5000 μg /cigarette	9,22
Duct liner, fiberglass	<20–25	17
Paint, water-based (2 days)	6000–9000	23
Paint, water-based (1 week)	3000–5000	23
Photocopier, dry-process	<100–1200	15,16

Low-Emitting Sources

Historically, environmental criteria have not played a major role in materials selection. In the late 1990s, however, environmental considerations were given greater weight (Levin 1996b, 1997). The *Environmental Resource Guide* by the American Institute of Architects (AIA 1996) encourages architects to consider life-cycle environmental impacts of materials used in buildings. The AIA life-cycle concept includes total environmental impacts during production, use, and disposal of the material.

A life-cycle concept is also important to apply to materials during the entire period when they are used in buildings. To date, most discussions of material selection for indoor air quality protection have dealt with building materials and furnishings, and have focused only on the period when they are new. This is mainly because of many well-publicized complaints of irritation by occupants of new and newly renovated buildings. Emissions of organic vapors can be high in such situations, but frequently decrease markedly over a period of days, weeks, or months.

Whether the emissions from any source will lead to “acceptable” indoor concentrations and occupant exposures will depend on a number of considerations, such as (1) emission rates; (2) the toxicity or irritation potential of substances emitted; (3) physical relationships between the source, the ventilation rate of the space, the persons present, and the space they occupy (the proximity of the source to people breathing its emissions can greatly affect the amount of dispersion and dilution of emissions, and therefore the concentrations actually breathed); and (4) the sensitivity of the occupants.

The complexity of these factors makes acceptability an essentially situation-specific issue. However, in spite of this complexity and the lack of a solid database on acceptable concentrations of complex mixtures of substances, many builders and architects are asking for lists of, or guidelines on, *low-emitting* or “clean” materials and products. There are a few quantitative guidelines [e.g., see Tucker (1990), Black et al. (1993), FiSIAQ (1995), Larsen and Abildgaard (1995)], but there is too little published emission rate data to list specifically recommended products. Buyers of large quantities of materials can require emission testing of products they are considering. However, qualitative information on product labels that are attached to products covered by an emission testing program, such as administered by the Carpet and Rug Institute for carpets (CRI 1992), is likely to be the best information available to the general purchaser of indoor materials and products.

Some situation-specific factors, such as toxicity of the VOCs from the source and dilution of the VOCs by ventilation air, can be used to make estimates of acceptable or low-emitting

FIGURE 31.1 Effect of source strength and air exchange rate on pollutant concentration in a small room (room volume = 25 m³, or 10 m² of floor area).

FIGURE 31.2 Effect of source strength and air exchange rate on pollutant concentration in a large room (room volume = 100 m³, or 40 m² of floor area).

sources. Figures 31.1 and 31.2 can be used to obtain rough estimates of maximum emission rates (source strengths) for all sources of a VOC in a small-room or large-room space, respectively. Starting with a maximum acceptable concentration for the compound, maximum emission rates can be estimated for various ventilation rates.

For example, maximum emission rates for sources in a small office (about 10 m², or about 100 ft² of floor area) can be estimated from Fig. 31.1. Suppose that the toxicologically based air quality standard for a particular compound was 1000 µg/m³ and the building designer wants to use a design safety factor to avoid concentrations above 10 percent of that, or 100 µg/m³. Following the 100 µg/m³ concentration line to the intersection with the ventilation rate of 1 ACH (air change per hour) leads to a maximum emission rate of about 2300 µg/h. If the 1 ACH were the outdoor air portion of total air supplied to the space, and that outdoor air contained a negligible amount of the compound, total emissions from all sources of that VOC in that office would meet the design goal if they were less than 2300 µg/h. Sources with total emissions much less than that, perhaps 100 to 500 µg/h, might be considered low-emitting in this particular situation. Although this example is greatly simplified, it illustrates how acceptable and low-emitting sources can be defined on a case-by-case basis.

31.3 INDOOR CONCENTRATIONS

Measured Indoor Concentrations

Many measurements have been made of VOC concentrations in residential and commercial buildings. Data collected and published up to the early 1990s are summarized by Brown et al. (1994). Since then, a major study of air pollutants in European office buildings has been conducted (Bluyssen 1996) and is still being reported. In the United States, a study of indoor air quality in 100 public and private office buildings has been completed

where about 50 VOCs were measured (Hadwen et al. 1997, USEPA 1998b). Table 31.7 summarizes selected data from the first 41 buildings investigated in that study.

Indoor concentrations are typically higher than outdoor concentrations for most VOCs, including the hazardous air pollutants listed in Table 31.2. The indoor concentrations of the compounds in Table 31.2 are generally 1 to 5 times outdoor concentrations; indoor exposures are 10 to 50 times outdoor exposures, because of the much greater time spent indoors by most people (Tucker 1998). As noted earlier, the concentrations of individual compounds are nearly always lower than concentrations of known concern.

IAQ Models

Various mathematical models have been developed to predict indoor concentrations of air pollutants, given data on or estimates of the physical and operational aspects of the building, outdoor air quality, emissions from indoor sources, and effects of indoor sinks. Some of these models can also be used to predict occupant exposures to the pollutants if occupancy pattern data are entered, and to predict health risks if appropriate toxicological data are entered. As with any mathematical model, the accuracy of the predictions is highly dependent on the availability and accuracy of the input data. In most building design situations there is little or no testing data on emissions from the actual sources that will be in the building, and the user must rely on default values for emissions that are in the models, or use literature values such as those in Tables 31.4 to 31.6. Under such circumstances, the user should not generally expect to predict concentrations closer than an order of magnitude (within a factor of 10) of the actual concentrations.

Two of the most highly developed and used models are CONTAM96 (Walton 1997) and Risk V1.0 (Sparks 1995). Earlier versions of the Risk model were titled EXPOSURE (Sparks 1991). Both of these models are usable on personal computers. Both are multi-compartmental, use mass-balance equations, and assume that the air in each compartment, zone, or room is well mixed. CONTAM96 requires detailed input on building-specific features and weather so that it can calculate infiltration, exfiltration, and room-to-room airflows. Further input on sources and pollutant emissions enables calculation of indoor concentrations and personal exposures. This model uses an MS-DOS format.

Risk V1.0 does not include calculations of airflows from infiltration/exfiltration models or buoyancy effects inside the building; outdoor air ventilation and intercompartmental airflows are set by the user and checked for balance by the model. Input on sources, occupancy, and pollution control devices enables calculation of indoor concentrations, occupant exposures, and health risks based on a simple risk assessment submodel. Source emission submodels are included and updated periodically from the most recent research. This model uses an MS Windows format.

Various publications have demonstrated applications of these models [e.g., Persily (1998), Sowa (1998), Sparks (1992)]. Applications range from research studies of sources, ventilation effectiveness, or occupant exposures to design studies of building ventilation strategies or product selection. For a discussion of the limitations of these and other indoor air quality models, see Chaps. 57, 58, and 59 in this handbook.

ACKNOWLEDGMENTS

The author wishes to acknowledge the diligent work of student interns Bethany A. Bolt, Michelle Galloway, Tyson L. Holt, and Nicholas T. Hong in compiling emissions data that were used in developing Tables 31.4 to 31.6.

CHAPTER 32

ALDEHYDES

Thad Godish, Ph.D., C.I.H.

*Department of Natural Resources
and Environmental Management
Ball State University
Muncie, Indiana*

32.1 INTRODUCTION

Aldehydes belong to a class of organic compounds called *carbonyls*. Carbonyls, which include aldehydes and ketones, have the functional group —C=O in their structure. In the aldehydes the carbonyl is in the end position so that any compound that contains one or more —C=O function groups is described as an *aldehyde*, a *dialdehyde* if it contains two functional groups, or a *trialdehyde* if it contains three.

Aldehydes include a number of saturated aliphatic, unsaturated aliphatic, aromatic, or cyclic compounds. Saturated aliphatic aldehydes include formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, valeraldehyde, and glutaraldehyde. Glutaraldehyde, as can be seen in Table 32.1, is a dialdehyde with carbonyls on both ends of the molecule. Other dialdehydes include malonaldehyde and succinaldehyde. Unsaturated aliphatic aldehydes contain carbon-carbon double bonds (Table 32.1). Among other compounds, they include acrolein (acrylaldehyde), crotonaldehyde, and methacrolein. Aromatic aldehydes include such common aldehydes as benzaldehyde and cinnamaldehyde.

The aldehydes include a large variety of compounds which differ in their chemical structure, size, solubilities, chemical reactivity, and other physical properties. However, only a relatively few have significant industrial and commercial applications and biological activities that pose major public health concerns. By far the most important of these are formaldehyde, acetaldehyde, acrolein, and glutaraldehyde. Many aldehydes are potent sensory (mucous membrane) irritants, some are skin sensitizers, and there is limited evidence that a few may be human carcinogens.

Since an ability to cause irritation is common to many if not all aldehydes, animal studies that characterize sensory responses to exposure provide a measure of the potency of individual aldehydes and their potential significance in workplace, indoor, and ambient exposures.

32.2 SENSORY IRRITATION

As a result of their water solubility (Table 32.1) and chemical reactivity, aldehydes can cause significant sensory irritation of the eyes and mucous membranes of the upper respiratory

TABLE 32.1 Chemical Structures and Properties of Common Aldehydes

Compound	Structure	Molecular weight	Solubility, g/L
Formaldehyde	$\begin{array}{c} \text{O} \\ \parallel \\ \text{H}-\text{C}-\text{H} \end{array}$	30.03	560
Acetaldehyde	$\begin{array}{c} \text{O} \\ \parallel \\ \text{CH}_3-\text{C}-\text{H} \end{array}$	44.05	200
Glutaraldehyde	$\begin{array}{c} \text{O} \qquad \qquad \text{O} \\ \parallel \qquad \qquad \parallel \\ \text{H}-\text{C}-(\text{CH}_2)_3-\text{C}-\text{H} \end{array}$	100.12	Miscible
Acrolein	$\begin{array}{c} \text{O} \\ \parallel \\ \text{CH}_2=\text{CH}-\text{C}-\text{H} \end{array}$	56.06	210
Crotonaldehyde	$\begin{array}{c} \text{O} \\ \parallel \\ \text{CH}_3-\text{CH}=\text{CH}-\text{C}-\text{H} \end{array}$	76.09	181
Benzaldehyde	$\begin{array}{c} \text{O} \\ \parallel \\ \text{C}_6\text{H}_5-\text{C}-\text{H} \end{array}$	106.11	3

tract on exposure. Such irritation is associated with maxillary and ophthalmic divisions of the trigeminal nerve in the nasal mucosa which respond to chemical and/or physical stimuli (such as airborne irritants). These responses include a painful burning sensation, a desire to withdraw from the offensive environment, a decrease in respiratory rate, and occasionally a sneeze reflex. These reflex actions to irritants serve as respiratory defense mechanisms through the perception of pain and minimization of inhalation. Concentration-dependent respiratory rate depression prevents penetration of irritants (such as the aldehydes) into the lower respiratory tract.

Measurements of decreases in respiratory rates in mice and rats on exposure to irritant chemicals have been used to evaluate the sensory irritation potential of 15 aldehydes using a standard mouse bioassay (Steinhagen and Barrow 1984). The RD_{50} values required to cause a 50 percent reduction in breathing rate (used as an indicator of the potency of tested chemicals in causing sensory irritation) are summarized for Swiss-Weber mice in Table 32.2. See Chaps. 24 to 28 for a more complete discussion of sensory irritation.

As can be seen, RD_{50} values ranged by more than three orders of magnitude. Unsaturated aldehydes (numbers 4, 7) and formaldehyde produced RD_{50} values in the range of 1 to 5 ppmv (parts per million by volume), cyclic aldehydes (numbers 12 to 15), from 95 to 300+ ppmv, and saturated aliphatic aldehydes from ~850 to 4200 ppmv (numbers 2 to 3, 5 to 6, 8 to 11).

On average the unsaturated aldehydes (acrolein and crotonaldehyde) as well as formaldehyde are about two orders of magnitude more potent than cyclic aldehydes and three orders more potent than saturated aliphatic aldehydes. These data, which do not include glutaraldehyde, indicate that only relatively few aldehydes are potent mucous

TABLE 32.2 RD₅₀ Values for Swiss-Weber Mice Exposed to Aldehydes

Number	Chemical	RD ₅₀ value, ppmv, 95% CI*
1	Formaldehyde	3.2 (2.1–4.7)
2	Acetaldehyde	2845 (1967–3954)
3	Propionaldehyde	2052 (1625–3040)
4	Acrolein	1.03 (0.70–1.52)
5	Butryaldehyde	1015 (925–1135)
6	Isobutryaldehyde	4167 (3258–5671)
7	Crotonaldehyde	3.53 (2.88–4.62)
8	Valeraldehyde	1121 (828–1757)
9	Isovaleraldehyde	1008 (754–1720)
10	Caproaldehyde	1029 (804–1384)
11	2-Ethylbutryaldehyde	843 (635–1206)
12	2-Furaldehyde	287 (216–402)
13	Cyclohexane carboxaldehyde	186 (144–251)
14	3-Cyclohexane 1-carboxaldehyde	95 (69–168)
15	Benzaldehyde	333 (244–506)

*Average value followed by 95% probability range in parentheses.

membrane irritants at the relatively low concentrations that can be expected in indoor environments, such as residences and some occupational environments.

Other studies (Cassee et al. 1996) have shown that sensory irritation in rats exposed to a mixture of irritant aldehydes (formaldehyde, acrolein, acetaldehyde) is more pronounced than that caused by each aldehyde separately. At high concentrations these effects were less than additive, indicating same degree of antagonism. However, in indoor environments where concentrations are relatively low, irritant effects of aldehydes are likely to be additive relative to their potencies determined from decreases in breathing rate studies (Kane and Alarie 1977, Steinhagen and Barrow 1984).

Although the studies described above indicate that many aldehydes have the potential to cause significant sensory irritation, only a few are sufficiently potent to warrant significant human exposure concerns. These would include formaldehyde, acrolein, and crotonaldehyde. Crotonaldehyde, however, appears to be little used industrially and commercially and thus may have only limited human exposure significance. The potency of glutaraldehyde has been evaluated in mice (Zessu et al. 1994), with a computed RD₅₀ of 2.6 ppmv, indicating that it has a sensory irritation potential in the same range as formaldehyde, acrolein, and crotonaldehyde. Studies of those occupationally exposed confirm that glutaraldehyde is a potent sensory irritant and as a result of increased use in the medical professions it is a major occupational health concern. Although a relatively weak sensory irritant, acetaldehyde is a common contaminant in workplace, indoor, and ambient environments. It is also a potential carcinogen. Within the context of these considerations, the uses and sources, exposures, and health effects of formaldehyde, acetaldehyde, acrolein, and glutaraldehyde, as reflected by their public health significance, are described in detail.

32.3 FORMALDEHYDE

Formaldehyde is the simplest member of the aldehyde family and is unique since the carbonyl is attached directly to two hydrogen atoms (Table 32.1). Because of this unique structure, formaldehyde has a high degree of chemical and photochemical reactivity and good

thermal stability relative to other carbonyls, and has the ability to undergo a variety of chemical reactions, which in many cases are useful in commercial processes. Indeed, formaldehyde is among the top 10 organic chemical feedstocks in the United States. Formaldehyde is a colorless gas with a strong pungent odor. It condenses to form a liquid of high vapor pressure which boils at -19°C , and forms a crystalline solid at -110°C . It polymerizes rapidly and must be held at low temperature or mixed with a stabilizing agent such as methanol to minimize polymerization (National Research Council 1981).

Uses and Sources

Formaldehyde can also exist as a cyclic trimer, trioxane ($\text{C}_3\text{H}_6\text{O}_3$), a colorless crystalline solid which has a nonirritating chloroformlike odor. Formaldehyde can also exist as paraformaldehyde, which contains varying numbers of formaldehyde molecules depending on the degree of polymerization. It is a colorless solid which vaporizes as monomeric formaldehyde at room temperature.

Formaldehyde is commercially available as formalin, an aqueous solution containing by weight 37 to 50% formaldehyde and 6 to 15% methanol (to suppress polymerization). Formalin has the strong pungent odor of formaldehyde. In solution it is present in the form of methylene glycol, $\text{CH}_2(\text{OH})_2$; in concentrated solutions it is one of many polymeric molecules, polyoxymethylene glycol, $(\text{HO}-\text{CH}_2\text{O})_n-\text{H}$.

As a major chemical feedstock, formaldehyde is used in a variety of chemical manufacturing processes. About 50 percent of formaldehyde consumed annually is used to produce urea and phenol formaldehyde resins. Urea formaldehyde resins are used as wood adhesives in the manufacture of pressed-wood products such as particleboard, medium-density fiberboard (MDF), and hardwood plywood, textile treatments (permanent-press finishes), finish coatings (acid-cured), and urea formaldehyde foam insulation (UFFI). Phenol formaldehyde receives significant use as an exterior-grade adhesive for such products as softwood plywood and oriented-strand board (OSB), and is widely used to produce a variety of rigid molded plastic materials.

Significant quantities of formaldehyde are consumed in the production of other resins or polymers (polyacetyls, melamine resins, and alkyl resins). Formaldehyde is also used in rubber/latex manufacture, textile treatment (other than permanent-press fabrics), dye manufacture and use, photoprocessing chemicals, laboratory fixatives, embalming fluid, disinfectants, and preservatives.

Formaldehyde is produced in the combustion and/or thermal oxidation of a variety of organic products. It can be found in the emissions of motor vehicles, combustion appliances, wood fires, and tobacco smoke. It is also produced in the atmosphere as a consequence of photochemical reactions and hydrocarbon scavenging processes, and indoor chemistry.

Exposures

Because of the extensive use of formaldehyde in product manufacture and numerous other applications, significant formaldehyde exposures occur in workplace environments. In 1992 OSHA estimated that the total number of corporations using formaldehyde was in excess of 100,000 with over 2 million employees exposed (USDOL 1992). Of these, 80,000+ employees were exposed to concentrations between 0.75 and 1.0 ppmv (mainly in apparel and furniture manufacture and foundries), 120,000+ employees to concentrations between 0.5 and 0.75 ppmv (apparel, textile finishing, furniture, laboratories, and foundries, and approximately 1,950,000 employees to concentrations in the range of 0.1 and 0.5 ppmv (apparel, furniture, papermills, and plastic molding).

Formaldehyde exposure is not limited to those who work with it or to products made from it. Elevated formaldehyde concentrations occur in many residential, institutional, and commercial buildings where they typically exceed ambient (outdoor) values by an order of magnitude or more. Concentrations vary from structure to structure depending on a variety of factors, which include the nature of sources present and environmental factors which affect formaldehyde emissions.

The major sources of formaldehyde emissions in nonindustrial indoor environments are wood products bonded with urea formaldehyde (UF) resins, urea formaldehyde acid-cured finishes, and in some houses urea formaldehyde foam insulation (UFFI). Formaldehyde emissions (Pickrell et al. 1983, Matthews et al. 1985, Grot et al. 1985) from a variety of construction materials, furnishings, and consumer products are summarized in Table 32.3. Note that these emission tests were conducted in the early 1980s and for pressed-wood products (e.g., particleboard, hardwood plywood paneling, and MDF) significant reductions in formaldehyde emissions have been achieved by wood product manufacturers since that time.

Pressed-wood products bonded with UF resins have been and continue to be the major sources of formaldehyde contamination in residential and other nonindustrial indoor environments. Particleboard use has been used extensively as an underlayment in conventional homes, for floor decking in manufactured homes, and as a component in cabinetry and furniture. Hardwood plywood paneling has been used as a decorative wallcovering, and as a component in cabinets, furniture, and wood doors. Medium-density fiberboard has been used in cabinet, furniture, and wood door manufacture. Acid-cured finishes which contain a mixture of urea and melamine formaldehyde resins are used on most exterior wood cabinet surfaces, on the surfaces of fine furniture, and in hardwood flooring.

A major source of formaldehyde contamination in U.S. and Canadian residences in the middle 1970s and early 1980s was UFFI. It was applied to over 500,000 homes in the United States and 80,000 in Canada before it was banned in Canada and almost banned in the United States. Although the ban was voided in the United States, this product has been little used in residences since 1982.

Formaldehyde concentrations in a variety of housing and formaldehyde source types (Godish 1989) are summarized in Table 32.4. It should be noted that these data were collected in the late 1970s to mid-1980s and reflect potential human exposures in the United States during that period. Since that time, significant changes have taken place relative to formaldehyde emission potentials of pressed-wood products (significantly reduced), and construction materials commonly used in home building. In the latter case many mobile homes are no longer constructed with particleboard decking, nor do they use hardwood plywood as an interior wallcovering; in conventional home construction, oriented-strand

TABLE 32.3 Formaldehyde Emissions from Construction Materials, Furnishings, and Consumer Products

Product	Range of emission rates, $\mu\text{g}/\text{m}^2$ per day
Medium-density fiberboard	17,600–55,000
Hardwood plywood paneling	1,500–34,000
Particleboard	2,000–25,000
UFFI	1,200–19,200
Softwood plywood	240–720
Paper products	260–280
Fiberglass products	400–470
Clothing	35–570

board is used instead of particleboard underlayment. Given these changes, exposure concentrations in residential buildings, including mobile homes constructed in the 1990s, are likely to be significantly lower. Although there are no published studies on contemporary formaldehyde exposures in new houses or in houses constructed after 1990, limited air testing by the author in conventional and manufactured homes indicate that formaldehyde levels in new conventional homes are usually less than 0.06 ppmv, and in manufactured homes less than 0.20 ppmv. Indeed, most residential buildings in the United States and Canada are likely to have exposure concentrations that average less than 0.10 ppmv; and concentrations in office buildings rarely exceed 0.05 ppmv, and concentrations in the range of 0.02 to 0.04 ppmv are common.

The concentration of formaldehyde that one is exposed to in indoor environments depends on the potency of formaldehyde-emitting products present, extent of their use, the loading factor (m^2/m^3) which is described by the surface area (m^2) of formaldehyde-emitting materials relative to the volume (m^3) of interior spaces, environmental factors (formaldehyde emissions and levels increase with increasing temperature and relative humidity), material age (formaldehyde emissions and levels decrease with time), interaction effects (formaldehyde sources interact with the most potent source suppressing emissions from less potent sources), and ventilation conditions (lowest levels are experienced on cold winter days when infiltration rates are high or on warm days when occupants open windows) (Godish 1988).

Smokers can be exposed to significant formaldehyde concentrations as (Leikauf 1992) indicated in Table 32.5. Nonsmokers are exposed to significantly lower concentrations because of dilution effects and interactions between urea formaldehyde-based formaldehyde sources.

Health Effects

Effects of formaldehyde on human health have been extensively investigated in human exposure studies and field and epidemiologic investigations of workplace and residential

environments. Major health concerns have included irritation and neurological-type symptoms, skin irritation, asthmatic/pulmonary symptoms and potential sensitization, and upper respiratory system cancers.

The ability of formaldehyde to cause a variety of irritating symptoms of the eyes, nose, and throat and symptoms of the central nervous system are known from controlled animal exposure studies (Kane and Alarie 1977), reports of occupational exposures (Olsen and Dossing 1982), controlled human exposure studies (Andersen and Molhave 1983, Cain et al. 1986), field investigations (Dally et al. 1981, Ritchie and Lehnen 1987), and epidemiologic studies of human exposures (Arundel et al. 1986, Sterling et al. 1986, Liu et al. 1987, Broder et al. 1988, Godish et al. 1990).

A number of investigators have conducted controlled studies on human volunteers. Cain et al. (1986), on exposing 33 subjects to concentrations of 0.0, 0.25, 0.5, 1.0, and 2.0 ppmv formaldehyde for 90 min, observed significant eye and nose irritation at all exposure concentrations compared to unexposed controls. Similarly, Andersen and Molhave (1983), exposing 16 healthy students over a similar concentration range for 5 h, reported significant decreases in flow of nasal mucus at 0.25 ppmv; slight but significant discomfort at 0.25 ppmv; eye irritation, and throat dryness were reported with increasing frequency with increasing formaldehyde concentration from 0.25 to 1.6 ppmv.

A variety of field investigations of formaldehyde exposure in residential and similar environments have reported elevated prevalence rates of mucous membrane symptoms (eye, nose, throat, and sinus irritation); central nervous system symptoms such as headache, fatigue, and sleeplessness; digestive symptoms such as nausea, diarrhea, and unnatural thirst; and menstrual irregularities (Dally et al. 1981, Olsen and Dossing 1982, Ritchie and Lehnen 1987).

Sterling et al. (1986), in epidemiologic investigations of UFFI houses, observed dose-dependent increases in eye symptoms, dry throat, headache, fatigue, and disturbed sleep in "high" formaldehyde exposure individuals. In another Canadian UFFI study, Arundel et al. (1986) reported significant increases in eye, nose, throat, and skin symptoms, as well as dizziness, irritability, fatigue, constipation, and wheezing. In a more intensive and epidemiologically strong study, Broder et al. (1988) reported significant dose-response relationships between formaldehyde exposure and eye irritation, cough, wheeze, sputum production, tiring easily, increased thirst, and nasal problems with average exposure concentrations of 0.045 ppmv. Significant increases in the objective symptom of squamous metaplasia of the nasal passages were observed in those individuals who lived in UFFI houses. Despite these dose-response relationships, Broder et al. (1988) concluded that formaldehyde alone may not have contributed to the increased symptom prevalence rates observed, since significant relationships were dependent on a relatively limited number of individuals exposed to concentrations above 0.12 ppmv. Additionally, a study of those who removed UFFI from their homes showed that symptom prevalence diminished without a corresponding decrease in formaldehyde levels (Broder et al. 1991).

In studies of mobile homes and houses with particleboard underlayment, Godish et al. (1990) observed significant dose-response relationships between formaldehyde levels and symptom severity for 14 symptoms and health problems including eye irritation, dry and sore throat, runny nose, bloody nose, sinus irritation, sinus infection, cough, headache, fatigue, depression, difficulty sleeping, nausea, diarrhea, chest pain, abdominal pain, and rashes for a range of concentrations with a median of 0.09 ppmv. In a large study of California mobile homes, Liu et al. (1987) observed significant relationships between formaldehyde exposures, including burning eyes and skin, chest pain, dizziness, fatigue, and sleeping problems. Individuals with allergies, asthma, and emphysema reported more symptoms. Average concentrations were below 0.1 ppmv.

As a group, these epidemiologic studies indicate that relatively low residential formaldehyde exposures (≤ 0.1 ppm) may cause or exacerbate a variety of mucous membrane and central nervous system symptoms in humans. Central nervous system effects associated with occupational formaldehyde exposures have been reported by Kilburn et al. (1987).

Skin exposure to formaldehyde solutions is common in a variety of occupations, including health care, laboratories, embalming, metal cutting (cutting oils), and specialized agricultural work. Such exposures are known to cause irritant contact dermatitis in most exposed individuals if concentrations and exposures are sufficiently high (3% solution). Allergic contact dermatitis may also occur with the induction of sensitization at liquid formaldehyde exposures of less than 1% with a threshold of 30 to 50 ppm w/v in very sensitive individuals. It has been estimated that 3.8 percent (Feinman 1988) of U.S. dermatitis patients develop clinical hypersensitivity reactions to standard 2% formaldehyde patch tests. Compared to unsaturated aldehydes, formaldehyde is reported to be a moderate skin irritant.

The ability of formaldehyde to cause both irritant and allergic contact dermatitis as a result of contact with liquid or solid formaldehyde-releasing products has been well established. Can formaldehyde also cause skin irritation as a result of skin exposures from formaldehyde vapors? When formaldehyde is in contact with the skin, it rapidly complexes with skin proteins. On long-term exposures, such skin reactions are likely at a minimum to cause some form of skin irritation. Godish et al. (1990) reported a dose-response relationship between skin rashes and airborne formaldehyde in mobile and other homes with elevated formaldehyde concentrations. A high prevalence of skin symptoms at residential concentrations of formaldehyde >0.30 ppmv has also been reported by Ritchie and Lehnen (1987) for Minnesota mobile homes.

Asthmatic reactions to occupational formaldehyde exposures have been reported by several investigators (Popa et al. 1969, Hendrick and Lane 1977) and asthmatic/pulmonary-type symptoms [wheeze, chest pain, cough, shortness of breath (dyspnea)] have been reported in field investigations of occupational and residential exposure to formaldehyde (Gammage and Gupta 1984, Marbury and Kreiger 1991). These studies have been interpreted to indicate that formaldehyde may be a pulmonary irritant and capable of inducing asthmatic attacks by specific sensitization reactions.

The ability of formaldehyde exposures to cause pulmonary changes sufficient to confirm asthma is commonly determined by bronchial challenges at concentrations of 2 to 3 ppmv formaldehyde. Three studies of asthmatic patients showed no change in pulmonary function following exposures up to 3 ppmv formaldehyde. Other studies of healthy volunteers and residents of UFFI homes showed no significant changes in pulmonary function unless volunteers were undergoing significant exercise during exposure. These studies did not support the thesis that formaldehyde causes significant pulmonary effects in asthmatics or healthy individuals (Marbury and Kreiger 1991).

However, several case studies provide evidence that formaldehyde can induce asthma. Nordman et al. (1985) reported that 12 of 230 workers responded positively to bronchio-

provocation tests to 2 ppmv formaldehyde, and concluded that formaldehyde-induced asthma occurred but the frequency of occurrence was relatively rare. Burge (1985) evaluated 15 workers for occupational asthma due to formaldehyde. They concluded that 3 workers had specific hypersensitivity to formaldehyde and 2 were affected by irritant mechanisms.

An epidemiologic study of formaldehyde exposure and respiratory symptoms and pulmonary function was conducted on children and adults in Arizona by Krzyzanowski et al. (1990). Prevalence rates of physician-diagnosed asthma and chronic bronchitis among children in homes with measured formaldehyde levels in the range of 0.06 to 0.12 ppmv (especially in those who were also exposed to environmental tobacco smoke) were significantly higher than in those less exposed. A linear decrease in peak expiratory flow rate (PEFR) with formaldehyde exposure was observed. On the basis of a random-effects model, the estimated decrement of PEFR at 0.06 ppmv was 22 percent. The epidemiologic results of Krzyzanowski et al. (1990), although significant, are not consistent with challenge studies conducted at 2 to 3 ppmv (reported above). Challenge studies are considered to be the standard in determining whether exposures to a substance can cause asthmatic responses. Exposures in the Krzyzanowski study were of a chronic rather than acute nature.

The induction of asthma or asthmatic symptoms may occur as a consequence of a specific hypersensitivity reaction or as an irritant response as indicated by Burge (1985). The former suggests that an immunologic mechanism is responsible. Although specific IgE antibodies to formaldehyde have not been demonstrated, several investigators (Patterson et al. 1986, Thrasher et al. 1987) have shown that some formaldehyde-exposed individuals develop antibodies against formaldehyde-human serum albumin conjugates. The clinical significance of these findings have not been established.

Formaldehyde has been shown in *in vitro* assays and cell culture to cause a variety of genotoxic effects including DNA-protein crosslinks, sister chromatid exchange, mutations, single-strand breaks, and aberrations in chromosomes (Report of the Consensus Workshop on Formaldehyde 1984, International Agency for Research on Cancer 1987). These studies indicate that formaldehyde is both genotoxic and mutagenic and therefore likely to be carcinogenic.

Chronic rodent exposure studies (Swenberg et al. 1980) have shown that formaldehyde at high concentrations causes squamous cell carcinomas in the nasal passages of rats (5.6 and 14.3 ppmv) and mice (14.3 ppmv). Similar results have also been reported (Albert et al. 1982). Thus formaldehyde's ability to cause cancer in animals has been well established.

Numerous epidemiologic studies on exposed workers and residents of mobile homes have attempted to determine whether formaldehyde exposure causes upper respiratory system cancer. These studies have not provided conclusive evidence of a strong association between formaldehyde exposure and nasal or sinus cancer. Such studies may have been confounded by the fact that humans, unlike rodents, are not obligate nasal breathers. More consistent with human exposures are reports of slight to moderate increases in risk for cancers of the buccal cavity, nasopharynx, oropharynx, pharynx, and lung (Leibling et al. 1984, Acheson et al. 1984, Sterling and Arundel 1985, Stayner et al. 1988, Vaughan et al. 1986, Blair et al. 1986). Vaughan et al. (1986) reported that individuals living in mobile homes for 1 to 9 years had a relative risk of developing nasopharyngeal cancer of 2.1 (CI = 0.7 to 6.6) and ≥ 10 -year mobile home residents had a relative risk of 5.5 (CI = 1.6 to 9.4), compared to a randomly surveyed population. Professionals exposed to formaldehyde (anatomists, pathologists, morticians) have been reported to be at increased risk of brain cancer and leukemia but not of respiratory cancers. Such individuals are exposed to complex mixtures, and it is unlikely that formaldehyde alone is responsible for such carcinomas (Marbury and Kreiger 1991).

On the basis of the results of *in vitro* assays of the genotoxicity of formaldehyde, the induction of squamous cell carcinomas in nasal passages of laboratory animals (with

correlated histopathologic changes), and limited but not conclusive evidence of upper respiratory system cancers in humans in epidemiologic studies, formaldehyde has been listed as a suspected human carcinogen (IARC group 2A) (International Agency for Research on Cancer 1987, OSHA 1987, USEPA 1987).

32.4 ACETALDEHYDE

Acetaldehyde is a colorless, volatile liquid or gas ($>20^{\circ}\text{C}$). It has a pungent fruity odor, with an odor threshold reported to be in the range of 0.05 to 2.3 ppmv. It is a two-carbon aliphatic aldehyde (Table 32.1) with a molecular weight of 44.1, a high vapor pressure (740 mmHg at 20°C), and moderate solubility in water and a number of organic solvents.

Uses and Sources

Acetaldehyde is used industrially to produce acetic acid, acetic anhydride, peracetic acid, pyridine derivatives, crotonaldehyde, 1,3 butylene glycol, and butanol. It is also used in the manufacture and production of plastics, phenolic and urea resins, photographic chemicals, rubber accelerants, antioxidants, varnishes, dyes, explosives, disinfectants, drugs, perfumes, flavorings, and vinegar (Pinnas and Meinke 1992, National Research Council 1981, NIOSH 1992a, Leikauf 1992).

Acetaldehyde is widely present in the ambient, work, and indoor environments since it is a major by-product of hydrocarbon oxidation when organic matter is combusted. It is produced when wood is burned for heating, cooking, land clearing, and forest fires. It is also produced in the incomplete combustion of fuels such as gasoline, liquid petroleum gas, oil, and kerosene. It is a major constituent of automobile emissions and the predominant aldehyde detected in mainstream and sidestream tobacco smoke (Leikauf 1992, National Research Council 1981, Pinnas and Meinke 1992).

Exposures

As could be expected, significant exposures to acetaldehyde occur in workspace environments where it is produced or used in product manufacture. There is, however, little documentation on exposure levels and how many workers may be exposed. In workplace assessments of acetaldehyde exposures resulting from thermal oxidation, concentrations have been reported to be in the range of a few ppbv to greater than occupational exposure limits.

Outside the workplace environment, acetaldehyde exposures are likely to occur from ambient air and infiltration of ambient air into building environments; smoker inhalation of tobacco smoke; nonsmoker exposure to environmental tobacco smoke; combustion by-products from unvented gas and kerosene appliances; flue-gas spillage; leakage from wood stoves, furnaces, and fireplaces; and in developing countries, unvented by-products of wood or kerosene cooking fuels. In the last case, significant acetaldehyde exposures to women and children from such unvented cooking fires are likely.

Daily average concentrations of 20 ppbv acetaldehyde have been reported for California cities, monitored in the early 1970s (National Research Council 1981). Compared to occupational standards/guidelines (Table 32.6), such exposure concentrations are relatively low.

An exposure concentration of 1 mg acetaldehyde per cigarette has been reported with 20 $\mu\text{g}/\text{min}$ estimated to enter blood circulation while smoking (Pinnas and Meinke 1992). Emissions of 12.5 and 84.7 mg/pack acetaldehyde have been reported for mainstream and

TABLE 32.6 Occupational Exposure Standards and Guidelines for Aldehydes*

Aldehyde	Organization or Agency

STEL/C	5.0 ppmv	—	—

*Key: TWA = 8-h time-weighted average; STEL = short-term exposure limit (15 min); C = ceiling (instantaneous, but up to 15 min due to sampling limitations); PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; A2 = suspected human carcinogen; A3 = confirmed animal carcinogen without known relevance to humans; A4 = potential carcinogen but animal studies are not sufficient.

sidestream smoke respectively; emissions of 3.2 mg/pack acetaldehyde have contributed to environmental tobacco smoke (integrated over 2 h) (Table 32.5). The acetaldehyde emission rate was approximately 4 times greater than that for formaldehyde (Leikauf 1992).

Health Effects

Like other aldehydes, acetaldehyde causes irritation of the mucous membranes. However, it is a relatively mild irritant of the eye and upper respiratory system. It is toxic to cilia of respiratory epithelia and may be one of several chemicals in tobacco smoke that interferes with respiratory clearance mechanisms. Acetaldehyde is also a central nervous system depressant in humans (NIOSH 1992a, Leikauf 1992, Pinnas and Meinke 1992). Liquid acetaldehyde is a skin irritant and on prolonged exposure may cause dermatitis due to primary irritation or sensitization.

Acetaldehyde is a potential carcinogen in humans. In vitro cellular studies have demonstrated that acetaldehyde causes crosslinking of DNA and induction of sister chromatid exchange in late cell division phases on repeated continuous exposure (Pinnas and Meinke

1992). In animal studies, acetaldehyde has caused squamous cell carcinomas and adenocarcinomas in the nasal cavities of rats and hamsters (NIOSH 1991). As such, it is a proven animal carcinogen. There have been no epidemiologic studies linking acetaldehyde exposure and human cancer.

32.5 ACROLEIN

Acrolein is a colorless to yellow liquid with an unpleasant choking odor (the threshold is reported to be 0.02 to 0.4 ppmv). It is a three-carbon unsaturated (containing a double bond) compound with a molecular weight of 56.1 and a vapor pressure of 210 mmHg (Table 32.1). Although highly volatile, it is considerably less volatile than formaldehyde.

Uses and Sources

Acrolein is used as an intermediate compound in the production of glycerine and methionine analogs which serve as poultry feed protein supplements; in the chemical synthesis of 1,3,6-hexanetriol, glutaraldehyde, and acrylates; in the production of pharmaceuticals, perfumes, and food supplements; and in the manufacture of colloidal forms of metals, artificial resins, synthetic fibers, and polyurethane foams. It is also used as a slimicide in the manufacture of paper, to fix tissue, and with its polymers to immobilize enzymes in biomedical applications, as a biocide in wastewater treatment systems, to denature alcohol, and as a fuel (NIOSH 1992b).

Acrolein is produced and released into the environment as a combustion/chemical oxidation product from the heating of oils and fats containing glycerol, wood combustion, metal fluxing, cigarette smoke, and automobile and diesel exhaust. It is also produced secondarily in photochemical smog (National Research Council 1981, Pinnas and Meinke 1992, NIOSH 1992b).

Exposures

Significant acrolein exposures may occur in workplace environments where acrolein is used in manufacturing, as an end-use product, or as a result of combustion reactions. There are few published reports on exposure concentrations to acrolein in workplace and other environments. In studies by Engstrom et al. (1990), acrolein concentrations were analyzed in worker breathing zone samples during welding, flame cutting, and strengthening of painted steel in shipyards. Concentrations ranged from 0.02 to 0.78 ppmv; the OSHA PEL (permissible exposure level) is 0.1 ppmv. In an unusual case, Godish (1996) reported significant concentrations of acrolein in school administrative office spaces associated with the application of a polyurethane insulation-rubberized roofing material. Concentrations were initially above OSHA PELs and STELs (short-term exposure limits), and foamed-in-place polyurethane was observed to be the major emission source. Concentrations in building spaces after roofing application were initially 14.4 ppmv and then declined to 0.15 to 0.17 ppmv within 4 months.

Acrolein emissions and potential exposures have been reported for cigarette smoke, as can be seen in Table 32.5. Acrolein emissions in mainstream smoke are significantly lower than formaldehyde emissions but are significantly higher in sidestream smoke. Acrolein emissions from cigarette smoking are important as it is widely believed that acrolein is primarily responsible for eye irritation reported to be associated with environmental tobacco smoke.

Acrolein exposures also occur in the ambient environment as a result of motor vehicle emissions and atmospheric photochemistry. Like other aldehydes, acrolein levels peak at midday on sunny days. Acrolein levels may be 10 to 25 percent of formaldehyde levels and represent 30 to 75 percent of total aldehyde present in urban atmospheres (National Research Council 1981).

As a combustion by-product, acrolein is present in wood smoke in significant quantities (Love and Bratzler 1966). Acrolein exposure from wood smoke may be potentially significant from leaking wood stoves and/or furnaces, or fireplaces and particularly in developing countries where wood fuel is used for cooking without provision for venting cooking fuel smoke from dwellings (Sharma et al. 1998).

Health Effects

Acrolein is a very potent eye irritant, causing lacrimation (tearing) at concentrations of approximately 1 ppmv with irritation at concentrations as low as 0.25 ppmv. Because of its lower (relative to formaldehyde) solubility, acrolein exposures can at high concentrations cause significant delayed-onset lung injury, including dyspnea, asthma, congestion, edema, and persistent respiratory insufficiency with decreased pulmonary function (NIOSH 1992b). Animal studies show that exposure to acrolein can cause bronchial hyperactivity mediator release and persistent changes in pulmonary histology (Leikauf 1992).

Acrolein is ciliotoxic with a potency similar to that of formaldehyde or crotonaldehyde. In addition acrolein exposures are reported to suppress pulmonary killing of bacteria, indicating that such exposures impair defense mechanisms of distal airways and alveoli (NIOSH 1992b, Leikauf 1992).

On chronic skin exposure, acrolein can cause contact dermatitis and sensitization, although acrolein appears to be a relatively weak sensitizer. It can be absorbed through the skin in sufficient amounts to cause systemic effects.

Acrolein may be a potential carcinogen. In various geno- and cytotoxic assays, acrolein has been reported to be at least as potent as formaldehyde and much more potent than acetaldehyde. Acrolein has been observed to induce DNA single-strand breaks and DNA-protein crosslinks in human bronchial cells (Leikauf 1992). It is also a suspected carcinogen because of its 2,3 epoxy metabolite and weak mutagenicity in *Salmonella* screening tests (Pinnas and Meinke 1992).

Despite observed geno- and cytotoxic effects, acrolein has not been shown to be an animal carcinogen in exposure studies, and no human epidemiologic studies have been reported which suggest a link between acrolein exposure and human cancer.

32.6 GLUTARALDEHYDE

Glutaraldehyde is a five-carbon dialdehyde; that is, it has a carbonyl group on each end of the molecule. At room temperature, it is a transparent colorless liquid with a sharp fruity odor. It is very soluble in water. It has a relatively low vapor pressure (0.20 mmHg at 20°C), and thus it volatilizes slowly.

Uses and Sources

Glutaraldehyde is the active ingredient found in disinfectant formulations widely used in the medical and dental professions (and to some extent in veterinary medicine as well). It

is also used as a hospital and medical or dental office cleaning agent. It has also been used as a therapeutic agent, in the preparation of microcapsules and implantable collagen, and in the manufacture of resins and dyes. Glutaraldehyde is used as a fixative in tissue sample preparation and in the processing of x-ray film. It has seen limited but increasing use in human embalming.

Formulations containing 2% glutaraldehyde, activated by the addition of sodium bicarbonate, are highly effective in sterilizing medical equipment of fungal, bacterial, and viral contaminants. Glutaraldehyde-containing products are also widely used to clean hospital, laboratory, or dental office work surfaces where infection control is of particular concern (Aw 1990, Burge 1989, Charney 1990).

The increasing use of glutaraldehyde formulations for cold sterilization of medical and dental equipment, and a surface cleaning agent, and even as a preservative in human embalming appears to be due at least in part to infection control concerns associated with the AIDS epidemic. As indicated previously, glutaraldehyde appears to be both a potent and effective sterilant.

Exposures

Exposures to glutaraldehyde in workspace environments have been reported to include a variety of hospital, medical service, dental, and veterinary personnel, as well as in funeral service workers. Significant exposures have been reported for nurses and other personnel working in gastroenterology units where glutaraldehyde formulations are routinely used to sterilize endoscopic equipment. Other exposed populations in hospital environments have included respiratory therapy, hemodialysis, radiovascular, radiography, and central supply personnel. In most instances, such exposures result from the use of glutaraldehyde solutions to clean or disinfect medical equipment. Radiological and even clerical staff have been reported to be exposed to glutaraldehyde in the processing and handling of x-ray film. In dental offices and clinics exposures have been reported for dentists, dental nurses, and assistants.

Exposures to glutaraldehyde occur as a result of percutaneous contact with sterilizing-cleaning solutions, as well as inhalation of vapors. Investigations of complaints of dermatitis among health care personnel have indicated direct worker contact with liquid solutions and allergic contact sensitization based on patch tests (Di Prima et al. 1988, Nethercott and Holmes 1988, Nethercott et al. 1988).

In several investigations air sampling for glutaraldehyde has been conducted with exposure concentrations varying widely. In a two-hospital study personal exposures ranged up to 0.37 to 0.49 ppmv with an area sample of 0.19 ppmv; in another hospital study personal exposures for workers in cold-sterilized and x-ray development ranged from 0.001 to 0.04 ppmv. Other studies have reported exposure concentrations which ranged up to 0.20 ppmv (Charney 1990).

Health Effects

Potential human health effects associated with glutaraldehyde exposures have been inferred or determined from case reports, field investigations, limited epidemiologic studies, challenge studies, and limited animal exposure studies. These have included irritant symptoms, occupationally induced asthma, and skin symptoms.

Exposed workers report a variety of upper respiratory symptoms, and eye and throat irritation, as well as headache. In a cross-sectional epidemiologic study of 107 Swedish and British medical workers exposed to glutaraldehyde, significant prevalence rates of nasal and throat irritation, nausea, and headache were reported (Norback 1988). Pulmonary

symptoms, such as chest tightening, asthma, and similar symptoms have been reported for some medical workers exposed to glutaraldehyde. Challenge studies have reported mixed results. In one case study (Cullinan et al. 1992) a workplace challenge indicated a dramatic decrease in lung function while a follow-up blind challenge did not. In another case, a challenge exposure to vapors from 11% glutaraldehyde solutions produced late asthmatic responses in two of four patients (Corrodo et al. 1986).

A variety of skin symptoms among medical and dental personnel and funeral service workers exposed to glutaraldehyde have been reported (Di Prima et al. 1988, Nethercott and Holmes 1988, Burge 1989, Aw 1990). Skin symptoms are most commonly reported for the hands and arms, and in some cases neck and cheeks. Patch testing with glutaraldehyde indicates that it is a potent contact allergen, although the incidence of sensitization appears to be low (<1 percent of those potentially exposed).

Other potential exposure health concerns have been expressed. These include reproductive effects and cancer. Some studies suggest that exposure to glutaraldehyde was associated with an increased risk of spontaneous abortion among pregnant females. However, such studies have been too limited to be conclusive.

In a review of the literature on aldehydes, NIOSH (1991) indicated that nine aldehydes, including glutaraldehyde, were of concern as being potential carcinogens because their chemical reactivities and mutagenic activities may be similar to those of acetaldehyde, malonaldehyde, and formaldehyde (for which there is animal exposure data to indicate that long-term exposures may cause cancer, and several assays indicate that they may have mutagenic properties). Glutaraldehyde has not been demonstrated to produce genotoxic effects in several mutagenic test systems.

32.7 EXPOSURE GUIDELINES AND STANDARDS

In many countries, occupational exposure to formaldehyde and other selected aldehydes in work environments is regulated by governmental agencies. Such agencies promulgate exposure limits for a period of 8-h time-weighted averages (TWAs) or for higher-concentration shorter-duration exposures (STELs), or ceiling concentrations not to be exceeded. Workplace exposure limits in the United States are promulgated by the Occupational Safety and Health Administration (OSHA) for a period of 8 h (PELs) and 15 min (STELs).

Occupational guideline values that do not carry regulatory obligations are recommended by the National Institute of Occupational Safety and Health (NIOSH) and the American Conference of Governmental Industrial Hygienists (ACGIH). Guidelines published by NIOSH are described as RELs (recommended exposure limits) and by ACGIH TLVs (threshold limit values). TLVs are often used as a basis for setting occupational exposure standards in many countries as well as the United States. Not surprisingly, guideline values which carry no regulatory obligation are often more stringent than occupational exposure standards, particularly in the United States.

Occupational exposure standards and guideline values for formaldehyde and selected other aldehydes are summarized in Table 32.6. Note that the TLV recommended by ACGIH for formaldehyde (ACGIH 1998) is less than half of that required by OSHA and the NIOSH REL is only a small fraction of the OSHA PEL. The NIOSH REL focuses primarily on protecting workers from exposures that may cause cancer while the ACGIH TLV and the OSHA PEL focus on irritant effects. ACGIH carcinogen classes A2, A3, and A4 correspond to the International Agency for Research on Cancer's (IARC) carcinogen classification group 2A, group 2B, and group 3, respectively.

Exposures to formaldehyde in indoor air poses health concerns different from those in workplace environments. Exposures are involuntary and occur among individuals of all

ages with varying health status over exposure durations of up to 24 h/day, 7 days per week. As a consequence, occupational standards or guidelines do not reflect the degree of protection needed in nonindustrial indoor environments. Thus indoor air quality guidelines tend to be more stringent than those recommended for workplace environments where individuals are working with formaldehyde or formaldehyde-releasing procedures. Recommended guideline values for formaldehyde in indoor air are summarized in Table 32.7.

At present an occupational exposure limit of 0.20 ppm glutaraldehyde as a ceiling value is used by the United States and many other countries. Studies of workplace exposures indicate that this exposure limit is not adequate to protect those occupationally exposed. As a consequence, ACGIH has proposed a ceiling exposure limit of 0.05 ppmv (ACGIH 1998).

32.8 MEASUREMENT

Aldehyde concentrations in air can be determined by a variety of dynamic and passive sampling techniques. As would be expected from exposure concerns, significant attention has been given to the development of techniques for the measurement of formaldehyde with lesser attention to other aldehydes. Formaldehyde sampling methods (and aldehyde sampling methods in general) have been extensively reviewed by Kennedy et al. (1984a) and Otson and Fellin (1988).

Formaldehyde

The most widely used formaldehyde sampling method for both occupational and indoor air quality measurements has been NIOSH method 3500, the impinger–chromotropic acid method (NIOSH 1984). It is a colorimetric method with a quantification limit of 0.02 ppmv for a 60-L sample. The method is subject to many negative interferences, including phenol, ethanol, higher-molecular-weight alcohols, and olefins.

TABLE 32.7 Guidelines for Acceptable Formaldehyde Levels in Indoor Air*

Organization or government	Permissible level, ppmv	Status
HUD, USA	0.40, target	Recommended
ASHRAE, USA	0.10	Recommended
California Department of Health, USA	0.10, action level	Recommended
	0.05, target level	Recommended
Health Canada	0.10, action level	Recommended
	0.05, target level	Recommended
Sweden	0.20	Promulgated
Denmark	0.12	Promulgated
Finland	0.12	Promulgated
Australia	0.10	Promulgated
Netherlands	0.10	Promulgated
Germany	0.10	Promulgated
Italy	0.10	Promulgated
WHO	0.08	Recommended

*Averaging time, typically based on 30- to 60-min sampling period.

Source: Godish (1989).

The chromotropic acid method has been adapted for use in passive monitors. Formaldehyde diffuses into the monitor and is collected on a reactive sorbent or a liquid medium separated by a gas-permeable membrane. The sample is desorbed or an aliquot taken of to the absorbing medium and analyzed by modifications of the chromotropic acid method.

Other colorimetric methods have also been used to measure formaldehyde concentrations. These include the pararosaniline (Miksch et al. 1981) and MBTH (3-methyl-2-benzothiazolinone hydrozone) methods (Lodge 1987). The pararosaniline method has a quantification limit of approximately 0.024 ppmv for a 60-L sample. It does not have the interference problems associated with NIOSH method 3500. The pararosaniline method has been adapted for use in commercial continuous monitors. The MBTH method is a total aldehydes method and is not specific for formaldehyde. It has been used for formaldehyde sampling and other aldehydes when a particular aldehyde is known to dominate concentrations.

Because of the limitations of colorimetric methods, the DNPH-HPLC method is increasingly becoming the most widely used sampling and analytic method for formaldehyde and other saturated aliphatic aldehydes (Levin et al. 1985). In the DNPH-HPLC method, formaldehyde and other carbonyls react with 2,4-dinitrophenylhydrazine to form 2,4-dinitrophenylhydrazone derivatives. Concentrations are determined by using a high-performance liquid chromatograph (HPLC) with an UV detector. Sampling can be done using dynamic collection in an aqueous DNPH solution or on DNPH-treated adsorption tubes containing silica gel or XAD-2. In the latter case, sample media are eluted with acetonitrile and injected into a HPLC for identification and quantification. The method is both highly specific and sensitive with a quantification limit for a 30-L sample collected at 1.5 L/min of 6 and 1.6 ppbv at 0.5 L/min, respectively. The DNPH-HPLC method has also been adapted for use in passive sampling and has been shown to produce excellent results. The DNPH-HPLC has a major limitation; it is subject to a significant negative ozone interference (Arnts and Tejada 1989). C18-coated cartridges (Grosjean and Grosjean 1995) and potassium iodide scrubbers (Kleindienst et al. 1998) have been used to reduce this interference.

Acetaldehyde

Acetaldehyde and other saturated aliphatic aldehydes are commonly sampled and analyzed by means of the DNPH-HPLC method described for formaldehyde above. It provides excellent resolution of peaks of up to 10 aldehydes and good quantitative recoveries.

Acrolein

A variety of sampling and analytical methods have been used to measure acrolein levels in air. A colorimetric method, based on the reaction of acrolein with 4-hexylresorcinol, has the longest history of use (Lodge 1987). A concentration of 10 ppbv can be determined from a 50-L sample. The limitations of the method include the use of corrosive and highly toxic reagents. To overcome these shortcomings, Kennedy et al. (1984b) developed a sampling method in which acrolein is collected on 2-(hydroxymethyl)piperidine-coated XAD-2 sampling tubes. The bicyclic oxazolidine (9-vinyl-1-aza- α -oxabicyclo[4.3.0]nonone) derivative desorbed from the sorbent is determined by gas chromatography with a nitrogen-specific detector. The limit of detection is reported to be 6 ng in a 48-L sample.

Acrolein measurements can in theory be made by means of the DNPH-HPLC method. However, acrolein's tendency to polymerize or form dimers makes it unsuitable for the determination of acrolein (Risner 1995).

Glutaraldehyde

Glutaraldehyde has been measured in workplace environments by the MBTH (3-methyl-2-benzothiazolinone hydrozone) method (Lodge 1987), the NIOSH (1989) 2-hydroxymethyl-piperidine gas chromatography method, and the OSHA (1987) 2, 4-dinitrophenylhydrazine (DNPH) method.

As indicated for formaldehyde above, the MBTH method is not selective for glutaraldehyde or any other aldehyde and has been shown to give relatively poor results compared to other methods.

In the OSHA method, glutaraldehyde vapor is collected on a filter impregnated with DNPH, where it forms the glutaraldehyde-DNPH derivative. Elution with acetone allows the resolution and quantification of the two isomers of the glutaraldehyde-DNPH derivative (Cuthbert and Groves 1995). For a sampling rate of 200 mL/min for 10 min, the minimum detection limit is about 3 ppbv.

32.9 INDOOR AIR CHEMISTRY

Generation of Aldehydes

Although many aldehydes are present in indoor air as a consequence of emissions from indoor sources (and likely from outdoor air as well), there is increasing evidence that chemical reactions between ozone (O_3) and unsaturated hydrocarbons, such as *d*-limonene, α -pinene, α -terpinene, styrene, and isoprene, at levels commonly found in indoor air can produce a variety of aldehydes which may significantly affect indoor air quality and human health (Zhang et al. 1994, Wescler and Shields 1997).

Aldehyde production may occur as a result of reactions between O_3 and unsaturated hydrocarbons or reaction pathways involving hydroxyl ($OH^\cdot$) or nitrate ($NO_3^\cdot$) radical produced as a result of O_3 -induced reactions.

Such reactions may produce simple aldehydes, such as formaldehyde, acetaldehyde, hexanal, nonanal, and decanal and aromatic aldehydes, such as benzaldehyde and tolu-aldehyde. Other chemical species produced may contain multiple carbonyls or a carbonyl and an unsaturated carbon bond (such as 2-nonenal). Methacrolein [$CH_2=C(CH_3)CHO$] can be produced by reactions involving O_3 and isoprene and $OH^\cdot$. Isoprene is emitted by plants but is also a human bioeffluent. α -Pinene, emitted from household and wood products, reacts with O_3 to produce pinonaldehyde.

Ozone reactions with building furnishings may produce a variety of aldehydes. Interactions between O_3 and carpet have been observed to produce significant emissions of 2-nonenal and *n*-nonanal and measurable emissions of C_1 to C_3 and C_6 to C_8 aldehydes (Morrison 1988).

Aldehydes as Reactants

Not only are aldehydes produced as a consequence of indoor chemistry they may also participate in chemical reactions. Aldehydes can react with NO_3 to form peroxy nitrates. The formation of peroxyacyl nitrate (PAN) begins with the reaction of either NO_3 or $OH^\cdot$ with acetaldehyde to form acetyl radical ($CH_3CO^\cdot$) which reacts with nitrogen dioxide (NO_2) to form PAN ($CH_3C(O)OONO_2$). Hydroxyl radical reactions with propionaldehyde produce peroxy propionyl nitrate; with benzaldehyde, peroxy benzoyl nitrate.

Sensory Responses and Indoor Air Quality Health Complaints

Aldehydes produced as a result of indoor chemical reactions have lower odor thresholds and cause more sensory irritation than do their precursors. Aldehydes that contain unsaturated carbon bonds have very low odor thresholds. These include 1.9 pptv for *cis*-2 nonenal and *trans*-6-nonenal, 17 pptv for 8-nonenal, and 24 pptv for *trans*-3 nonenal and *cis*-3-nonenal. Methacrolein, a four-carbon unsaturated aldehyde is a particularly potent sensory irritant (Wescler and Shields 1997).

Aldehyde reactions with OH⁻ and NO₂ produce peroxy nitrate compounds described above. These compounds are potent eye and mucous membrane irritants. Peroxybenzoyl nitrate, for example, produces severe eye irritation at a concentration of 20 ppbv.

Indoor chemistry involving aldehyde production has been suggested to be a potential cause of air-quality-related complaints in problem buildings. Sundell et al. (1993) observed significant dose-response relationships between building-related symptoms (such as fatigue, heavy-headedness, hoarse or dry throat, and dry facial skin) and the logarithm of the change in total volatile organic compounds (TVOCs) from supply to room air. This decrease in TVOC concentration ("lost TVOCs") was associated with increased room formaldehyde levels, which also showed a significant correlation with sick building syndrome (SBS) symptom prevalence. Similar observations have been used to explain the prevalence of SBS symptoms and low TVOC levels (Groes et al. 1996).

Indoor chemistry involving the production of aldehydes and aldehydes as reactants has emerged as a potential explanation of indoor air quality complaints in buildings in the late 1990s. To date, such research has been limited, and considerable additional research efforts need to be expended to elucidate the potential role of aldehyde-related indoor chemistry in contributing to symptoms and health complaints in indoor environments.

CHAPTER 33

ASSESSING HUMAN EXPOSURE TO VOLATILE ORGANIC COMPOUNDS¹

Lance A. Wallace, Ph.D.
*U.S. Environmental Protection Agency
Reston, Virginia*

33.1 INTRODUCTION

Volatile organic chemicals (VOCs) comprise some thousands of compounds, many of which are in wide use as solvents, fragrances, and other ingredients in processes and consumer products. Although no standard definition of VOCs has been accepted, they would generally be considered to have vapor pressures greater than about 10^{-2} kPa. Compounds with vapor pressures between about 10^{-2} and 10^{-8} kPa are often described as *semivolatile* organic compounds (SVOCs), a class that includes pesticides, herbicides, polychlorinated biphenyls (PCBs), polychlorinated benzodioxins, and polyaromatic hydrocarbons (PAHs).

VOCs have great economic importance. Many chemicals with the highest annual production figures are VOCs. Entire industries such as petrochemicals and plastics are based on VOCs. They are used as industrial solvents, in paints and coatings, in pressed-wood products, and in literally thousands of consumer products.

VOCs are ubiquitous. Even a rural outdoor air sample will contain some 50 to 100 VOCs at levels on the order of 0.01 to 1 part per billion by volume (ppbv). Indoor air samples may contain twice as many VOCs at levels several times higher than outdoors. Common VOCs and their sources are shown in Table 33.1. New buildings contain some airborne VOCs at concentrations that are 100 times outdoor levels.

Human exposure to most VOCs is mainly through inhalation; a small number of VOCs are in drinking water, food, and beverages as contaminants. Some VOCs may travel in groundwater or through soil from hazardous-waste sites, landfills, or gasoline spills to inhabited areas.

VOCs often exist as vapors or liquids at room temperature but may also be in the form of solids (e.g., naphthalene and *para*-dichlorobenzene, used as mothballs and bathroom deodorants) that sublime at room temperature.

¹*Disclaimer:* This chapter has not been reviewed for policy implications by the U.S. Environmental Protection Agency and does not necessarily reflect USEPA policy.

TABLE 33.1 Common Volatile Organic Chemicals and Their Sources

Chemicals	Major sources of exposure
Acetone	Cosmetics
Alcohols (ethanol, isopropanol)	Spirits, cleansers
Aromatic hydrocarbons (toluene, xylenes, ethylbenzene, trimethylbenzenes)	Paints, adhesives, gasoline, combustion sources
Aliphatic hydrocarbons (octane, decane, undecane)	Paints, adhesives, gasoline, combustion sources
Benzene	Smoking, automobile exhaust, passive smoking, driving, refueling automobiles, parking garages
Butylated hydroxytoluene (BHT)	Urethane-based carpet cushions
Carbon tetrachloride	Fungicides, global background
Chloroform	Showering, washing clothes, dishes
<i>p</i> -Dichlorobenzene	Room deodorizers, moth cakes
Ethylene glycol, Texanol	Paints
Formaldehyde	Pressed wood products
Furfural	Cork parquet flooring
Methylene chloride	Paint stripping, solvent use
Methyl- <i>tert</i> -butyl ether (MTBE)	Gasoline, groundwater contaminant
Phenol	Vinyl flooring, cork parquet flooring
Styrene	Smoking
Terpenes (limonene, α -pinene)	Scented deodorizers, polishes, cigarettes, food, beverages, fabrics, fabric softeners
Tetrachloroethylene	Wearing/storing dry-cleaned clothes
Tetrahydrofuran	Sealer for vinyl flooring
1,1,1-Trichloroethane	Aerosol sprays, solvents, many consumer products
Trichloroethylene	Unknown (cosmetics, electronic parts, printer or typewriter correction fluid)

For most VOCs, air is the main route of exposure. Two main health effects are of interest: cancer and acute irritative effects (e.g., sick building syndrome). The latter may have an economic effect as great as or greater than that of the former (Hall et al. 1992).

33.2 MEASUREMENT METHODS

Air

Sampling Methods

Activated Charcoal. Historically, the measurement method of choice for *occupational* exposures (generally 1 to 100 ppm for a given VOC) has been to pump a sample of air across a sorbent (usually activated charcoal) in order to concentrate the VOCs. They are then recovered by a solvent such as carbon disulfide.

In the early 1980s, passive badges employing activated charcoal were developed for use in occupational sampling. The badges operate on the principle of diffusion, and are often operated over an 8-h workday to provide an integrated average exposure for comparison to the occupational standards [e.g., the threshold limit value (TLV)]. However, the manufacturing process for these badges leaves residues of VOCs on the activated carbon that render the badges unsuitable for short-term sampling at *environmental* concentrations, which are usually at ppb levels. However, the high background contamination on the badges can

be overcome by extending the time of sampling to a week or more, and several studies of indoor air pollution have adopted this technique (Mailahn et al. 1987, Seifert and Abraham 1983). Attention has been refocused on employing these badges for environmental sampling. Morandi et al. (1997) conclude that the 3M (The 3M Company) 3520 OVM badge may be suitable for sampling periods as short as 48 h. Of the ten VOCs tested at varying concentrations, temperatures, and relative humidities, 8 showed adequate precision and stability under the varying conditions; only styrene and 1,3-butadiene appeared unsuitable for analysis. However, the method detection limits remained uncomfortably high, at levels somewhat above typical environmental levels—the authors suggested a simple modification (opening both sides of the sampler to double the sampling rate) to improve the detection limits.

Tenax. The background problems associated with activated charcoal, as well as problems in obtaining reliable recoveries of sorbed chemicals, led to a search for a more suitable sorbent. A polymer known as *Tenax* was widely adopted during the 1970s as a more reliable sorbent than charcoal for ppb levels (Barkley et al. 1980, Krost et al. 1982). *Tenax*, properly cleaned, has low background contamination. It is also stable at temperatures up to 250°C, allowing thermal desorption instead of solvent desorption. (Solvent desorption involves a redilution of the VOCs, thus partially negating the concentration made possible by the sorbent.) Although expensive, *Tenax* can be reused many times. Drawbacks include artifact formation of several chemicals (e.g., benzaldehyde, phenol) and an inability to retain very volatile organic chemicals (e.g., vinyl chloride, methylene chloride). Although most uses of *Tenax* sorbent have been with active (pumped) samplers, a passive badge containing *Tenax* has also been developed (Coutant et al. 1986).

Multisorbent Systems. In the late 1980s, attempts were made to combine the best attributes of charcoal and *Tenax* into a multisorbent system. Newer types of activated charcoal (Spherocharb, Carbosieve) were developed to provide more reliable recoveries. Tandem systems employing *Tenax* as the first sorbent and activated charcoal as the second, or backup, sorbent were employed. The *Tenax* collected the bulk of the VOCs and the activated charcoal collected those more volatile VOCs that “broke through” the *Tenax*. Systems were also developed using three sorbents, such as *Tenax*, Amborsorb, and Spherocharb or Carbosieve (Hodgson et al. 1986). All such systems allow collection of a broader range of chemical types and volatilities.

Direct (Whole-Air) Sampling. This method, first developed in the 1970s for upper atmosphere sampling, avoids the sorption-desorption step, which should theoretically allow less chance for contamination. (However, it requires great sensitivity on the part of the detection instruments.) The method may involve real-time sampling in mobile laboratories, with direct injection of the air sample into a cold trap attached to a GC (gas chromatograph); or sampling in evacuated electropolished aluminum canisters for later laboratory analysis (Oliver et al. 1986).

Comparison of Sampling Methods. No single method of sampling VOCs in the atmosphere or indoors has become a standard or reference method. In the United States, the two preferred methods are *Tenax* and evacuated canisters. These two methods were compared under controlled conditions in an unoccupied house (Spicer et al. 1986). Ten chemicals were injected at nominal levels of about 3, 9, and 27 $\mu\text{g}/\text{m}^3$. The results showed that the two methods were in excellent agreement, with precisions of better than 10 percent for all chemicals at all spiked levels.

In Europe, the two most common methods are *Tenax* and activated charcoal. One study employing both methods side by side (Skov et al. 1990) found consistently higher levels of total VOC on the charcoal sorbent. The difference may be due to very volatile organics such as pentane and isopentane, which are collected by charcoal but that break through *Tenax* readily.

The sorbent methods lend themselves to personal monitoring—a small battery-powered pump is worn for an 8- or 12-h period to provide a time-integrated sample. Until the

mid-1990s, the whole-air methods employed bags or canisters that were too bulky or heavy to be used as personal monitors; however, a small canister sampler has been modified for use as a personal sampler (Lindstrom and Pleil 1996; Pleil and Lindstrom 1995a, 1995b, 1997). A valuable and comprehensive review of sampling methods for VOCs is provided by Lewis and Gordon (1996).

Analysis. Samples are usually analyzed by first separating the components using gas chromatography. Three detection methods in common use are flame-ionization detection (FID), electron-capture detection (ECD), and mass spectrometry (MS). Only GC-MS has the ability to unambiguously identify many chemicals. Neither GC-FID nor GC-ECD is able to separate chemicals that coelute (emerge from the chromatographic column at the same time). Also, GC-FID response is depressed by chlorine and other halogens, so it is not suitable for samples containing halogens. Mass spectrometry, by breaking chemicals into fragments and then identifying these fragments, is often capable of differentiating even among coeluting chemicals. However, since chemicals are identified by comparing these mass fragment spectra to existing libraries, and the libraries are incomplete, even GC-MS identifications are often tentative or mistaken. (One study using known mixtures of chemicals found about 75 percent accuracy of identification for several different GC-MS computerized spectral search systems.)

Olfactory Analysis. Because of the complexity of most indoor and outdoor air samples, the cost and inaccuracy of measurement methods, and the almost complete lack of knowledge of the relationship of measured VOC levels within complex mixtures to resulting health effects, an alternative to chemical measurement methods has arisen: use of a trained panel to judge the possible health or comfort effects of an air sample directly. This method, pioneered by Ole Fänger of Denmark (Fänger 1987), employs panels of 6 to 10 persons previously trained by sampling known mixtures of odorous compounds. When exposed to a test atmosphere, the judges provide an instantaneous estimate of its pollution potential, measured in units called *decipols*. One decipol is equivalent to the amount of pollution (body odor) produced by one person in a room ventilated at one air change per hour (ACH). This method is capable of predicting how persons will react to air of a given quality, and also of estimating the relative contribution of various sources (e.g., ventilation system, office machines, employees) to indoor air quality.

Body Fluids

Similar techniques to those above are used to sample breath, blood, and urine. Exhaled breath can be collected in Tedlar bags, pumped across Tenax cartridges, and analyzed by GC-MS (Wallace and O'Neill 1987); alternatively, the breath may be collected in electropolished canisters (Raymer et al. 1990, Thomas et al. 1992). Urine may be analyzed by a purge-and-trap approach similar to the Bellar and Lichtenberg method for water (Michael et al. 1980). Mothers' milk has been analyzed by a similar purge-and-trap method (Pellizzari et al. 1982). Blood may be analyzed by an isotope dilution technique (CDC 1990).

Pharmacokinetic models may be used to relate exposure to body burden (Pellizzari et al. 1992; Wallace et al. 1993b, 1997).

33.3 HUMAN EXPOSURE

Personal Air

Between 1979 and 1987, the USEPA carried out the TEAM (total exposure assessment methodology) studies to measure personal exposures of the general public to VOCs in sev-

eral geographic areas in the United States (Pellizzari 1987a, 1987b; Wallace 1987). About 20 target VOCs were included in the studies, which involved about 750 persons, representing 750,000 residents of the areas. Each participant carried a personal air quality monitor containing 1.5 g Tenax. A small battery-powered pump pulled about 20 L of air across the sorbent over a 12-h period. Two consecutive 12-h personal air samples were collected for each person. Concurrent outdoor air samples were also collected in the participants' backyards. In the studies of 1987, fixed indoor air samplers were also installed in the living rooms of the homes.

The initial TEAM pilot study (Wallace et al. 1982) in Beaumont, Texas, and Chapel Hill, North Carolina, indicated that personal exposures to about a dozen VOCs exceeded outdoor air levels, even though Beaumont has major oil producing, refining, and storage facilities. These findings were supported by a second pilot study in Bayonne-Elizabeth, New Jersey (another major chemical manufacturing and petroleum refining area) and Research Triangle Park, North Carolina (Wallace et al. 1984a). A succeeding major study of 350 persons in Bayonne-Elizabeth (Wallace et al. 1984b) and an additional 50 persons in a nonindustrial city and a rural area (Wallace et al. 1987a) reinforced these findings. A second major study in Los Angeles, in southern California, and in Antioch-Pittsburg, in northern California (Wallace et al. 1988), with a follow-up study in Los Angeles in 1987 (Wallace et al. 1991a), added a number of VOCs to the list of target chemicals with similar results. The TEAM studies are summarized in Wallace (1987, 1993).

Major findings of these TEAM studies included the following:

1. Personal exposures exceeded median outdoor air concentrations by factors of 2 to 5 for nearly all prevalent VOCs (Tables 33.2 and 33.3). The difference was even greater (factors of 10 or 20) when the maximum values were compared. This is so despite the fact that most of the outdoor samples were collected in areas with heavy industry (New Jersey) or heavy vehicular traffic (Los Angeles).
2. Major sources are consumer products (bathroom deodorizers, moth repellents); personal activities (smoking, driving); and building materials (paints and adhesives). In the United States, one chemical (carbon tetrachloride) has been banned from consumer products, and exposure is thus limited to the global background of about $0.7 \mu\text{g}/\text{m}^3$.
3. Traditional sources (automobiles, industry, petrochemical plants) contributed only 20 to 25 percent of total exposure to most of the target VOCs (Wallace 1987). No difference in exposure was noted for persons living close to chemical manufacturing plants or petroleum refineries.

Indoor Air

Concentrations. Three large studies of VOCs, involving 300 to 800 homes, have been carried out in the Netherlands (Lebret et al. 1986), Germany (Krause et al. 1987), and the United States (Wallace 1987). A smaller study of 15 homes was carried out in northern Italy (De Bortoli et al. 1986). Observed concentrations were remarkably similar for most chemicals, indicating similar sources in these countries. One exception is chloroform, present at typical levels of 1 to $4 \mu\text{g}/\text{m}^3$ in the United States but not found in European homes. This is to be expected, since the likely source is volatilization from chlorinated water (Wallace et al. 1982; Andelman 1985a, 1985b); the two European countries do not chlorinate their water.

Major findings of these indoor air studies include

- Indoor levels in homes and older buildings (>1 year) are typically several times higher than outdoor levels. Sources include dry-cleaned clothes, cosmetics, air fresheners, and cleaning materials.

†One very high value removed.

- New buildings (<1 month) have levels of some VOC (aliphatics and aromatics) 100 times higher than those outdoors, falling to 10 times the outdoor level about 2 to 3 months later. Major sources include paints and adhesives.
- About half of 750 homes in the United States had total VOC levels (obtained by integrating the total ion current response curve of the mass spectrometer) greater than 1 mg/m³, compared to only 10 percent of outdoor samples (Wallace et al. 1991c).
- More than 500 VOCs were identified in four buildings in Washington, DC, and Research Triangle Park, NC (Sheldon et al. 1988a).

One study (Wallace et al. 1989) involved seven volunteers undertaking about 25 activities suspected of causing increased VOC exposures; a number of these activities (using bathroom deodorizers, washing dishes, cleaning an automobile carburetor) resulted in 10- to 1000-fold increases in 8-h exposures to specific VOCs.

These studies of VOCs in homes have been supplemented by studies of VOCs in buildings. One study of 12 California office buildings (Daisey et al. 1994) found some chemicals to be emitted primarily by indoor sources (cleaning solvents, building materials, bioeffluents) and others to be likely intrusions from outdoor air (e.g., motor vehicle emissions).

Sources. Early studies of organics indoors were carried out in the 1970s in the Scandinavian countries (Johansson 1978; Mølhave and Møller 1979; Berglund et al. 1982a, 1982b). Mølhave (1982) showed that many common building materials used in Scandinavian buildings emitted organic gases. Seifert and Abraham (1982) found higher levels of benzene and toluene associated with storage of magazines and newspapers in German homes. Early U.S. measurements were made in nine Love Canal (in Niagara Falls, NY) residences (Pellizzari et al. 1979); 34 Chicago homes (Jarke and Gordon 1981); and in several buildings (Hollowell and Miksch 1981, Miksch et al. 1982).

Hundreds of VOCs have been identified in environmental tobacco smoke (Higgins 1987, Guerin et al. 1987, Jermini et al. 1976, Löfroth et al. 1989, Hodgson et al. 1996, Gundel et al. 1997), which contaminates about 60 percent of all U.S. homes and workplaces (Repace and Lowrey 1980, 1985). Among these are several human carcinogens, including benzene. Benzene was elevated in the breath of smokers by a factor of 10 above that in the breath of nonsmokers (Wallace et al. 1987b). The amount of benzene in mainstream smoke appears to be directly related to the amount of tar and nicotine in the cigarette (Higgins et al. 1983). In the United States, it is calculated that the 50 million smokers are exposed to about half of the total nationwide "exposure budget" for benzene (Wallace 1990). Other indoor combustion sources such as kerosene heaters (Traynor et al. 1990) and woodstoves (Highsmith et al. 1988) may emit both volatile and semivolatile organic compounds.

Later studies also investigated building materials (Sheldon et al. 1988a, 1988b) but added cleaning materials and activities such as scrubbing with chlorine bleach or spraying insecticides (Wallace et al. 1987c) and using adhesives (Girman et al. 1986) or paint removers (Girman et al. 1987). Knöppel and Schauenburg (1987) studied VOC emissions from 10 household products (waxes, polishes, detergents); 19 alkanes, alkenes, alcohols, esters, and terpenes were among the chemicals emitted at the highest rates from the 10 products. All of these studies employed either head-space analysis or chambers to measure emission rates.

Other studies estimated emission rates from measurements in homes or buildings. For example, Wallace (1987) estimated emissions from a number of personal activities (visiting dry cleaners, pumping gas) by regressing measurements of exposure or breath levels against the specified activities. Girman and Hodgson (1987) extended their chamber studies of paint removers to a residence, finding similar [and very high (ppm)] concentrations of methylene chloride in this more realistic situation.

The U.S. National Aeronautics and Space Agency (NASA) has measured organic emissions from about 5000 materials used in space missions (Nuchia 1986). Perhaps 3000 of these materials are in use in general commerce (Özkaynak et al. 1987). The chemicals emitted from the largest number of materials included toluene (2076 materials), acetone (2131), and xylenes (1194) (Table 33.4).

A 41-day chamber study (Berglund et al. 1987) of aged building materials taken from a “sick” preschool indicated that the materials had absorbed about 30 VOCs, which they reemitted to the chamber during the first 30 days of the study. Only 13 of the VOCs originally present in the first days of the study continued to be emitted in the final days, indicating that these 13 were the only true components of the materials. This finding has significant implications for remediating “sick buildings.” Even if the source material is identified and removed, weeks may be needed before reemission of organics from sinks in the building stops.

Another study (Seifert and Schmahl 1987) of sorption of VOCs and SVOCs on materials such as plywood and textiles concluded that sorption was small for the VOCs studied.

Emission rates of most chemicals in most materials are greatest when the materials are new. For “wet” materials such as paints and adhesives, most of the total volatile mass may

be emitted in the first few hours or days following application (Tichenor and Mason 1987, Tichenor et al. 1990). EPA studies of new buildings indicated that eight of 32 target chemicals measured within days after completion of the building were elevated 100-fold compared to outdoor levels: xylenes, ethylbenzene, ethyltoluene, trimethylbenzenes, decane, and undecane (Sheldon et al. 1988b). The half-lives of these chemicals varied from 2 to 6 weeks; presumably some other nontarget chemicals, such as toluene, would have shown similar behavior. The main sources were likely to be paints and adhesives. Thus new buildings would be expected to require about 6 months to a year to decline to the VOC levels of older buildings.

For dry building materials such as carpets and pressed-wood products, emissions are likely to continue at low levels for longer periods. Formaldehyde from pressed-wood products may be slowly emitted with a half-life of several years (Breysse 1984). According to several studies, 4-phenylcyclohexene (4-PC), a reaction product occurring in the styrene-butadiene backing of carpets, is the main VOC emitted from carpets after the first few days. 4-PC is likely to be largely responsible for the new carpet odor.

The European Commission Joint Research Centre Environment Institute has published a series of 19 reports (as of 1997) on indoor air quality. Many of these reports deal with VOCs, including formaldehyde (ECA-IAQ reports 2 and 7), VOCs emitted from building products (reports 8, 13, 16), sick building syndrome (report 4), sampling strategies for VOCs (report 14), VOC emissions from building products (report 18), and total VOCs (report 19).

A recent study of VOC emissions from building materials included three common materials: paint, carpets, and vinyl flooring (Hodgson 1998). For the paints, the dominant VOCs were a solvent component (ethylene glycol or propylene glycol) and Texanol, a coalescent aid. The carpets emitted lower levels of VOCs, but all emitted 4-PC. Two types of carpet cushions were tested. The urethane-based cushions all emitted butylated hydroxytoluene (BHT) and a mixture of unsaturated hydrocarbons, whereas the synthetic fiber cushions emitted alkanes primarily. The vinyl flooring emitted *n*-tridecane and phenol. The associated seam sealer emitted tetrahydrofuran and cyclohexanone, and the adhesive emitted toluene.

This study also tested the effectiveness of several procedures that have been suggested for reducing exposures. Increased ventilation on the days following application of the paints resulted in decreased concentrations on those days, followed by a rise to higher levels thereafter. Similarly, heating immediately following application reduced concentrations only temporarily, with no indication that a permanent decrease had been achieved. Airing out the carpet assembly materials reduced the total exposure to some VOCs, but not 4-PC or BHT in any significant amount. Long-term emissions of Texanol from the paints were considerably reduced, but emissions of BHT from carpets tended to increase over time. BHT and TXIB emissions from vinyl flooring tended to remain constant over the 12 weeks of the study. The authors concluded that most of these procedures had limited value, and that selection of low-emitting materials showed the most promise for reducing exposures.

A major category of human exposure to toxic and carcinogenic VOCs is room air fresheners and bathroom deodorants. Since the function of these products is to maintain an elevated indoor air concentration in the home or the office over periods of weeks (years with regular replacement), extended exposures to the associated VOCs are often the highest likely to be encountered by most (nonsmoking) persons. The main VOCs used in these products are *para*-dichlorobenzene (widely used in public restrooms), limonene, and α -pinene. The first is carcinogenic to two species (NTP 1986); the second, to one (NTP, 1988); and the third is mutagenic. Limonene (lemon scent) and α -pinene (pine scent) are also used in many cleaning and polishing products, which would cause short-term peak exposures during use, but which might not provide as much total exposure as the air freshener.

Awareness is growing that most exposure comes from these small nearby sources. In California, Proposition 65 focuses on consumer products, requiring manufacturers to list carcinogenic ingredients. EPA carried out a "shelf survey" of solvents containing just six

VOCs, finding some thousands of consumer products containing the target chemicals (EPA 1987a). Environmental tobacco smoke (ETS) was declared a known human carcinogen by EPA in 1991; smoking has been banned from many public places and many private workplaces since the late 1990s.

However, an unintended result of increased consumer awareness of VOC emissions from building materials may be the replacement of some volatile and odorous chemicals with less volatile but longer-lasting chemicals of unknown toxicological properties. For example, a study of 51 renovated homes in Germany with complaints included a number in which the complaints had only begun 2 years after renovation (Reitzig et al. 1998). On investigation, a number of “new” VOCs were found, including longifolene, phenoxyethanol, and butyldiglycolacetate. These may represent a class of less traditional compounds that have been added to building materials to replace the “bad actors” identified by toxicological and carcinogenic studies; however, these compounds may themselves have toxic properties that will emerge following new studies. They have the property that instead of being emitted in large quantities shortly following application of the surface coating, they are emitted in smaller quantities at first but tend to keep a steady emission rate for much longer periods of time.

Outdoor Air

Outdoor air levels of many of the most common VOCs, even in heavily industrialized areas or areas with high densities of vehicles, are usually considerably lower than indoor levels (Wallace 1987). This fact has not been fully recognized or incorporated into regulations. For example, in the United States, the recent (1990) reauthorization of the Clean Air Act continues to deal only with outdoor air (“air external to buildings”), while adding 189 toxic chemicals to the list of those to be regulated. Many of these chemicals, which include common solvents and household pesticides, have been shown to be far more prevalent and at higher concentrations in homes than outdoors. A partial exception to this general rule was noted in a Harvard University study of the heavily industrialized Kanawha Valley in West Virginia, where outdoor levels of chloroform were quite high at times (Cohen et al. 1989, 1990).

For many hydrocarbons, the major source of outdoor air levels is gasoline vapor or automotive exhaust (Sigsby et al. 1987, Zweidinger et al. 1988). For example, about 85 percent of outdoor air benzene levels in the United States is from mobile sources and only about 15 percent from stationary sources. Exposure to certain aromatics (benzene, toluene, xylenes, ethylbenzene) while inside the automobile can exceed ambient levels by a factor of approximately 6 (SCAQMD 1989).

A “new” VOC of considerable interest and concern has arisen as a result of attempts to reduce the carbon monoxide emitted from incomplete combustion in automobiles. To improve combustion, oxidizers are required to be added to gasoline in some areas of the United States. One of the most popular of these is methyl-*tert*-butyl ether (MTBE), added to gasoline in amounts as high as 17 percent. MTBE appears to have some serious toxic effects and complaints have been received from residents of some (but not all) of the areas where it has been added to gasoline. Additionally, enough time has passed for it to have become one of the most common contaminants of groundwater. Several studies have documented the human exposure resulting from refueling autos (Pleil et al. 1998, Buckley et al. 1997).

Comparisons of Personal, Indoor, and Outdoor Air Concentrations

Benzene. Exposures to benzene have been measured for about 750 people representing about 800,000 residents of seven locations. Outdoor air levels were measured near the

homes of about 300 participants. Indoor air levels were measured in three locations in the United States. The personal exposures averaged about $16 \mu\text{g}/\text{m}^3$; the indoor air levels averaged about $10 \mu\text{g}/\text{m}^3$; and the outdoor air levels averaged about $6 \mu\text{g}/\text{m}^3$. If we assume that outdoor air infiltrates homes and workplaces with no losses as it crosses the building envelopes, then we can attribute no more than $6 \mu\text{g}/\text{m}^3$ to outdoor sources: indoor sources must have been responsible for an additional $4 \mu\text{g}/\text{m}^3$. The remaining $6 \mu\text{g}/\text{m}^3$ observed in the personal exposures must be due to personal activities such as driving or passive smoking.

About half a dozen large-scale studies of personal or indoor air levels of benzene have occurred since 1990 (Wallace 1996). They are briefly described below.

Personal Exposure Studies. In Woodland, California, a community in a largely agricultural region, 128 homes were studied (Sheldon et al. 1991). Personal, indoor, and outdoor concentrations were measured using both Tenax and evacuated canister samplers. Good agreement was noted between the side-by-side Tenax and canisters. Mean concentrations were 5.0, 4.0, and $1.2 \mu\text{g}/\text{m}^3$ for the personal, indoor, and outdoor samples.

Day and night 12-h average concentrations of benzene were measured for 58 residents of Valdez, Alaska (Goldstein et al. 1992). The mean benzene concentrations in the personal, indoor, and outdoor samples were 20, 16, and $5 \mu\text{g}/\text{m}^3$ during the summer, and 28, 25, and $11 \mu\text{g}/\text{m}^3$ during the winter, respectively.

Personal exposures to benzene were measured over a 3-h period in the evening for 49 nonsmoking females in Columbus, Ohio (Heavner et al. 1995). The median value in 25 homes with a smoker was $4.0 \mu\text{g}/\text{m}^3$, compared to $2.4 \mu\text{g}/\text{m}^3$ in 24 homes without smokers. The difference was statistically significant.

Indoor Air Studies. A nationwide Canadian study (Fellin and Otson 1993) measured 24-h indoor air concentrations of benzene in 754 randomly selected homes. Benzene mean indoor concentrations were 6.39, 5.60, 2.72, and $6.98 \mu\text{g}/\text{m}^3$ in the winter, spring, summer, and fall seasons, respectively.

Indoor and outdoor 48-hour average concentrations of benzene were measured at 161 homes throughout much of California (Wilson et al. 1993). The Pro-Tek charcoal badges formerly manufactured by DuPont were used. Indoor mean concentrations were $8.3 \mu\text{g}/\text{m}^3$, compared to $6.1 \mu\text{g}/\text{m}^3$ outdoors.

Seventeen volunteers in Windsor, Canada, wore 3-stage adsorbent tubes with pumps in three microenvironments: at home, at work, and during commuting (Bell et al. 1994). Benzene concentrations were 3.5, 4.7, and $15.7 \mu\text{g}/\text{m}^3$ in these three locations during summer 1991 and 2.7, 2.7, and $15.1 \mu\text{g}/\text{m}^3$ during winter 1992. Outdoor levels near homes were 3.8 and $2.0 \mu\text{g}/\text{m}^3$ during summer and winter, respectively. A later study (summer 1992) considered various microenvironments. Benzene levels averaged $2.2 \mu\text{g}/\text{m}^3$ in homes of 26 asthmatics, $4.6 \mu\text{g}/\text{m}^3$ in 13 samples from hotel rooms, $6.0 \mu\text{g}/\text{m}^3$ in 17 samples collected during commuting, $20.8 \mu\text{g}/\text{m}^3$ in 39 samples from four bingo halls, and $34.5 \mu\text{g}/\text{m}^3$ in two taverns.

Brown and Crump (1996) reported on a study of 173 homes in Avon, England. Passive Tenax tubes (Perkin-Elmer) collected 28-day samples in the living room and main bedroom of the home for one year. Thirteen sets of 12 month-long outdoor samples were also collected over the course of the study (Nov. 1990 to Feb. 1993). The mean indoor concentration was $8 \mu\text{g}/\text{m}^3$ ($N = 3000$ samples), compared to an outdoor mean of $5 \mu\text{g}/\text{m}^3$ ($N = 125$).

Ambient Concentrations. Benzene concentrations were reported for 586 ambient air samples collected from 10 Canadian cities (T. Dann, unpublished data, Environment Canada). The overall mean was $4.4 \mu\text{g}/\text{m}^3$, with Ottawa and Montreal ranging between 5.1 and $7.6 \mu\text{g}/\text{m}^3$. A more recent survey (Dann and Wang, unpublished report, Environment Canada) found similar levels, with three rural sites ranging from 0.6 to $1.2 \mu\text{g}/\text{m}^3$.

Throughout the state of California, 24-h average benzene levels have been measured every 12th day at about 20 sites since 1986. Statewide average annual values fluctuated

between 5 and 7 $\mu\text{g}/\text{m}^3$ until 1993 and 1994, when they dropped to about 4 $\mu\text{g}/\text{m}^3$. This decline appears to be real, and may be due to one or more of several factors: (1) the 50 percent reduction in hydrocarbon emissions mandated for new cars; (2) the stage II vapor recovery controls recently in effect; (3) a reduction in benzene content in gasoline down to the 1 percent mandated in the 1990 Clean Air Act amendments.

The California database also allows analysis of seasonal variation. A clear sinusoidal curve is apparent, with winter values about twice summer values. This may be due to changes in the blend of the gasoline toward greater volatility in the winter or to increased likelihood of inversions during the winter.

In-Vehicle Studies. The largest study of in-vehicle benzene exposure continues to be the 200-trip study (SCAQMD 1989) of Los Angeles commuters carried out in the summer and winter seasons. This study found an average benzene exposure of 13 ppb (40 $\mu\text{g}/\text{m}^3$) for commuters during rush hour, on the order of 5 times the concentration measured at a fixed outdoor site.

A small study in North Carolina (Chan 1990) also showed in-vehicle concentrations 3–8 times background ambient levels. A second small study in Boston (Chan et al. 1991) resulted in passenger levels 1.5 times roadway levels on an interstate highway.

More recently, a study (Weisel et al. 1992) of benzene levels in two passenger vehicles during typical commutes in the New Jersey–New York area resulted in measured exposures of 9 to 12 $\mu\text{g}/\text{m}^3$ in suburban and turnpike conditions, and 26 $\mu\text{g}/\text{m}^3$ in the Lincoln Tunnel. The author stated that the concentrations during the commutes to New York City were about 10 times the ambient background concentration measured the same day in suburban New Jersey.

Unfortunately, none of the studies measured the benzene concentration in the gasoline used, so it is not possible to determine whether the lower concentrations in the later studies might be due to lower amounts of benzene in gasoline.

Gasoline Spill Study. A study of exposure to benzene while showering with gasoline-contaminated groundwater (Lindstrom et al. 1994) was carried out in a home in North Carolina. The groundwater had a measured benzene concentration of 292 $\mu\text{g}/\text{L}$, well above USEPA's maximum contaminant level of 5 $\mu\text{g}/\text{L}$. Three 20-min showers on consecutive days resulted in peak shower stall concentrations of 800 to 1670 $\mu\text{g}/\text{m}^3$. Bathroom concentrations reached 370 to 500 $\mu\text{g}/\text{m}^3$, and concentrations in the remainder of the house peaked (0.5 to 1 h later) at 40 to 140 $\mu\text{g}/\text{m}^3$. The inhalation dose during the 20-min shower ranged from 80 to 100 μg . A dermal dose of 160 μg was also calculated, using measured breath concentrations. The combined dose of about 250 μg from the 20-min shower is roughly equal to the mean total daily inhalation dose of about 200 μg for all nonsmokers in the TEAM study (assuming 15 $\mu\text{g}/\text{m}^3 \times 14 \text{ m}^3/\text{day}$ alveolar inspiration).

Active Smoking. Based on measurements of benzene in mainstream cigarette smoke (Higgins et al. 1983), Wallace (Wallace 1987, Wallace et al. 1988) has estimated that mainstream smoke contributes about 1.8 mg/day to the average smoker's intake of benzene. This corresponds to an average *additional* exposure for smokers of about 90 $\mu\text{g}/\text{m}^3$ (assuming 20 m^3/day respiration rate). Since there are about 50 million smokers in the United States, the total benzene exposure for them is roughly equal to the total benzene exposure from all other sources for the remainder of the population.

Passive Smoking. Studies of 500 homes in both the United States (Wallace et al. 1987) and Germany (Krause et al. 1987) have indicated that homes with smokers have median indoor air benzene concentrations about 3 to 4 $\mu\text{g}/\text{m}^3$ higher than in homes without smokers. Since at least half of U.S. homes contain smokers, we can calculate that about 2 $\mu\text{g}/\text{m}^3$ is contributed, on average, by passive smoking.

Automobile Travel. The SCAQMD study in California (SCAQMD 1989) indicates that automobile interior concentrations of benzene during commutes in Los Angeles average about 13 ppb (40 $\mu\text{g}/\text{m}^3$). The same concentration was estimated based on the

TEAM studies in California (Wallace et al. 1989). Assuming these levels are applicable to the rest of the country, and assuming about one hour per day in the automobile, this exposure would contribute roughly another $2 \mu\text{g}/\text{m}^3$ to average exposure. Besides traveling in autos, filling gas tanks could contribute a portion of benzene exposure, although the total estimated contribution is only $0.2 \mu\text{g}/\text{m}^3$ (about 10 percent of the effect of automobile travel).

Attached Garages. Gammage et al. (1984) and McClenney et al. (1986) reported finding gasoline vapor in homes with attached garages. This could arise from evaporative emissions following parking, or from storage of gasoline in the garage. A study of four homes with attached garages (Thomas et al. 1993) showed that three of the homes received extensive emissions from gasoline vapors or exhaust in the garage.

Products and Materials. More than 200 products and materials were found to emit benzene in studies carried out by NASA (Nuchia 1986). Sheldon et al. (1988a, 1988b) found benzene being emitted from several paints and adhesives, although indoor concentrations in two buildings constructed from these materials were not elevated. Thus these sources may contribute to exposure, although no estimates have been made of the contribution of products and materials to personal exposure.

Occupational. Workers in the chemical, manufacturing, and transportation industries may be exposed to elevated levels of benzene. A number of occupations were associated with significantly elevated benzene exposures in the TEAM studies (Wallace 1987).

Outdoor Air. A study of morning rush-hour (6AM-9AM) concentrations of benzene in 39 cities (Seila 1987) gave a median concentration of $6 \mu\text{g}/\text{m}^3$, agreeing well with the mean value of $6 \mu\text{g}/\text{m}^3$ observed over 24-h periods in residential areas in the TEAM study. The major sources of benzene in the atmosphere are mobile sources (auto exhaust and evaporative emissions) and industrial (petroleum refineries, petrochemical manufacturing, coke ovens) sources. Mobile sources appear to be more important than stationary sources in contributing to outdoor benzene levels. For example, in the 39-city study, cities with heavy petrochemical industries such as Houston, Texas (ranked 7th); Beaumont, Texas (17th); Lake Charles, Louisiana (19th); and Orange, Texas (31st) were not particularly elevated in benzene concentrations. Other estimates of emissions attribute about 85 percent of emissions to mobile sources, 15 percent to stationary sources.

Residence Near Industry. The first TEAM study (Wallace et al. 1987) found no difference in benzene exposures of 150 subjects living within 1 km of chemical and petroleum refineries in Bayonne and Elizabeth, NJ, compared to 150 subjects living more than 1 km distant. Since such facilities are concentrated in only a few places in the United States, even a positive finding would have little effect on the nationwide average exposure to benzene.

Food. Although a number of publications have referred to benzene in vegetables, meat, and eggs, the TEAM study found little evidence that diet made any difference in benzene levels in breath. Since the same breath measurements were conclusive in identifying smoking as an important source, the absence of an effect suggests that food cannot be an important source of exposure to benzene. A recent study of benzene levels in 30 foods found trace levels only in all foods except red wine and peanuts (API 1992).

Wood Smoke. Few measurements are available to allow an estimate of the importance of wood smoke on benzene exposure. Since only a few localities use wood burning to an appreciable extent, and then for only a few months of the year, wood smoke should not make an appreciable contribution to nationwide average exposure to benzene.

Summary: Sources of Benzene Exposure. From the considerations described above, we can construct a nationwide benzene exposure budget (Table 33.5) apportioning the observed benzene exposures to the most important sources. The results indicate that smoking accounts for roughly half of the exposure, with the remaining half split fairly evenly between personal activities (≈ 30 percent) and the traditional outdoor sources (≈ 20 percent).

On the other hand, emissions present a very different picture. The traditional sources—motor vehicles and industry—account for 99 percent of the total emissions, compared to 1

TABLE 33.5 Benzene Exposure Budget: Major Sources of Benzene Exposure and Risk

Activity	Intake, $\mu\text{g/day}$	Population at risk, $\times 10^6$	Total risk, %
Smoking	1,800	53	50
Unknown personal	150	240	20
Ambient	120	240	20
Passive smoking	50	190	5
Occupational	10,000	0.25	1
Filling petrol (gas) tank	10	100	<1

percent from cigarettes and materials. The relative importance of these different sources are compared for emissions and exposures in Fig. 33.1.

These findings have important effects on our regulatory and control strategies. For example, if emissions from all stationary sources were reduced by a draconian 50 percent, the total reduction in population exposure would be an unnoticeable 2 percent ($50 \times 15 \times 20$ percent). The same total effect (although affecting different people) could be achieved by reducing the average benzene content of cigarettes by 4 percent (from 57 to 55 $\mu\text{g/m}^3$). The idea of trading in exposure rather than emissions is described in Roumasset and Smith (1990), based on earlier work by Smith (1988a).

Tetrachloroethylene. Exposures to tetrachloroethylene are compared to outdoor levels in Table 33.6. The difference between personal exposures and outdoor concentrations is even more striking than for benzene, with outdoor air providing only about 20 percent of total exposure. Unlike benzene, however, tetrachloroethylene has few sources of exposure. The main source of exposure for most people is probably dry-cleaned clothes.

Dry-Cleaned Clothes. Early TEAM studies showed that tetrachloroethylene levels were higher among employed people, suggesting that exposure to one's own or to coworkers' dry-cleaned clothes could be important. A later TEAM study (Thomas et al. 1991a) has indicated that tetrachloroethylene levels in homes increase by factors of 100-fold (to levels exceeding 100 $\mu\text{g/m}^3$) following the introduction of dry-cleaned clothes into the home. (The study also indicated that indoor air levels decrease when the clothes are removed from the home and increase when they are put back, thus supporting the notion that "airing out" the clothes on a balcony or patio before introducing them into the home can be effective in reducing exposure.) The same study showed that wearing the clothes also increased personal exposure. Finally, a small but noticeable source of exposure occurs during the few minutes the clothes are being picked up at the dry-cleaning shop; earlier TEAM studies (Pellizzari et al. 1984) indicated that levels in dry-cleaning shops varied between 10,000 and 20,000 $\mu\text{g/m}^3$. Thus a 5-min exposure would provide as much tetrachloroethylene as would 5 days of normal exposure. The contributions to total exposure of these four sources (the home, the office, the dry-cleaning shop, and the outdoors) are assessed in Table 33.7.

More recently, a series of studies of indoor air and body burden of persons living in the same building with a dry cleaner have documented large and chronic exposures (Schreiber 1992, 1993; Schreiber et al. 1993). Because tetrachloroethylene is highly lipophilic and long-lived in the human body, it tends to concentrate preferentially in breast milk—Schreiber documented large concentrations in breast milk of persons living in apartments above dry-cleaning shops in New York City.

Outdoor Air. The main use of tetrachloroethylene is as a dry-cleaning solvent—a majority of U.S. dry-cleaning shops employ tetrachloroethylene as the primary solvent. Thus the dry-cleaning shop is considered the major source of outdoor tetrachloroethylene. However,

33.16

FIGURE 33.1 Benzene emissions versus exposures.

these emissions account for no more than 20 percent of total exposure. Thus, reducing emissions from dry-cleaning shops by our unrealistic factor of 50 percent would result in a barely noticeable 10 percent reduction in exposure. The same reduction might be achievable if people hung their dry cleaning outside for an 8-h period before taking it into the house. The major sources of exposure are compared to the major emission sources in Fig. 33.2.

para-Dichlorobenzene. Results from six TEAM study cities showed that *para*-dichlorobenzene (*p*-DCB) was almost exclusively an indoor air pollutant, outweighing outdoor air by more than 20:1. Assuming that one-third of homes contain *p*-DCB, we may

calculate that users of these products are increasing their exposures by factors of roughly 60 compared to nonusers.

Sources of Exposure. This chemical has two major uses: to mask odors and to kill moths. Both uses require that the chemical maintain a high concentration in the home for periods of months or even years. A large number of American homes may contain high levels of *p*-DCB. Many schools, offices, hotels, and other places with public restrooms also use *p*-DCB to mask odors.

About 12 million pounds annually is used to kill moths. An estimated 25 percent of American households contain mothballs, moth crystals, or moth cakes formed from nearly pure *p*-DCB, although only 12 percent of TEAM study homes in Baltimore and Los Angeles reported having moth repellents in their homes.

About 70 percent of TEAM study homes in Baltimore and Los Angeles reported using air fresheners or bathroom deodorants. *Para*-dichlorobenzene accounts for a fraction of the air freshener market (perhaps 10 percent). Assuming that 25 percent of homes have *p*-DCB moth repellents and an additional 7 percent have *p*-DCB air fresheners, we may calculate that about a third of the 85 million homes in the United States contain *p*-DCB.

In 1986, following a 2-year test of male and female rats and mice, the National Toxicology Program announced that *p*-DCB caused several different types of malignant tumors in both sexes of the mice and in male rats (NTP 1986). Traditionally, when a chemical causes cancer in two different species of mammals, it is considered a probable human carcinogen. In this case, because the tumors occurred in the male rat kidney and the mouse liver, both of which have been questioned for their relevance to human cancer, *p*-DCB has been provisionally classified as a possible human carcinogen.

33.18

FIGURE 33.2 Tetrachloroethylene: emissions versus exposures.

Total VOCs (TVOCs). At any given time, air in a home may contain scores or hundreds of VOCs at low concentrations. Some researchers have hypothesized that the complex mixture itself may have health effects that the individual components do not when administered singly (Mølhave 1987). Several studies have measured TVOCs both indoors and outdoors, and all find indoor levels higher than outdoors (Mølhave 1986, Valbjørn and Skov, 1987, Wallace et al. 1991b). Personal air samples ($N = 1500$) had a geometric mean of 1.1 mg/m^3 , compared to indoor ($N = 198$) and outdoor ($N = 371$) concentrations of 0.7 and 0.3 mg/m^3 , respectively (Wallace et al. 1991c). These values, obtained by summing the area under the curve of a chromatogram and multiplying by an average response factor for about 20 tar-

get compounds, are somewhat higher than has been observed by other researchers using different TVOC sampling and analytic methods; however, even these values are much less than the actual total organic loading, since the Tenax collects only a subset of nonpolar compounds within a certain window of volatility.

Other Routes of Exposure

Drinking Water. In areas that chlorinate their drinking water, chlorination by-products such as chloroform and other trihalomethanes (THMs) contaminate the finished water (Rook 1974, 1976, 1977; Bellar and Lichtenberg 1974; IARC 1991). The discovery of chloroform in the blood of New Orleans residents (Dowty et al. 1975) led to the Safe Drinking Water Act (SDWA) of 1974, which set a limit of 100 $\mu\text{g/L}$ for total THMs in finished water supplies.

A series of nationwide surveys of THM levels in water supplies have been carried out in the United States since the passage of the SDWA. The National Organics Reconnaissance Survey of 80 treatment plants (Symons et al. 1975) indicated that about 20 percent exceeded the THM standard of 100 $\mu\text{g/L}$. A more recent survey of 727 utilities (McGuire and Meadow 1988) representing more than half of consumers indicated that only about 3.6 percent of water supplies surveyed continued to exceed the standard.

In succeeding years, it has become more evident that THM exposure occurs in ways other than drinking chlorinated water. Since treated water is normally used for all other household purposes, volatilization from showers, baths, and washing clothes and dishes is an important route of exposure. Studies of experimental laboratory showers by Andelman (1985a, 1985b, 1990; Andelman et al. 1986, 1987) resulted in the estimate that chloroform exposure from volatilization during a typical 8-min shower could range from 0.1 to 6 times the exposure from drinking water from the same supply, depending on the amount of water ingested per day. Other studies of full-scale showers corroborate these conclusions, with estimates of exposure equivalent to ingestion of 1.3 to 3.7 L/day of tap-water at the same concentrations as the water in the shower (Hodgson et al. 1988; Jo et al. 1990a, 1990b; McKone 1987; McKone and Knezovich 1991; Wilkes et al. 1990). Inhalation of airborne chloroform during the rest of the day was also found to be comparable to ingestion, based on measurements of 800 persons and homes in the TEAM study. Weisel and Chen (1993) found that water kept in hot-water heaters overnight increased the chloroform levels by 50 percent. Wallace (1997) summarized the scientific literature on human exposure to chloroform through all routes (inhalation, ingestion, dermal absorption). Corsi and Howard (1998) studied volatilization of five compounds from baths, showers, washing machines, and dishwashers.

Food and Beverages. Food and beverages made from treated water (ice cream, soft drinks) have been found to contain chloroform and other THMs (Entz et al. 1982). Some natural components of fruits and vegetables, such as limonene, have been found to be mutagenic and/or carcinogenic in animal testing (NTP 1988). Although benzene has been reported at high levels in certain foods (Pearson and McConnell 1975), more recent investigations (API 1992) have failed to find benzene in any of a large number of foods tested from various food groups. Margarine and butter in supermarkets have been found to absorb tetrachloroethylene from nearby dry cleaners (Uhler and Diachenko 1987), and trichloroethylene from the glue in the containers (Entz and Diachenko, 1988). Some chlorinated chemicals were found in food in Germany (Bauer 1981).

Dust and Soil. A few studies (Hodgson et al. 1988) indicate that migration of VOC through soil from hazardous-waste sites or municipal landfills could contribute to exposure of nearby residents. Organics contained in soil could be absorbed through the skin;

McKone (1990) estimates that for benzene in soil on the skin, uptake would be less than 3 percent over a 12-h period.

Dermal Absorption. Several studies in Italy and the United States indicate that dermal absorption during showers, baths, or swimming at indoor pools or spas may be an important route of exposure to VOC in treated water. Early studies by Stewart and coworkers (Hake et al. 1976, Hake and Stewart 1977, Stewart and Dodd 1964) provided absorption coefficients for human volunteers who immersed their hands in pure solvents such as tetrachloroethylene. Experimental studies on animals (Bogen et al. 1992, Shatkin and Brown 1991) provided absorption coefficients for more realistic situations involving dilute solutions. One study of swimmers (Aggazzotti et al. 1990) measured high concentrations of chloroform in blood, but could not disentangle the contributions of inhalation and dermal absorption. Two later studies estimated a dermal contribution while swimming of 25 percent (Levesque et al. 1995) and 75 percent (Lindstrom et al. 1997). A study of chloroform in exhaled breath of volunteers showering both with and without rubber suits (Jo et al. 1990a, 1990b; Weisel and Jo 1990) indicated that dermal absorption during the shower provided about 50 percent of total exposure. A later study of the influence of bath water temperature on dermal exposure provided a hypothesis explaining the varying findings of the three studies: increased blood flow to the skin during either hot showers or physical activity can increase dermal absorption of chloroform by a factor of 30 as bath water temperatures increase from 30 to 40°C (Gordon et al. 1998). In the case of the Levesque study (25 percent dermal absorption), the swimming-pool water was cool and the swimmers were exercising only moderately. In the Pleil study (75 percent dermal absorption), the swimmers were undergoing agonistic Olympic training. In the Jo et al. study, the shower water was at a high temperature of 41°C, leading to increased blood flow to the skin to promote faster heat loss. Thus the finding of Gordon et al. (1998) of the importance of increased blood flow is able to explain the differing results of the three studies.

33.4 BODY BURDEN

Measurement of body burden provides a direct indication of the total dose through all important environmental pathways. Coupled with adequate pharmacokinetic models (Ramsey and Andersen 1984) including knowledge of how the VOC partitions between blood, air, and fat (Sato and Nakajima 1979), measurement of a single body fluid such as breath or blood can give an indication of the total body burden and sometimes even an indication of the mode of exposure. For example, the breath measurements of smokers in the TEAM study indicated that they were exposed to 6 to 10 times as much benzene as nonsmokers. The personal air quality monitors had been unable to document this increase, since most of the exposure came from direct smoking with no external pathway.

Breath

For many VOCs, the most sensitive method of determining body burden is measurement of exhaled breath. Detection limits using Tenax sorbents or evacuated canister samples are usually well under 1 $\mu\text{g}/\text{m}^3$. For comparable sensitivity, blood measurements would have to detect levels as low as 10 ng/L. Early breath measurements at environmental (ppb) levels were made by Krotoczynski (1977, 1979), who measured levels of more than 50 VOC

in the breath of 54 healthy nurses. Additional measurements were made of 800 participants in the TEAM study (Wallace 1987, Wallace et al. 1991a). These measurements first documented the overwhelming importance of smoking as a source of exposure to benzene and styrene.

Although it is true that breath measurements reflect only the most recent exposure, it is also true that if the time of taking the breath measurement is carefully chosen, it can reflect long-term exposure. That is, persons who have been in their normal environment for a few hours are not likely to be far out of equilibrium with their surroundings (provided the exposure of their previous environment was not vastly different). Also, some experimental studies using room-size chambers (Gordon et al. 1988, 1990) or specially designed spirometers (Raymer et al. 1991) have determined the residence times of more than a dozen VOCs in various “compartments” of the body: blood (2 to 10 min), tissues rich in blood vessels (1 to 2 h), and “vessel-poor tissues” (4 to 8 h). An effort to reconstruct previous exposures from a breath measurement together with a PBPK model was described recently by Roy and Georgopoulos (1998).

Blood

Blood measurements at occupational levels have been made for many years (Monster and Houthooper 1979; Monster and Smolders 1984). Blood measurements at environmental levels have been done for chloroform (Aggazzotti et al. 1990, Pfaffenberger and Peoples 1982) and benzene (Brugnone et al. 1987). The 1989–1993 National Health and Nutrition Examination Survey (NHANES III) included 1000 persons whose blood was analyzed for a dozen of the most prevalent VOCs (Ashley et al. 1992, 1994, 1996).

33.5 CARCINOGENIC RISK

Some VOCs are considered to be human carcinogens (e.g. benzene, vinyl chloride). Others are animal carcinogens and may be human carcinogens (methylene chloride, trichloroethylene, tetrachloroethylene, chloroform, *p*-dichlorobenzene). Others are mutagens (α -pinene) or weak animal carcinogens (limonene).

At present, methods of assessing carcinogenic risk are widely viewed as unsatisfactory. One method is to use the results of long-term animal studies to establish the carcinogenic potency of a given chemical (Gold 1984), and then to extrapolate from animals to man and from high doses to low doses, assuming that there is no threshold. These twin extrapolations are the weak points of the method. For example, one species may have a completely different metabolic pathway than another, or may have a better mechanism of DNA repair, which could lead to an effective threshold. These uncertainties are such that a given chemical may not cause human cancer at all—the actual cancer risk may be zero despite a high upper-bound estimate.

A second method is to use short-term animal toxicity studies to estimate carcinogenic potential. This is based on the assumption that toxicity is correlated with carcinogenicity (Zeise et al. 1986). If the assumption holds, this greatly increases the number of chemicals that can be considered, since many more toxicity studies have been done than carcinogenicity studies. However, the same uncertainties apply—plus the additional uncertainty of the basic assumption of toxicity as correlated with carcinogenicity.

In the United States, the first method has been employed in a standardized way by the U.S. Environmental Protection Agency (USEPA) to estimate upper limits of the carcinogenic potencies of more than 50 chemicals, including a number of VOCs. Since the method

chooses the most conservative assumption at each of several points (only the results from the most sensitive animal species are used to extrapolate to humans; the dose-response curve giving the highest measure of risk at environmental concentrations is employed) the resulting potency is considered to be an upper-bound estimate—the true potency is unlikely to be greater, but could very well be smaller. A failing of this method is that it provides no best estimate—only an upper limit.

Several attempts to estimate risk from certain VOCs have been based on the first method above (Wallace 1986) or on the second (Tancrede et al. 1987), or on both (McCann et al. 1987). Since all these assessments depended on results from the TEAM study for estimates of population exposure, they tend to agree fairly well on the VOCs with the highest population risk: benzene, chloroform, and *p*-dichlorobenzene.

In a more recent estimate of risk (Wallace 1991b), six VOCs exceeded the de minimus or negligible lifetime risk level of 10^{-6} (one chance in a million of contracting cancer) by a factor of 10 or more: benzene, vinylidene chloride, *p*-dichlorobenzene, chloroform, methylene chloride, and carbon tetrachloride (Table 33.8).

Indoor sources accounted for the great majority (80 to 100 percent) of the total airborne risk associated with most of these chemicals. Carbon tetrachloride is the only one of these chemicals for which outdoor sources account for a majority of the airborne risk, because it had been banned from consumer products by the U.S. Consumer Product Safety Commission. However, its long life in the atmosphere has led to a global background sufficiently high to result in a nonnegligible risk.

Only one of these chemicals is considered a human carcinogen: benzene. Therefore the risk estimate associated with benzene is on more solid ground than any of the others. Benzene is also the only one of the chemicals with human epidemiologic studies showing a possible influence of environmental levels of exposure on cancer risk; two studies show that children of smokers die of leukemia at 2 or more times the rate of children of nonsmokers (Sandler et al. 1985, Stjernfeldt et al. 1986). The higher mortality rate is consistent with the measured elevated levels of benzene in the breath of smokers (suggesting exposure of the fetus in the womb of the pregnant smoker). Elevated levels of benzene in the air of homes have also been documented by both the TEAM study and the study in Germany (Krause et al. 1987); however, the increase (on the order of 50 percent in both studies) does not seem enough to explain the increase in the mortality rate unless children are more susceptible to benzene-induced leukemia at some point in the first 8 to 9 years of life.

33.6 ACUTE HEALTH EFFECTS

Many common VOCs have well-documented health effects, often neurobehavioral, at high (occupational) concentrations. Acute effects at lower environmental concentrations are often difficult to observe under controlled conditions, although Mølhave and coworkers (Mølhave and Møller, 1979; Mølhave 1982, 1986; Mølhave et al. 1984, 1986) was able to observe some subjective effects such as reported headache using a mixture of 22 common VOCs at a total concentration of 5 mg/m^3 , which is high but is sometimes encountered in new or renovated buildings. The EPA later confirmed these findings (Otto et al. 1990).

Despite the difficulty of observing effects under controlled conditions, a very common worldwide phenomenon is the sickening of large numbers of workers following occupation of a new or renovated building (Berglund et al. 1984, Wilson and Hedge 1987, Zweers et al. 1990, Sundell et al. 1990, Stenberg et al. 1990, Preller et al. 1990). Since such new buildings have very high levels of VOCs for a period of 6 months or more after completion, the

TABLE 33.8 Upper-Bound Lifetime Cancer Risks of 12 VOCs Measured in the TEAM Studies (1980–1987)

Chemical	Exposure, ^a μg/m ³	Potency, μg/m ³ -1 (×10 ⁻⁶)	Risk (×10 ⁻⁶)	Outdoor air concentration, ^b μg/m ³

^aArithmetic means based on 24-h average exposures of ≈750 persons in six urban areas measured in the TEAM studies.

^bBased on backyard measurements in 175 homes in six urban areas.

^cThe risk estimates for benzene are based on human epidemiology and are therefore mean as opposed to upper-bound estimates.

^dSix measurements exceeding 1000 μg/m³ dropped from the calculation; inclusion of the measurements leads to an average exposure of 150 μg/m³.

^eThese figures are in μg/L or ppb rather than μg/m³.

^fBased on only eight 24-h measurements in 1987.

^gData from EPA (1983).

so-called sick building syndrome (SBS) (Mølhave 1987) has been thought to be a possible effect of VOC exposure.

However, only one study has succeeded in linking a VOC-based metric to SBS symptoms (Ten Brinke et al. 1998). In this study of 12 buildings in California without perceived health problems, seven different VOC-based metrics, such as total VOC (TVOC) and irritancy-weighted VOC, were tested using multivariate regression analysis for their effect on reported symptoms. Only one of the seven metrics showed relatively strong significant correlations with multiple reported symptoms, including eye, nose, throat, and skin irritation: a principal-components vector identified in association with carpet emissions (with styrene as the VOC with the highest loading) and with cleaning products (2-butoxyethanol and 2-propanol having the highest loadings).

Ironically, the EPA headquarters building itself was felt to be a sick building by many workers in the 1980s, leading to a comprehensive study (EPA 1989a, 1989b, 1990; Wallace et al. 1991b, 1993a, 1995). One conclusion of the study was that perceived dust exposure was associated with the largest number of symptom groupings. This was also the conclusion of the Danish Town Hall study (Gravesen et al. 1990; Skov et al. 1989, 1990).

A similar, more serious, syndrome, *multiple-chemical sensitivity* (MCS), has also been suggested to be a result of VOC or pesticide exposure, either chronic or following a single massive dose. A comprehensive recent review of MCS is found in Ashford and Miller (1997).

A less serious but possibly very costly result of VOC exposure may be reduced productivity resulting from minor ailments such as headache and eye irritation. The total annual cost of poor indoor air quality has been estimated to be in the neighborhood of \$100 billion (Fisk et al. 1997).

33.7 DISCUSSION

For each chemical discussed above, the “traditional” sources of emissions (mobile sources, industry) have accounted for only 2 to 20 percent of total human exposure. This same conclusion has been documented for a number of other volatile organic chemicals: styrene, xylenes, ethylbenzene, trimethylbenzenes, chloroform, trichloroethylene, α -pinene, limonene, decane, undecane, etc. (Wallace 1987, Sheldon 1988). For most of these chemicals, the major sources of exposure have been identified (personal activities, consumer products, building materials), but cannot be regulated under existing environmental authorities.

This situation has led to a peculiar split in the perception of risk. The public perceives indoor air pollution as considerably less risky than, say, hazardous-waste sites (Smith 1988b) whereas experts at EPA put indoor air and consumer product exposure at the top of the list of health risks, with hazardous-waste sites near the bottom (EPA 1987a, 1987b, 1989a). Nonetheless, the amount of resources devoted to these two problems reflects the public perception, not that of the experts.

How can this situation be rectified? A continuing process of consumer information and media attention may ultimately result in greater public awareness of the problem. Some steps to reduce exposure can be taken by the public without waiting for cumbersome government attempts at regulation. Other actions, such as setting up consensus guidelines, can be taken by professional organizations, such as ASHRAE (ventilation requirements) and ASTM (standardized testing for organic emissions from building materials). Information on the economic impacts of indoor air pollution may ultimately convince employers to improve their employees’ working conditions. Market forces may also play a role—manufacturers may find substitute chemicals or processes leaving less residue in their products, if the public demands it.

We have seen that in every case the major sources of exposure to these four chemicals have been small but nearby: cigarettes (benzene), air fresheners (*p*-dichlorobenzene), dry-cleaned clothes (tetrachloroethylene), and the shower (chloroform). These sources are different from those that have usually been implicated. While these findings indicate that we have been (and still are) pursuing the “wrong” (i.e., less important) sources, they also point the way to a more efficient control of exposure to these carcinogens. For example, the exposure of children (and that of fetuses) to benzene from mothers’ smoking may be reduced by warning women of this risk. Advising consumers of air freshener ingredients and their possible human carcinogenicity could reduce exposure to *p*-DCB. “Airing out” dry-cleaned clothes and ventilating bathrooms while showering could reduce exposure to tetrachloroethylene and chloroform, respectively, at very little cost.

However, these consumer-oriented recommendations can be effective only if they can be efficiently communicated. At present, few of these findings appear to be general knowledge. Organizations such as the American Lung Association have been in the forefront in trying to communicate this information. The USEPA has completed a booklet on these and other sources of indoor air pollution aimed at the consumer. It would also be helpful if medical organizations could join in the communication of this information to physicians and through them to their patients.

33.8 SUMMARY

A general rule of VOC concentrations appears to be that personal exposures > indoor concentrations > outdoor concentrations, often in the ratio of about 3:2:1.

Probably the one central finding of all of these studies has been the following: *The major sources of exposure to all chemical groups studied have been small and close to the person—usually inside that individual's home.* This finding is so at odds with the conventional wisdom—that the major sources are industry, autos, urban areas, incinerators, landfills, and hazardous-waste sites—that it seems safe to say that most decisionmakers have not yet grasped its import. For example, if these studies are correct, it makes little sense to spend millions of dollars a year monitoring the outdoor air, since so little of our exposure is provided by that route. Similarly, the present allocation of research for outdoor air versus indoor air (about \$50 million to \$2 million) appears out of balance. Moreover, the main control options—national air quality standards or emission controls—obviously would need to be replaced by more innovative approaches. One such approach—exposure trading, in which the “currency” is units of human exposure rather than the more common units of source emissions—has been outlined.

Long-term health effects may include cancer. However, with the exception of benzene, a human carcinogen, most other prevalent VOCs are not known to cause human cancer, and risk estimates are highly uncertain. However, the possible acute effects of VOCs include reduced productivity, which alone has been estimated to cost the nation on the order of scores of billions of dollars annually. If SBS or MCS ultimately prove to be caused or exacerbated by VOC exposure, additional costs would be due to indoor VOC exposures.

CHAPTER 34

POLYCYCLIC AROMATIC HYDROCARBONS, PHTHALATES, AND PHENOLS

Ruthann Rudel, M.S.

*Silent Spring Institute
Newton, Massachusetts*

Chemicals identified as indoor air pollutants include naturally occurring agents such as radon gas, products of combustion such as environmental tobacco smoke, and chemicals present in consumer products and building materials. Other chapters in this book have discussed certain volatile organic compounds, pesticides, PCBs, aldehydes, fibers, environmental tobacco smoke, and radon.

This chapter presents available data on indoor air concentrations for polycyclic aromatic hydrocarbons (PAHs), phthalates, and selected phenolic compounds, and summarizes the potential health effects from exposure to these compounds. PAHs, which are products of incomplete combustion, have long been known to be important indoor air pollutants and have been identified as carcinogens since the late nineteenth century. Measurements of phthalates and phenols show relatively high concentrations of these compounds in indoor environments, and new evidence of their ability to disrupt normal hormone signaling systems has focused attention on their potential for causing endocrine-mediated adverse health effects.

In addition to the PAHs, phthalates, and phenols that are the focus of this chapter, and the agents covered in other chapters, many other chemicals may be important contaminants of indoor environments. For example, of the 3000 chemicals produced in the United States at over 1 million pounds per year, almost 500 are identified as consumer product chemicals (USEPA 1999a). No doubt many of these chemicals and their degradation products are contaminants of indoor environments, and exposure assessment efforts in the future will be necessary to identify those of particular importance for human health.

34.1 SOURCES AND MEASURED CONCENTRATIONS IN AIR

PAHs

Polycyclic aromatic hydrocarbons (PAHs) are products of combustion processes and are also formed during high-temperature processing of crude oil. PAHs represent a large family of compounds that contain multiple benzene rings that share a pair of carbon atoms. Figure 34.1 shows the chemical structures of some common PAHs. The three- and four-ringed PAHs are

Naphthalene

Chrysene

Benzo[a]pyrene

Phenanthrene

1,8-Dinitropyrene

FIGURE 34.1 Selected PAHs and nitro-PAHs.

more volatile than the five- to seven-ring PAHs, and so are typically found in air at higher concentrations. These smaller PAHs are present in the vapor phase while five- to seven-ring PAHs occur in air in the particulate phase (Sheldon et al. 1992). Naphthalene, which is the smallest and most volatile of the PAHs, consists of just two fused benzene rings.

Major sources of these compounds in indoor air include emissions from the combustion of wood or other fuel for residential heating (e.g., kerosene heaters, wood or coal stoves, fireplaces), unvented gas appliances, environmental tobacco smoke, and fumes from cooking, grilling, and frying (Dubowsky et al. 1999, National Toxicology Program 1998, Schwarz-Miller et al. 1998, Shuguang et al. 1994). Basement and foundation soil contaminated by diesel oil or heating oil, for example, from a leaking oil storage tank, is also likely to generate elevated indoor air concentrations of vapor-phase PAHs, although no publications reporting measured levels were located.

In addition, major outdoor sources of PAH emissions, such as automobiles and power plants, increase PAH concentrations in outdoor air and, in turn, affect levels indoors. In a study in southern California, a strong correlation was observed between indoor and outdoor concentrations of PAHs, indicating that in the absence of major indoor combustion sources (e.g., smoking, heating), outdoor PAHs make a substantial contribution to indoor PAH levels (Sheldon et al. 1992). Diesel vehicles contribute significantly to PAH pollution beyond the impact of automobiles—60 to 84 percent of PAH emissions from traffic in one urban study were from diesel vehicles (Lim et al. 1999). Traffic was again identified as a major source of indoor PAHs in urban, suburban, and rural locations in a separate study of non-smokers' homes (Dubowsky et al. 1999).

Nitroarenes or nitro-PAHs are a related family of compounds that are also products of combustion. These compounds have been identified in stack gases from coal-fired power plants and other stationary sources as well as from diesel and gasoline engines. Levels of nitro-PAHs are higher in diesel emissions than in other combustion processes, such as gasoline-fueled engines (Scheepers et al. 1994). Specific nitro-PAHs, such as 1-nitropyrene and dinitropyrenes, have been detected in ambient airborne particulate matter in a high-traffic area in Japan (see Table 34.1). These compounds were determined to be due to diesel vehicles based on the ratio of dinitropyrenes to 1-nitropyrene (Murahashi et al. 1995). Prior to 1980, some carbon black products used in photocopy machines were found to contain considerable quantities of nitropyrenes (National Toxicology Program 1998).

Measurement methods for PAHs in air typically require collecting both particulate phase (five- to seven-ring) and vapor-phase (three- and four-ring) PAHs. Particulate phase PAHs are collected on particle filters such as quartz fiber filters and vapor-phase PAHs are collected on sorbents, most commonly XAD. Samples may be collected over 24-h periods or for shorter lengths of time, depending on the design of the study. Sampling volumes of about 10 m³ are generally sufficient to achieve detection limits in the range of 0.1 to 1 ng/m³ if sensitive GC-MS analytic methods are used. XAD sorbent and quartz filters may be extracted separately or together in solvents such as dichloromethane or ether/hexane. Standard analytic methods for determination of PAHs in ambient air have been published by USEPA, NIOSH, and ASTM (ASTM 1999; NIOSH 1994; USEPA 1988, 1990). Specialized methods for nitro-PAHs in air have also been reported (Scheepers et al. 1994). Considerations for sample collection are similar to those for pesticides and are described in more detail in Chap. 35 of this book.

Concentrations of individual PAHs, such as benzo[*a*]pyrene, have been measured in a range of indoor and ambient outdoor environments. Naphthalene, which is the most volatile of the PAHs, is typically the most abundant in air. The three- and four-ring PAHs, such as phenanthrene, are next most abundant, and particulate phase PAHs such as benzo[*a*]pyrene are generally present in air at lower concentrations.

In the absence of major indoor sources of PAHs, indoor air concentrations of benzo[*a*]pyrene are generally less than 0.65 ng/m³ (Sheldon et al. 1992). Benzo[*a*]pyrene

TABLE 34.1 Selected PAHs and Nitro-PAHs in Indoor and Outdoor Air

Chemical (CAS number)	Indoor air measurement, ng/m ³	Outdoor air measurement, ng/m ³
Acenaphthylene (208-96-8)	2.05–533 range; 43.9 average, in 24 low-income NC homes* (Chuang et al. 1999) 40.50 average smokers; 13.24 average nonsmokers, in 8 suburban Columbus, OH homes (Mitra and Ray 1995) 68 kerosene heater on; 21 kerosene heater off, in 1 NC mobile home (Mumford et al. 1991) 6–753 range; 35 median; 162 average, in 60 urban Indian homes using cattle dung as cooking fuel (Raiyani et al. 1993) 11 average smokers; 5.3 average nonsmokers; 3.9 24-h median, in 125 suburban southern CA homes (Sheldon et al. 1992)	4.33 average, suburban Columbus, OH (Mitra and Ray 1995) 4.4 24-h median, suburban southern CA (Sheldon et al. 1992)

†Mix of urban and rural locations in Brownsville, TX.

‡Reported as 2/3-nitrofluoranthene.

levels in indoor environments where smoking occurs, for example, in restaurants or coffee shops, are more typically in the range of 3 to 5 ng/m³ and have been reported as high as 760 ng/m³ (Chuang et al. 1999, Grimmer et al. 1977, Perry 1973, Sheldon et al. 1992). In a study of restaurant kitchens in China where fumes from cooking oils were a major source of indoor air pollutants, benzo[*a*]pyrene levels ranged from 4 to 42 ng/m³ (Shuguang et al. 1994). Another study reported indoor air levels of PAHs such as benzo[*a*]pyrene ranging from 39 to 1645 ng/m³ in homes in India using traditional biomass fuels such as cattle dung in open fires for cooking (Raiyani et al. 1993). Table 34.1 summarizes data from a number of studies measuring concentrations of individual PAHs and nitro-PAHs in indoor and outdoor ambient air. Findings from these studies are briefly described in the following paragraphs.

PAHs and nitro-PAHs were found to be elevated when kerosene heaters were being used inside mobile homes in North Carolina (Mumford et al. 1991). Indoor air concentrations of individual PAHs are reported for only one of the eight homes tested in this study. Benzo[*a*]pyrene levels in this home were 0.24 ng/m³ with the heater off and 2 ng/m³ when the heater was running. Nitro-PAHs, including 1-nitronaphthalene, 2/3-nitrofluoranthene, and 1-nitropyrene were also detected in these indoor air samples (0.008 to 0.1 ng/m³). No smokers, other gas appliances, or wood stoves were present in this home. Vapor-phase PAH levels were similar with the heater on and off, suggesting these levels might be associated with direct volatilization of fuel. Detected concentrations for PAHs and nitro-PAHs reported in this study are presented in Table 34.1.

In a study of indoor and outdoor ambient air in an urban area in Italy (Minoia et al. 1997), PAH levels in indoor air were almost ten times lower than levels in outdoor air samples. Samples were taken in high- and low-traffic areas in the study city. In the eight homes sampled, benzo[*a*]pyrene levels indoors were less than 0.21 ng/m³ (mean of 0.11 ng/m³); outdoor levels ranged from 0.68 to 2.85 ng/m³ (mean 1.19 ng/m³). Some of the sampled homes did have smokers, but none had wood or coal stoves or fireplaces. These samples were collected during the winter—the study authors also report that sampling during summer showed lower outdoor levels of PAHs than during winter.

In a study that measured indoor and outdoor PAH levels in Tokyo and Beijing during winter, indoor and outdoor concentrations of benzo[*a*]pyrene ranged from <1 to 4 ng/m³ in Tokyo near a high-traffic roadway (Ando et al. 1996). In Beijing, in residential areas where a mixture of coal, coal gas, and natural gas are used for heating, indoor concentrations of benzo[*a*]pyrene were in the range of 1 to 40 ng/m³ and outdoor levels were slightly higher. In both studies, indoor and outdoor benzo[*a*]pyrene levels were highly correlated. No study participants were smokers.

Indoor and outdoor air measurements in a low traffic area of Columbus, Ohio during winter showed indoor PAH levels to be higher than outdoor levels (Chuang et al. 1991). Average indoor levels of benzo[*a*]pyrene were 0.99 ng/m³ in smokers' homes and 0.44 ng/m³ in nonsmokers' homes. Average outdoor benzo[*a*]pyrene levels were 0.23 ng/m³. Modeling analysis of these data showed that 87 percent of PAH indoors was due to environmental tobacco smoke (Mitra and Ray 1995). In nonsmokers' homes, gas appliances, especially heat, contributed to indoor PAH levels but were not a major source. Of all the PAHs measured in this study, naphthalene was the most abundant, with indoor levels of 1377 ng/m³ and outdoor levels of 171 ng/m³ (Chuang et al. 1991, Mitra and Ray 1995). Naphthalene is a constituent of consumer products such as mothballs. Other studies have also found naphthalene to be abundant in air. For example, in the study of kerosene heaters in mobile homes, naphthalene levels ranged from 950 to 2300 ng/m³ (Mumford et al. 1991).

Indoor and outdoor PAH levels were measured in 24 homes of low-income families in North Carolina (Chuang et al. 1999). In this study, indoor PAH levels were higher than outdoor levels. For example, average levels of benzo[*a*]pyrene were 0.70 ng/m³ indoors and 0.46 ng/m³ outdoors. Smokers had higher indoor PAH levels than did nonsmokers,

and both indoor and outdoor PAH levels were higher in winter than in summer. Indoor and outdoor PAH levels were also higher in inner-city homes than in rural homes, presumably as a result of urban mobile source emissions.

Paired indoor and outdoor PAH measurements were made for 125 homes in Riverside, California (Sheldon et al. 1992). Median indoor air levels of benzo[*a*]pyrene were 0.19 ng/m³, and median outdoor levels were 0.16 ng/m³. Benzo[*a*]pyrene measurements in 90 percent of homes tested were below 0.65 ng/m³, but two homes had levels above 5 ng/m³. Smoking indoors was associated with higher PAH levels—average daytime benzo[*a*]pyrene levels in homes without smokers were 0.2 ng/m³ compared with 0.51 ng/m³ in homes with smokers. Reported levels for PAHs measured in this study are presented in Table 34.1.

The Riverside (CA) study reported strong correlations between outdoor and indoor air concentrations of PAHs, suggesting that outdoor sources such as automobile traffic make an important contribution to indoor PAH levels (Sheldon et al. 1992). Homes located near a busy roadway had slightly higher indoor PAH levels compared to homes not close to the busy road. On the other hand, participants who reported starting a car in an attached garage on the day of sampling did not show higher PAH levels in indoor air. Another interesting finding of this study is that daytime and nighttime concentrations of PAHs indoors were relatively similar, while outdoor PAH levels were much higher overnight than during the day. The researchers hypothesize that this is due to photodegradation of PAHs during the day.

Phthalates

Phthalates, also known as *phthalate esters*, are the most commonly used plasticizers in polyvinyl chloride (PVC) resins. These PVC resins are used to manufacture many consumer products and building materials, including vinyl upholstery, shower curtains, food containers and wraps, toys, floor tiles, automobile interiors, lubricants, sealers, and adhesives. Some phthalates are also used in nonplasticizer applications, including those used as an inert ingredient in pesticides, a component of cosmetics, and an acaricide (pesticide for mites and spiders) (National Toxicology Program 1998). Over 1.4 billion lb of phthalates were produced in the United States in 1994 (SRI International 1995). Bis(2-ethylhexyl)phthalate (DEHP), diisononyl phthalate (DINP), and diisodecyl phthalate are the most common and each is produced at over 200 million lb per year. Other common phthalates include butyl benzyl phthalate (BBP), dibutyl phthalate (DBP), and diethyl phthalate (DEP). Figure 34.2 shows chemical structures for some phthalate esters.

While ambient PAH levels have been relatively well studied, fewer data are available on phthalate concentrations in indoor or outdoor air. Typically, phthalates are present in indoor air at much higher concentrations than outdoor air due to their high concentration in consumer products and building materials. Overall, reported concentrations of DBP range up to 1500 ng/m³ indoors and 50 ng/m³ outdoors. Table 34.2 summarizes concentrations for specific phthalates in a number of studies.

Sampling and analytic methods for phthalates typically involve collecting both particulate and vapor phase compounds, although some studies only report levels collected in suspended particulate or vapor phase. The particulate fraction is generally collected on a glass fiber filter using a pump to draw air through the filter (active sampling). Vapor-phase compounds are most often collected on polyurethane foam (PUF), also using active sampling. One study reported concentrations of two phthalates in air using a charcoal canister and passive sampling (Shields and Weschler 1987). Only one study reported the relative concentrations of phthalates in both particulate and vapor phases. In this study, about 25 percent of the DBP and DEHP was collected on the filter and the remaining 75 percent was collected on a PUF cartridge (Atlas and Giam 1988). While no standard methods have been

FIGURE 34.2 Selected phthalates.

published for analysis of phthalates in ambient air, selected phthalates are occasionally included as target compounds in standard methods for analysis of air samples for neutral organic compounds such as PAHs and some pesticides (ASTM 1994, NIOSH 1994, USEPA 1988).

Outdoor levels of phthalates are typically less than 5 ng/m³ (Table 34.2). Testing of remote marine atmospheric samples from Enewetak Atoll in the northern Pacific Ocean showed vapor-phase DBP levels from 0.4 to 1.8 ng/m³ and DEHP from 0.32 to 2.68 ng/m³ (Atlas and Giam 1981). These same compounds in outdoor rural locations in Texas were present at 0.48 to 3.6 ng/m³ and 0.77 to 3.6 ng/m³ for DBP and DEHP, respectively, in combined particulate and vapor-phase samples (Atlas and Giam 1988). A range of outdoor sampling locations in Sweden, including some in the vicinity of a phthalate-consuming factory, showed DBP levels from 0.23 to 49.9 ng/m³ (median 1.7 ng/m³) in combined PUF and particle-phase extracts (Thuren and Larsson 1990). In suburban southern California (Riverside), median outdoor DBP levels were 18 ng/m³ in extracts of respirable particles plus XAD sorbent (Sheldon et al. 1992). Annual average levels of DBP and DEHP were 3 to 6 ng/m³ and 10 to 17 ng/m³, respectively, in particulate samples collected in New York

City; in a suburban New York forest levels were 0.4 to 2 and 2 to 4 ng/m³, for DBP and DEHP, respectively (Bove et al. 1978). These particulate matter measurements are the earliest reported values and reflect methods and concentrations of the mid-1970s. These levels probably underestimate air concentrations by a factor of 4, based on reports that 75 percent of these phthalates are typically collected in the vapor phase (XAD) and 25 percent in the particulate phase (Atlas and Giam 1988).

Indoor levels of phthalates are much higher than outdoor levels, and many more phthalates can be detected indoors. Table 34.2 presents levels detected in available studies for specific phthalates. In a study of indoor air in 125 homes in suburban southern California, 12-m³ air samples were collected on quartz fiber filters in combination with XAD resin. Levels are reported for DBP (median 410 ng/m³; 90th percentile 1500 ng/m³), DEHP (median 103 ng/m³; 90th percentile 215 ng/m³) and three additional phthalates (Sheldon et al. 1992). Another study of indoor air in residences, shops, and offices using a particle filter (<10 µm) combined with PUF and XAD reported five phthalates detected, including DBP from 101 to 431 ng/m³ and DEHP from 20 to 114 ng/m³. In this same study, a sample taken in a workplace where plastics are heated, shaped, and glued showed DEHP at 11,500 ng/m³ and DBP at 2,810 ng/m³ (Rudel et al. in press).

Using the same methods for sample collection and analysis, Spengler et al. (unpublished) found dibutyl phthalate levels ranging from 1400 to 8700 ng/m³ in five Japanese homes made of similar construction materials. Sampling in the factory where the homes were constructed did not identify the source of the high levels in these homes (J. Spengler, unpublished).

One study of phthalates in indoor air particulate matter reported lower levels for phthalates, especially DBP, probably because these compounds are present predominantly in the vapor phase. In this study, particulate matter (<15 µm) in two U.S. office buildings showed a maximum DBP level of 0.2 ng/m³ and DEHP of up to 55 ng/m³. BBP and DINP were also reported up to 20 ng/m³ in these samples, with most of the phthalates present in the fine (<2.5 µm) fraction (Weschler 1984).

Shields and Weschler report dimethyl phthalate and diethyl phthalate (DEP) detected in indoor air sampled using a charcoal canister and passive sampling (Shields and Weschler 1987). This sampling method collects only vapor-phase compounds. In this study, DEP is reported at 1800 ng/m³ in a telephone office building. This level is consistent with results of two studies mentioned earlier that used active sampling with filter combined with XAD or PUF + XAD. Rudel et al. (Rudel et al. in press) up to 1290 ng/m³ DEP in residences, shops, and offices and Sheldon et al. (1992) reported a median of 350 ng/m³ (90th percentile 850 ng/m³) for DEP in 125 homes.

Alkylphenols and Selected Phenols

Alkylphenols, such as nonylphenol (NP), are high-production-volume chemicals with a number of consumer uses that make them a common air contaminant, particularly indoors. The alkylphenol polyethoxylates are common surfactants and are present in a range of detergents and cleaners, personal-care products, latex paints, lubricating oils, and as inert ingredients in some pesticide formulations. In 1996, U.S. consumption of nonylphenol polyethoxylates was 443 million lb; 102 million lb of that was for use in household detergents. Another major use of NP is in tris(4-nonylphenol)phosphite, an antioxidant used as a stabilizer in some plastics (SRI International 1995). Structures of some alkylphenols and other phenols discussed in this section are shown in Fig. 34.3.

Limited indoor and outdoor measurement data are available for NP (Table 34.3). One study of NP levels in the coastal atmosphere in the lower Hudson River estuary, an area receiving large amounts of treated sewage, found outdoor concentrations ranging from 2.2

FIGURE 34.3 Selected phenols.

to 70 ng/m³ (Dachs et al. 1999). In this study, samples were collected using quartz fiber filters in combination with PUF. NP levels were fairly evenly distributed between vapor and particulate phases in this study, with higher levels in the gas phase in samples collected near large-surface water bodies. These surface waters were reported to be the source of NP volatilization to air (Dachs et al. 1999). A study of suspended particulate matter inside two office buildings reported average NP levels of 15 and 30 ng/m³, with nondetectable levels in outdoor samples collected simultaneously (Weschler 1984).

In a study of phenolic compounds used in consumer products or building materials, NP levels in residences, offices, and shops were measured up to 118 ng/m³ and levels in a workplace where plastics are melted and glued were 347 ng/m³ (Rudel et al. in press). Sample collection in this study was done using quartz fiber filters in combination with PUF and XAD resin, and analysis involved extraction with dichloromethane, derivatization, and GC-MS with selective ion monitoring.

Other compounds detected in this study include bisphenol A, a monomer used to make polycarbonate plastics and epoxy resins, which is produced at more than 1.7 billion lb per year in the United States (SRI International 1995). Indoor air in homes, offices, and shops had bisphenol A levels in the range of 2 to 3 ng/m³, and a workplace where plastics were melted, shaped, and glued had 208 ng/m³ bisphenol A (Rudel et al. in press). Phenolic resins, surface coatings, and polycarbonate materials contain 4-*tert*-butylphenol, which

4- <i>tert</i> -Butylphenol (98-54-4)	11–48 range, 31 average, in 7 suburban homes/workplaces; 69 in 1 plastics-melting workplace (Rudel et al. in press)	—
4-Nitrophenol (100-02-7)	ND–8 range, in 7 suburban homes/workplaces (Rudel et al. in press)	—
4-Nonylphenol (104-40-5)	ND–118 range, in 7 suburban homes/workplaces; 347 in 1 plastics-melting workplace (Rudel et al. in press) 15–30 range, in 2 office buildings, combined nonylphenol isomers (Weschler 1984)	2.2–70 range; 19.2, 10.2, 2.5 gas-phase average; 6.1, 9.8, 5.6 aerosol-phase average, urban New York/New Jersey sites, 11 nonylphenol isomers combined (Dachs et al. 1999)
<i>o</i> -Phenylphenol (90-43-7)	4–18 range, 10 average, in 7 suburban homes/workplaces; 694 in 1 plastics-melting workplace (Rudel et al. in press) 96.0 summer average, 70.4 spring average, 59.0 winter average, in 208 Jacksonville, FL homes; 44.5 spring average, 22.8 winter average, in 101 Chicopee, MA homes (Whitmore et al. 1994)	1.2 summer average, Jacksonville, FL; 1.6 spring average, Chicopee, MA (Whitmore et al. 1994)

was detectable in residences, offices, and shops at 11 to 48 ng/m³ (Rudel et al. in press). The disinfectant and hard-surface cleaner *o*-phenyl phenol was detected in homes, offices, and shops at between 4 and 18 ng/m³ and in the plastics melting workplace at 694 ng/m³ (Rudel et al. in press). A study of pesticides in homes included *o*-phenyl phenol as a target analyte. Average outdoor concentrations of *o*-phenyl phenol in different seasons and U.S. locations ranged from nondetectable to 1.6 ng/m³, while residential indoor averages ranged from 23 to 96 ng/m³ (Whitmore et al. 1994) (see summary data in Table 34.3).

34.2 POTENTIAL HEALTH EFFECTS

PAHs

PAH-containing mixtures such as soots, tars, and tobacco smoke have been demonstrated to cause cancer in humans in many epidemiologic studies. These PAH mixtures, as well as some of the individual PAHs, have also been demonstrated to be carcinogenic in animal studies and mutagenic in *in vitro* tests (Agency for Toxic Substances and Disease Registry 1995; International Agency for Research on Cancer 1982, 1985; National Toxicology Program 1998; Schwarz-Miller et al. 1998; USEPA 1993, 1999b). Other PAH-containing mixtures, such as diesel exhaust, also show evidence of increasing lung cancer risk in exposed workers and data from animal studies and mutagenicity tests support this finding (Health Effects Institute 1999, International Agency for Research on Cancer 1989, World Health Organization 1996).

In humans, inhalation exposure to PAH mixtures has been associated primarily with lung or bladder cancer, while dermal contact with these mixtures has been associated with skin cancers (Agency for Toxic Substances and Disease Registry 1995, Schwarz-Miller et al. 1998). These findings are reproducible in animal studies of PAH mixtures and of some individual PAHs.

Many PAHs increase the incidence of mammary gland tumors in animal studies (National Toxicology Program 1998), raising the question of whether PAH exposure might be associated with increased breast cancer risk in humans. While risk of breast cancer has not generally been elevated in epidemiologic studies of tobacco smoking (Palmer and Rosenberg 1993), some studies have shown an increased risk for women exposed to active or passive tobacco smoke (Lash and Aschengrau 1999, Morabia et al. 1996), and for women with variant forms of certain metabolizing enzymes (Ambrosone et al. 1995, 1996). Most data on human cancers associated with PAH mixtures other than tobacco have come from studies of occupationally exposed individuals, but because these studies have seldom included women, they are not a source of information about breast cancer risk from PAH exposure (Goldberg and Labreche 1996, Schwarz-Miller et al. 1998).

Although there are no human data that specifically link exposure to individual PAHs with human cancers, the individual PAHs are components of mixtures that have been associated with human cancer. Individual PAHs have been tested in animal studies and in assays that identify mutagenic activity so that they may be classified according to the likelihood that they are human carcinogens. Nitro-PAHs appear to be particularly potent carcinogens and mutagens, based on tests in animals.

Table 34.4 lists individual PAHs as well as some common PAH mixtures and indicates how each has been classified with respect to carcinogenic potential. Classifications assigned by the International Agency for Research on Cancer (IARC) and the U.S. Environmental Protection Agency (USEPA) are included. For example, Table 34.4 shows that IARC has classified soot and tobacco smoke as known human carcinogens, diesel exhaust and the PAH benzo[*a*]pyrene as probable human carcinogens, and gasoline engine

*USEPA weight-of-evidence classification of carcinogenic potential to humans: A—human carcinogen; B1—probable human carcinogen, limited epidemiologic evidence; B2—probable human carcinogen, inadequate or no epidemiologic evidence; C—possible human carcinogen; D—not classifiable as to potential carcinogenicity; E—evidence of noncarcinogenicity; blank cell (—) means no assessment available (USEPA 1999b).

†IARC classification of carcinogenic potential to humans: group 1—known human carcinogen, group 2A—probably carcinogenic to humans, group 2B—possibly carcinogenic to humans, group 3—not classified, group 4—probably not carcinogenic to humans, blank cell (—) means no assessment available (International Agency for Research on Cancer 1999).

‡USEPA risk-based ambient air concentrations represent a concentration expected to be associated with less than 1 excess cancer per million exposed individuals and minimal potential for other adverse health

TABLE 34.4 Health Effects Data for Selected PAHs, Phthalates, and Phenols (Continued)

effects, based on available toxicity information. There is considerable uncertainty in these levels, since toxicity testing data are often inadequate for making a confident determination of an exposure level expected to be without adverse health effects in humans. (Caldwell et al. 1998, USEPA-3 1999).

§In addition to other toxic and carcinogenic effects, PAHs appear to cause adverse endocrine-mediated health effects by indirect mechanisms, and so can be identified as potential endocrine-disrupting compounds. One mechanism for endocrine toxicity by PAHs is likely to be mediated by PAH activation of Ah receptors and subsequent induction of specific cytochrome P450 enzymes that modify the synthesis and metabolism of endogenous hormones (Baron et al. 1990, Palmer and Rosenberg 1993, Till et al. 1997). There are also reports that extracts of urban air particulate matter, cigarette smoke, and diesel exhaust exhibit estrogenic activity, indicating that some PAHs mimic the effects of estrogen directly (Clemons et al. 1998, Meek and Finch 1999, Meek 1998). Information on specific PAHs is not available.

¶Identified as potential endocrine disrupting chemicals based on in vitro or in vivo screening and toxicity tests (Gray et al. 1998; Harris et al. 1997; Illinois Environmental Protection Agency 1997; Perez et al. 1998; Shelby et al. 1996; Soto et al. 1995, 1997).

exhaust as possibly carcinogenic to humans. A number of PAHs are not classified because of lack of toxicity test data.

PAH-containing mixtures have also been demonstrated to cause adverse noncancer health effects. Effects on respiratory function have been observed following occupational exposure to diesel and gasoline exhaust (Mauderly 1994), environmental tobacco smoke (USEPA 1993), and urban air particulate matter (Ostro et al. 1999, Peters et al. 1999). Exposure to environmental tobacco smoke has also been shown to increase the frequency and severity of symptoms in asthmatic children (USEPA 1993). A few studies have evaluated the impact of air pollution, primarily particulate matter and sulfur dioxide, on reproductive health (Sram 1999). One study in an industrialized area of Poland with high levels of PAH pollution from coal burning showed that newborns with higher umbilical-cord levels of PAH-DNA adducts, a measure of PAH damage to DNA, had significantly decreased birth length, weight, and head circumference (Perera et al. 1998).

In addition to other toxic and carcinogenic effects, PAHs have been identified as potential endocrine-disrupting compounds, meaning that they may cause adverse health effects by disrupting normal hormonal signaling pathways (Illinois Environmental Protection Agency 1997). One mechanism for endocrine toxicity by PAHs is likely to be mediated by PAH activation of Ah receptors and subsequent induction of specific cytochrome P450 enzymes that modify the synthesis and metabolism of endogenous hormones (Baron et al. 1990, Palmer and Rosenberg 1993, Till et al., 1997). However, there are also reports that extracts of urban air particulate matter, cigarette smoke, and diesel exhaust exhibit estrogenic activity, indicating that some PAHs mimic the effects of estrogen directly (Clemons et al. 1998, Meek and Finch 1999, Meek 1998).

For some chemicals, including some PAHs, USEPA has established air concentrations expected to be associated with less than one excess cancer per million exposed individuals and minimum potential for other adverse health effects. These concentrations are available from U.S. Environmental Protection Agency Region 3 (USEPA-3 1999) and in a publication by Caldwell et al. (1998), also from USEPA. There is considerable uncertainty in these levels, since toxicity test data are inadequate for making a confident determination of an exposure level expected to be without adverse health effects in humans. One particularly important source of uncertainty is that most toxicity tests are conducted by feeding or injecting the chemical, and so the tests do not necessarily provide information relevant for inhalation exposures. Table 34.4 lists USEPA risk-based ambient air concentrations for PAHs. While these air concentrations are useful as bench-

marks for comparing measured levels, it is prudent to prevent exposures to PAHs whenever possible based on the many adverse health effects associated with exposure to these compounds.

Phthalates, Alkylphenols, and Selected Phenols

Compared with PAHs, there is much less information available about health effects associated with exposures to phthalates, alkylphenols, and the other chemicals discussed in this chapter, despite their widespread use. Of the chemicals listed in Tables 34.2 and 34.3, bis(2-ethylhexyl)phthalate is the most extensively studied; very little toxicity or epidemiology data are available for the others. The greatest concern associated with exposure to these compounds is the potential for them to produce adverse effects on reproduction and development, because most of them have been shown to disrupt normal endocrine signaling in *in vitro* and *in vivo* animal studies (Gray et al. 1998; Harris et al. 1997; Illinois Environmental Protection Agency 1997; Perez et al. 1998; Shelby et al. 1996; Soto et al. 1995, 1997). In addition, there is evidence that certain phthalates may be carcinogenic (Doull et al. 1999, International Agency for Research on Cancer 1999, National Toxicology Program 1998, USEPA 1999b). These findings are discussed in more detail in the paragraphs below.

A number of phthalates have been found to be weak estrogen mimics *in vitro*—that is, at high concentrations they are able to activate estrogen receptor regulated genes by binding to the estrogen receptor (Harris et al. 1997, Jobling et al. 1995). This estrogenic activity indicates that they have the potential to disrupt normal reproductive system development and function. Many phthalates have also been identified as testicular toxicants, acting by a mechanism in which the monoester metabolite of the compound is the active agent (Richburg and Boekelheide 1996). Phthalates have also been shown to cause fetal loss and abnormalities in animal studies, and there is one report of increased spontaneous abortion and menstrual cycle abnormalities among women exposed to phthalates at work (Aldyreva et al. 1975, Chapin 1997, National Toxicology Program 1997). While effects have typically been observed at fairly high levels of exposure, more recent animal studies on dibutylphthalate (DBP) have shown that it interferes with androgen signaling and that exposure *in utero* affects reproductive system development at lower doses than the effects previously described (Ashby et al. 1997, Foster 1997, Gray et al. 1998, Mylchreest et al. 1998). Additional studies are necessary to fully characterize the endocrine-mediated toxicity of phthalates. Studies of occupationally exposed individuals are especially important, and these studies need to evaluate the reproductive experience of the workers as well as developmental and reproductive outcomes in their children.

Although DEHP and a few other phthalates have been shown to be carcinogenic in rats, their potential as human carcinogens is the subject of debate (Doull et al. 1999, International Agency for Research on Cancer 1999, USEPA 1999b, Youssef and Badr 1998). DEHP, for example, causes liver tumors in rats by a mechanism involving peroxisomal proliferation. While humans are probably less sensitive than rats to agents that act by this mechanism, some toxicologists believe that the sensitivity difference is so great that DEHP should not be considered a potential human carcinogen (Doull et al. 1999). Others maintain that the differences between humans and rats mean that humans are less sensitive, but not completely insensitive to the potential carcinogenicity of these compounds. Classifications as to potential carcinogenicity of these compounds by IARC and USEPA are provided in Table 34.4.

With the exception of one Russian occupational exposure study (Aldyreva et al. 1975), no data are available on the effects of inhalation exposure to phthalates, from studies of either animals or humans. Because phthalate metabolites play an important role in phthalate toxicity, route of exposure is likely to affect toxicity and observations from studies

using oral administration may not be relevant to inhalation exposures. In addition, some researchers have postulated that inhalation exposure to phthalates may play a role in asthma (Oie et al. 1997).

Most of the phenolic compounds discussed in this chapter were included because despite their general low toxicity in traditional toxicological tests, they have been shown to disrupt normal endocrine signaling in *in vitro* and *in vivo* animal studies, and therefore are expected to cause adverse reproductive and developmental effects, particularly following *in utero* exposure. The phenolic compounds identified as potential endocrine disruptors in Table 34.4 can mimic estrogen by binding the estrogen receptor and initiating transcription of estrogen-regulated genes (Illinois Environmental Protection Agency 1997; Perez et al. 1998; Shelby et al. 1996; Soto et al. 1995, 1997; Steinmetz et al. 1997).

Some longer-term studies have evaluated the potential reproductive toxicity for some of these compounds. A multigenerational study of nonylphenol in rats showed reproductive effects, including effects on sperm morphology, as well as effects on kidney function (Chapin et al. 1998). Neonatal exposure to bisphenol A has been reported to increase prostate weight in some studies (vom Saal et al. 1998); other studies have not seen that effect (Ashby et al. 1999).

Unfortunately, these studies are not adequate for characterizing the potential adverse health effects and dose-response relationships for these compounds, and none of the studies has been conducted by inhalation. Additional studies, particularly studies of exposed workers and their children, are necessary to help understand and manage these widely used chemicals (Rudel 1997). In the meantime, on the basis of their potential endocrine-mediated toxicity, exposure to these compounds should be prevented where possible.

ACKNOWLEDGMENTS

This work was conducted with support from the Susan G. Komen Breast Cancer Foundation/Boston Race for the Cure. I thank Christina Spaulding, Sharon Gray, Martha Montague, and Cindy Soto, who provided research support for the preparation of this manuscript. I am also grateful to Julia G. Brody for manuscript review.

CHAPTER 35

PESTICIDES

Robert G. Lewis, Ph.D.

*U.S. Environmental Protection Agency
National Exposure Research Laboratory
Research Triangle Park, North Carolina*

35.1 INTRODUCTION

A *pesticide* is any substance used to control, repel, or kill a pest (insect, weed, fungus, rodent, etc.). Pesticides encompass a very large and diverse group of substances and may be subclassified according to their mode of action into many classes, including insecticides, acaricides, fungicides, herbicides, rodenticides, avicides, larvicides, repellents, plant growth regulators, germicides (disinfectants), and other types of biocides. There are at least 600 different pesticides and 45,000 to 50,000 pesticidal formulations (which may include one or more active ingredients, along with adjuvants, synergists, surfactants, and solvents) in use (Baker and Wilkinson 1990). Pesticides may be simple inorganic substances such as sulfur, chlorine, chlorine oxide, arsine, copper arsenate, and potassium bromide; organometallic compounds such as zinc bis(dimethyldithiocarbamate); volatile organic compounds (VOCs) such as carbon tetrachloride, methyl bromide, 1,4-dichlorobenzene, and naphthalene; semivolatile organic compounds (SVOCs) such as diazinon, chlorpyrifos, pentachlorophenol, and propoxur; or nonvolatile organic compounds (NVOCs) such as 2,4-dichlorophenoxyacetic acid (2,4-D) dimethylamine salt, and permethrin. The scope of this chapter is limited to SVOCs and some NVOCs, which constitute the principal groupings of chemicals typically classified as conventional pesticides.

35.2 PESTICIDE REGULATION

The sale, distribution, use, and disposal of pesticides is regulated by the U.S. Environmental Protection Agency (USEPA), under the Federal Insecticide, Fungicide and

Rodenticide Act (FIFRA) (7 USC 136, et seq.) and the Food Quality Protection Act (FQPA) of 1996. The USEPA is responsible for registering new pesticides and reviewing existing pesticides for reregistration to ensure that they will not present unreasonable risks to human health or the environment. FIFRA requires the USEPA to take into account economic, social, and environmental costs and benefits in making decisions. Registration and regulatory decisions are based on evaluation of data provided by the registrants from tests that may be specified by the USEPA. These required tests include studies to show whether a pesticide has the potential to cause adverse effects to individuals using pesticide formulations (applicators) and to persons who may be exposed postapplication. Potential human risks include acute (short-term) reactions such as toxic poisoning and skin and eye irritation, as well as possible chronic (long-term) effects such as cancer, birth defects, or reproductive system disorders. If pesticides are to be registered for residential or institutional use, USEPA requires that studies be performed to determine postapplication dissipation rates and dislodgeable, or transferable, residues.

The Food Quality Protection Act not only sets tolerances for all pesticide residues in food based on a “reasonable certainty” that they will do “no harm” to human health, but it also requires USEPA to consider all routes of exposure when setting tolerances. When setting a food tolerance level, USEPA must aggregate exposure information from all potential sources, including pesticide residues in the specific food of concern and those in other foods for which tolerances have already been set, residues in drinking water, and residues from other nondietary, nonoccupational uses of the pesticide (i.e., residential and other indoor/outdoor uses). FQPA further mandates that potential risks to infants and small children be specifically addressed. In order to assure “that there is a reasonable certainty that no harm will result to infants and children from aggregate exposure to the pesticide’s chemical residues,” FQPA calls for a “tenfold margin of safety for pesticide residues and other sources of exposure” to be applied to estimating risks to children, taking into account “potential pre- and post-natal toxicity.” It allows USEPA to use a different margin of safety “only if, on the basis of reliable data, such margin will be safe for infants and children.”

An example of the USEPA regulatory process that relates to permissible indoor pesticide uses is the recent action taken on chlorpyrifos (Dursban®). The insecticide has been one of the most heavily used pesticides for control of fleas and crawling insects indoors and grubs in residential lawns. It also was the principal termiticide replacing chlordane after its discontinuation in 1988. Because of concern over its toxicity and the high potential for exposure from residential use, USEPA reached an agreement with the manufacturer, DowElanco, in June 2000 to cancel and phase out nearly all indoor and outdoor residential uses of chlorpyrifos. This will eliminate the pesticide from products for indoor crack and crevice treatment, broadcast flea control, total release foggers, postconstruction termite treatment, lawn insect control, and pet care (shampoos, dips and sprays). Remaining uses will be limited to certified professional and agricultural applicators. The agreement also restricts the uses of chlorpyrifos on certain foods that pose the greatest dietary exposure risks to children.

35.3 RESIDENTIAL AND COMMERCIAL BUILDING USE

Conventional pesticides are used both indoors and outdoors at residences, office buildings, schools, hospitals, nursing homes, and other public facilities. A wide variety of pesticide products are available “off the shelf” for use by the homemaker. These include preparations for flies, cockroaches, ants, spiders, and moths within the home; flea and tick sprays and

shampoos for pets; insecticides for use on house plants and home gardens; and herbicides, insecticides, and fungicides for lawn treatment. Most homemakers use disinfectants routinely as kitchen and bathroom cleaners, room deodorizers, or laundry aids. Many homeowners and landlords utilize professional pest control services for routine indoor treatments or lawn care. In many parts of the country, pre- or postconstruction treatment for termite protection is essential. Exclusive of disinfectants and insect repellents, the most common indoor uses are for control of cockroaches and ants (crack and crevice treatment, baits), flies (sprays, pest strips), fleas (broadcast sprays and foggers), and rodents (baits). Outdoor uses in addition to lawn and garden care include perimeter and crawlspace treatments for termites and crickets.

The major exposure of the general population of the United States to pesticides occurs inside the home. Studies have shown that about 90 percent of all U.S. households use pesticides (USEPA 1979, Savage et al. 1981, Godish 1997, Whitmore et al. 1993). A national survey conducted by the USEPA during 1976/77, revealed of the 90.7 percent of U.S. homeowners used pesticides, with 83.7 percent using them inside the house, 21.4 percent in the garden, and 28.7 percent on the lawn (USEPA, 1979). The survey found that over 90 percent of the households used disinfectants (antimicrobials), 36 percent used moth repellents, and 26 percent were treated with termiticides. The USEPA-sponsored National Home and Garden Pesticide Use Survey in 1990 found that 82 percent of the 66.8 million U.S. households used pesticides and that about 20 percent of them (~16 million households) were commercially treated for indoor pests such as cockroaches, ants, or fleas (Whitmore et al. 1993). It further showed that some 18 million U.S. households use pesticides on their lawns, 8 million in the garden, and 14 million on ornamental plants. About 15 percent of the U.S. residences with private lawns employ commercial lawn care companies that apply pesticides. A survey of 238 households in Missouri in 1989/90 revealed that 97.8 percent of all families used pesticides at least once per year and 75 percent used them more than five times per year (Davis et al. 1992). The Missouri survey also determined that 70 percent of the respondents used household pesticides during the first 6 months of a child occupant's life.

Direct purchases of conventional pesticides for home and garden use accounted for 17 percent of the \$12 billion spent on pesticide products in the United States in 1997 (USEPA 1998a). Nonagricultural commercial sales made up 13 percent of the total. Most of the latter was intended for commercial home, office, and institutional application. Home and garden use in 1997 consumed nearly 62 million kilograms of pesticide active ingredients (AIs), compared to 429 million kg for agricultural use and 69 million kg for other nonagricultural commercial use. On the basis of quantity of AIs, herbicides made up 64 percent of the total home and garden use by individuals; insecticides and miticides, 22 percent; and fungicides, 11 percent. Not included in these figures were 14 to 16 million kg of 1,4-dichlorobenzene (moth repellent, insecticide, germicide, and deodorant), 1 to 2 million kg of naphthalene (moth repellent), and 2 to 3 million kg of *N,N*-diethyl-*m*-toluamide (DEET, insect repellent). The major pesticides used by homeowners and professional applicators during 1995/96 are shown in Table 35.1.

Misuse of pesticides by homemakers and commercial applicators is an all-too-frequent occurrence. In California during 1983–1986, nearly 300 cases of illness or injury reported to physicians were attributed to three popular household insecticides: chlorpyrifos, dichlorvos (DDVP), and propoxur (Edmiston 1987). In 1991, the American Association of Poison Control Centers received 78,177 calls regarding pesticide poisonings at 73 centers across the United States (Litovitz et al. 1991), 70 percent of which involved insecticides. Pesticide poisoning calls ranked seventh in frequency (behind cleansers, analgesics, cosmetics, plants, cough and cold medications, and bites). Perhaps of greater concern, however, are potential chronic health effects that may derive from long-term exposures to pesticides in indoor environments.

TABLE 35.1 Approximate Annual Quantities of Conventional Pesticides Consumed by the Homeowner and Commercial Markets in the United States during 1995/96

Pesticide	Type*	Quantity used, 10 ⁶ kg/year	
		Homeowner	Commercial†,‡
2,4-D (2,4-dichlorophenoxyacetic acid and salts)	H	3–4	7–8
Glyphosate [Roundup—isopropylamine salt of <i>N</i> -(phosphonomethyl)glycine]	H	2–3	4–6
Dicamba (3,6-dichloro-2-methoxybenzoic acid; 3,6-dichloro- <i>o</i> -anisic acid and salts)	H	1.5–3	<1
MCPP [mecoprop—2-(4-chloro-2-methylphenoxy) propionic acid and salts]	H	1.5–3	<1
Chlorpyrifos [Dursban— <i>O</i> , <i>O</i> -diethyl- <i>O</i> -(3,5,6-trichloro-2-pyridinyl)-phosphorothioate]	I	1–2	2–3
Diazinon [<i>O</i> , <i>O</i> -diethyl- <i>O</i> -(6-methyl-2-(1-methylethyl)-4-pyrimidinyl)phosphorothioate]	I	1–2	<1
Carbaryl [Sevin—1-naphthylmethylcarbamate]	I	0.5–1.5	<1
Benefin [<i>N</i> -butyl- <i>N</i> -ethyl- <i>a,a,a</i> -trifluoro-2,6-dinitro- <i>p</i> -toluidine]	H	0.5–1.5	<1
Dacthal (dimethyltetrachloroterephthalate)	H	0.5–1.5	<1
MSMA (monosodium methanearsonate)	H	<1	2–3
Chlorothalonil (tetrachloroisophthalonitrile)	F	<1	1–2
Pendimethalin [<i>N</i> -(1-ethylpropyl)-3,4-dimethyl-2,6-dinitrobenzenamine]	H	<1	1–2
Malathion [diethyl(dimethoxythiophosphorylthio) succinate]	I	<1	0.5–1.5

*H = herbicide, I = insecticide, F = fungicides.

†Industrial, institutional, and governmental.

‡Does not include 2 to 3 million kg of copper sulfate and 1.5 to 2 million kg of methyl bromide.

35.4 MONITORING METHODS

Air sampling can be classified as instantaneous (grab), real-time (or continuous), or integrative (over a period of exposure). Except for a few reactive pesticides present in air at relatively high concentrations (e.g., occupational levels), integrative sampling is necessary in order to obtain a sufficient quantity of the pesticide for analysis. General air-sampling methodology for pesticides was reviewed in depth in the 1970s (Van Dyk and Visweswariah 1975, Lewis 1976) but not recently. Pesticide air sampling typically involves the collection of pesticides from air onto a solid sorbent or a combination trap consisting of a particle filter backed up by a sorbent trap. Solvent extraction and chemical analysis by gas chromatography or high-performance liquid chromatography are most commonly employed.

Sampling media that have shown to be efficient for collection of multiclass pesticides from air are polyurethane foam (Bidleman and Olney 1974, Orgill et al. 1976, Lewis et al. 1977, Lewis and MacLeod 1982, Billings and Bidleman 1980, Wright and Leidy 1982, Lewis et al. 1994); Chromosorb 102 (Thomas and Seiber 1974, Hill and Arnold 1979); Amberlite XAD-2 (Farewell et al. 1977, Johnson et al. 1977, Lewis and Jackson 1982, Billings and Bidleman 1983, Williams et al. 1987, Leidy and Wright 1991, Wright et al. 1993, Lu and Fenske 1998); Amberlite XAD-4 (Woodrow and Seiber 1978, Jenkins et al.

1993), Tenax-GC or TA (Billings and Bidleman 1980, 1983; Lewis and Jackson 1982; Lewis and MacLeod 1982; Roinestad et al. 1993), Poropak-R (Lewis and Jackson 1982), and Florisil (Yule et al. 1971, Lewis and Jackson 1982). These sorbents appear to be about equally efficient for trapping most pesticides. Polyurethane foam (PUF) has enjoyed the most widespread popularity because it is more convenient to use and has much less resistance to airflow than do the granular sorbents. However, a few of the more volatile pesticides may not collect efficiently on PUF.

Samples may be collected over 24-h periods or for shorter periods of exposure time, depending on the design of the study and the sensitivity of the method. When the usual gas or liquid chromatographic analysis procedures are used, air volumes of 0.01 to 1 m³ are sufficient for occupational exposure levels (i.e., 0.1 to 10 mg/m³) and 1 to 10 m³ for nonoccupational exposures (i.e., 0.01 to 10 µg/m³).

Methods for several pesticides at occupational levels in air are given in the *NIOSH Manual of Analytical Methods* (Eller and Cassinelli 1994). The NIOSH methods for organochlorine and organophosphate utilize small traps with a particle filter backed up by two Amberlite XAD-2 resin beds. They are designed for use with personal sampling pumps at 0.2 to 1 L/min for a maximum sample volume of 60 to 240 L. Detection limits are in the 5 to 600 ng/m³ range.

There are two American Society of Testing and Materials (ASTM) methods designed primarily for determining airborne pesticides at nonoccupational levels. ASTM Standard D4861 describes a sampling method and recommended analytical procedures for a broad spectrum of pesticides at concentrations in the 0.001 to 50 µg/m³ range (ASTM 2000a) and D4947 is a specific method for chlordane and heptachlor (ASTM 2000b). D4861 is based on EPA Compendium Method TO-10A, and is the method used in many large surveys conducted by the Agency (USEPA 1999a). The sampling device employed by both ASTM methods consists of a 22 × 76-mm PUF cylinder (plug), which may be used with or without a particle filter attached to the inlet. The PUF cartridge with or without an open-face particle filter (see Fig. 35.1) is commercially available from several vendors (e.g., Supelco Model Orbo 1000; SKC Catalog no. 226-124). A size-selective inlet for this method has been designed and used in several EPA indoor air studies. It is an integral system incorporating either a 2.5- or 10-µm inlet based on a design by Marple et al. (1987) and can be used at flow rates up to 4 L/min for up to 24 h (Camann et al. 1994, Lewis et al. 1994). The glass sampling cartridge and particle filter are contained in a rugged high-density polypropylene case, which is highly resistant to breakage and tampering. The sampler, shown in Fig. 35.2, is commercially available (URG model 2500). The EPA and ASTM methods are designed to be used with portable air sampling pumps capable of pulling about 4 L/min of air through the collector for a total sample volume not to exceed 5 to 6 m³. Depending on the analytic finish, the minimum detection limits of the ASTM methods range from 1 to 100 ng/m³. The World Health Organization has published a method that is essentially identical to D4861 (Lewis 1993).

Most of the large studies employing the USEPA/ASTM method [e.g., the Non-Occupational Exposure Study (NOPES)] have not used a particle filter; however, one is recommended if pesticides associated with respirable particulate matter are likely to be present. While fine particles (1 µm or smaller) have been shown to be poorly retained by the PUF plug (Kogan et al. 1993), simultaneous, collocated sampling of residential indoor air with and without a quartz fiber particle filter showed no significant measurement differences even when sweeping and vacuuming activities took place in the same room (Camann et al. 1990). The backup PUF trap should always be used, even for collection nonvolatile pesticides (e.g., when sampling for airborne acid herbicides indoors). As much as 20 percent of airborne 2,4-D, applied as the trimethylamine salt, has been detected on the backup PUF plug, presumably as a result of hydrolysis to the semivolatile free acid (USEPA 1999b).

FIGURE 35.1 Simple air-sampling cartridge with open-face particle filter: (a) O-ring seal; (b) filter holder; (c) stainless-steel support screen; (d) particle filter; (e) PTFE filter gasket; (f) screw cap.

Except for herbicide salts and a few other nonvolatile compounds, most of the pesticides will either be present in air primarily in the vapor phase or will volatilize from airborne particulate matter readily after collection on a filter (Lewis and Gordon 1996). Solid sorbent beds will collect most particulate-associated pesticides along with vapors; however, evidence suggests that some penetration of fine particulate matter (0.1 to 1 μm) may occur with PUF and Florisil (Kogan et al. 1993). Fine particles were not found to penetrate XAD-2 beds, presumably because of their retention by static charge. It may be good practice, therefore, to use a particle filter in front of the sorbent bed. In this case, the filter and sorbent bed should be extracted together for analysis to provide for better detection and prevent misinterpretation of the analytical results with respect to original phase distributions.

Air samples should be taken within the residence or other building in the optimum location to estimate human exposure (e.g., family rooms, bedrooms, office spaces). Occupant activity logs may be required in order to obtain accurate estimates of human exposure. The sampler may be conveniently positioned on a table, desk, or countertop, during which time it may be operated by means of an AC-to-DC (AC/DC) power converter-charger. For monitoring periods longer than 8 h, the latter procedure will usually be necessary because of limited battery life and to cover the sleep period. Air intakes (inlets) should be positioned 1 to 2 m above the floor or ground and oriented downward or horizontally to prevent contamination by nonrespirable dustfall. If two or more samplers are to be used for collocated sampling, intakes should be at least 30 cm apart for low-volume samplers (1 to 5 L/min) and 1 to 2 m apart for high-volume samplers (up to 1000 L/min).

Indoor residential sampling can be restricted because of available space or by homeowner objections. Equipment noise can also be an issue, depending on the size of the space being monitored, the acoustics of the area, and the presence of occupants. Noise from sampling equipment used in residences, schools, offices, and other relatively noise-free areas should be limited to 35 dB (1 sone) at 8000 Hz (ASTM 2000c). Many battery-operated portable pumps designed for personal respiratory exposure monitoring are quiet enough for

FIGURE 35.2 Air-sampling assembly with size-selective inlet, particle filter, and glass sorbent cartridge.

this purpose, although additional acoustic insulation may be required for use in bedrooms and family rooms. Nonindustrial workplace monitoring is often more flexible with respect to space and noise restrictions. Security of sampling equipment should be considered in the plan. Typically, samplers that cannot either easily be tampered with or changed by the homeowner or office worker, are preferable to those with exposed sampling elements or controls (e.g., the possibility of electrical power disruption or contamination by onlookers or passersby should be considered in the sampling plan for any effort).

No method should be assumed to perform adequately unless it has been validated (preferably by the user) under the conditions of its intended application. At a minimum, the sampling media should be spiked with the analytes of interest (or their isotopically labeled analogs) and subjected to the same or greater airflow rates and sampling volumes that will be encountered in the field. This dynamic retention test will usually provide a reasonable

estimate of sampling efficiency. It is, of course, better to generate spiked atmospheres to be introduced into the sampler, but this is difficult for less volatile compounds. A simple low-volume vapor generator (see Fig. 35.3) that can be used for semivolatile pesticides is described in ASTM Standard D4861 (ASTM 2000a). Sorbents and filters also need to be evaluated for storage stability, as well as artifact formation during sampling. Sampling media should be chilled or frozen immediately after sampling (including during transit to the laboratory) and be extracted as soon as possible after arrival at the laboratory. Extracts can usually be safely stored for extended periods (e.g., up to a year) at temperatures below -20°C . Sampling media should not be stored for more than 30 days in a freezer unless kept under nitrogen. The use of isotopically labeled internal standards or other surrogates is very helpful in determining losses during storage, as well as during sampling and sample workup.

At least 10 percent of the samples should be quality control samples. Blank sampling cartridges should be taken to the field and returned to the laboratory for analysis; however, they should not be exposed to the air. Spiked sampling media may also be similarly transported as field controls.

FIGURE 35.3 Low-volume pesticide vapor generator for determination of air-sampling efficiencies.

35.5 OCCURRENCE, SOURCES, FATE, AND TRANSPORT IN THE INDOOR ENVIRONMENT

Pesticides applied indoors vaporize from treated surfaces (e.g., carpets and baseboards) and can be resuspended into air on particles. Those applied to the foundation or perimeter of a building may penetrate into interior spaces, resulting in measurable indoor air levels. Pesticides used on the lawn or in the garden may be tracked indoors, where they can accumulate in house dust that may be resuspended into air. Pesticides may also be added to carpets, paints, and other furnishings and building materials at the time of manufacture. Consequently, the presence of pesticide residues in indoor air does not necessarily indicate their use within or on the premises.

The most commonly used household pesticides are disinfectants. Pine oil and phenols are widely used disinfectants that contribute to indoor air pollution. α -Pinene, a component of pine oil, has been recognized as a ubiquitous indoor air constituent since the mid-1990s. It is a volatile organic compound (vapor pressure 6×10^{-1} kPa at 25°C) and not amenable to the sampling methods discussed previously. The average concentration of α -pinene in 539 U.S. households has been reported to be $2.4 \mu\text{g}/\text{m}^3$ (Wallace 1987). *o*-Phenylphenol and 2-benzyl-4-chlorophenol (BCP) are two of the most popular phenolic antimicrobials. In 1984 Reinert (1984) estimated an annual use of 680,000 kg of *o*-phenylphenol and 5.3 million kg of BCP in U.S. homes. In California, total sales in 1986 amounted to 146,600 kg of *o*-phenylphenol as the free acid and 102,576 kg as the sodium and potassium salts (CDPR 1988). By comparison, 88,563 kg of free BCP was sold, along with only 5331 kg of the salts. *o*-Phenylphenol was detected in the indoor air of 70 to 90 percent of residences monitored in Florida and Massachusetts during 1986/87 at 0.03 to $1 \mu\text{g}/\text{m}^3$ (Whitmore et al. 1994). In a small New Jersey study in 1991, it was found in 43 percent of the homes monitored at levels ranging from 0.04 to $0.06 \mu\text{g}/\text{m}^3$ (Roinestad et al. 1993). The use of *o*-phenylphenol in household disinfectants in the United States has declined since the late 1990s.

Although its use in the United States has been very limited, pentachlorophenol (PCP) is a widespread environmental pollutant and may be a major component of indoor air. Relatively little indoor air data on PCP exists because of the analytic difficulties in measuring it. It was, however, detected in over 80 percent of the air samples collected inside homes studied in North Carolina and was present at a mean concentration of $0.05 \mu\text{g}/\text{m}^3$ (Lewis et al. 1994). PCP has also been reported at relatively high air levels inside office buildings (Levin and Hahn 1984). PCP has been used as a wood preservative, principally on porches and patio decking. It has also been used as a fungicide to protect leather goods, some paints, and other materials that may be used inside the home. In Europe, where use of PCP in indoor paints and stains has been common, indoor exposures via the air route are considered potentially serious [e.g., Maroni et al. (1987)]. In the United States, it is ubiquitously present in household dust (Lewis et al. 1999).

Insecticides that have been commonly used indoors are pyrethroids (natural and synthetic), chlorpyrifos, diazinon, propoxur, dichlorvos, malathion, and piperonyl butoxide (and synergist). Two of the most widely used broad-spectrum insecticides have been permethrin and chlorpyrifos. Chlorpyrifos has been one of the most frequently detected insecticides in indoor air.

The most heavily used household pesticides are acid herbicides. They are readily detected in house dust (generally at much higher concentrations than in surface soils), but rarely reported in indoor air. Phenoxyacetic acid herbicides (e.g., 2,4-D, dicamba, and mecoprop) and glyphosate are the mostly commonly used as postemergence herbicides. Preemergence herbicides, such as triazines (e.g., atrazine, simazine), are used in lesser quantities.

Pesticides may be periodically introduced into indoor air by direct application (e.g., insect and sprays and bombs, disinfectant sprays, room deodorizers). In addition, there are often sources that continually emit vapors into the living space (e.g., continuous evaporation of residues from crack and crevice treatments, emissions from pest control strips or other devices). Whether used inside the home or office, or outside on the lawn or garden, pesticides accumulate on indoor surfaces, especially in carpet dust, and also in upholstery and in or on children's toys (Lewis et al. 1994, Simcox et al. 1995, Nishioka et al. 1996, Gurunathan et al. 1998). Insecticides and disinfectants applied indoors may persist for extended periods, protected from sunlight, rain, temperature extremes, and most microbial action. Pesticides applied to the lawn or used in the garden may be tracked indoors, where they can persist for months or years, as opposed to perhaps days outside on the grass (Nishioka et al. 1996). Termiticides, the efficacy of which depends on persistence, continually migrate from the building foundation into the living space by both the air route and track-in of foundation soil (Wright et al. 1994). Typically, pesticide concentrations in indoor air and house dust are 10 to 100 times those found in outdoor air and surface soil (Lewis et al. 1988, 1994; Whitmore et al. 1994).

Most household pesticides are used during spring and summer months when pest infestations are greatest. Warmer weather may also increase volatilization of termiticides from the soil beneath the house resulting in increased contributions to living spaces. Consequently, air concentrations should be highest during these times. For example, in a USEPA study in Jacksonville, Florida, the mean indoor air concentrations for the 23 detected pesticides were $0.11 \mu\text{g}/\text{m}^3$ in summer, $0.05 \mu\text{g}/\text{m}^3$ in spring, and $0.03 \mu\text{g}/\text{m}^3$ in winter (Whitmore et al. 1994). The mean air concentrations of the four predominant pesticides (propoxur, diazinon, chlorpyrifos, chlordane) found in Jacksonville were 0.32 to $0.53 \mu\text{g}/\text{m}^3$ in summer, 0.11 to $0.25 \mu\text{g}/\text{m}^3$ in spring, and 0.08 to $0.22 \mu\text{g}/\text{m}^3$. Since insect populations are generally larger in more moderate climates, pesticide usage and corresponding exposure levels should be greater in the southern states. The aforementioned USEPA study found total indoor levels of pesticides to be 6 to 8 times higher in Jacksonville, Florida, than in Springfield, Massachusetts, during the same seasons.

Most pesticides are semivolatile (saturation vapor pressures between 10^{-2} and 10^{-8} kPa) and tend to vaporize when applied to indoor surfaces (e.g., carpets and baseboards). The rate of volatilization will depend on the vapor pressure of the compound, the formulation (solvent, surfactants, microencapsulation, etc.), the ambient and surface temperatures, indoor air movement (ventilation), the type of surface treated, and the time lapsed after application. The vapor pressure of the pure pesticide is frequently known and may be of value for assessing the relative importance of potential respiratory exposures. Good compilations of vapor pressure data and other physical properties of pesticides are *The Pesticide Manual* (Tomlin 1994), Howard (1991), and Wauchope et al. (1992).

All organophosphate (OP) insecticides are semivolatile and will vaporize from surfaces after applications. The most volatile OP is dichlorvos (vapor pressure = 7×10^{-3} kPa at 25°C). Dichlorvos has been a common household insecticide for many years, particularly in slow-release insecticide strips and flea collars for cats and dogs. Several studies showed that air concentrations of $100 \mu\text{g}/\text{m}^3$ or greater were not unusual in rooms in which DDVP pest strips were deployed (Leary et al. 1974, Lewis and Lee 1976). In 1988, USEPA estimated that lifetime exposures to dichlorvos vapors from pest strips may result in a 10^{-2} cancer risk (Consumers Union 1988). Although dichlorvos is still registered for use in pest strips, foggers, and flea collars, use in the United States has declined dramatically since 1988. The insecticide is currently undergoing special review for registration. The use of other OP pesticides, such as chlorpyrifos (2.5×10^{-6} kPa at 25°C) and diazinon (1.1×10^{-5} kPa at 25°C) have also been declining in favor of pyrethroid insecticides.

The majority of pyrethroid insecticides have low volatilities. The heavily used synthetic pyrethroid permethrin is classified as nonvolatile on the basis of its vapor pressure (1.3×10^{-9}

kPa at 20°C) and is rarely found in indoor air. However, it was recently the major pesticide residue recently found in house dust (Lewis et al. 1999). Cypermethrin and cyfluthrin are two other low-volatility pyrethroids commonly used for indoor flea and cockroach control.

Most acid herbicides used on lawns (e.g., 2,4-D and glyphosate) are applied in the form of amine salts that possess very extremely low vapor pressures; hence they may be found in air only at low concentrations and mostly associated with suspended particulate matter. For example, 2,4-D was detected in the air inside of 64 of 82 homes commercially treated with the herbicide (Yeary and Leonard 1993). The time-weighted average concentration over seven hours on the day of application was determined to be 34 ng/m³ in six homes with the highest measured air levels. 2,4-D has also been measured in residential indoor air for several days after application to lawns at concentrations of 1 to 15 ng/m³ (USEPA 1999b). Indoor air concentrations of 2,4-D increased from nondetectable before lawn treatment to 0.2 to 10 ng/m³ (10- μ m inlet) after homeowner application, with about 65 percent of the total particulate 2,4-D associated with inhalable particles (<10 μ g/m³). 2,4-D associated with <1 μ m and smaller particles made up of 25 to 30 percent of the total mass. Triazine herbicides, which are used for preemergent control of weeds, are more volatile than acid herbicide salts, but are still largely classified as nonvolatile. There have been very few reports of their presence in indoor air. Atrazine (3.7×10^{-8} kPa at 20°C) has been reported in concentrations of 3 to 12 ng/m³ in indoor air of farm residences and homes near agricultural operations (Camann et al. 1993, Mukerjee et al. 1997).

The influence of the volatility of a pesticide on measurable indoor air levels is evident by comparing semivolatile chlorpyrifos with nonvolatile permethrin. Room air concentrations of these two insecticides (monitored at 12.5 and 75 cm above the floor) were comparable (means 30 μ g/m³ and 42 μ g/m³, respectively) 0 to 2 h after broadcast spraying, but the air levels of permethrin declined so rapidly that nothing (<1 μ g/m³) could be detected in air after 8 h, while chlorpyrifos levels remained high at 31 μ g/m³ (Koehler and Moye 1995b). Immediately after spraying, permethrin was most likely present in air as an aerosol, which underwent little or no volatilization after deposition. Unfortunately, it is not possible to accurately predict rates of volatilization or expected air concentrations on the basis of vapor pressures. Even when ambient conditions, substrates, and formulations are similar, emission rates for pesticides will depend on other factors such as the concentration and molecular structure of the active ingredient. Jackson and Lewis (1981) compared emission rates from three kinds of pest control strips in the same room under constant conditions of temperature ($21 \pm 1^\circ\text{C}$) and humidity (50 ± 20 percent) and found that room air concentrations over a period of 30 days were much higher for diazinon than for chlorpyrifos, but similar to those for propoxur. On day 2 room air levels were 0.76 μ g/m³ for diazinon, 0.14 μ g/m³ for chlorpyrifos, and 0.79 μ g/m³ for propoxur. After 30 days, the air concentrations were 1.21, 0.16, and 0.70 μ g/m³, respectively. The vapor pressure of diazinon is nearly 10 times higher than that of chlorpyrifos and nearly 100 times lower than that of propoxur (4×10^{-7} kPa at 20°C).

The rate of volatilization of microencapsulated pesticides is much slower than that of emulsifiable concentrates (Jackson and Lewis 1979, Koehler and Patterson 1991). Indoor air levels of chlorpyrifos applied as a microencapsulated formulation were measured at 3.1 μ g/m³ 0 to 2 h after broadcast spraying and 5.2 μ g/m³ after 24 h compared to 30 μ g/m³ and 15 μ g/m³, respectively, for the emulsifiable concentrate (Koehler and Moye 1995a). After 48 h, levels were still about double for the emulsifiable concentrate application (8.5 vs. 4.0 μ g/m³).

There may be significant temporal and spatial variations in the concentrations of pesticides in indoor air, especially if monitoring is performed after an indoor application. Air concentrations typically drop rapidly for about 3 days after application as the pesticide is absorbed into furnishings or dissipates to the outdoor air. However, concentrations of the more volatile pesticides may still be 20 to 30 percent of those on the day of application after as much as 21 days (Leidy et al. 1993, Lewis et al. 1994). Dissipation rates will also depend

on the method of application. Aerosol sprayers have been shown by some to result in higher postapplication air levels than compressed air sprayers (Leidy et al. 1993, Koehler and Moye 1995a). Likewise, broadcast spraying has been shown to result in higher air concentrations than crack and crevice treatments (Fenske and Black 1989). However, Lu and Fenske (1998) recently reported finding little differences in air concentrations for chlorpyrifos applied by pressurized broadcast spraying and aerosol (fogger) release. One day after treatments, chlorpyrifos levels averaged 23 to 64 $\mu\text{g}/\text{m}^3$ for broadcast application and 43 to 48 $\mu\text{g}/\text{m}^3$ for the fogger. Air concentrations of chlorpyrifos declined more rapidly after aerosol release than they did after broadcast spraying, declining on the second day by 75 and 50 percent, respectively. Seven days later, air concentrations were similar (aerosol, 0.4 to 8.6 $\mu\text{g}/\text{m}^3$; broadcast, 0.9 to 8 $\mu\text{g}/\text{m}^3$).

When there has not been a recent application, pesticide levels in the air of most rooms vary little with vertical distance from the floor (Leidy et al. 1993, Lewis et al. 1994). However, after an application, air concentrations near the floor (in the breathing zone of small children) may be several times higher than those in the adult breathing zone (Fenske et al. 1990, Lewis et al. 1994, Lu and Fenske 1998). This is particularly true for broadcast and aerosol spray applications, where concentrations of chlorpyrifos have been found to be more than 4 times higher at 25 cm above the floor than at 100 cm 5 to 7 h after application (Fenske et al. 1990). Lu and Fenske (1998) observed concentration gradients for chlorpyrifos when samples were taken at 25, 100, and 175 cm above the floor after broadcast and aerosol treatments of carpeted floors, but the gradients had largely disappeared after 3 to 5 days. Conversely, Lewis et al. (1994) found air concentrations of chlorpyrifos to be twice as high at 12 cm as at 75 cm 2 days after crack and crevice treatment and 1.5 to 2 times as high at 8 and 15 days postapplication. Koehler and Moye (1995a) reported concentration gradients after broadcast application of chlorpyrifos up to 175 cm. Diazinon (1×10^{-5} kPa at 20°C) levels were found to be higher at 1.2 m than a ceiling level 21 days after crack and crevice treatment but to have equalized after 35 days (Leidy et al. 1993). Although the synthetic pyrethroids *d*-phenothrin and *d*-tetramethrin have relatively low vapor pressures (1.6×10^{-7} and 9.4×10^{-7} kPa, respectively), they were found in room air immediately after crack and crevice treatment at 752 and 1040 $\mu\text{g}/\text{m}^3$, respectively, but declined rapidly to 2 to 3 $\mu\text{g}/\text{m}^3$. No differences in concentrations were observed at heights of 25 and 120 cm above the floor after the air levels dropped to several $\mu\text{g}/\text{m}^3$ (Matoba et al. 1998).

The only large-scale monitoring survey of pesticides in residential indoor air was the Non-Occupational Pesticides Exposure Study (NOPES) conducted by USEPA during 1985–1990 (Whitmore et al. 1994). This Congressionally mandated study was carried out in two cities—Jacksonville, Florida and Springfield/Chicopee, Massachusetts—which were selected to represent high and low household pesticide usage areas, respectively. In each city, households were selected by statistical sampling of population census districts and stratified prior to monitoring into low-, medium-, and high-use categories. Approximately 175 homes in Jacksonville and 85 homes in Springfield (representing about 300,000 and 140,000 residents, respectively) were chosen for study of air, dermal, drinking water, and dietary exposures to 33 of the most commonly used household pesticides. Exposure measurements were made during the spring, summer, and winter seasons.

In Jacksonville, where three seasons of monitoring were conducted, 25 to 27 of the targeted pesticides were detected in indoor air. Total mean air concentrations were 2.3 $\mu\text{g}/\text{m}^3$ in summer, 1.2 $\mu\text{g}/\text{m}^3$ in spring, and 0.81 $\mu\text{g}/\text{m}^3$ in winter. Outdoors (on porches and patios), 9 to 16 were detected at total mean concentrations of 0.11, 0.03, and 0.06 $\mu\text{g}/\text{m}^3$ for summer, spring, and winter, respectively. Summertime monitoring was not performed in Springfield/Chicopee. During spring and winter, 20 and 16 pesticides were found indoors at total mean air concentrations of 0.40 and 0.10 $\mu\text{g}/\text{m}^3$, respectively. Ten and six were found outdoors at 0.03 and 0.01 $\mu\text{g}/\text{m}^3$, respectively. Seven of the most prevalent pesticides shown in Tables 35.2a and 35.2b made up more than 90 percent of the total mass of

all pesticides monitored. These were the indoor insecticides chlorpyrifos, propoxur, diazinon, and dichlorvos; the termiticides chlordane and heptachlor (both now discontinued); and the disinfectant *o*-phenylphenol.

35.6 EXPOSURE RISKS AND HEALTH EFFECTS

Pesticide residues found inside the home contribute significantly to the overall exposure of the general population. Of the several possible routes of exposure to household pesticides, the air route is one of the most important. Average residents of the United States spend the majority of their time indoors, mostly inside their own domiciles. Full-time homemakers and small children may spend over 21 h/day inside the home, with another 2.5 h inside other buildings (stores, offices, etc.) or in transit vehicles (Robinson 1977; Shoaf 1991; USEPA 1996a, 1996b, 1997). Even when employed, urban dwellers spend about the same amount of time indoors, 63 percent of it at home and 28 percent at work. For many persons, at least 90 percent of our daily cumulative exposure to pesticides occurs at home. Results from simultaneous 24-h indoor air and personal exposure monitoring in NOPES showed that 85 percent of the total daily adult exposure to airborne pesticides was from breathing air inside the home (Whitmore et al. 1994).

Whereas occupational inhalation exposure guidelines have been established for many pesticides, the United States has no current guidelines for nonoccupational indoor air exposures. Workplace exposure limits are established by National Institute for Occupational Safety and Health (NIOSH), the Occupational Safety and Health Administration (OSHA), and the American Conference of Governmental Industrial Hygienists (ACGIH). Recommended time-weighted average inhalation exposure limits are typically in the 0.5- to 5-mg/m³ range for 8- to 10-h exposures, far above the levels normally observed in indoor air in residences, public buildings, or commercial buildings outside the pesticide control industry. The National Research Council and USEPA did issue interim guidelines for indoor air exposures to five termiticides in 1982 (NRC 1982). They were 1 μ g/m³ for aldrin and dieldrin, 2 μ g/m³ for heptachlor, 5 μ g/m³ for chlordane, and 10 μ g/m³ for chlorpyri-

fos. The four cyclodiene termiticides have been discontinued since 1989 and postconstruction use of chlorpyrifos was phased out in 2000.

A number of pesticides have been classified by EPA as known (group A), probable (group B), or possible (group C) human carcinogens. Inorganic arsenic and chromium compound, which are used as wood preservatives, are the only group A pesticides that may have residential applications. Since these are nonvolatile compounds, the potential for air route exposure to them is low. Several pesticides used for residential and institutional indoor pest control are classified as B2 carcinogens (probable human carcinogens based on animal data): *o*-phenylphenol, fenoxycarb, propoxur, and lindane. The former termiticides aldrin, chlordane, dieldrin, heptachlor, and heptachlor epoxide; the wood preservative pentachlorophenol (canceled in 1986); and perchloroethylene (a VOC, canceled in 1992) are also classified B2. Group C pesticides of concern include atrazine, benomyl, bromacil, dinoseb (canceled in 1992), ethalfuralin, *N*-octylbicycloheptene dicarboximide (MGK-264), and paradichlorobenzene (a VOC). Chlorothalonil was under review at the time of writing and will likely be classified as a probable or possible human carcinogen.

For suspect human carcinogens, EPA uses probability-based risk assessment. An acceptable nonoccupational risk for the general public is considered to be 1×10^{-6} or a one-in-a-million chance above the background probability (currently 1:13) that one will develop cancer over one's normal lifetime. The estimated excess lifetime cancer risks from inhalation exposure as determined by NOPES were highest for the now discontinued cyclodiene termiticides. In Jacksonville, Florida they ranged from 1×10^{-6} for heptachlor epoxide to 2×10^{-4} for heptachlor. In Springfield/Chicopee the range was from 5×10^{-7} for aldrin to 4×10^{-5} for heptachlor. For other pesticides, the lifetime excess cancer risks for Jacksonville ranged from 6×10^{-9} for 2,4-D (measured as the esters) to 2×10^{-6} for α -hexachlorocyclohexane; for Springfield they ranged from 2×10^{-9} for chlorothalonil to 2×10^{-7} for 2,4-D. Noncancer risk assessments were not performed in NOPES.

The EPA has published general guidelines for exposure assessment, which are applicable to indoor air inhalation exposures (USEPA 1997). Specific guidelines for postapplication residential pesticide exposure assessment have been recently published by USEPA (USEPA 2000). These guidelines cover sampling protocols, monitoring methods, analytic methods, and data presentation, but do not mandate the use of specific methods or protocols. They also cover the fundamentals of exposure and risk assessments, human activity patterns, and modeling. Under the pesticides registration process, the USEPA is generally interested in data on exposure to total airborne pesticide residues, as opposed to inspirable or respirable fractions, because of the potential for absorption of pesticides through the mouth and gastrointestinal tract, as well as the lung. The absorbed, or internal, dose received via the air route is assumed to be the same as the potential dose; thus, the dosage is calculated on the basis of 100 percent absorption of the pesticide that potentially enters the body through breathing, assuming no filtration of particles by the nose. The average daily inhalation dose (ADD_I) in microgram of pesticide absorbed per kilogram of body weight per day is, therefore, determined to be

$$ADD_I = \frac{CR_I t_E}{wt_A} \quad (35.1)$$

where ADD_I = average daily inhalation dose, $\mu\text{g}/\text{kg}$

C = measured air concentration of period of exposure, $\mu\text{g}/\text{m}^3$

R_I = inhalation rate, m^3/day

t_E = duration of exposure, days

t_A = averaging time, days

w = body weight, kg

For noncarcinogenic effects, t_A is taken to be equal to t_E . For carcinogenic or chronic health effects, t_A is 70 years (25,550 days), or the average human lifespan. When conducting a risk assessment, the calculated ADD_I may be compared to the reference dose RfD for the specific pesticide of interest, which may be obtained from the USEPA *Integrated Risk Information System* (IRIS) database (Dwyer 1998, USEPA 1998c) or other sources.

The *reference dose* (RfD) is defined by EPA as “An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime.” It is determined from the following equation:

$$\text{RfD} = \frac{\text{NOAEL}}{U_F M_F} \quad (35.2)$$

where NOAEL = the no-observable-adverse-effect level, mg/kg/day

U_F = composite uncertainty factors

M_F = situation specific modification factor

A U_F of 10 is used to account for variations in sensitivity among human subpopulations. An additional 10- to 100-fold uncertainty factor is invoked when animal toxicity data is used for extrapolation to human health effects (which is most often the case). If the extrapolation is from valid long-term animal studies, the additional U_F is 10; when extrapolating from less than chronic animal toxicity data and there are no useful long-term human data studies available, an additional 10-fold factor is applied. If the RfD from a *lowest-observable-adverse-effect level*, instead of a NOAEL, still another 10-fold uncertainty factor is applied. Finally, FQPA calls for another 10-fold uncertainty factor for children. The M_F may vary from a default value of 1 up to 10 depending on the weaknesses or uncertainties in the scientific data used.

IRIS uses a default inhalation rate of 20 m³/day for respiratory exposure, which is close to the estimated average daily inhalation rates published by the International Commission on Radiological Protection for adults (ICRP 1981): 22.8 m³/day for adult males and 21.1 m³/day for adult females. However, for a child of 10 years of age, ICRP estimates 14.8 m³/day; an infant (age 1 year), 3.8 m³/day; and a newborn, 0.8 m³/day. Use of the IRIS methodology for determining reference doses for inhalation exposure risk assessment is described in detail by USEPA (USEPA 1997). Shoaf (1991) and Swartout et al. (1998) also provide good overall discussions on the use of reference dose in risk assessment.

Meaningful exposure and risk assessments require knowledge of human activity patterns as well as environmental concentrations. The amount of time spent indoors, the distribution of time spent within various rooms, and the levels of physical exertion must be known to accurately determine the extent of respiratory exposure in a given indoor environment. When small children are of concern, air measurements made in their breathing zones (10 to 75 cm above the floor) should also be considered. Computer-based models for prediction of potential residential inhalation exposures that take into account human activity patterns have been developed. One such program is USEPA's *THERdbASE* (Pandian et al. 1993, USEPA 1998d). However, it has not been applied to semivolatile pesticides. As stated previously, risk assessments required to establish the safe use of pesticides must be based on the potential total, or aggregate, exposure from all sources. Multimedia, multipathway models for human exposure *via* the air, water, and soil ingestion routes have been published [e.g., McKone and Daniels (1991)], but there have been few, if any, reported studies in which such models have been field-tested for pesticides exposures. While models may be used to predict human exposure or health risks associated with pesticides, the accuracies of such models can improve only as better measurement data become available.

CHAPTER 36

POLYCHLORINATED BIPHENYLS

Donna J. Vorhees, Sc.D.

Menzie-Cura & Associates, Inc.

Chelmsford, Massachusetts

Polychlorinated biphenyls (PCBs) were valued historically for their thermal stability, chemical inertness, low flammability, low vapor pressure at ambient temperature, and resistance to microbial degradation (de Voogt and Brinkman 1989). These properties made them excellent dielectric fluids in transformers and capacitors as well as for other applications. Today, these same properties make PCBs problematic contaminants that persist and bioaccumulate in the environment.

PCBs were manufactured in the United States from 1929 to 1977 as commercial mixtures called Aroclors. Similar commercial mixtures produced elsewhere in the world include Clophens (Germany), Kanechlors (Japan), Phenoclors (France), Fenclore (Italy), and Sovol (Russia). PCB production peaked in the United States in 1970 prior to use and manufacturing restrictions implemented in the late 1970s. Despite these restrictions, PCBs persist in air, water, soil, sediment, and biota.

Because PCB mixtures are generally hydrophobic and not volatile, they partition to soils and sediments more than air or water. PCBs can bioaccumulate in fish and higher-trophic-level organisms that are consumed by people. In fact, the diet is generally regarded as the main source of human exposure. Exposure to PCBs in indoor air might be second only to dietary exposure given the substantial amount of time people spend indoors (Robinson and Thomas 1991), although the specific congener mixtures in air would differ from congener mixtures in food. Individuals working in PCB-using industries (e.g., transformer repair) commonly experience the highest indoor exposures; however, this chapter focuses on nonindustrial indoor environments.

36.1 WHAT ARE PCBs?

Aroclors and other commercial mixtures of PCBs were produced by chlorinating molten biphenyl with anhydrous chlorine in the presence of a catalyst. The biphenyl molecule can accommodate between one and ten chlorine substitutions, resulting in 209 possible congeners (Fig. 36.1). PCB congeners with the same number of chlorines are isomers referred to col-

FIGURE 36.1 Structure of polychlorinated biphenyl compounds.

lectively as *homolog groups*. Commercial mixtures are composed of different but overlapping congener mixtures. Four-digit numbers assigned to Aroclors reflect the chemical composition of these mixtures. The first two numbers indicate the 12 carbon atoms in the biphenyl ring, and the last two numbers denote the weight percentage of chlorine. For example, Aroclor 1242 contains 42 percent chlorine by weight. Aroclor 1016, with 41 percent chlorine by weight, is an exception to this nomenclature. It contains almost the same amount of chlorine as Aroclor 1242, but with a lower proportion of high-molecular-weight congeners. Aroclor 1016 was developed as an alternative to Aroclor 1242 after concern arose about the environmental persistence of the heavier congeners (de Voogt and Brinkman 1989).

36.2 PCBs IN THE ENVIRONMENT

Mixtures and congeners with high chlorine content tend to adhere to soils, sediments, and organic materials. Fish and other organisms bioaccumulate PCBs, particularly congeners with high chlorine content that are resistant to metabolism and elimination (Oliver and Niimi 1988, Schwartz and Stalling 1987, Lake et al. 1995). The major destructive pathway for PCBs is biologically mediated reductive dechlorination under anaerobic conditions to less chlorinated congeners, followed by slow anaerobic and/or aerobic biodegradation (Brown and Wagner 1990, Lake et al. 1992, Lang 1992). These processes are slow, and PCBs persist in the environment for many years as complex mixtures.

Aroclor mixtures and individual congeners with low chlorine content tend to be more volatile and soluble than those with high chlorine content. Therefore, they can be dispersed to remote locations such as the Arctic (Tanabe et al. 1983, Gregor and Gummer 1989) and can impact indoor air (MacLeod 1981, Oatman and Roy 1986, Vorhees et al. 1997, Currado and Harrad 1998). PCBs exist in the air in both the gas and particle phases. Recent work demonstrates that PCB gas/particle partitioning in air is governed primarily by PCB vapor pressures and total suspended particulate levels (Baker and Eisenreich 1990, Duinker and Bouchertall 1989, Ligocki and Pankow 1989, Foreman and Bidleman 1987).

Figure 36.2 depicts PCB congener patterns in various environmental media collected from the New Bedford Harbor region of Massachusetts. These patterns illustrate how heavier congeners partition to soil and dust while lighter congeners partition to air and water. Brown and Wagner (1990) concluded that the New Bedford Harbor sediment congener pattern depicted in Fig. 36.2 reflects some microbial dechlorination, because the pattern is shifted toward a lower-molecular-weight congener mixture than the Aroclors historically released to the harbor.

Only about half of the 209 congeners have been quantified in environmental samples, and even fewer are prevalent in these samples (McFarland and Clarke 1989). Congener

FIGURE 36.2 Example PCB congener patterns from environmental media collected near New Bedford Harbor, Massachusetts.

FIGURE 36.2 Example PCB congener patterns from environmental media collected near New Bedford Harbor, Massachusetts. (Continued)

patterns in environmental samples differ from Aroclors because individual congeners differ in properties that affect partitioning, persistence, and bioaccumulation (Schwartz and Stalling 1987, Lang 1992). In addition, PCB congeners in environmental samples might originate from multiple Aroclor sources.

Historically, analytic methods and toxicological studies focused on commercial mixtures, such as Aroclors. PCBs were quantified by matching congener patterns found in samples to the most similar Aroclor pattern and reporting "total PCBs." This approach is not appropriate given how mixtures change following release to the environment. Advances in analytic chemistry during the 1980s allow identification and quantification of individual congeners (Erickson 1997). Animal toxicological studies in the United States continue to employ Aroclors (Brunner et al. 1996). However, in evaluating the carcinogenic potency of PCBs, the U.S. Environmental Protection Agency (USEPA) interprets and uses study results after considering their applicability to congener mixtures as they exist in the environment (USEPA 1996, Cogliano 1998).

36.3 HISTORIC USES OF PCBs THAT COULD IMPACT INDOOR AIR QUALITY

PCBs were used extensively around the world in many products. In the United States, Aroclor 1242 was used predominantly, followed by Aroclors 1016, 1254, and 1260. Table 36.1 summarizes PCB-containing products and each Aroclor's percent of total U.S. production from 1957 to 1977. PCBs were used primarily as dielectric fluids in transformers and capacitors. They were also used in hydraulic systems, heat-transfer systems, lubricating oils, cutting oils, wax extenders, paints (as plasticizers), wood product coatings (to reduce flammability), carbonless copy paper, adhesives, sealants, and plastics as ink solvent/carriers (Hutzinger et al. 1974; Pomerantz et al. 1978; USEPA 1994, 1999a).

TABLE 36.1 Historic Uses of PCBs

Aroclor	Product	Percent of U.S. production (1957–1977)
1016	Capacitors	13
1221	Capacitors, gas transmission turbines, rubbers, adhesives	1
1232	Hydraulic fluids, rubbers, adhesives	<1
1242	Capacitors, transformers, heat transfer, hydraulic fluids, gas-transmission turbines, rubbers, carbonless copy paper, adhesives, wax extenders	52
1248	Hydraulic fluids, vacuum pumps, rubbers, synthetic resins, adhesives	7
1254	Capacitors, transformers, hydraulic fluids, vacuum pumps, rubbers, synthetic resins, adhesives, wax extenders, dedusting agents, inks, cutting oils, pesticide extenders, sealants and caulking compounds	16
1260	Transformers, hydraulic fluids, synthetic resins, dedusting agents	11
1262	Synthetic resins	1
1268	Rubbers, synthetic resins, wax extenders	<1

Source: IARC (1978); Brown (1994).

Although PCBs are no longer used in these products, they persist in soil, sediment, biota, and old PCB-containing products such as transformers, capacitors, and paints (Welsh 1995). Cycling of previously released PCBs among environmental media (e.g., soil and sediment) represents the major source of PCBs in the atmosphere (ATSDR 1999, Murphy et al. 1985). Old PCB-containing products can also be sources if PCBs are released due to a leak, fire, or improper handling and disposal.

PCBs persist inside some public buildings, offices, and residences in old electrical appliances, fluorescent lights, paint, and building materials (USEPA 1994). Fluorescent lights and capacitors have long been recognized as potential sources of PCBs in indoor air (Staiff et al. 1970, USEPA 1979). In a public building complex, PCBs in indoor air were attributed to ceiling tiles (Todd 1987). A 1981 study demonstrated PCB exposure inside homes possibly due to electrical appliances (MacLeod 1981). Oatman and Roy (1986) measured PCBs in the indoor air of public buildings with and without transformers. PCB-containing sealants and caulking materials also can impact indoor air quality (Benthe et al. 1992; Balfanz et al. 1993a, 1993b; Williams et al. 1980). PCBs in the indoor air of a Massachusetts school were attributed to joint caulking, wood fiber ceiling material, and paint (Leung 1996).

36.4 HEALTH EFFECTS OF PCBs

Human exposure to PCBs elicits concern because of their wide range of possible cancer and noncancer effects. The health effects associated with PCBs have been reviewed extensively (Kimbrough and Jensen 1989, Silberhorn et al. 1990, Safe 1994, Swanson et al. 1995, Longnecker et al. 1997, Rice 1997, Jacobson and Jacobson 1997, Coglianò 1998, Geisy and Kannan 1998, ATSDR 1999, Brouwer et al. 1999, NRC 1999). This section provides a brief summary of this large and growing literature, emphasizing evidence of effects in human populations.

In occupational studies where people are generally exposed to higher PCB concentrations than the general population, PCB mixtures have been associated with chloracne, diverse hepatic effects, pulmonary function decrease, decrease in birthweight in children of occupationally exposed mothers, eye irritation, and cancer (Safe 1994).

Exposure to low-level background PCB concentrations may have subtle effects on neurologic development and immune function (Lawton et al. 1985, Smith 1984, Svensson et al. 1994, Weisglas-Kuperus et al. 1995, Jacobson and Jacobson 1997), and, in susceptible groups, thyroid function (Koopman-Esseboom et al. 1994). Laboratory assays suggest that some PCB congeners exhibit endocrine disrupting potential (Soto et al. 1995, Birnbaum 1994, Brouwer et al. 1999). Members of a National Institute of Environmental Health Sciences (NIEHS) workshop recently concluded that some PCB effects demonstrated in experimental animals can be induced at tissue concentrations near body burdens present in human populations exposed to background concentrations in industrialized nations (Brouwer et al. 1999).

Animal studies suggest that some PCB Aroclor mixtures may cause skin irritations, reproductive and developmental effects, immunologic effects, liver damage, and cancer (ATSDR 1999, WHO 1993).

Challenges in Assessing Exposure to PCBs in Health Studies

With few exceptions, epidemiologic and animal studies focus on total PCBs or Aroclors rather than specific congeners, despite the fact that PCBs are present in the environment as

complex mixtures of congeners that differ from the original Aroclor mixtures. The toxicity of PCB mixtures depends on the type of congeners in the mixture and the number and position of chlorine atoms on each congener. PCB congener metabolites may also exert toxic effects (Soto et al. 1995).

Individual congeners have been associated with dioxinlike effects, neurotoxic effects, estrogenic and antiestrogenic activity, interference with thyroid hormone homeostasis, and enzyme induction. Recognizing that risk assessments based on “total PCBs” may not address dioxinlike toxicity, USEPA advocates use of a toxic equivalency quotient (TEQ) approach to evaluate possible dioxinlike toxicity of PCB mixtures. However, several investigators note that this approach does not account for PCB toxicity by other mechanisms (Safe 1994, Wolff et al. 1997). Therefore, Wolff et al. (1997) propose congener groupings according to these different mechanisms for use in future epidemiologic studies. Hansen (1998) provides a detailed description of why such groupings are important to improve understanding of the toxicity of complex PCB mixtures.

Some studies of PCB toxicity may be confounded by other contaminants. In many studies, the polychlorinated dibenzofuran (PCDF) content of PCB test materials is not provided, so its contribution to PCB-induced toxic effects is not known (Safe 1994). In epidemiologic investigations, PCB concentrations in environmental media (i.e., food, soil, and water) might be correlated with PCDF, polychlorinated dibenzodioxin (PCDD), and methyl mercury concentrations, which could potentially confound analyses.

Health Effects of PCBs Following Accidental Dietary Exposures

In 1968 and 1979, two Asian communities were accidentally exposed to PCBs, PCDFs, polychlorinated terphenyls (PCTs), and polychlorinated quaterphenyls (PCQs) in contaminated rice oil (Schecter 1994). Exposed individuals developed chloracne, pigmentation of skin and nails, swelling of limbs, jaundice, paresthesias, headache, dizziness, altered immunoglobulin levels, and increased incidence of lung and liver cancer. Yu et al. (1997) detected increased mortality from chronic liver disease and cirrhosis 13 years after the poisoning incident in Taiwan and recommended additional study of the young cohort. Offspring of exposed adults were born with low body weight and exhibit slight learning deficits and hyperactivity (Rogan et al. 1988, Chen et al. 1992, Guo et al. 1995).

In both incidents, people were primarily exposed to PCBs. However, laboratory studies exposing rodents to simulated “rice oil PCBs” or reconstituted PCB and PCDF mixtures resembling the distribution of these compounds in Yusho patients show that PCDFs were more potent than the PCBs. Safe (1994) concluded that this evidence, combined with the observation that some poisoning victims had serum PCB levels similar to those of industrial workers who did not exhibit adverse effects, suggests that PCDFs are the major etiologic agent in these incidents (Safe 1994).

Cancer

Human Evidence. Epidemiologic data from occupational cohorts provide mixed evidence of PCB carcinogenicity. In at least one of nine occupational cohorts, there was a positive association between PCB exposure and the following cancer sites: rectum, liver, biliary, pancreas, skin, prostate, kidney, brain, and the lymphatic system (Longnecker et al. 1997). However, PCBs do not appear to cause consistent increases in one or more cancers in the occupational setting, except possibly kidney cancer (Longnecker et al. 1997).

Rothman et al. (1997) detected a strong dose-response relationship between PCB exposure and non-Hodgkin’s lymphoma in a case-control study of a nonoccupational

population. PCBs can suppress the immune system, and immunosuppression is a risk factor for non-Hodgkin's lymphoma, although only severe changes in immune function have been linked with this cancer (Rothman et al. 1997). The authors caution that this finding should be considered hypothesis-generating rather than conclusive evidence of an association.

Several epidemiologic studies examined the possible association between PCB exposure and breast cancer (Krieger et al. 1994, Hunter et al. 1997, Hoyer et al. 1998, Moysich et al. 1998, Kimbrough et al. 1999). Longnecker et al. (1997) and Laden and Hunter (1998) conclude that these investigations generally do not support an association between breast cancer and PCBs.

U.S. Environmental Protection Agency Classification. USEPA concluded that there is inadequate evidence of carcinogenicity in human populations (USEPA 1999b, Bertazzi et al. 1987, Brown 1987, Sinks et al. 1992). Therefore, it classified PCBs as probable human carcinogens (group B2) based on animal toxicity data. PCBs generally test negative for genotoxic activity (ATSDR 1999). However, initiation-promotion studies for several commercial mixtures and congeners show tumor-promoting activity in the lung and liver and begin to reveal significant contributors to cancer induction (Silberhorn et al. 1990).

A 1996 study found liver tumors in female rats exposed to Aroclors 1260, 1254, 1242, and 1016, and in male rats exposed to 1260 (Brunner et al. 1996, Mayes et al. 1998). Earlier studies detected statistically significant incidences of liver tumors in rats ingesting Aroclor 1260 or Clophen A60 (Kimbrough et al. 1975, Norback and Weltman 1985, Schaeffer et al. 1984). Congeners present in the four Aroclor mixtures tested by Brunner et al. (1996) span the range of congeners most often found in environmental mixtures, although they are not identical to any particular mixture found in the environment. PCBs suppressed tumors in mammary glands of Sprague-Dawley rats, and enhanced tumor formation in the thyroid gland of the males and the liver of both sexes, but primarily in the liver of females (Mayes et al. 1998).

Some PCB congeners persist in the body, remaining biologically active after exposure ceases (Anderson et al. 1991). In one study, rats exposed to a persistent mixture (Aroclor 1260) developed more tumors than did rats exposed to a less persistent mixture (Aroclor 1016) (Brunner et al. 1996). To explore the possible effect of persistence, some rats were dosed for one year, then allowed to live one more year without exposure before being sacrificed. Brunner et al. (1996) found that one-half lifetime (i.e., 52 weeks) exposure to Aroclor 1260 resulted in more than one half the tumor incidence associated with lifetime (i.e., 104 weeks) exposure. Consequently, there may be greater than proportional effects from less-than-lifetime exposures to persistent mixtures (Cogliano 1998).

Mayes et al. (1998) recommend that PCB risk assessment distinguish among different PCB mixtures because they differ in tumor-inducing potency. In fact, current USEPA guidance for PCB risk assessment requires that such a distinction be made (USEPA 1999b).

Dioxinlike PCB Congeners. Several congeners appear to have 2,3,7,8-tetrachlorodibenzo-*p*-dioxinlike activity (Safe 1994). Strong evidence points to a common aryl hydrocarbon (Ah)-receptor signal transduction pathway mechanism of action. A toxic equivalency (TEQ) approach has been developed to represent the fractional toxicity of PCB congeners relative to TCDD for congeners exhibiting the following characteristics:

- Structurally similar to PCDDs and PCDFs
- Bind to the Ah receptor
- Elicit dioxin-specific biochemical and toxic responses
- Persistent and accumulate in the food chain (Van den Berg et al. 1998).

TEQs are calculated as follows:

$$\text{TEQ} = \sum [\text{PCB}_i \cdot \text{TEF}_i]_n$$

where PCB_i = concentration of dioxinlike PCB congener i

TEF_i = toxic equivalency factor for PCB congener i (unitless) provided in Table 36.2

n = number of PCB nonortho, monoortho, and diortho congeners in mixture of concern

PCBs with coplanar structure are similar to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin. Congeners with no chlorine substitutions or only one substitution in the ortho positions (2, 2', 6, 6') are regarded as coplanar (Fig. 36.1). TEFs for these congeners are derived from results of quantitative structure-activity studies (Table 36.2). The single TEQ value then represents the calculated concentration of dioxin equivalents in a sample.

In its review of the USEPA dioxin reassessment, the Science Advisory Board expressed concern that dioxinlike PCB congeners contribute more than 90 percent of the calculated TEQs in many cases, emphasizing the importance of exploring antagonistic relationships between dioxin- and nondioxinlike congeners (USEPA 1995).

There is some concern about relying too heavily on TEF and TEQ values for PCB risk assessment (Safe 1999). This approach assumes additivity among congener effects, neglecting possible synergism or antagonism. Safe (1999) describes nonadditive antagonistic interactions between AhR agonists (PCDDs, PCDFs, and dioxinlike PCB congeners) and other PCB congeners. Safe (1999) concludes that these nonadditive interactions along with the wide range of TEF values observed for some individual congeners compromise applications of the TEQ approach. Birnbaum (1999) acknowledges these nonadditive effects, but notes that the variability in TEFs for specific congeners narrows when pharmacokinetic factors are taken into account (DeVito and Birnbaum 1995).

Safe (1999) recommends more research on the utility, applications, and limitations of the TEQ approach. Birnbaum (1999) advocates use of the TEQ approach until a better

TABLE 36.2 Toxic Equivalency Factors for Selected PCB Congeners

IUPAC number	PCB congener chlorobiphenyl structure	Toxic equivalency factor (TEF)
77	3,3',4,4'	0.0001
81	3,4,4',5	0.0001
105	2,3,3',4,4'	0.0001
114	2,3,4,4',5	0.0005
118	2,3',4,4',5	0.0001

189	2,3,3',4,4',5,5'	0.0001

Source: Van den Berg et al. (1998).

approach is developed, especially given that several studies reveal correlations between predicted and observed responses based on TEQ evaluations.

Reproductive Effects

Reproductive toxicity observed in animal studies of PCBs include fetal death in rabbits; fetal toxicity, resorption, abortion, low birthweight, and impaired ovulation in monkeys; reproductive failure in mink; and fetal death, reduced litter weight, and male fertility effects in rats (Safe 1994). There is limited information describing possible reproductive developmental effects of PCBs. Postnatal lactational exposure of infant male rats to Aroclor 1254 resulted in adverse effects on mating behavior and reproductive success (Sager 1983).

Women occupationally exposed to PCBs gave birth to children about 60 g lighter than children born to women from the same plant with less exposure (Taylor et al. 1989). No relationship was found between occupational PCB exposure and decreased sperm motility (Emmett et al. 1988).

Studies of populations with relatively low levels of PCB exposure provide conflicting results about possible adverse reproductive effects. Some studies suggest that PCBs are associated with low birthweight (Fein et al. 1984, Wasserman et al. 1982), but others suggest increased birthweight (Dar et al. 1992, Smith 1984). No association was found between blood PCB levels in women living near the Great Lakes and spontaneous abortion (Dar et al. 1992, Mendola et al. 1995).

Neurodevelopmental Effects

PCBs may be neurodevelopmental toxicants. Neonatal hypotonia (decreased muscle tone) or hypoflexia at birth was found among babies in the top fifth to tenth percentile of prenatal PCB exposure for a North Carolina cohort, with slower motor development until 2 years of age (Rogan and Gladen 1992). In a Michigan cohort, children born to frequent fish consumers exhibited hyporeflexia at birth more often than did children born to fish abstainers (Jacobson et al. 1990a, 1990b). This effect was not as apparent when prenatal exposure levels were based on measured blood concentrations. A study in the Netherlands also found increased incidence of hypotonia among babies with greater PCB exposure, but PCB levels were correlated with dioxin levels that might confound study results (Huisman et al. 1995).

Jacobson and Jacobson (1996) found that prenatal exposure to PCBs in the Michigan cohort was associated with lower IQ scores, with the strongest effects related to memory and attention. The authors concluded that in utero exposure to PCBs in concentrations slightly higher than background concentrations found in the general population can have a long-term impact on intellectual function. Jacobson and Jacobson (1996, 1997) note that much larger quantities of PCBs are transferred to the infant postnatally via breastfeeding than across the placenta. Despite this fact, data from Michigan and North Carolina cohorts indicate greater vulnerability when the exposure occurs in utero. None of the measures of physical, cognitive, or motor development were related to the level of postnatal PCB exposure. Yucheng mothers were advised not to breastfeed infants and largely complied, so it is not possible to assess effects of postnatal exposure among the children of these women.

Rice (1997) reviewed epidemiologic and animal study evidence of PCB neurobehavioral effects and concluded that PCB concentrations typically observed in individuals in industrialized countries may result in neurotoxicity to offspring.

Immune System Effects

Svensson et al. (1994) and Weisglas-Kuperus et al. (1995) found that PCB exposure can result in alteration of lymphocyte subtypes, but these changes were detected in populations where dioxins or fatty acids from fish might confound the PCB-lymphocyte relationship. PCB exposure was associated with the frequency of infectious illness in the first 4 months of life in a Wisconsin cohort (Smith 1984), but not in a Dutch cohort of breastfed infants in the first 18 months of life (Weisglas-Kuperus et al. 1995).

Endocrine System Effects

The National Research Council (NRC) reviewed (1999) the potential endocrine-disrupting effects of PCBs and other hormonally active compounds. Specifically, the NRC summarized evidence of reproductive, immunotoxic, estrogenic, and carcinogenic effects related to disruption of endocrine function.

PCB congeners may be estrogenic (Soto et al. 1995, Li and Hansen 1995) or antiestrogenic (Moore et al. 1997). Exposure to PCBs is associated with decreased thyroid hormone levels (Koopman-Esseboom et al. 1994, Desaulniers et al. 1997). In mothers and their children from Rotterdam, background PCB exposures were associated with lower maternal T3 and T4 levels and higher infant TSH levels (Koopman-Esseboom et al. 1994). However, hormone levels were within normal limits and observed associations might be due to dioxins, which were highly correlated with PCB concentrations (Longnecker et al. 1997). Morse et al. (1996) found that orally administered doses of Aroclor 1254 were associated with decreases in fetal, neonatal, and weanling plasma total thyroxine and brain T4 concentrations, possibly due to selective accumulation of a hydroxylated PCB metabolite in fetal plasma and brain.

Some adverse effects may be thyroid-mediated. Haddow et al. (1999) found that undiagnosed hypothyroidism in pregnant women may adversely affect their fetuses, possibly by impaired neuropsychological development. In addition, in utero exposure to PCBs has been linked to reduced serum concentrations of thyroid hormones (Koopman-Esseboom et al. 1994). Goldey et al. (1995) prenatally exposed rats to Aroclor 1254, causing a reduction in circulating thyroid hormones that might have resulted in observed hearing deficits. This evidence collectively suggests that prenatal PCB exposure could cause adverse effects via thyrotoxicity.

Dermatologic Effects

Relatively high occupational exposures have been associated with chloracne and other skin abnormalities (Meigs et al. 1954, Fischbein et al. 1982). Consistency among studies leaves little doubt that PCBs cause chloracne (Longnecker et al. 1997).

36.5 U.S. ENVIRONMENTAL PROTECTION AGENCY TOXICITY CRITERIA FOR PCBs

Carcinogenic Effects

USEPA recommends a tiered approach to assess cancer risk associated with exposure to PCBs (USEPA 1999b). Studies to date suggest that more highly chlorinated, less volatile

congeners are associated with greater cancer risk. These congeners tend to persist in the environment in soils and sediment and bioaccumulate in biota. If congener data are not available, the exposure pathway can be used to indicate how the potency of a mixture might have changed following release to the environment. For example, more volatile, less chlorinated congeners are more likely to be metabolized and eliminated than are highly chlorinated congeners that persist in environmental media and bioaccumulate in biota.

Therefore, a higher cancer slope factor [upper-bound estimate = 2.0 per (mg·kg)/day, central estimate = 1.0 per (mg·kg)/day] is used to evaluate risk from exposure to highly chlorinated congeners or exposure via pathways that tend to involve highly chlorinated congeners. This higher slope factor is used for (1) food-chain exposure; (2) sediment or soil ingestion; (3) dust or aerosol inhalation; (4) dermal exposure, if an absorption factor has been applied; (5) presence of dioxinlike, tumor-promoting, or persistent congeners; and (6) early-life exposure (all pathways and mixtures).

A lower cancer slope factor [upper-bound estimate = 0.4 per (mg·kg)/day, central estimate = 0.3 per (mg·kg)/day] is used for more volatile PCB congener mixtures that are less persistent. This lower slope factor is used for (1) ingestion of water-soluble congeners, (2) inhalation of evaporated congeners, and (3) dermal exposure, if no absorption factor has been applied.

If congener or isomer analyses verify that congeners with more than four chlorines comprise less than 0.5 percent of total PCBs, USEPA (1999b) recommends use of an even lower cancer slope factor [upper-bound estimate = 0.07 per (mg·kg)/day, central estimate = 0.04 per (mg·kg)/day].

Cogliano (1998) states that bioaccumulated PCBs appear to be more toxic than Aroclors (Aulerich et al. 1986, Hornshaw et al. 1983) and more persistent in the body (Hovinga et al. 1992). However, cancer studies to date use Aroclor mixtures as test materials; therefore, Coglian (1998) recommends conducting a cancer study comparing commercial and bioaccumulated PCB mixtures.

With congener data, the slope factor approach can be supplemented by analysis of dioxin TEQs to evaluate dioxinlike toxicity. USEPA recommends that risks from dioxinlike congeners should be added to risks from the rest of the mixture estimated using an appropriate PCB cancer slope factor. However, because PCB test materials used in the 1996 cancer study contain some amount of dioxinlike congeners as well as PCDDs and PCDFs (Mayes et al. 1998), adding these risks together could be overly conservative if the PCB carcinogenicity is due, at least in part, to the dioxinlike congener content.

Noncarcinogenic Effects

Table 36.3 lists reference doses (RfDs) for PCBs. USEPA defines RfDs as estimates (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of adverse effects. RfDs are compared to estimates of average daily dose to determine whether noncancer effects are likely to occur. RfDs assume that a concentration or dose threshold exists, below which no adverse effects are expected.

USEPA last revised the RfDs in Table 36.3 in November 1996. The RfD for Aroclor 1016 is based on studies of perinatal toxicity and long-term neurobehavioral effects in infant monkeys. In this study, decreased birthweight and possible neurologic impairment were observed among infants born to exposed monkeys. The Aroclor 1254 RfD also is based on a study of monkeys. Preliminary analysis of reproduction and histopathology data suggest that effects on female reproductive function may occur at doses as low as 0.005 (mg·kg)/day and the RfD is derived from this value.

TABLE 36.3 U.S. Environmental Protection Agency Reference Doses (RfDs) for PCBs

Both RfDs were revised in 1996, but the PCB toxicity literature continues to grow. They are both based on animal studies rather than human studies, primarily because it is not possible to specify the type of PCB mixture, pattern of exposure, and route of exposure in most human studies.

36.6 INDOOR AIR PCB CONCENTRATIONS

Table 36.4 summarizes indoor air concentrations of PCBs reported in the literature for offices, homes, and laboratories. Outdoor air concentrations were provided where these measurements were collected simultaneously. Indoor air concentrations typically exceed outdoor air concentrations by at least a factor of 10. Except for indoor environments with known PCB sources, measurements in the mid- to late 1990s (Vorhees et al. 1997) are lower than measurements made in the early to mid-1980s (MacLeod 1981, Oatman and Roy 1986). Comparison of these numbers is complicated by the differing laboratory analytic and PCB quantification techniques used. However, the difference might reflect a general decline since the mid-1980s as the number of possible PCB sources decreases.

PCB concentrations as high as 580 ng/m³ have been measured in the indoor air of homes not identified as being affected by any local PCB source (MacLeod 1981). Much higher PCB concentrations have been measured in buildings with known PCB sources. For example, Balfanz et al. (1993a, 1993b) measured indoor air levels as high as 7500 ng/m³ in buildings with PCB-containing permanently elastic sealant composed of about 40% PCBs by weight. Fromme et al. (1996) measured PCB concentrations as high as 7360 ng/m³ in school community rooms with PCB-containing caulking compound.

Offices, Schools, and Laboratories

Canadian Laboratories. Williams et al. (1980) measured PCB concentrations in a laboratory in Ottawa where PCBs contaminated sample blanks. Air samples as well as caulking material samples were analyzed to isolate the source of PCBs in sample blanks. Indoor air samples were collected on Florisil and a filter using MDA Accuhaler, model 808, personal sampling pumps at rates from 1 to 2 L/min. PCBs were quantified using gas chromatography with electron-capture detection.

Concentrations in the laboratory ranged from 120 to 320 ng/m³. Levels elsewhere in the laboratory building ranged from 21 to 294 ng/m³. Chromatograms for indoor air samples resembled Aroclor 1254. The caulking material contained 28 to 36% PCBs, also exhibiting an Aroclor 1254 congener pattern. The PCBs contaminating sample blanks were attributed to this caulking material.

North Carolina Office Buildings and Laboratories. MacLeod (1981) measured PCB concentrations in an industrial research facility, an academic laboratory building, and a shopping complex. Outdoor air concentrations were measured outside two laboratory buildings when indoor and outdoor air temperatures were similar. All laboratories and offices contained fluorescent lights.

Indoor air samples were collected on polyurethane foam plugs (PUFs, 0.022 g/m³ density), using the low-volume mine safety appliance (MSA) portable pump model S and the Du Pont constant-flow sampling pump model P4000A. Sampling rates ranged from 2.5 to 4.0 L/min for 8- to 16-h sampling periods. Outdoor air samples also were collected on PUFs, using a Bendix hurricane pump to collect at rates of 100-500 L/min. Samplers were

positioned 1 to 2 m above the floor. All laboratory analyses of PUF extracts were conducted using a Tracor 222 gas chromatograph equipped with a ^{63}Ni electron-capture detector. PCB concentrations were reported as Aroclors 1242 and 1254.

Average laboratory indoor air concentrations exceeded outdoor air concentrations by a factor of 5. Laboratory indoor air concentrations ranged from 200 to 240 ng/m^3 , higher than those in the laboratory offices (80 to 110 ng/m^3). PCB concentrations in the shopping center office were lower, with a mean of 44 ng/m^3 .

Minnesota Office Buildings and Schools. Oatman and Roy (1986) provided background concentrations of PCBs in five state-owned office buildings and two elementary schools in 1984. All buildings used fluorescent lighting. All samples were collected on PUFs, using a Bendix high-volume pump to collect at rates of 570 to 590 L/min. Samplers were positioned 0.75 m above the floor. Both PUFs and filters were extracted for analysis with a Varian 3700 gas chromatograph equipped with a ^{63}Ni electron-capture detector. PCB concentrations were reported as Aroclors 1242 and 1254.

The average PCB concentration in buildings with transformers exceeded the concentration in buildings without transformers by a factor of ~ 2 (460 and 230 ng/m^3 , respectively). Overall, concentrations were slightly higher than those measured by MacLeod (1981).

German Office Buildings. Benthe et al. (1992) measured indoor air PCB concentrations in an office building where a PCB-containing sealant was used to join fabricated concrete elements. Samples were collected on Florisil at a sampling rate of 2.5 L/min. Analyses were conducted with a Varian gas chromatograph 3500 equipped with an electron capture detector. Indoor air concentrations in 45 rooms ranged from non-detected values to 1200 ng/m^3 . Nearly all of these concentrations were contributed by the most volatile congeners.

Balfanz et al. (1993a, 1993b) measured PCB concentrations in more than 100 buildings in Germany with PCB-containing permanently elastic materials. These products were used mainly in buildings constructed from fabricated concrete. Some buildings also contained particleboard ceiling panels with PCB-containing coatings.

Samples were collected on polyurethane foam plugs and glass fiber filters at a sampling rate of about 50 L/min. Both PUFs and filters were extracted for analysis with a Hewlett-Packard model 5890 gas chromatograph equipped with an electron capture detector. About 80 percent of PCBs passed the filter and adsorbed onto the PUFs.

Concentrations were reported for six PCB congeners: IUPAC (International Union of Pure and Applied Chemistry) numbers 28, 52, 101, 153, 138, and 180. Detected concentrations for the sum of these congeners ranged from 40 to 7500 ng/m^3 (Balfanz 1993a, 1993b). The more volatile the PCB commercial mixture contained in the sealant, the higher the measured indoor air PCB concentration.

German Schools and Childcare Centers. Fromme et al. (1996) collected indoor air samples in German schools and childcare centers to determine any impacts from PCB-containing elastic sealants. Average PCB concentrations in 308 community rooms of schools exceeded concentrations in 102 childcare centers by about a factor of 4 (geometric means of 230 and 48 ng/m^3 , respectively). About 15 percent of schools and 3 percent of childcare centers had concentrations greater than 300 ng/m^3 , and 5 percent of schools had concentrations greater than 3000 ng/m^3 , the level warranting intervention under German law.

Indiana University Offices and Laboratories. Wallace et al. (1996) collected indoor air samples from a number of public buildings on the Indiana University campus from 1987 to 1995. One high-volume and two low-volume sampling techniques were used over this period. Two techniques employed PUFs, while one low-volume technique involved a

diffusion denuder. All samples were analyzed with a Hewlett-Packard model 5890 gas chromatograph with an electron-capture detector.

Outdoor air PCB concentrations ranged from 1 to 2 ng/m³. Indoor air PCB concentrations sometimes exceeded outdoor air concentrations by a factor of 100. Indoor air PCB concentrations were highly correlated with building construction date. The highest concentrations were detected in the oldest buildings constructed prior to the ban on manufacture and use of PCBs. Capacitors might be the source of PCBs measured in this study. However, other sources (e.g., PCB-containing caulks and sealants) could not be ruled out.

Residences

North Carolina Residences. In addition to laboratory and office measurements, MacLeod (1981) measured PCB concentrations in nine private residences, using the same sampling and analytic methods. PCB concentrations were reported as Aroclors 1242 and 1254. Outdoor air concentrations were measured outside one home when indoor and outdoor air temperatures were similar.

Indoor air concentrations ranged from 39 to 580 ng/m³. The air outside one home contained 4-ng/m³ PCBs while indoor air collected on the same day contained 310 ng/m³, a factor of ~10 higher than the outdoor air. Four of the nine homes sampled had pre-1972 fluorescent lighting fixtures in their kitchens, but there was no correlation between lighting and PCB concentrations. MacLeod (1981) postulated that electrical appliances might be the source of PCBs detected in this study.

Residences Near the New Bedford Harbor Superfund Site. Vorhees et al. (1997) analyzed PCB concentrations and congener patterns in indoor and outdoor air in homes surrounding the New Bedford Harbor Superfund site during dredging of highly contaminated harbor sediments. PCBs volatilize from harbor sediments or waters, exposing residents living in nearby neighborhoods. The study was conducted while the most highly contaminated sediments ("hot spot" sediments) were dredged and piped to a confined disposal facility (CDF) along the western shoreline of the harbor about 1.5 km south of dredging activity (Fig. 36.3). The study assessed PCB levels in residential indoor air during disturbance of these highly contaminated harbor sediments. PCBs are ubiquitous in the environment (Eisenreich et al. 1981; Gregor and Gummer 1989; Hoff et al. 1992a, 1992b). Therefore, samples were collected concurrently in an appropriate comparison neighborhood removed from the harbor to discern the portion of contamination attributable to harbor proximity.

Indoor and outdoor air samples were collected for 34 homes between April 1994 and April 1995 on days when harbor dredging was scheduled (Fig. 36.3). These homes were recruited from five neighborhoods: three harbor neighborhoods (Acushnet, Fairhaven, and New Bedford "hot spot") immediately downwind of the hot spot and CDF (based on prevailing winds during fair weather when warm temperatures induce the greatest amount of volatilization from sediments and water) and two comparison neighborhoods (Dartmouth and New Bedford "downtown"). On each sampling day, two homes were sampled: one harbor neighborhood home and one comparison neighborhood home. Because higher PCB concentrations have been measured historically in urban areas than in rural areas (Eisenreich et al. 1981), rural Dartmouth homes were paired with rural Acushnet and Fairhaven homes and urban New Bedford "downtown" homes were paired with urban New Bedford "hot spot" neighborhood homes. Outdoor air samples were collected concurrently from a central site in each neighborhood (Fig. 36.3).

All samples were collected on quartz fiber filters followed by PUFs. Indoor air sampling rates ranged from 5 to 10 L/min, while outdoor airflow rates ranged from 190 to 230 L/min.

FIGURE 36.3 Residential indoor air and outdoor air sampling locations (Vorhees et al. 1997).

All analyses were conducted with a Hewlett-Packard 5890 series II gas chromatograph, using a ^{63}Ni electron-capture detector.

Indoor Air and Outdoor Air PCB Concentrations. On each sampling day, 24-h indoor and outdoor air samples were collected simultaneously and analyzed for 65 PCB congeners

to evaluate the relative importance of the harbor and indoor sources for human inhalation exposure. Outdoor air concentrations were highest in neighborhoods closest to the harbor (0.4 to 53 ng/m³) and contained slightly higher proportions of volatile PCB congeners compared to outdoor air concentrations from comparison neighborhoods (0.1 to 8.2 ng/m³). Indoor air concentrations in homes near the most contaminated part of the harbor (7.9 to 61 ng/m³) were slightly higher than concentrations in homes distant from this area (5.2 to 51 ng/m³).

In all neighborhoods, indoor air concentrations exceeded corresponding outdoor air concentrations (mean ratio = 32), suggesting the importance of indoor PCB sources even near a highly contaminated waste site. Figure 36.4a and b depicts daily indoor and corresponding outdoor air PCB concentrations for all harbor and comparison homes, respectively. With few exceptions, indoor air concentrations exceed outdoor air concentrations, regardless of neighborhood. In winter, these ratios increase, probably because colder outdoor temperatures reduce PCB volatilization from outdoor sources, while indoor temperatures remain relatively constant throughout the year. Indoor air PCB concentrations were not found to be significantly correlated with outdoor air PCB concentrations, regardless of neighborhood. Indoor air and outdoor air PCB concentrations in harbor neighborhoods often exceed concentrations in comparison neighborhoods.

PCB Concentrations and Congener Patterns on Filters. Filters were analyzed for a subset of indoor and outdoor air samples collected over the range of ambient temperatures that occurred during the study. The results of this filter analysis were used to assess the congener pattern and PCB mass fraction retained on filters under different sampling conditions. Filters are expected to collect the particulate-phase PCBs while gas-phase PCBs adsorb to the PUF. However, separation of the gas- and particulate-phase PCBs is hindered by the sampling procedures used in this study and most others (high-volume air sampling using a filter and solid adsorbent). Previous studies in which PCBs were quantified on both filters and PUFs from the type of high-volume air sampler used in this study demonstrate that nearly all the PCB mass ends up in the PUF (Ligocki and Pankow 1989, Manchester-Neesvig and Andren 1989, Foreman and Bidleman 1990), where the rate of particulate-phase PCB loss from filters is primarily a function of sampler flow rate and ambient temperature.

In this study, sampling condition differences in indoor and outdoor environments could result in different congener patterns and masses on filters. The indoor sampler flow rate is lower and subject to more constant indoor temperatures relative to outdoor temperatures. Gas/particle concentration ratios for PCBs rise with temperature (Manchester-Neesvig and Andren 1989); therefore winter air filters may contain more PCBs than do filters collected in summer.

On average, indoor air filters ($n = 12$) contained 6 percent of the PCB mass found on corresponding PUFs, while outdoor air filters ($n = 12$) contained only 1 percent. No obvious pattern difference was observed between indoor and outdoor air pairs, regardless of outdoor temperature during sampling. As other investigators have detected (Foreman and Bidleman 1990, Hoff 1992a, Duinker and Bouchertall 1989, Burdick and Bidleman 1981), all indoor and outdoor air filter congener patterns consistently show a higher proportion of more highly chlorinated congeners than PUF congener patterns.

Influences on Indoor Air PCB Concentration. Although indoor air PCB concentrations appear to be affected by neighborhood location, other factors may influence indoor PCB levels. These factors include the number of potential indoor PCB sources present during sampling and past or present occupational exposure to PCBs of residents. Residents were asked to provide their occupational histories and the number of potential PCB sources in their homes so that the relationship between these factors and indoor air PCB concentration could be explored.

(a)

(b)

FIGURE 36.4 Comparison of indoor air and outdoor air PCB concentrations for homes located (a) adjacent to New Bedford Harbor in Massachusetts and (b) in Dartmouth, Massachusetts, nearly 4 mi away from New Bedford Harbor.

Potential indoor sources were defined as electrical appliances and fluorescent lights more than 10 years old. No significant correlation was found between indoor air concentration and the number of potential indoor PCB sources reported by residents. The non-significant test result must be considered in light of the fact that electrical appliances and

fluorescent lights are the most obvious PCB sources, but do not necessarily represent all possible indoor sources.

Three residents with occupational exposure lived in harbor neighborhoods. Of the three homes with residents who were occupationally exposed to PCBs, one resident was currently employed in a PCB-using industry, one had not worked for 13 years, and the third resident had not worked for 30 years. After excluding these three homes, harbor and comparison indoor air concentrations were still significantly different ($p = 0.008$). This result suggests some influence of harbor contamination on indoor air.

PCB Congener Patterns in Indoor Air and Outdoor Air. Volatility decreases and molecular weight generally increases with increasing IUPAC congener number. Therefore, it is not surprising that congener patterns reflect a high proportion of the most volatile congeners. Figure 36.5 compares average congener weight-percent patterns in indoor air and outdoor air. In 30 of 34 homes, congener patterns in indoor air closely resemble the patterns in outdoor air. However, Fig. 36.5 shows a slightly higher proportion of more volatile congeners in outdoor air compared to indoor air. This difference reflects four homes with congener patterns that include high proportions of less volatile congeners. Indoor air in one home closely resembled Aroclor 1254. These “heavier” patterns may suggest indoor sources.

Importance of Exposure to PCBs in Indoor Air

There are no applicable indoor air quality guidelines for PCBs in private or public buildings. Occupational limits for PCBs are listed in Table 36.5. Indoor air PCB concentrations in Table 36.4 do not exceed regulatory limits, except in buildings with known indoor PCB sources. However, occupational limits are applicable to 8-h/day exposure periods for adults and do not necessarily protect against adverse health effects for commercial and residential exposure scenarios.

Office and laboratory concentrations ranged from 6 to 7500 ng/m³. Potential cancer risk for adults associated with these concentrations can be calculated using standard USEPA default exposure parameters for the workplace, the average daily inhalation dose equation (USEPA 1989), and the cancer slope factor of 0.4 (mg·kg)/day for inhalation exposure (USEPA 1999b). Using this information, potential cancer risk estimates range from 4×10^{-7} to 5×10^{-4} for this range of indoor air concentrations. Residential concentrations range from 5 to 580 ng/m³. Potential cancer risk estimates associated with these concentrations range from 5×10^{-7} to 7×10^{-5} . The non-cancer-hazard quotient for adult residents ranges from 0.07 to 2.3; a hazard quotient of 1 is typically the upper bound that is acceptable to regulatory authorities. These hazard quotients were estimated using the RfD for Aroclor 1016 because this commercial mixture might more closely resemble congener patterns in air than does Aroclor 1254.

The highest potential cancer risk estimates (i.e., 5 in 10,000 and 7 in 100,000) and potential non-cancer hazard estimates (i.e., 2.3) represent levels of possible concern to many federal and state regulatory authorities. However, people are likely to experience greater risk from consumption of PCB-contaminated seafood, meats, and dairy products.

36.7 REDUCING EXPOSURE TO PCBs IN INDOOR AIR

The ubiquitous nature of PCB contamination makes it difficult to reduce exposure. However, indoor air PCB concentrations appear to be declining over time as PCB-containing materials

FIGURE 36.5 Comparison of indoor air and outdoor air PCB congener patterns. Error bars indicate one standard deviation.

TABLE 36.5 Occupational Regulations and Guidelines for PCB Indoor Air Concentrations

Agency or government	Acronym*	Chlorodiphenyl– 42% chlorine, mg/m ³	Chlorodiphenyl– 54% chlorine, mg/m ³
U.S. Occupational Safety and Health Administration (OSHA)	PEL-TWA	1	0.5

are gradually discarded. Despite this trend, some buildings have unacceptably high concentrations of PCBs in indoor air (Balfanz et al. 1993a, 1993b; Fromme et al. 1996). Indoor air exposure to PCBs can be reduced by properly disposing of old appliances, fluorescent lighting, and other indoor sources of PCBs. Track-in of PCBs from the outdoor environment can be decreased through use of doormats and removal of shoes on entering buildings. PCB-containing building materials are more difficult to identify and remove. Therefore, these PCB sources might impact indoor air for some time.

ACKNOWLEDGMENTS

Portions of the research described in this section were made possible by grant 5 P42 ES-05947 from the National Institute of Environmental Health Sciences, NIH, with funding provided by USEPA and a grant from the Harvard Center for Risk Analysis. Its contents are the sole responsibility of the author and do not necessarily represent the official views of the NIEHS, NIH, or USEPA. The contributions of Alison C. Cullen, Sc.D., Larisa M. Altshul, Jeffrey Silverman, Craig De Ruisseau, Raisa Stolyar, and Thomas Dumyahn are greatly acknowledged and appreciated.

CHAPTER 37

FIBERS

José Vallarino, M.S.

*Environmental Science and Engineering
Harvard School of Public Health
Boston, Massachusetts*

37.1 INTRODUCTION

Products made from fibrous substrates are ubiquitous in present-day buildings. The most common applications of these materials are for acoustic or thermal insulating products. Ceiling tiles, wall panels, interior duct lining, treatments applied to ceilings to absorb noise, and batten pads are examples of acoustic insulating products. Blown-in wall insulation, blanket insulation, pipe and exterior duct insulation, and boiler jackets are examples of thermal insulating products. Today, these products are made from vitreous fibers and cellulose fibers. Prior to 1980, asbestos fibers were also used in the manufacture of these products. In some applications, such as fireproofing, duct lining, ceiling tiles, and acoustic surface treatments, large surface areas of these fibrous materials are inside or part of the building's air distribution systems. Experience with similar applications containing asbestos has resulted in some public concern about the soundness of replacing a fibrous component—*asbestos*—with other fibrous components—*vitreous fibers* and *cellulose fibers*—in applications where large surface areas are exposed to air currents that can potentially disseminate fibers throughout the building.

This chapter presents a brief overview of three different classes of fibrous materials commonly found in today's buildings: *asbestos*, *vitreous*, and *cellulose*. The chapter continues with a discussion of the key differences among these three classes of fibers with respect to potential health effects, physical properties, and how each type of fiber may affect the quality of the indoor environment. We review recommendations and legal requirements on how to identify and assess the condition of these materials, and what control methods are necessary for situations arising from the presence of *asbestos-containing materials* or from the deterioration of materials containing these various fibers. For a more

detailed discussion of the health effects associated with these materials, the reader is referred to Chaps. 38 and 39.

37.2 ASBESTOS

Historically, the term *asbestos* has referred to fibrous silicate minerals that are resistant to heat, moisture, and chemical agents. The term asbestos, in its regulatory usage, constitutes naturally occurring fibrous silicate minerals that have been used as components of building materials, and whose underlying crystalline structure is such that larger fibers fracture into very thin fibers. Definitions of “critical” fibers, or those that are biologically of more significance, require the fiber to be greater than 5 μm in length and less than 3 μm in diameter with a length:width or aspect ratio greater than 3:1 (Sawyer 1979). The small size of many of these fibers renders them capable of penetrating into the alveolar region of the human lung. The minerals included in the regulatory term *asbestos* vary from country to country. In the United States, this term includes fibrous forms of the following minerals: chrysotile, reibeckite, anthophyllite, grunerite, actinolite, and tremolite. Reibeckite is known by its commercial name, crocidolite, and grunerite is known by its trade name Amosite. Materials containing these minerals are treated equally with respect to federal health and safety and environmental regulations in the United States. In Canada, the amphibole forms—reibeckite, anthophyllite, grunerite, actinolite, and tremolite—fall under different regulatory requirements from the serpentine form: chrysotile. In the United States, chrysotile has had the most widespread use. Chrysotile is estimated to represent 80 to 95 percent of the asbestos installed in buildings, based on usage figures (Langer and Nolan 1988).

Health Effects Associated with Asbestos Fibers

The adverse health effects of occupational exposure to asbestos have been exhaustively documented since early in the twentieth century (Cooke 1927, Dresser 1938). *Asbestosis* is the scarring of the lung tissue (interstitial fibrosis), as a result of inhalation of asbestos fibers (American Thoracic Society 1986). Chronic irritation results in damage to the lung tissue from sustained inflammation that leads to scarring and fibrosis, causing loss of pulmonary elasticity. The amount of scarring depends on the quantity of fibers inhaled, the duration of the exposure, the length:width ratio or aspect ratio of the fibers, biological persistence of the fiber type, and each individual’s susceptibility (Begin et al. 1986). Asbestosis is an occupational disease that is caused by high-level exposures to asbestos fibers, yet some asbestosis cases have been confirmed among household members of asbestos workers (Anderson et al. 1979). Even very brief high-level exposures have been linked to asbestosis. For asbestosis, an exposure threshold or lower limit below which there is no detectable manifestation of the disease has been reported in the literature (Berry 1980). These exposure thresholds are higher than the estimated exposure to asbestos of a person working a lifetime in a public and commercial building containing asbestos. However, the same cannot be said about the risk to a building maintenance worker in the same building, whose duties require work on or near friable asbestos-containing materials. As with the other asbestos-related diseases summarized below, it is to this worker that various asbestos regulations afford the greatest protection.

Among workers chronically exposed to asbestos, such as miners and insulators, there is an increased incidence of lung cancer (Sébastien et al. 1989). There is a synergistic effect

associated with asbestos exposure and cigarette smoking that can lead to substantially increased risks for asbestos-exposed workers (Saracci and Boffetta 1994). A minimum latency period of more than 20 years from the onset of initial exposure to the manifestation of the disease is typical. Asbestos has been classified as a confirmed human carcinogen by the American Conference of Governmental Industrial Hygienists (ACGIH) and as a known human carcinogen by the International Agency for Research on Cancer (IARC). Lung cancer has been associated with all types of asbestos.

Mesothelioma is a cancer of the mesothelial cells lining body cavities. Pleural mesothelioma occurs on the cells lining the lung, and peritoneal mesothelioma occurs in the cells lining the pleural and abdominal cavity. Mesothelioma is strongly associated with asbestos exposure. In an early review of approximately 3700 cases of mesothelioma, occupational exposure to asbestos had been identified in 43 percent of the cases (McDonald and McDonald 1977). Yet more remarkable, 9 percent of the cases were associated with family members of asbestos workers. In 48 percent of the cases, asbestos exposure was not reported, although almost all cases are thought to result from asbestos exposure. This strong association with asbestos exposure, even incidental asbestos exposure associated with living with an asbestos worker, suggested that low levels or ambient asbestos exposure might be responsible for the remaining 48 percent of the cases. Yet calculated risks of an occupant, in a building with asbestos-containing materials, contracting either mesothelioma or lung cancer disease are negligible (Spengler et al. 1988). The estimated risk of additional cancers due to environmental asbestos exposure is approximately 4 in 1×10^6 (Health Effects Institute 1991). These risks are much less than those attributable to radon. The greatest risk for developing mesothelioma has been associated primarily with crocidolite exposure and the extent of risk associated with chrysotile is controversial (Rom 1998, Landrigan 1998, National Research Council 1984).

In the United States, the public concern, over low-level exposure to asbestos causing mesothelioma and long latency periods associated with mesothelioma and lung cancer, was the rationale behind Congress enacting a comprehensive regulation requiring identification of asbestos-containing materials, and an active in-place asbestos management plan in all school buildings. The comprehensive regulation known as the Asbestos Hazard Emergency Response Act (AHERA) was enacted following school districts' failure to effectively comply with an earlier asbestos law known as the *Asbestos in Schools Rule*. The AHERA regulation required all school districts to name a "designated person" to be held responsible should the school district fail to comply with the regulation.

Physical Structure of Asbestos

The underlying microscopic crystalline structure of asbestos fibers is analogous on a macroscopic scale to the structure of a rope. Examination of the fibrous structure shows that each fiber is composed of a bundle of smaller fibrils. Asbestos maintains this structure to the molecular level. The result is that the strength of the fiber bundle is across its width, where it can bend and not break. However, across its length, the fibrils making up the larger fibers easily fray off. The result is that daughter fibers have diameters smaller than those of the parent fiber. These same physical properties, which give asbestos products their high tensile strength and make them commercially valuable, are what make asbestos fibers extremely hazardous. Long and thin fibers on the order of $<0.5 \mu\text{m}$ thick and $20 \mu\text{m}$ long pose the greatest health threat. The different toxicities of different types of asbestos fibers are due in part to the size of the fibers that typically break off the parent material. In terms of both the aspect ratios of fibrils sampled in air, and toxicity, crocidolite is greater than amosite, and amosite is greater than chrysotile (Lippman 1988).

Background Airborne Concentrations of Asbestos in Buildings

In 1992 the Health Effects Institute published available data on airborne asbestos concentrations measured in public and commercial buildings, schools, and residences. In 231 buildings, the mean asbestos fiber level was 0.00010 fibers per cubic centimeter (f/cm^3), the 90th percentile value was 0.00051 f/cm^3 , and the maximum was 0.0021 f/cm^3 . Over 50 percent of the samples had fiber levels below the limit of detection of the methods used (Health Effects Institute 1992).

37.3 VITREOUS FIBERS

The generic term *synthetic vitreous fiber* (SVF) designates a variety of manufactured amorphous fibrous products. These products are formed when a molten liquid mixture containing a large proportion of common oxides of high-ionic-charge elements, such as silicon, aluminum, and phosphorus, is quickly cooled to room temperature, solidifying yet retaining an amorphous atomic structure. Small amounts of cations such as Ca^{2+} , Mg^{2+} , and Na^{1+} are added to the liquid mixture. The quantity and type of cations added determine the chemical and physical properties of the final product. Sand, rocks, and slags are the most common raw materials for these products. Various commercial processes make the fibrous materials. The most common are spinning (wools), and drawing (continuous filaments or fibers).

In the literature, these fibers have been referred to as man-made (synthetic) mineral fibers (MMMFs), *man-made vitreous fibers* (MMVFs), and glass fibers (GFs). Some authors have used these terms to represent specific groups of fibers based on the raw material used to manufacture the product, such as glass fibers for products made from sand, rock, or mineral wool for products made from rock, and slag wool for products made from slag. Yet other authors have used the acronyms GF and MMMF interchangeably. This inconsistent nomenclature creates ambiguity when comparing studies published on nonoccupational exposure to these fibers.

Vitreous fibers are found in many common building materials including spray-applied fireproofing, ceiling tiles, thermal insulation, sound insulation, fabrics, filtration components, plasters, and acoustic surface treatments. In some applications, such as fireproofing, duct lining, ceiling tiles, and acoustic surface treatments, large surface areas of these fibrous materials are exposed to the building's airstream. The principal concern is erosion of fibers from the parent material into the building's airstream.

Health Effects Associated with Vitreous Fibers

Several epidemiologic studies have shown statistically higher risks of lung cancer and other respiratory system cancers among workers employed in vitreous fiber manufacturing facilities (Enterline et al. 1987, Shannon et al. 1987, Simonato et al. 1987, Marsh et al. 1990). Other investigators have argued that the elevated risks identified may be due to other cofactors such as cigarette smoking and not vitreous fiber exposure (Chiazze et al. 1995).

The ACGIH classifies vitreous fibers into two categories of carcinogenic potential. Continuous filament glass fibers are not classified as a human carcinogen due to lack of data. Agents receive this classification if there is some concern that the agent could be carcinogenic, but the available data are still inconclusive for classification of the compound as a carcinogen. Glass, rock, and slag wool and ceramic fibers are classified as confirmed animal carcinogens with unknown relevance to humans. Agents receive this classification if the agents have been shown to cause cancer in animals at relatively high doses, by routes of administration or by

mechanisms that may not be relevant for human exposure. The National Toxicology Program, in the *Seventh Annual Report on Carcinogens*, has identified glasswool (respirable size) and ceramic fibers (respirable size) as substances that may be reasonably anticipated to be carcinogens (National Toxicology Program 1994). The ACGIH has set the threshold limit value (TLV) for all vitreous fibers at 1 f/cm^3 on the basis of irritation. The ACGIH is proposing to reclassify ceramic fibers as a suspected human carcinogen. Beginning in 1999, the ACGIH began to separate ceramic fibers from other vitreous fibers and establish a distinct TLV for ceramic fibers at 0.1 f/cm^3 , which is analogous to the asbestos TLV of 0.1 f/cm^3 (American Conference of Governmental Industrial Hygienists 1998). Ceramic fibers are primarily used in high-temperature applications such as boiler or furnace insulation.

There have been several review articles that have documented the levels of airborne exposure to vitreous fibers in commercial buildings (Health Effects Institute 1991, Altree-Williams and Preston 1985, Gaudichet et al. 1989, Harrison and Llewellyn 1977, International Agency for Research on Cancer 1989a). The general conclusion reached in these reviews is that airborne vitreous fiber levels, which have been measured in buildings, imply that public health risks for cancers from projected lifetime fiber exposures are below reasonably estimable limits. The crux of these studies has been on health risks associated with chronic inhalation of these vitreous fibers (Valleron et al. 1992). The primary target organ identified in these studies is the lung. The primary route of exposure is the inhalation of airborne fibers. As a result, most studies have relied on criteria that discounted nonrespirable fibers and focused exclusively on respirable fibers. The most common criteria used is the WHO criteria of a fiber (diameter $<3 \text{ }\mu\text{m}$, length $>5 \text{ }\mu\text{m}$, aspect ratio >3) (International Agency for Research on Cancer 1989b). Studies on both products made with vitreous fibers and settled dust in buildings with vitreous fibers have shown that the average and median fibers diameters are wider than the WHO cutoff value of $3 \text{ }\mu\text{m}$ (Schneider et al. 1990, Christensen et al. 1994, Lenvik 1992, Kauffer et al. 1983, TIMA 1993, Schneider 1986, Skinner et al. 1988).

Since 1984 or 1985, vitreous fibers have been suspected as a possible cause of certain symptoms associated with sick building syndrome, primarily skin irritation and irritation of the mucous membranes (Sainmi 1990, Abbritti et al. 1990, Franck 1986, Kreiss and Hodgson 1984, Lob et al. 1984, Hedge et al. 1993). Vitreous fibers have been implicated as a possible cause of outbreaks of "office eye syndrome," "collective dermatitis," and upper respiratory tract irritation. In occupational settings, similar symptoms have been associated with vitreous fiber exposure. The fibers associated with these symptoms are thicker than those examined under the WHO criteria, and airborne fiber levels in occupational settings are at least an order of magnitude greater and often several orders greater than fiber levels measured in nonoccupational settings. In occupational studies of the dermal symptoms caused by vitreous fibers, the most severe manifestations of these symptoms are generally among the more recent hires, with severity decreasing with length of employment. Acclimation to the fibers as well as self-selection of workers, who perhaps are more tolerant to the irritation, have been identified as possible explanations for this temporal effect. One limitation of these occupational exposure studies is that the exposure is primarily from a single type of fiber. In nonoccupational exposures, the exposures are from a mixture of several types of fibers, arising from several source materials.

Several studies have shown that fine fibers below $4.6 \text{ }\mu\text{m}$ ($10 \times 10^{-15} \text{ in.}$) do not cause cutaneous reactions (Heisel and Hunt 1968, Sulzberger and Bear 1942, Schwartz and Botvinick 1943, Milby and Wolf 1969, Stockholm et al. 1982). Therefore, the irritation is thought to be mechanical or physical and not immunologic. Fibers, with diameters greater than $4 \text{ }\mu\text{m}$, do not remain airborne for extended periods of time. Settling velocities are typically greater than 0.1 cm/s . The types of exposures that best describe these are cutaneous and mucous. The exposure routes are generally local in nature and result from the contact and transfer of fibers from surface to skin, from skin to mucous membranes, or from surfaces

to mucous membranes, and an airborne transfer route from surfaces to mucous membranes as a result of disturbance of the settled fibers as a result of occupants' activity. Most exposure data available are based on the WHO criteria and thus are not suitable for assessing exposure for these symptoms.

Physical Structure of Vitreous Fibers

It should be noted that unlike asbestos fibers, which can split along the length of the fiber, resulting in smaller-diameter fibers ($\ll 1.0\ \mu\text{m}$) that can penetrate more deeply into the lung, SVF break only along their diameters, resulting in shorter fibers of the same diameter. This difference is due to the unique crystalline structure of asbestos fiber, while SVF fibers are amorphous. If the structure of a rope is the macroscopic analog of an asbestos fiber, then a glass rod is the macroscopic analog of a vitreous fiber. Vitreous fibers break along their widths and are stronger across their lengths. This is a key difference when evaluating what happens to a fiber after it has been dislodged from its parent material. Some asbestos fibers can remain entrained in the air and travel great distances, considering their small diameters $<0.5\ \mu\text{m}$, via the air distribution system. On the other hand, vitreous fibers, because of their relatively wider diameters and generally larger size, may not travel as far from their parent material before settling out.

Vitreous fibers found in building materials are not homogeneous. Depending on the specific product end use, they have different physical and chemical properties on both microscopic and macroscopic scales. Vitreous fibers are coated with a variety of different binders, including phenolic resins, mineral oils, organometallic compounds, microvermiculite, and high-temperature polymers. These coatings alter the physical and chemical properties of the vitreous fiber, and can affect the toxicity of each individual fiber.

The Health Effects Institute published available data on airborne vitreous fiber concentrations measured in public and commercial buildings. The mean vitreous fiber level measured ranged from 0.00022 to $0.00005\ \text{f/cm}^3$, and the maximum measured was from $0.0062\ \text{f/cm}^3$ (Health Effects Institute 1992).

37.4 CELLULOSE

Cellulose building thermal insulation is a recycled product made from newsprint. Boric acid is typically added to the product for fire retardation. As a result of the classification of vitreous fibers as possible carcinogens, cellulose insulation has been marketed as a "healthier" alternative (Cellulose Insulation Manufacturers' Association 1997). Cellulose is also manufactured as a "greener" alternative since it is made from recycled newspapers. Cellulose has less embodied energy than vitreous fibers, which are produced in furnaces.

Health Effects Associated with Cellulose Fibers

Cellulose is classified as a nuisance dust. As with vitreous fibers, cellulose fibers may cause irritation to the mucous membranes and the upper respiratory tract. The ACGIH has established a TLV of $10\ \text{mg/m}^3$ for cellulose based on irritation. According to IARC, paper and pulp are not classifiable as to its carcinogenicity to humans. This category is used most commonly for agents, mixtures, and exposure circumstances for which the evidence of carcinogenicity is inadequate in humans and inadequate or limited in experimental animals (International Agency for Research on Cancer 1987). As with the health effects of asbestos and vitreous fibers, the data on health effects originate primarily from occupational expo-

tures and not from building-related exposures. On the basis of a few cases, some researchers have suggested that an increased risk of lymphoproliferative neoplasms, Hodgkin's disease, may be linked to employment in the pulp and paper industries (Greene et al. 1978, Milham and Demers 1984). In a case-control study of the paternal occupations of 692 children who had died of cancer in Massachusetts, researchers showed an association between paternal employment at a pulp or paper mill and tumors of the brain and other parts of the nervous system (six cases observed; relative risk 2.8) (Kwa and Fine 1980). Because of the number of associations tested in the study, this result may be due to chance (International Agency for Research on Cancer 1995).

The IARC has classified wood dust as a known human carcinogen. Adenocarcinoma of the nasal cavities and paranasal sinuses has been clearly associated with exposure to hardwood dust (International Agency for Research on Cancer 1981). *Wood dust*, also known as *sawdust*, is composed mainly of cellulose, polyoses, and lignin and a large and variable number of substances of lower relative molecular mass that may significantly affect the properties of the wood.

Health Effects Associated with Microbiological Growth

A key concern with all fibrous insulation products is moisture. Cellulose is used as a binder in many applications such as ceiling tiles or thermal insulation. Materials containing cellulose are prone to microbiological growth in the presence of moisture. Although asbestos and vitreous fiber insulation when new are not susceptible to microbiological growth, and insulation made from cellulose is treated with biocides, dust deposited over time often is sufficient to support microbiological growth in the presence of moisture. *Stachybotrys chartarum*, identified with upper respiratory tract irritation and acute pulmonary hemorrhage in infants (Croft et al. 1986, Centers for Disease Control and Prevention 1997), grows readily on wet cellulose material.

Background Airborne Concentrations of Cellulose Fibers in Buildings

Several researchers have reported that concentrations of cellulose fibers in indoor air are much more prevalent than asbestos and vitreous fibers (Schneider et al. 1996, Altree-Williams and Preston 1985). This observation is not unexpected since, in addition to building materials, commonly used paper products are also a source of cellulose in the indoor environment. Cellulose airborne concentrations have been reported to range from 0.01 to 0.63 f/cm³.

37.5 EXPOSURE ASSESSMENTS

Exposure Assessment for Asbestos

Asbestos exposure assessment is a two-step process. The first step is to identify the materials that may contain asbestos in the building. Once these materials have been identified, the risk of exposure associated with each material is evaluated. The assessment includes factors such as type, condition, and accessibility of the material. Following the hazard assessment, appropriate response actions can be undertaken. Response actions include instituting an operations and maintenance program for asbestos, which includes employee training, specialized work practices, and recordkeeping; or repair, removal, or isolation of the material.

Identification of Asbestos-Containing Materials

An exposure assessment for asbestos begins by conducting a materials inventory or an asbestos survey in the facility to identify all asbestos-containing materials. In the United States, people who conduct these inventories and collect samples must be trained and licensed by the state where the work is performed. It is crucial that this survey be carried out completely and accurately to assure the success of any management programs, which will be inherently based on the survey. Failure to identify asbestos-containing materials can lead to unnecessary exposures, delays, costly cleanups, and legal and regulatory difficulties. For the facilities manager or facilities engineer to evaluate the quality of an asbestos survey, the manager should be familiar with the general principles and requirements behind an asbestos survey. The next section provides an overview of those principles.

In 1990 USEPA published in the *Federal Register* a list of products that have been made with asbestos (U.S. Environmental Protection Agency 1990). The list was compiled as part of the Asbestos Information Act of 1988. All present and past manufacturers of asbestos-containing materials were compelled by law to submit to the USEPA a list of all asbestos-containing products that they had compiled, including product name, product use, and dates of manufacture. Table 37.1 contains a list of materials that may contain asbestos. The table was compiled from personal information and the USEPA list. The table is not all-inclusive; however, it is clear from examining the list that most buildings will contain several materials that could possibly contain asbestos.

In the United States, for every building in which there are people working and where asbestos-containing materials may be present, the building owner has the following legal responsibilities:

- Identify potential asbestos hazards.
- Keep records about potential asbestos hazards.
- Post signs warning about potential asbestos hazards.
- Communicate to workers and employers about potential exposure hazards.

The regulation requires building owners to determine the presence, location, and quantity of asbestos-containing materials in the building. The building owners are required to maintain these records for as long as they own the building, and to transfer the documentation to the subsequent owner. In the absence of any samples, certain materials falling under the heading “presumed asbestos-containing materials” must be assumed to contain asbestos if the building was constructed prior to 1981. The phrase “presumed asbestos-containing material” as used in the standard does not include all possible asbestos-containing materials, but is limited to thermal system insulation, surfacing materials that have been “troweled on or otherwise applied” and resilient floorcoverings. Once all “presumed asbestos-containing materials” have been identified, the employer can sample the materials to document whether the materials contain asbestos, should the owner wish not to treat all “presumed” materials as asbestos-containing materials. If the building owner chooses not to collect samples, the building owner must inform employers and people working in the building about the location of the materials. The employers of those who may disturb or come in contact with these presumed asbestos-containing materials during the course of their work must implement appropriate asbestos work practices, employee training, and start a medical monitoring program.

Although federal regulations do not mandate that building owners collect samples of all materials that could potentially contain asbestos, the due-diligence clause in the regulation places the burden on the owner to identify these materials. Often, asbestos surveys are standard lender requirements for purchase and sales and refinances, and thus documentation of the asbestos content or presumed asbestos content of certain materials may already exist.

TABLE 37.1 Selected Building Materials That May Contain Asbestos

Surfacing materials

- Spray-applied fireproofing on structural steel
- Cementitious troweled-on fireproofing on structural steel
- Spray-applied acoustic insulation on concrete or plaster
- Troweled on acoustic plaster on wire lathe (ceiling and walls)
- Plaster on lathe
- Acoustic ceiling plaster
- Firewall plaster in boiler rooms
- Decorative spray coatings on walls and ceilings
- Stucco

Thermal system insulation

- Wool felt insulation
- Preformed thermal insulation products (batts, blocks and pipe, duct and boiler covering)
- Pipe paper insulation, i.e., "aircell" pipe insulation
- Pipe fitting and valve insulation
- Radiator wall lining
- Pipe hanger support pads, pipes; otherwise insulated with glass fiber insulation
- Cork pipe insulation with aluminum foil/asbestos paper backing
- Glass fiber insulation with an asbestos felt backing
- Animal felt pipe insulation
- Glass fiber insulation joint sealant

Cementitious products

- Asbestos-cement piping
- Asbestos-cement boards
- Asbestos-cement ebony boards
- Asbestos-cement shingles
- Asbestos-cement siding
- Asbestos-cement corrugated panels
- Asbestos cement office partition panels
- Asbestos-cement airducting
- Finishing cement
- Asbestos cement ceiling tiles
- Insulating cement
- Asbestos cement electric ducts
- Thermal cement
- Millboard
- Cement
- Countertops, bare or vinyl-lined

Roofing products

- Roof coating
- Roofing felts
- Roofing shingles
- Roofing cement
- Roof paint
- Roll roofing

Flooring products

- Vinyl floor tile, 9 × 9 in.
- Vinyl floor tile, 12 × 12 in.
- Rubber floor tile
- Asbestos sheet flooring
- Concrete floor coating
- Asphalt tile
- Linoleum
- Vinyl sheet flooring using an asbestos felt backing

TABLE 37.1 Selected Building Materials That May Contain Asbestos (*Continued*)

Sealants and adhesives
Undercoating
Vinyl floor tile adhesive (either black or tan)
Drywall adhesive
Cement adhesive for glued-on ceiling tiles
Window pane caulking
Caulking compounds
Plastic cement
Fire-resistant vapor barrier and adhesive for cork (either black or tan)
Brush-applied vapor barrier to concrete (black, white, tan)
Polyurethane coatings and sealants
Sealers
Acrylic sealant
Steel floor plate adhesive
Black spot adhesive
Metal coatings
Masonry coatings
Other products
Asbestos rope
Vibration damping cloths on ducts
Joint compound
Ceiling tiles various sizes and styles
Gypsum board
Gaskets
Insulating tape
Taping and finishing compounds
Packings
Phenolic resin in electrical switches, plug receptacles and switch boxes
Textured paint
Countertop covering
Asbestos fabrics
Wicks
Gasketing tape
Wire insulation
Felt asbestos sheets
Electrical insulation
Oil-based paints

Source: The list was compiled from personal data and the USEPA list published in the *Federal Register*, Vol. 55, No. 30; Tuesday, Feb. 13, 1990.

There has been some confusion as to which materials fall into the mandatory “presumed” category that must be treated as asbestos-containing if the appropriate samples are not on file. Certain materials that have been considered surfacing materials have been exempted from the category of “presumed asbestos-containing materials” by OSHA in published interpretations. OSHA has issued the following interpretation on plaster: “unless the plaster is acoustical plaster as indicated by a honeycombed structure, or the plaster is decorative plaster with an appearance similar to acoustical plaster, it is not surfacing material” (U.S. Occupational Safety and Health Administration 1998). In the same letter of interpretation, OSHA indicates that stucco, paint, and joint compounds are not surfacing materials. However, USEPA has often ruled that plaster is a surfacing material, under its AHERA program.

The required documentation, to discount a material from the list of “presumed asbestos-containing materials,” is a predetermined number of bulk samples of the material for asbestos analysis (all with no asbestos detected in any of the samples). The required number of samples to be collected depends on the category of material and the amount of material as indicated in Table 37.2.

An inspector licensed under the USEPA-AHERA program, or a certified industrial hygienist must collect the samples. A laboratory licensed and accredited under the USEPA-AHERA program must analyze the samples. If any of the required samples show any asbestos content, even trace amounts, the material is considered asbestos-containing, unless a more sensitive analysis of the samples is undertaken. Samples showing up to 10% asbestos content can be further analyzed by a point-counting technique. Under the standard, the mandatory bulk sample analysis method, the percent abundance of asbestos is estimated visually. The sample under the microscope is compared to photographs of various fields on a visual assessment standard chart. The chart shows fields with increasing percentages of asbestos, typically 3, 5, 10, 20, 40, and 60%. Because of the imprecise estimating technique, if the analysis of a bulk sample shows even a trace asbestos content, a more sensitive means of estimation is required to determine whether the material has less than 1% asbestos. The more sensitive point-counting technique requires the analyst to examine 400 points over eight slide mounts of each sample using a microscope reticule known as a *Chalkley point array*. The percent asbestos is determined by dividing the number of points that contained asbestos by the total number of points observed. If under the point counting technique, all required samples contain less than 1% asbestos, the material is not considered asbestos-containing. The point-counting technique was adapted from a petrographic technique used to estimate mineral abundance in rock thin sections. Critics of using point counting for asbestos bulk samples argue that the method requires all components to be on a single plane and to have the same thickness as in a petrographic thin section (National Institute of Occupational Safety and Health 1994). A bulk sample for asbestos is not on a single plane; thus at each point examined there may be more than one component. Also the sample must be finely ground by mortar and pestle to facilitate this analysis; this milling will break up the asbestos fibers and spread them throughout the sample. Because of these two limitations, point counting will tend to overestimate the asbestos content (Jankovic et al. 1988). In lieu of the point-counting technique, bulk samples containing less than 10%

TABLE 37.2 Bulk Sampling Requirements to Determine Whether a Material Contains Asbestos

Surfacing material—each homogeneous area			
Area	<1000 ft ²	>1000 ft ² ; <5000 ft ²	>5000 ft ²
Number of samples	3	5	7
Thermal system insulation—each homogeneous area			
Length or area	>6 linear or square feet	<6 linear or square feet	Patches
Number of samples	3	1	1
Miscellaneous materials—each homogeneous area			
The number of samples is left to the discretion of the inspector with the following guidelines—in a manner sufficient to determine whether material is ACM*, collect bulk samples from each homogeneous area of miscellaneous material that is not assumed to be ACM			

*Asbestos-containing material.

asbestos content by the visual estimation analysis may be analyzed by electron microscopy to ascertain whether the samples contain more than 1% asbestos.

In most products containing asbestos, the various components are not thoroughly mixed in the product. In several applications, such as spray-applied fireproofing, the materials are mixed on site in very large batches, using very crude mixing devices. This lack of homogeneity is one reason why a single sample is insufficient to document whether the material contains asbestos. For miscellaneous materials, the inspector must consider the homogeneity of the material when determining the number of bulk samples to collect of each material.

Older buildings that have been partially renovated on several occasions pose difficulties for the inspector. In these buildings, materials such as ceiling tiles may appear to be the same material, yet they may have been produced by several different manufacturers at different times. Therefore, one sample is insufficient to determine whether the materials contain asbestos. A sampling scheme consisting of a number of samples collected at random from the entire area may be appropriate, or the inspector may rely on documentation provided by the building owner to decide how many different treatments are present and collect multiple samples from each treatment. One possible random sampling scheme is described in an USEPA booklet, *Asbestos in Buildings: Simplified Sampling Scheme for Friable Surfacing Materials* (U.S. Environmental Protection Agency 1995a).

Asbestos-containing materials associated with systems that have been abandoned in place could also be hidden behind new layers of sheetrock or false ceilings. If these items go unnoticed until a renovation project is under way, significant cleanup cost and project delays can occur. The renovation project design staff, the building management team, and the asbestos inspector should work together, each providing their expertise to ensure that all potential asbestos-containing materials are identified.

Another difficulty encountered when conducting an asbestos inspection is how to treat composite materials. Composite materials are applied in various layers but later harden into one. A wallboard system is an example of a composite material. It consists of the wallboard, the joint compound or finish plaster, the joint tape, and the surface treatment (paint or wallpaper). Various regulatory agencies have different requirements for composite materials. Current OSHA regulations require that these samples be split into their various components for analysis (U.S. Occupational Safety and Health Administration 1997a). The sample is usually collected as a composite, and a request is made to the laboratory to split the sample under the stereoscopic microscope. USEPA issued a ruling stating that for purposes under its NESHAP regulation wallboard samples can be analyzed as composite samples (U.S. Environmental Protection Agency 1994). If the composite sample shows less than 1% asbestos content, then the material is exempt from the NESHAP requirements, eliminating listing the material in the renovation or demolition notification to USEPA prior to removal, and permitting the material to be disposed of as construction waste rather than as asbestos-containing material. Notification to USEPA is still required for any renovation or demolition project, regardless of whether asbestos is present. However, the OSHA requirements, which are designed to protect the worker, still require the sample to be split with separate analysis of each of its components. USEPA allows composite sampling only on wallboard systems. All other composite materials, including wall plaster, must be split into their various components (U.S. Environmental Protection Agency 1995b). Efforts are currently being made by federal regulators to streamline and unify testing requirements across the various regulatory agencies. Yet, the different interpretations on the classification of surfacing materials and on composite samples of wallboard systems illustrate the difficulties faced by facility managers when they attempt to comply with the various asbestos regulations. Adding to the confusion is that state regulators often issue similarly inconsistent and vague interpretations.

Building owners must exercise due diligence in regard to identifying the presence of asbestos in thermal system insulation, surfacing material, vinyl flooring material, ceiling tile, joint compound, and other materials installed in buildings constructed after 1980. Materials installed after 1980 may need to be analyzed for asbestos, if there is no docu-

mentation on file confirming that they do not contain asbestos (U.S. Occupational Safety and Health Administration 1997b).

Although the use of asbestos in spray-applied fireproofing and thermal insulation has been banned in the United States, several building components may still be legally manufactured with asbestos and installed in buildings, such as

Asbestos cement	Gaskets
Corrugated sheet	Nonroof coatings
Asbestos cement flat sheet	Roof coatings
Asbestos clothing	Asbestos cement pipe
Pipeline wrap	Friction products
Roofing felt	Millboard
Vinyl asbestos floor tile	Asbestos cement shingle

According to the U.S. Geologic Service, 21,000 metric tons of asbestos was consumed in the United States in 1997 (Vita 1997). Although the quantity of asbestos consumed in the United States has dropped by 40 percent since 1991 (Fig. 37.1), over 50 percent of the asbestos consumed in the United States is used in the manufacture of building components (Fig. 37.2).

Assessment of Asbestos-Containing Materials

Once all asbestos or presumed asbestos-containing materials have been identified, the next step is to perform a hazard risk assessment. The objective of an asbestos hazard assessment

FIGURE 37.1 United States domestic asbestos consumption in metric tons. Consumption equals production plus imports minus producer exports of asbestos, plus adjustments in government and industry stocks. Data are rounded to three significant figures. (Source: Robert L. Vita, *Asbestos*, U.S. Geological Survey—Mineral Information, 1997.)

FIGURE 37.2 United States domestic asbestos consumption by end use for 1997. Consumption equals production plus imports minus producer exports of asbestos, plus adjustments in government and industry stocks. Value in parentheses is metric tons consumed. Data are rounded to three significant figures. (Source: Robert L. Vita, *Asbestos*, U.S. Geological Survey—Mineral Information, 1997.)

is to predict or determine when building occupants, employees, contractors, or utility personnel might come in contact with friable asbestos-containing material. A material is friable if it can be crushed, pulverized, or turned into dust by hand pressure. This distinction between a friable material and a nonfriable material is an important one for a building manager to understand. Asbestos regulations are aimed at assuring that all contact with friable asbestos-containing materials are controlled events. Contact with nonfriable asbestos-containing materials is not controlled unless the contact renders the nonfriable material friable. Asbestos-containing floor tile illustrates this example. Routine work on floor tile such as mopping or waxing is not covered under asbestos regulations; however, sanding of asbestos-containing floor tile, to prepare the tile surface to receive carpet adhesive, is covered under the regulation due to abrasion of the surface and release of fibers.

Once the situations in which there is potential for direct contact with friable asbestos-containing materials are identified, it must be determined whether the friable asbestos-containing material should be removed or if the individuals conducting the work should be trained, monitored, and outfitted with personal protective equipment according to OSHA regulations. In the case of a renovation or demolition project, there are no options. The friable asbestos-containing materials must be removed before the renovation demolition project begins. As for other maintenance projects that fall outside the scope of the renovation or demolition definition, such as changing HVAC filters above a ceiling in which the deck

is sprayed with friable asbestos-containing fireproofing, the employer of the person performing the work must comply with OSHA asbestos regulations. Provisions must also be made to ensure that other building occupants are not inadvertently exposed to asbestos during the maintenance activity.

The first criterion in an asbestos hazard assessment is to evaluate the friability of the material. If the material is nonfriable in its present state, one must determine the type of activities that could make the material friable. For instance, asbestos-cement panels can be made friable by sawing, grinding, or drilling into the material. Asbestos pipe insulation with its exterior covering intact is considered nonfriable; however, if the covering is removed on the pipe, the material is then considered friable. OSHA has lengthy regulations on work on friable asbestos-containing material. The employer is required to provide specialized training, respiratory protection, medical monitoring, and specialized equipment for work on friable asbestos-containing material.

If the material is friable but is not accessible to direct contact by untrained personnel, such as spray-applied fireproofing on steel beams above a ceiling, the inspector must determine the potential for fiber release. To determine the potential for fiber release of a friable material, the physical condition of the material is evaluated. The condition of the material is used to estimate the probability of fibers being released into the air. If a material is in the same physical condition as on the day it was installed, one can assume that the probability for fiber release is small. If the material shows signs of damage, deterioration, or abrasion, then one can anticipate possible fiber release in the future.

Typically asbestos inspectors rate the condition of a friable material into three categories: good, damaged, or significantly damaged. For each functional space (room or set of rooms with the same function), the inspector evaluates the condition of the friable material. A material is evaluated as *good* if it is the same color, texture, and appearance as on the day it was installed. A material is evaluated as *damaged* if the material has damaged areas representing less than 10 percent of its surface or 25 percent of a localized area. A material is evaluated as *significantly damaged* if the damage is to greater than 10 percent of its entire surface or greater than 25 percent of a localized area.

A final assessment criterion is to assign an access rating to each material, again by functional space. An *access rating* identifies the population that may potentially come in contact with friable asbestos-containing material. Most access ratings in use rely on work descriptions or labor categories. The most common system separates building occupants into four categories: general public, housekeeping, building engineering staff, and outside contractors.

Since the objective of an asbestos hazard assessment should be geared toward identifying, limiting, and controlling events when building occupants come in direct contact with friable asbestos-containing material, air samples are not recommended by the USEPA as a component of the hazard assessment (U.S. Environmental Protection Agency 1984). However, air samples are a necessary part of an asbestos operation and maintenance program. Air samples should be used to document worker exposure during contact with friable asbestos-containing materials to document that the level of respiratory protection is appropriate for the activity undertaken. Air samples are also used to confirm that the air quality in areas adjacent to areas in which asbestos-containing materials are being disturbed has been adequately isolated by the engineering controls. After an asbestos abatement activity or after work in which asbestos-containing materials are disturbed, air samples are used to document that fiber levels inside the contained area are below certain established guidelines so that the engineering controls can be removed and the area can be reopened for general occupancy.

Air samples for asbestos are typically analyzed by two methods: *phase-contrast microscopy*, which is the most common method used because it is relatively inexpensive (however, it is not specific for asbestos fibers, and in areas where other fibers are present,

i.e., vitreous and cellulose fibers, the fiber counts will be elevated) and *transmission electron microscopy*, which is specific for asbestos fibers (however, the analysis cost is generally >10 times as much as the phase-contrast microscopy analysis).

Once the assessments have been completed, an operations-maintenance program for the building must be designed and implemented. For an operations and maintenance program to be successful, it must be designed with the input from people who will have to implement the program.

Exposure Assessment for Vitreous and Cellulose Fibers

The previous section detailed assessment strategies for asbestos, in which the hazard assessment does not focus on determining the extent to which building occupants are exposed to asbestos fibers, as is the case with traditional exposure assessments: for radon, formaldehyde, and other hazards. Rather, the objective of the hazard assessment is to document the presence of asbestos-containing materials and to prevent the uncontrolled contact or disturbance to friable asbestos-containing materials by workers and building occupants. The preventive nature of the asbestos assessment is due primarily to regulatory mandate, which requires specific work practices, specialized training, engineering controls, and medical monitoring for anyone coming in direct contact with friable asbestos-containing materials. For vitreous fibers and cellulose, there is no regulatory mandate that prohibits workers or building occupants from direct contact with friable materials containing these fibers. For these materials, the objective of the exposure assessment is not to minimize exposure to the fibers in order to protect the workers against a potential cancer-causing agent, but rather to protect workers and building occupants from dermal and mucosal irritation arising from these fibers.

There are many methods for analyzing samples to determine their makeup, for both airborne fibers and fibers deposited on surfaces. The methods described in the chapters on vitreous fibers and asbestos fibers are all applicable to cellulose and all other nonorganic components of dust. As an initial assessment in response to complaints of mucosal and dermal irritation, identification of the various components present in the dust should not be the first course of action. There are several components common to dust apart from vitreous and cellulose fibers that can be irritating to the skin and mucous membranes. In addition to the vitreous and cellulose fibers present in building materials, the binders, fillers, and additives in these same materials may also provoke irritation to the skin and mucous membranes. A more effective approach is to attempt to determine the sources and/or causes of dust buildup and the rate of dust accumulation. Causes of dust buildup include material disturbance or degradation, ineffective house cleaning, electrical fields, and faulty HVAC filters.

If the cause of the dust buildup is determined to be ineffective housekeeping, then the cleaning procedures should be evaluated. However, if the dust accumulation is due to maintenance activities around or above the ceilings, requiring contractors and maintenance personnel to clean the area around their activity may be an appropriate response action.

Several sick building syndrome investigations and building surveys have reported an association between frequency of complaints and the dustiness of the environment. Symptoms associated with poor indoor air quality have been correlated with components of indoor dust (Skov et al. 1990). Gyntelberg et al. (1994) studied the relationship between qualitative, physical, chemical, and biological composition of indoor dust and symptom prevalence. They found significant correlations between the concentration of gram-negative bacteria and general symptoms such as fatigue, headache, dizziness, difficulty in concentrating, and irritation of the mucous membranes and upper respiratory tract. Symptoms associated with mucous membrane irritation were also correlated with particle count per unit area. A significant correlation was found between the total volatile organic compounds

in the dust and concentration difficulties. Potentially allergenic materials in the dust or the macromolecular components were significantly correlated to the prevalence of headaches, general malaise, and dizziness.

Attempts at identifying a specific culprit for the experienced symptoms, specifically when dust is visible on surfaces, can lead to misguided and ineffective mitigation. Investigators have focused on individual components found in the dust and have obtained inconsistent results. Since the mid-1990s the focus has shifted from attempting to identify a specific component to comparing symptoms with various levels of cleaning.

The indications that dust buildup is an important factor influencing the prevalence of some symptoms have been supported by other studies. Hauschildt et al. (1996) found significant effects on eyes from dust in a climate chamber. Sundell et al. (1994) reported that the frequency of floor cleaning was inversely associated with an overrepresentation of skin symptoms among videodisplay terminal workers. In terms of overall perceptions of air quality, certain studies have suggested that buildings that appear cleaner will tend to have fewer indoor air quality complaints (Franke et al. 1997).

Conventional micro-vacuuming dust sampling techniques are often used to support conclusions linking the cause of the cutaneous and mucous symptoms reported in vitreous or cellulose fibers. This sampling method is highly qualitative and is selectively biased in favor of larger species such as vitreous or cellulose fibers. Because these materials are ubiquitous in modern building materials, they are very conspicuous in office dust samples, and are easily identifiable components that make up building dust. Vitreous fibers lack a specific crystalline structure (periodicity) and have a uniform morphology. Cellulose fibers have a variable anisotropic structure and readily identifiable morphology. Although determination of the particular type of fiber and source material of individual fibers in a surface dust sample is often attempted, the conclusions drawn are generally not defensible by light microscopic analysis and qualitative by electron microscopy, even when coupled with x-ray elemental analysis. Several vitreous fibers and cellulose products inside the building may have fibers with a similar elemental composition, and there may be several other natural sources or sources exterior to the building with similar elemental composition that can contribute to the indoor dust (Tiesler and Draeger 1993, Spurny and Stober 1981, Schneider et al. 1996).

Several researchers have looked at the release of fibers from building materials containing vitreous fibers (Balzer et al. 1971, Cholak and Schafer 1971, Gamboa et al. 1988, Hays 1991, Shumate and Wilhelm 1991, Nielsen 1987). The results of these studies have shown that most of these materials emit fibers primarily during the product installation phase, that no significant quantity of fibers is emitted during the lifetime of these products, and that with proper cleanup after installation, fibers do not remain in occupied spaces. Yet in most surface dust samples collected inside buildings, vitreous fibers and cellulose fibers are often present (McCrone 1982). These fibers may be present in the dust because they are left over from building construction or renovation, or may result from erosion of fibrous material or disturbance to the material during routine maintenance activities. A simple maintenance activity such as replacing a filter in a heat pump located above the ceiling can dislodge fibers from several different materials. To access the heat pump, ceiling tiles need to be removed. As the tile is removed, it comes in contact with the ceiling tile grid and supporting wires, causing a visible discharge of dust. On top of the ceiling tiles, fibers from the tile itself, the fireproofing, and any batten or sound insulation are then introduced into the occupied space when the tile is lifted. If there is glass fiber batten placed atop the ceiling for sound insulation, it, too, will release fibers as it is disturbed. Finally, fibers from the duct insulation on the heat pump and the spray-applied fireproofing may be inadvertently released on abrasive contact while working in the limited space above most suspended ceilings. Activity such as running cable for new computer or phone systems, installation of security and fire safety systems, repair of leaks, pest extermination, or indoor air quality investigations are common in office buildings.

Considering the number and frequency of different types of maintenance activities requiring access to the space above the ceiling, it is clear that disturbance of material containing vitreous and cellulose fibers may be a significant source of fibers found in building dust. The episodic nature of these disturbances, where relatively large amounts of fibers can be introduced into the occupied spaces in a short period of time, makes it difficult to resolve the contribution of fibers to surface dust caused by erosion of the parent material.

The importance of considering the affected population and its exposure history when assessing exposures is illustrated by the case of vitreous fibers. People who are consistently exposed to a noxious or irritating agent in an occupational setting may become acclimated to the agent and are able to tolerate larger doses. There is also a self-selection of workers, who perhaps are more tolerant to the agent causing the irritation than is the general population. Construction personnel and maintenance workers who work in environments that are very dusty and where the dust is laden with vitreous fibers, such as cellulose and other irritating agents, typically become acclimated to the conditions, or change occupations. The typical building occupant has not undergone this self-selection process and may manifest symptoms such as rashes at relatively low contamination levels as compared to the construction or maintenance worker.

37.6 CONCLUSION

Fibrous materials are commonly used building products throughout the world. The materials differ dramatically in their physicochemical characteristics and potential to cause adverse health effects. Therefore, evaluation and risk management techniques should be developed that are appropriate for the various materials and their usage.

Building owners and facility managers should attempt to identify asbestos-containing materials in the workplace. Some materials, primarily thermal insulation and surfacing materials applied to buildings before 1980, must be presumed to contain asbestos unless adequate sampling documentation is on file. There are specific sampling requirements, including who can collect the samples, who analyzes the samples, and the minimum number of samples to be collected, which must be followed. Once all the materials have been identified, the conditions under which building occupants and maintenance workers can come in contact with friable asbestos should be evaluated. Uncontrolled contact with friable asbestos-containing materials is prohibited by regulation. If building occupants can come in direct contact with friable asbestos-containing material, the material in question must either be removed or rendered nonfriable by encapsulation or enclosure of the material. An example is asbestos-containing pipe insulation. If the protective outer non-asbestos-containing covering is intact, it is considered a nonfriable material and may remain in an area accessible to building occupants. However, if the outer covering is damaged, the same material is considered friable, and it must be either removed or the protective covering must be repaired. Trained personnel should perform the removal, repair, encapsulation, or enclosure, and they should use appropriate work practices that include personal protective equipment and engineering controls to protect themselves and building occupants from exposure to asbestos. If the friable material in question is accessible only to maintenance and service personnel, the service personnel must be trained, use appropriate work practices (including engineering controls and personnel protective equipment), and receive personal exposure and medical monitoring. If trained and equipped personnel are not available to perform the work, the friable or potentially friable material must be removed prior to the onset of the maintenance or service work. A carefully performed asbestos survey and an asbestos operation-maintenance program designed with input from the individuals who will be carrying out the program are essential to protect building occu-

pants and maintenance and service personnel from unwanted asbestos exposure and to avoid costly work stoppages and legal and regulatory liabilities.

Vitreous and cellulose fibers are two common components of indoor air and surface dust. These materials, along with a myriad of other components of building dust, can be irritating to skin and mucous membranes. The building manager should be aware that different populations in the building, mainly building occupants and maintenance and construction personnel, will have different exposure histories. The maintenance and construction personnel have generally become acclimated to the irritant effects of these materials through their day-in/day-out contact with construction dust. The building occupants have not undergone this acclimation process and are thus susceptible to irritation from contact with these agents. Proper housekeeping and isolation of maintenance and construction activities may go a long way toward preventing discomfort to building occupants. Because of the irritant nature of dust, attempts at identification of the specific component causing the discomfort may be counterproductive. A more productive approach is to focus mitigation efforts on controlling the various causes of dust accumulation.

CHAPTER 38

ASBESTOS

Stephen K. Brown, M.App.Sc., G.Dip.Occ.Hyg.

*CSIRO Building, Construction, & Engineering
Highett, Australia*

This chapter summarizes asbestos products that are relevant indoors and describes the types of asbestos and the building products in which they were used in the past, especially in relation to the composition and the physical properties of products that can influence their impact on indoor air. Airborne asbestos exposures and the risks presented to building occupants are considered for activities associated with asbestos release from building products. Information on where products occur in buildings and procedures for their inspection, sampling, and identification are described. Regulatory requirements differ between countries and receive little attention here, apart from where they are considered to be common and to demonstrate best practice. Much of this chapter is based on key reviews (Brown 1981, Levine 1978, National Research Council 1984, Bignon 1989, Health Effects Institute 1991) which the reader is advised to consult for more information.

38.1 COMMERCIAL ASBESTOS AND HEALTH RISKS

Description of Asbestos

Asbestos is a generic term used to describe a group of different types of hydrated, crystalline silicate minerals, all of which possess the attribute of breakdown into individual fibers (or groups of fibers) when crushed and processed. Such fibers exhibit good thermal and chemical resistance as well as a number of valuable mechanical properties. Within each commercial type of asbestos, there is a broad range of chemical compositions, crystal structures and fiber size,

shape and properties, which have been described with diverse terminology (National Research Council 1984). The principal types are forms of either serpentine or amphibole minerals. Chrysotile $[(\text{Mg,Fe})_6(\text{OH})_8\text{Si}_4\text{O}_{10}]$ is a serpentine mineral and tends to form long, silky fibers that are easily woven, a property utilized in many of its applications. It constituted more than 90 percent of the asbestos produced throughout the twentieth century. Three amphibole asbestos minerals have major industrial applications (Bignon 1989):

Amosite:	$\text{Mg}_7(\text{OH})_2\text{Si}_8\text{O}_{22}/\text{Fe}_7(\text{OH})_2\text{Si}_8\text{O}_{22}$
Crocidolite:	$\text{Na}_2(\text{Fe}^{3+})_2(\text{Fe}^{2+})_3(\text{OH})_2\text{Si}_8\text{O}_{22}$
Anthophyllite:	$(\text{Mg,Fe})_7(\text{OH})_2\text{Si}_8\text{O}_{22}$

Other amphiboles are tremolite, which has very limited industrial application but has been present as a contaminant in talcum preparations, and actinolite, which has rarely been used commercially.

Exposure Measurement

The fibers in each type of asbestos differ from each other in crystal structure and chemical compositions, and these differences are responsible for variations in physical properties and probably adverse effects on human health. While the specific properties that are necessary and sufficient to affect health are unknown, clearly important properties are respirability, (small) fiber diameter and (high) aspect ratio, the number of fibers (rather than mass) that become airborne, and fiber durability. A definition for asbestos *fibers* that has been used in the measurement of an *index of exposure* relevant to health effects has been particles viewed under phase-contrast optical microscopy (PCOM) which have length:diameter aspect ratios of 3:1 or more, lengths greater than 5.0 μm , and diameters less than 3.0 μm . However, the limit of fiber diameter resolution by PCOM is approximately 0.2 μm and all asbestos types can exhibit fine fibrils and fibril bundles with diameters below this limit. Detection of these requires the use of transmission electron microscopy (TEM) procedures. There is a range of methodological issues that arise with TEM procedures (e.g., sampling, handling and transformation, fiber definition, data interpretation), although procedures (for air sampling and for surface sampling) are in the process of standardization by the American Society for Testing and Materials (ASTM, Subcommittee D2207, Asbestos). By contrast, PCOM procedures have existed as standard methods in many countries since the early 1980s and most health assessment studies have been based on this index of exposure.

PCOM procedures are useful in industrial settings where asbestos products are handled and most of the airborne fiber is expected to be asbestos. However, since the procedures cannot specifically identify the fibers that are counted as asbestos, and have limited resolution for fine fibers, they have been widely rejected for assessing environmental asbestos concentrations in buildings or outdoor air. Specifically defined TEM procedures have found application for such assessment. This report provides clear distinction between asbestos concentration measurements on the basis of these two procedures: PCOM and TEM. A detailed review of their use and limitations can be found elsewhere (Health Effects Institute 1991).

Health Risks

Exposure to airborne asbestos in occupational situations has resulted in a number of adverse health effects to those exposed. A detailed review of these effects was presented by Rom (1998). The primary health effects noted are

1. *Asbestosis*. A diffuse or multifocal interstitial fibrosis (scarring) of lung tissue due to inflammatory damage of the interstices of the airways and the alveoli, the area of the lung where oxygen transfers from inhaled air to the blood. Unless exposures are extremely high, asbestosis degrades lung function slowly with occupational exposure and typically requires more than 10 years to develop. It is a long-term, irreversible and disabling disease that can progress even after exposure to asbestos ceases. Severe cases are fatal. All types of asbestos can cause asbestosis.

2. *Lung cancer*. An increased incidence of lung cancer has been observed in asbestos workers. Histologically and cytologically, these cancers are indistinguishable from those caused by cigarette smoking. The risk tends to be greater for those with higher exposures (e.g., up to a fivefold increase in risk), and smokers may be at a more than additive risk (up to 50-fold) (National Research Council 1984). All types of asbestos are regarded as potent carcinogens (Landrigan 1998).

3. *Mesothelioma*. This is a rare cancer, generally fatal (despite therapy), consisting of a lumpy growth arising in the mesothelial cells lining the pleural (lung) and peritoneal (abdomen) cavities. Exposure to airborne asbestos has been shown to cause pleural and peritoneal mesothelioma, usually after a long latency period (20 to 40 years) from first exposure and without any influence from cigarette smoking. All fiber types have been implicated in causing mesothelioma, although this remains an area of controversy for chrysotile (Rom 1998, Landrigan 1998, Camus et al. 1998); the greatest risk is found for crocidolite exposure. For example, up to 2 percent of chrysotile miners and textile workers have been reported to develop mesothelioma, while incidence has been up to 10 percent for workers using crocidolite in gas masks (National Research Council 1984), although different degrees of dust control in the workplaces could have influenced these findings (Rom 1998). Most cases have been associated with occupational exposure (directly or by second-hand household contact from fibers brought into the home on the clothes of workers), but in 10 to 30 percent of cases in the United States, no asbestos exposure could be determined (Health Effects Institute 1991). Measurements of lung fiber counts of victims in Australia (NIOHS 1993) have suggested that asbestos exposures can be unrecognized in many cases. Also, environmental risk is a concern since mesothelioma cases have been recorded in residents near crocidolite mines who had never worked in the mines or mills (Rom 1998) and in French populations with cumulative exposures far below industrial exposure limits (Iwatsubo et al. 1998).

There is also some evidence that occupational exposure to asbestos can increase the risk of other cancers, for example, in the stomach, intestines, larynx, esophagus, kidneys, and pancreas. However, the evidence is less conclusive and the incidence is much lower than that found for lung cancer (National Research Council 1984, Health Effects Institute 1991).

These observations have largely been made for people who are occupationally exposed to asbestos at levels that are many thousands of times greater than exposure levels in buildings constructed with asbestos products which are stable and not subject to damage (see this chapter, "Physical Properties and Fiber Release"). The health hazards associated with typical indoor air (nonoccupationally related) exposures cannot be directly measured and are generally estimated by extrapolation of occupational findings using the following assumptions (National Research Council 1984, Health Effects Institute 1991):

- The different types of asbestos cause similar health effects at similar risks, and so need not be differentiated in risk estimates.
- Asbestosis is not significant at the low exposures encountered in indoor environments.
- Lung cancer and mesothelioma risks are proportional to the level of exposure, even at levels 100,000 times lower than those of epidemiologic studies.
- The concentration of the number of fibers longer than 5 μm and visible in a "direct" TEM procedure is the appropriate measure for estimating risk.

- Concentrations measured can be used to assess risk using the dose-response relationships derived from historical industrial measurements based on PCOM procedures.

Because of the reliance on such assumptions, it is important to view these risk estimates as “guides to the qualitative assessment of non-occupational health risks from asbestos...not as definitive estimates of the amount of disease to be anticipated” (National Research Council 1984). Based on the measurements of indoor air and ambient air asbestos concentrations (see this chapter “Degradation”), the estimates shown in Table 38.1 have been reached for lifetime cancer risks from exposure to asbestos in different scenarios (Health Effects Institute 1991).

The lifetime risk estimates for general occupants of office buildings containing asbestos construction materials or for children attending schools range from 4 to 6 (estimated from average indoor asbestos concentrations) to 40 to 60 (estimated from “high” concentrations found in some buildings) deaths per million persons exposed. For a perspective on the public health consequences of these exposures, the lifetime U.S. risks of lung cancer projected from exposure to indoor radon and environmental tobacco smoke were 5000 to 20,000 per million and 2000 to 5000 per million, respectively (Health Effects Institute 1991).

Building trade and maintenance workers in buildings containing asbestos construction materials are known to intermittently disturb these materials in the course of their work; depending on the friability of the asbestos materials and the work practices utilized, significantly high (albeit short-lived) exposures to asbestos dust will occur to these workers. A reliable estimation of average exposures to these workers is presently not possible, but it is

TABLE 38.1 Estimated Lifetime Cancer Risks for Different Scenarios of Exposure to Airborne Asbestos Fibers*

Conditions	Premature cancer deaths (lifetime risks) per million exposed persons
Lifetime, continuous outdoor exposure	
0.00001 f/mL from birth (rural)	4
0.0001 f/mL from birth (high urban)	40
Exposure in a school containing asbestos building materials, from age 5 to 18 (180 days/year, 5 h/day)	
0.0005 f/mL (average)†	6
0.005 f/mL (high)†	60
Exposure in a public building containing asbestos building materials, age 25 to 45 (240 days/year, 8 h/day)	
0.0002 f/mL (average)†	4
0.002 f/mL (high)†	40
Occupational exposure from age 25 to 45 0.1 f/mL (current occupational levels)‡	2000

*This table represents the combined risk (average for males and females) estimated for lung cancer and mesothelioma for building occupants exposed to airborne asbestos fibers (TEM measurements) under the circumstances specified. These estimates should be interpreted with caution because of reservations concerning the reliability of the estimates of average levels and of the risk assessment models.

†The “average” levels for the sampled schools and public buildings represent the means of building averages; the “high” levels shown as 10 times the average, are approximately equal to the average airborne levels of asbestos recorded in approximately 5 percent of schools and buildings with asbestos building materials.

‡The concentration shown (0.1 f/mL) represents the permissible exposure limit (PEL) proposed by the U.S. Occupational Safety and Health Administration. Actual worker exposure, expected to be lower, will depend on a variety of factors including work practices, and use and efficiency of respiratory protective equipment.

Source: Health Effects Institute (1991).

expected to be much lower than 0.1 f/mL (fiber per milliliter) (see this chapter, “Maintenance and Trade Occupants”). Lifetime cancer risk estimated from this level of exposure is also presented in Table 38.1 as an upper estimate of the risk to this population.

Exposure Guidelines

Occupational exposure standards exist in many countries to protect asbestos workers. In practice, industrial hygienists use these standards as guidelines to control health hazards to workers (ACGIH 1997) and may control asbestos concentrations to lower or “minimum practicable” levels of exposure, or may require respiratory protection to minimize exposures. Occupational exposure standards for asbestos are generally in the region of 0.1 to 2 f/mL (depending on the type of asbestos; lower standards are generally specified for crocidolite and amosite) as measured by PCOM procedures. These are inappropriate for use as indoor air guidelines, where exposure and control scenarios are somewhat different from those in industry.

Specific indoor air guidelines for asbestos are seldom recommended since all asbestos types are regarded as carcinogens with no “safe” level of exposure. The World Health Organization concluded that there were two actions for risk management of carcinogens: prohibition or the regulation at levels resulting in “acceptable” risk. Unit risk estimates for asbestos were provided to assist the latter action (WHO 1987), but it is generally acknowledged that the degree of acceptability of risk will vary between societies.

Indoor air guidelines for asbestos are generally specified as “clearance” measurements which are required prior to reoccupancy of a building after asbestos abatement works (e.g., removal, encapsulation) have been completed. Clearance requirements are commonly set at 0.01 f/mL by modified PCOM procedures (NOHSC 1988) or by TEM (direct) procedures (Health Effects Institute 1991), or 70 asbestos “structures” per square millimeter by an indirect TEM procedure (currently being standardized by ASTM) (ISO/CDI 13794).

38.2 ASBESTOS BUILDING PRODUCTS

Types of Products

By the 1970s, asbestos was used in over 3000 products, and these were not only building products; for example, uses varied from asbestos clothing in foundries, heat shields in hair dryers, to automotive friction (brake and clutch) materials. However, the greatest use for asbestos was in building products (Table 38.2), and although these uses have been progressively banned since the late 1970s, many of the products still remain in buildings of all types. Where these products are managed in place, their physical properties and liability to damage and degradation are important considerations.

Typical asbestos products manufactured in the 1970s and their compositions are presented in Table 38.3. For any product type there can be substantial variation in the type and content of asbestos used. Hazard evaluation requires an analytical assessment for each product to determine whether asbestos is present and, if so, the type and approximate quantity.

Uses in Buildings

Asbestos products were used in a wide range of applications in buildings, as summarized in Table 38.4. Many of the major uses in the United States were ceased during the 1970s, including spraying of asbestos-containing materials (1973), certain pipe coverings (1975),

TABLE 38.2 Estimated Asbestos Fiber Usage in Products

Product	Proportion of total consumption used in products, %

certain plaster patching compounds and artificial fireplace logs (1977), and sprayed-on asbestos decorative surfacing (1978). The production of all asbestos-containing materials for home construction and use in the United States was banned in three stages over 7 years, beginning in 1990 (American Lung Association 1998). Experience in other countries may differ somewhat from this, but it is believed that many have progressively reduced the use of asbestos products in buildings beginning in the 1970s. For example, it is reported that the European Commission chose to restrict asbestos use to chrysotile alone, which could be used in some 20 applications, including asbestos cement, friction products, gaskets, sealants, and asphalt (The Asbestos Institute 1998).

It is claimed that current world asbestos production is 99 percent chrysotile (consisting of 2.3 million metric tons in 1995) and that 90 percent of this is used in manufacturing asbestos-cement products in 60 countries (7 percent is used in friction products and 3 percent in couplings, plastics, and miscellaneous applications). In 1994 the major countries consuming chrysotile were (in decreasing order) Commonwealth of Independent States, China, Japan, Brazil, Thailand, India, South Korea, Iran, France, Indonesia, Mexico, Colombia, Spain, United States, Turkey, Malaysia, and South Africa (The Asbestos Institute 1998).

Physical Properties and Fiber Release

Virtually all asbestos products will release airborne asbestos fibers if the products are machined, that is, cut, sanded, abraded, or drilled. The levels of fiber release and the asbestos concentrations attained will depend on

TABLE 38.4 Uses of Asbestos Products in Buildings

Use	Product type
Floor systems	Tile underlay
	Vinyl floor tiles
	Vinyl sheet flooring (backing layer)
Internal walls and ceilings	Asbestos-cement sheeting
	Plaster spackle/filling compounds
	Textured decorative surfaces

Electricity supply	Duct insulation
	Switchboard insulation with asbestos millboard
	High-voltage insulators

- Physical properties of the asbestos products related to the ease with which they can be broken down (e.g., asbestos content, brittleness of binder material)
- The aggressiveness of the machining process (e.g., power tools will be more aggressive than hand tools) and the use of local exhaust ventilation
- The degree of ventilation of the work area

Short-term asbestos concentrations (PCOM measurements) are summarized in Table 38.5 to demonstrate the order of asbestos release experienced.

Products that are high in asbestos content and that use brittle binders (e.g., plaster, cement, starch) are generally classified (loosely) as *friable*, that is, they are easily crumbled and reduced to powder by hand pressure. Sprayed insulations are generally the most friable of asbestos products, followed by preformed insulation products (e.g., pipe coverings and board products) and asbestos millboard. Vinyl tiles tend to be nonfriable, as does asbestos-cement sheeting, except for roofing, which has been observed to undergo surface degradation by loss of cement binder (Brown 1998).

Light surface contact with friable asbestos products will lead to a release of asbestos fibers and is one factor that must be considered in the hazard evaluation of any building. Examples of such contact and resultant asbestos release are presented in Table 38.6. It is seen that light contact with insulation products or their debris can lead to substantial short-term concentrations of asbestos in indoor air. In a controlled brush erosion test, it was shown that fiber release from asbestos products with light surface contact occurred in the following order (Brown and Angelopoulos 1991), consistent with the abovementioned

TABLE 38.5 Asbestos Concentrations (Short-Term, PCOM Measurements) during Machining of Indoor Asbestos Products

Operation	Asbestos fiber concentration, f/mL
Machine sanding of vinyl tiles or resilient flooring residues	~1
Removal of vinyl tiles by scraping (Lundgren et al. 1991)	0.04–0.14 (0.0004–0.006 by SEM measurement)
Asbestos-cement sheet	
Hand saw	1–4
Jigsaw	2–10
Circular saw	10–20
Asbestos insulation board	
Handsaw	5–12 (20–60 in ship)
Drilling	2–10
Sanding	6–20
Jigsaw	5–20 (20–60 in ship)
Circular saw	>20
Plaster taping compound	
Hand sanding	5–10
Floor sweeping	>40

field observations: sprayed insulation $\gg$ millboard/insulation board $\sim$ weathered asbestos cement (AC) roofing sheet $>$ weathered AC wall sheet $>$ new AC sheet $>$ vinyl floor tile (no release). This same test was applied to several encapsulated sprayed insulations, where it was found that fiber release was still possible depending on the physical characteristics of and the quantity applied for each encapsulant.

Degradation

Degradation of asbestos building products with interior applications is not well understood, but there is sufficient anecdotal evidence to show it does occur for some products, especially those of high friability. It is presumed to be associated with some degree of physical contact by occupants or physical process in the building (e.g., vibration, air currents, vermin). Generally, physical degradation has been observed with friable insulation products; where these are above other items in the building (e.g., ceiling tiles, carpet, books), debris fallout from the insulation contaminates such items, and subsequent activities that disturb the items (Table 38.6) lead to asbestos exposures to occupants (Brown 1981, Health Effects Institute 1991).

An evaluation of the extent of degradation of asbestos building products requires an individual assessment for each product in each building by a technically competent person, such as an industrial hygienist with specialized knowledge in this area. Such evaluation should form part of the hazard evaluation and asbestos management strategy for the building (see Sec. 38.5). There may be a high degree of subjectivity in the evaluation, such as in rating of the current degree of damage and that expected with future occupation of the building; this will be less of a problem for less friable products and products that cannot be contacted by occupants.

The proportion of asbestos that is degraded or friable in typical buildings is also not well understood. An extensive survey of 886 public, private, and commercial buildings in New York City (Lundy and Barer 1992) revealed that 68 percent of the buildings contained insulation products: 19 percent of these buildings contained insulation in poor condition (>10 percent of surface damaged), 68 percent contained insulation in fair condition (surface

TABLE 38.6 Asbestos Fiber Concentrations (Short-Term, PCOM Measurements) in Buildings, Resulting from Surface Contact by Occupants or Their Activities

Activity	Asbestos fiber concentration, f/mL

damage <10 percent), and 13 percent were rated as good (little or no visible damage or degradation). It is not known if this survey is representative of the situation elsewhere.

In many countries (Australia, Europe), asbestos cement has been widely used as roofing sheets. These products have been observed to undergo a surface degradation process in which the cement binder in the weather-exposed surface is lost, exposing an asbestos-enriched surface layer. The degradation generally becomes visible after 15 to 20 years of roof installation, and occurs much more slowly on walls. Other physical (strength) properties of the asbestos-cement sheet are maintained, but several studies have demonstrated that an extremely low but measurable release of asbestos fibers occurs from the degraded surfaces to air around such buildings (Brown 1998).

Encapsulation

Encapsulation is the process of applying material to asbestos materials to surround or embed the asbestos fibers in an adhesive matrix to prevent the airborne release of asbestos fibers. The encapsulants must prevent such release not only during normal building conditions but also when the products are accidentally contacted by maintenance and trade workers. Specifications for encapsulants thus consider the strength properties of encapsulated friable products (ASTM 1997a, Brown 1990) as much as their ability to prevent fiber release (Brown and Angelopoulos 1991).

38.3 ASBESTOS EXPOSURE TO BUILDING OCCUPANTS

General Building Occupants

An extensive assessment of asbestos concentrations and risks in buildings has been published (Health Effects Institute 1991) using data from direct TEM measurements of asbestos fibers greater than 5 μm long. Building types included schools, residences, and public and commercial buildings. Some buildings contained friable products while others contained nonfriable products, but the presence and condition of friable products were not factors that could be evaluated because of data limitations. Some measurements were made in response to litigation. All measurements were made in the occupied spaces of the buildings to determine the levels of exposure to general occupants. Measurements were pooled for the different types of buildings and are presented in Table 38.7.

It was concluded that

- Building-average concentrations of asbestos ranged up to 0.008 f/mL in buildings containing asbestos materials under normal occupation.
- This upper-level concentration was relatively rare and could have been associated with building maintenance activities.
- Average concentrations in public and commercial buildings were approximately 0.0001 f/mL, and single samples rarely exceeded 0.001 f/mL.
- Average concentrations in school buildings were higher than those in public and commercial buildings, possibly due to a greater level of activity.

On the basis of these conclusions, the following (worst-case) estimates were made for asbestos concentrations in order to estimate the cancer risks (Table 38.1) to general building occupants:

	Average level, f/mL	High level, f/mL
Public/commercial buildings	0.0002	0.002
School buildings	0.0005	0.005

Maintenance and Trade Occupants

Maintenance and trade occupants of buildings are expected to work in the vicinity of friable asbestos products and to be exposed to higher concentrations of asbestos than general building occupants as a result of

- Disturbance of debris released previously from friable products
- Incidental contact with and accidental damage to asbestos products
- Uncontrolled removal or machining of small quantities of asbestos products

As presented in Tables 38.5 and 38.6, such activities are expected to lead to short-term asbestos concentrations that are much greater than those experienced by general building occupants. However, there has been a lack of study of time-activity patterns and air sampling for maintenance and trade occupants by which their asbestos exposures can be accurately evaluated. This was an identified research need, and in the absence of better data, it has been assumed for risk estimates that such exposures were below the minimum occupational exposure standard of 0.1 f/mL (Health Effects Institute 1991) (Table 38.1).

Postremoval of Asbestos

Practices for removal of friable asbestos products from buildings involve stringent containment, product handling and disposal, postremoval cleaning and encapsulation of contaminated surfaces, and clearance air sampling. In the United States, USEPA has provided guidelines for clearance sampling that must be met before the contractor is released from further cleaning of the site. This required aggressive air sampling (whereby residual

TABLE 38.7 Distribution of Average Asbestos Concentrations (Direct TEM Measurements) in Occupied Spaces of Buildings

asbestos will be resuspended from surfaces) with at least five samples collected; all concentrations must be below 0.01 f/mL by PCOM measurement. However, TEM is reported as the method of choice, with five samples collected inside and outside of each homogeneous work area; averages of inside and outside measurements should not be statistically different or the average work area concentration should be below 70 asbestos structures/mm² (by an indirect TEM procedure) (Health Effects Institute 1991).

Removal of asbestos products (particularly friable insulation products) from buildings is an extremely disruptive process that may lead to contamination of building surfaces and building air with asbestos fibers after completion of the process. Several studies have investigated indoor air concentrations before and after the removal, the latter not only at the clearance stage but also with reoccupancy of the building.

A summary of these studies (Table 38.8) shows that in many cases asbestos concentrations were higher shortly after removal of asbestos products than before, but that levels after several weeks were similar to those before removal (in the limited number of cases where this was investigated). One further study (Kominsky et al. 1992) determined asbestos concentrations (TEM method, all fiber lengths) at 20 sites approximately 2 years after asbestos removals. Four of the sites exhibited significantly ($p < .05$) higher concentrations in indoor air (0.0033 to 0.015 f/mL) than outdoor air (0 to 0.002 f/mL). Three sites exhibited significantly ($p < .05$) higher concentrations after 2 years (0.004 to 0.011 f/mL), although for one of these sites the outdoor air concentration was similar to that in the building (0.013 and 0.011 f/mL, respectively) and for the other two sites, concentrations were initially measured as zero. By contrast, 16 sites exhibited lower asbestos concentrations after 2 years, a difference that was significant ($p < .05$) for 11 sites.

38.4 BUILDING INSPECTION FOR ASBESTOS

Location in Buildings

Because of the large number of products that have used asbestos in the past, virtually all locations within buildings should be inspected and samples taken of suspected asbestos-containing materials for asbestos analysis. This audit is a critical link that will allow hazard evaluation and decisions on whether product removal or management-in-place programs are to be implemented. It will require a technically competent (and government-certified, if applicable) person to make such inspection and collect such samples, and to adopt the appropriate health and safety precautions in performing these tasks. Specific guidance on suitable approaches is available (USEPA 1983, 1984; ASTM 1997b) and includes factors such as

- Priority for friable materials, especially those accessible to occupants and prone to damage (e.g., pipe and boiler insulation)
- Special attention to crawlspaces with dirt floors contaminated with asbestos debris as there may be practical limitations to the amount of soil that can be removed
- Identification of homogeneous sampling areas for friable materials, where the materials exhibit the same texture and appearance
- Evidence of asbestos product (e.g., fireproofing) delamination from its supporting substrate or of product damage by physical contact or water leaks
- Degree of activity (occupant movement, direct airstream, vibration) near the asbestos product

- Changes in building use
- Contamination of other building surfaces (ceiling tiles, carpets, furniture, and other contents)
- Adequacy of visual inspection only where the inspector is close enough to touch the surface being inspected
- Attention to nonfriable products if they are damaged or if it is anticipated that practices will occur that render the products into a dust capable of becoming airborne (e.g., during building demolition) (USEPA 1990)

Sampling and Identification of Bulk Asbestos

Building products are sampled during inspections so that they can be analyzed for the presence of asbestos. Sampling practices with friable products may cause release of asbestos fibers into building air and require procedures and precautions to minimize this effect (USEPA 1984, ASTM 1997b). There is a range of analytic procedures by which asbestos can be identified in bulk samples (Asbestosis Research Council 1978):

- Polarized light microscopy
- Dispersion staining microscopy
- SEM (scanning electron microscopic)/energy-dispersive X-ray analysis
- X-ray diffraction
- Infrared spectroscopy

The first two procedures are reliable, are economical, and find the greatest use. Several milligrams of product (possibly pretreated to break it down to dust or to remove binder) are dispersed in a suitable liquid and examined at high magnification (200 to 600 $\times$) to determine whether asbestiform fibers are present (based on isotropy under crossed polarizers) and to identify such fibers (by their dispersion staining behavior in liquids of suitable refractive indexes). For greatest reliability, these procedures must be used by experienced laboratories, must ensure that suitably sized fibers free of binding material are analyzed, and must employ at least one replicate analysis for each product. Additionally, asbestos fibers in products heated above $\sim 400^{\circ}\text{C}$ or exposed to strong acids will be partially degraded (Hodgson 1966) and may not all be identifiable by these and other analytic procedures. Other procedures which can be applied to degraded asbestos fibers [e.g., infrared spectroscopy (Marconi 1983)] may prove useful for these cases.

Asbestos Abatement Projects

Hazardous asbestos products may be abated by three approaches:

- Removal
- Encapsulation with a suitable coating
- Enclosure behind a sealed, rigid barrier

Inspection is an important component of hazard management to control airborne asbestos fibers in all of these approaches, especially removal, and detailed inspection procedures have been described (ASTM 1997b). These consider the completeness of the abatement activity (e.g., removal of all visible and accessible asbestos, especially if it is difficult to reach or see; proper and adequate application of encapsulant; complete inaccessibility of

asbestos by enclosure), and completeness of cleanup of residues and debris generated in the abatement. The latter is particularly relevant to minimizing airborne asbestos contamination after asbestos removal. Although inspection is not a substitute for clearance air sampling after abatement works, it is considered that it will improve the likelihood of meeting clearance requirements and will minimize potential emissions by disturbance of residues after reoccupancy. Some of the requirements in postasbestos removal inspections are

- Inspection to ensure that all visible (without magnifying devices) and accessible asbestos is removed from the item involved before progressing to the next stage of abatement
- Inspection of complete work area prior to clearance air sampling to ensure that no asbestos residues or other dust and debris are visually detectable on any surfaces of the building or the contractor's equipment (while other dust and debris may be present from other building materials, all are assumed to be potentially contaminated with asbestos and must be cleaned)
- Enhancement of visual inspection by use of strong light parallel to surfaces, wiping surfaces with a clean cloth to make residues more evident, and use of an air sampling pump and filter cassette to collect visible residues

38.5 RECOMMENDED PRACTICE FOR MANAGING ASBESTOS IN BUILDINGS

As seen from the previous discussion, asbestos products in buildings, the risks they present to occupants, and an appropriate response to such risks are not clear-cut issues for which simple practices can be recommended for all buildings. Management of asbestos in buildings requires four major, progressive responses to be applied to individual buildings:

- An audit to determine all locations in a building where there are asbestos products (refer to Secs. 38.2 and 38.4)
- An assessment of the physical condition of the products and their accessibility by occupants, in order to evaluate the risk of occupant exposure (refer to Secs. 38.2 and 38.3)
- Action to abate or remediate those products where risks to occupants are considered unacceptable (e.g., remove, enclose, encapsulate according to the specific code relevant to each state or country)
- Continued management of asbestos products in buildings by appropriate labeling to identify the products to custodial and trade workers, and by regular inspection and reevaluation of risks from the products to determine appropriate actions in the future

CHAPTER 39

SYNTHETIC VITREOUS FIBERS

Thomas Schneider, M.Sc.

*National Institute of Occupational Health Denmark
Copenhagen, Denmark*

39.1 CHARACTERIZATION

Introduction

End uses of synthetic vitreous fibers (SVF) cover a broad range of fiber types and applications, including industrial and commercial insulation, residential insulation batts, blankets and blowing wool, air-handling ducts, and acoustic wall and ceiling panels. The more temperature-resistant SVF made of slag and stone are also used for fire protection and high temperature insulation. SVF are also used as horticultural growing media. Textile glass fibers (continuous filaments) are used in fiber-reinforced plastic composites and as fabrics (air filters, yarn, wire insulation, printed-circuit boards, protective apparel, reinforced tape) (TIMA 1991).

SVF containing products and materials have the potential to generate a low-background SVF contamination of the indoor environment air during normal use of the building and are considered primary sources. Disturbances brought on by building repair and maintenance, accidents, and vandalism have the potential to increase SVF levels above background. Living spaces may also become contaminated during installation of SVF insulation in the attic or walls in existing buildings. SVF infiltrating from the outdoor air contribute to the background indoor contamination.

Fibers may deposit on surfaces such as floors, desktops, shelves, and filing cabinets. If not removed by regular cleaning, such dust deposits act as sources (secondary sources) if agitated.

SVF are only one of many other fiber types found in the indoor environment, including asbestos, other natural or synthetic mineral fibers as well as synthetic, natural organic fibers including cellulose fibers.

Fiber Size

A simple way to characterize the aerodynamic property of a particle irrespective of shape and density is by its aerodynamic diameter D_{ac} . For any particle its equivalent aerodynamic diameter D_{ac} is the diameter of a sphere of unit density having the same settling speed in air as the particle in question. As a rule of thumb for SVF $D_{ac} = 3D$. Schneider (1987) gives the following approximations to D_{ac} and settling velocity v_s :

$$D_{ac} = 1.29 \left(\frac{\rho}{\rho_0} \right)^{1/2} D \beta^{0.13} \quad (\mu\text{m}) \quad v_s = 0.005 \left(\frac{\rho}{\rho_0} \right) D^2 \beta^{0.27} \quad (\text{cm/s}) \quad (39.1)$$

where $\beta = L/D$

ρ = particle density (2.4 to 2.6 g/cm³ for glass wool, 2.7 to 2.9 g/cm³ for stone/slag wool (TIMA 1991))

ρ_0 = unit density

D = fiber diameter, μm

L = fiber length, μm

v_s = settling velocity, cm/s

The potential hazard of airborne particles depends in part on their aerodynamic diameter. Several definitions of biologically relevant particle size fraction have been used in the past, but the terms *inhalable*, *thoracic*, and *respirable fractions* with corresponding definitions are now generally adopted (ACGIH 1998).

For fibers, a different approach to size criteria has been used because fiber concentrations have to be quantified by microscopy. The criteria were driven by the need to characterize asbestos fibers and established by the Asbestos Research Council in the late 1950s and early 1960s (Walton 1982):

1. An upper diameter limit of 3 μm was introduced because (a) for asbestos $D = 3 \mu\text{m}$ is roughly equivalent to $D_{ac} = 10 \mu\text{m}$ (taking 10 μm as the upper limit for particles that can reach the pulmonary airspace) and (b) amphibole asbestos fibers found in the lungs had a maximum diameter of 3 μm .
2. A lower length limit of 5 μm was introduced. The choice was somewhat arbitrary, but was intended to provide a safety margin. It was considered that fiber length in the range 10 to 50 μm represented the major asbestosis hazard.
3. A fiber was defined as being a particle with an aspect ratio $L:D$ greater than 3:1. There are no records for the reason for choosing this 3:1 ratio.

This size convention (with minor modifications) has been adopted by several national and international bodies. The World Health Organization (WHO 1996) specifies the size convention $D < 3 \mu\text{m}$, $L > 5 \mu\text{m}$, and $L:D > 3:1$. Fibers conforming to these size criteria are often referred to as *WHO fibers*.

In the past, fibers with $D < 3 \mu\text{m}$ were termed *respirable fibers*. With the now generally accepted terminology and definitions of the biologically relevant size fractions, the term *thoracic fibers* would be more appropriate. Baron has shown that the 3- μm fiber-diameter-limit fraction agrees well with the thoracic fraction within about ± 25 percent for a wide range of possible fiber size distributions (Baron 1996).

The shape of most SVF is rodlike (Fig. 39.1), but some fibers may have a tapered end, be curled, or have bulges of resin adhering. The diameters of individual fibers in a typical insulation material vary widely because of the random nature of the fiberizing process. The best description of fiber diameter in a product thus is in terms of statistical measures of the distribution. SVF do not split longitudinally when milled (Assuncao and Corn 1989). Thus

the original diameter distribution in the bulk material is an important characteristic. However, fibers do break transversally, and fiber number per diameter interval depends on how the sample was generated. TIMA (1991) thus recommends that manufacturers characterize the diameter distribution of their bulk SVF by the distribution of the total length of fibers in each diameter class (length-weighted diameter distribution), and not by the usual number of fibers in each class. The median length-weighted diameter can be calculated as follows. Place all fibers in the sample in succession of each other and with increasing diameters. The diameter half way along this single row of fibers is the median length-weighted diameter. Christensen et al. (1993) analyzed typical SVF insulation wool products and found geometric-mean length-weighted diameters in the ranges of 1.3 to 6.5 μm (glass) and 1.7 to 3.6 μm (stone and slag). Geometric standard distributions were of the order 2 to 2.5. All SVF wool products can generate WHO fibers. Complete aerosolization of 1 mg SVF having a length-weighted geometric-mean diameter of 6 μm would generate on the order 10^4 WHO fibers. For a geometric-mean diameter of 1 μm it would be on the order 10^7 WHO fibers (Schneider and Grosjean 1996).

Textile glass fibers (continuous filaments), on the other hand, have a very uniform diameter. The diameter of various textile glass fibers is in the range 6 to 15 μm (IPCS 1988). Thus these fiber products do not generate fibers that conform to the WHO definition.

For a given population of rodlike SVF, both D and L have been found to be approximately lognormally distributed (Schneider et al. 1983). Furthermore, there is a small but positive correlation $\tau_{D,L}$ between $\log_e(L)$ and $\log_e(D)$; thus, large-diameter fibers tend to be longer than small-diameter fibers. A complete size characterization thus requires measurement of D and L simultaneously for each fiber (joint distribution). Schneider and colleagues found that SVF approximately follow a bivariate lognormal distribution. This distribution is completely specified by count geometric mean and standard deviation $\text{GM}(D)$, $\text{GSD}(D)$, $\text{GM}(L)$, $\text{GSD}(L)$ of D and of L , respectively, and $\tau_{D,L}$. Table 39.1 presents parameter values as determined by optical microscopy.

39.2 MEASUREMENTS

Sampling Strategy

Measurements may serve a range of purposes such as detecting intermittent SVF sources, documenting the effect of an intervention, and assessing exposure for epidemiology. For each purpose different strategies will be needed. The VDI 3492 guideline (VDI 1994) describes a strategy, which is not intended to predict long-term changes in fiber concentrations but to collect and determine short-term maximum fiber concentrations. The strategy is summarized in Table 39.2. Rules are given for selecting number and position of samples. A key part of the strategy is the "simulation of the conditions of use" with the intention of activating secondary sources. Activation is obtained by either air movement using a blower generating a velocity at the surface of 4 m/s $\pm$ 20 percent, by producing vibrations by bouncing a ball 40 times or slamming a door forcefully 5 times from a right-angle position, or if there are carpeted floors, by dropping an object typical for that room from a height of 1 m.

Some examples are given in the following paragraphs to further guide the occupational hygienist when designing a strategy.

The Completely Mixed Air Scenario. Short-term variations in concentration are caused by the turbulent mixing process of the pollutant plume with the surrounding air. This is seen as "noise" on the output of a fast-response photometer. Temporal variations on a larger timescale are caused by variations in source position and output rate and by the removal

TABLE 39.2 Type of Indoor Air Monitoring and Type of Simulation of Conditions of Use

Measurement objective	Problem or question	Simulation method
1. Air monitoring to establish the current indoor air conditions (status quo measurement)	How high is the fiber concentration during normal usage of the room? Are preliminary abatement measures necessary to further use the room?	Producing air movements of specified velocity and vibrations if required
2a. Air monitoring after preliminary abatement measures have been carried out	Has the fiber concentration been reduced below the allowed value, e.g., were the preliminary measures successful? Do they continue to be successful?	
2b. Air monitoring before removing the safety precautions	Is the fiber concentration so low that the safety precautions can be removed?	
2c. Final clearance air monitoring	Is the fiber concentration below the permissible limit value?	
3. Air monitoring to assure that all protective precautions are effective	Are containment barriers, negative pressure, and other protective precautions effective in preventing fiber contamination of area outside the work area? Has area outside the work area been contaminated with fibers?	Producing air movements of specified velocity; no simulation is required if air sampling is conducted during normal usage.

Source: VDI (1994).

process. The influence of the removal process is illustrated by the example of a well-stirred room. Assume that at time $t = 0$, the concentration of particles is $C(0)$ and that there are no active sources, then the total rate of removal N_{tot} is (Lidwell 1948):

$$N_{\text{tot}} = N + \frac{A}{W} v = N + N_e \quad (39.2)$$

where N_{tot} = rate of removal
 W = room volume, m^3
 A = room surface, m^2
 N = air exchange rate
 v = area averaged particle deposition velocity
 N_e = equivalent air exchange rate

For each given particle size the concentration will decay as

$$C(t) = C(0) \exp(-N_{\text{tot}} t) \quad \int_{t=0}^{t=\infty} C(t) dt = \frac{1}{N_{\text{tot}}} C(0) \quad (39.3)$$

where $1/N_{\text{tot}}$ is the average residence time in the air of a particle entering the room air at $t = 0$. Thus, to quantify the contribution of a single burst of fibers at $t = 0$ to the time-weighted average (TWA) concentration, sampling should last at least $3/N_{\text{tot}}$. The settling speed v of a fiber with $D = 3 \mu\text{m}$, $L = 60 \mu\text{m}$, and $\rho = 2.5 \text{ g/cm}^3$ is 0.25 cm/s . The dominant deposition mechanism thus is settling to the floor. For a room of height 300 cm $A/W = 1/H$, where H is room height, and the removal rate N_e is $0.25/300 \text{ s}^{-1}$ or 3 h^{-1} . If the air exchange rate is 0.5 h^{-1} , this means that six fibers will settle out in the room for each one removed by ventilation.

Surface Dust. On deposition, particles will be available for resuspension. Resuspension from room surfaces is caused by mechanical impact (disturbance by room occupants) and to a lesser degree by air movements. During exposure measurements, use of the rooms should be normal. Alternatively, conditions of usage, which would induce resuspension should be simulated (VDI 1994). Dust deposits also may cause direct skin exposure to SVF. Schneider (1986) demonstrated the pickup of fibers on the hands of persons touching dusty surfaces.

As surfaces accumulate dust settled from the air, the surface dust stores information of episodic releases of SVF. Thus, nonaccessible surfaces cleaned infrequently can be sampled to show whether SVF sources were active since last cleaning. It has been shown that surface sampling could demonstrate the presence of SVF in rooms where air sampling was below the detection limit (Schneider et al. 1990a).

Breathing Zone. The convective plume around the body carries dust (skin scales, textile fibers, bacteria, etc.) originating from the body as well as dust resuspended by the person's activity to the breathing zone (Clark and Cox 1973, Brohus 1997). Thus a significant dust source "follows" the person. This phenomenon has been termed "personal cloud" by Özkaynak et al. (1996). They found that exposure measured by personal samplers during daytime in homes was more than 50 percent above concurrent concentration measurements by stationary indoor samplers. They also provided evidence that the major source could indeed be resuspension of coarse particles.

Probability of Detecting Single Events. SVF may be released from SVF containing building materials in an unpredictable and episodic way. How certain can the investigator

be that an event is included during an air-sampling program? Consider a time period of D days (24 h), E of which include an episode. Assume that N whole days are measured, and that events are independent of measurement days. Then the probability p of having included at least one event is (Leidel et al. 1977):

$$p = 1 - \frac{(D - E)!}{(D - E - N)!} \frac{(D - N)!}{D!} \quad (39.4)$$

Table 39.3 shows N calculated for $p = .8, .9$, and $.95$. It is seen that cost of air sampling for detecting random events with a high degree of certainty can become prohibitive. Targeted sampling of identifiable events or alternatively, sampling during simulation of events likely to resuspend fibers such as door slamming, HVAC startup, or walking on an attic, may considerably reduce sampling efforts.

Contribution of Episodes to Average Concentration. Some insight into the contribution of episodes to the average concentration can be gained from the following example. Suppose that M fibers are dispersed into a well-stirred room E times (E episodes) during a reference period T . The TWA concentration over T is then [using Eq. (39.3)]

$$C_{TWA} = \frac{1}{T} \frac{E}{N_{\text{tot}}} \frac{M}{W} \quad (39.5)$$

When cleaning is frequent, N_{tot} approaches $N + N_{\text{eq}}$; when resuspension is intensive, N_{tot} approaches N . Thus, cleaning frequency is an important determinant of the contribution of episodes to the long-term average concentration and most for coarse fibers where $N_{\text{eq}} \ll N$.

Consider a case where there are 10 episodes per year. Let $T = 365$ days and $N = 2$ air changes per hour (ACH). Then $C_{TWA} \leq 10 / (365 \cdot 24 \cdot 2) M/W = 0.00057 M/W$. If these episodes should contribute to a yearly average concentration equaling a (background) concentration C_B , each episode must generate an initial peak concentration of at least $1/0.00057 C_B = 1750 C_B$. This example disregards that episodes may contribute to surface dust deposits.

External Exposure Factors. External factors should be identified and recorded during an investigation. Examples are

- Weather conditions
- Type of house or building, insulation, and HVAC system, size of rooms, floorcovering, physical condition of SVF containing materials, recent SVF work
- Use of rooms, number of occupants per room, activity level, orderliness, cleaning methods and frequency

TABLE 39.3 Number of Whole Days N to Sample during One Year (365 days) to Catch at Least One Event with Confidence p

E^*	6	12	26	52
$p = 95\%$	—	80	39	19
$p = 90\%$	115	63	30	15
$p = 80\%$	85	45	21	11

A diary prepared by the occupants of the area being studied is useful for identifying possible causes if outlying results are obtained. Outdoor samples should always be taken as a reference.

Sampling Methods

Air. For determination of airborne concentrations of all natural or synthetic fibers, WHO (1996) and NIOSH (1994) recommend a membrane filter sampling method followed by optical microscopy. The method given by VDI 3492 (VDI 1994) is for indoor air and is based on scanning electron microscopy (SEM). Table 39.4 presents a summary of key parameters.

Chen and Baron (1996) reviewed evidence on cowl and other losses during and after sampling and recommended the following to minimize fiber losses:

- Sample at the highest flow rate possible or specified.
- Avoid sampling in locations with high air velocities.
- Filters should be transported carefully. Large SVFs can easily become detached during transport and handling, thereby also carrying other fibers off the filter surface.

TABLE 39.4 Summary of Sampling Methods for Airborne SVF

	WHO (1996)	NIOSH (1994)	VDI (1994)
Filter	Membrane filter of mixed esters of cellulose, or cellulose nitrate, pore size 0.8–1.2 μm and 25 mm diameter; if sampling under low-humidity conditions, immersion in a 0.1% Hyamine solution and drying on a sheet of blotting paper is recommended to make the filter conductive under low-humidity conditions	Cellulose ester membrane, pore size 0.45–1.2 μm and 25 mm diameter; 0.8 μm for personal sampling, 0.45 μm if analysis is by electron microscopy	Pre-gold-coated track-etched polycarbonate filter and backup filter; maximum pore size 0.8 μm , filter diameter 25–50 mm
Filter holder	Open-faced, fitted with an electrically conducting cowl of length 1.5–3 times the effective filter diameter; during sampling the cowl should point downward; cowl rinsing is not recommended	Open-faced, fitted with an electrically conducting cowl of length 50 mm; during sampling the cowl should point downward	Open-faced, cowl with length 0.5–2.5 times effective filter diameter
Sampling flow rate	Pulsation-free, range 0.5–2 L/min	Pulsation-free, range 0.5–16 L/min; if fiber concentration is expected to be below 100,000 f/m ³ , sample 3000–10,000 L of air	Sampling flow rate: 2 L/min per 1-cm ² filter
Storage and transport	Fixatives must not be used; transport in the original filter holders should be preferred	Transport in the original filter holders in rigid container	

The VDI method (VDI 1994) uses pre-gold-coated track-etched polycarbonate filters. No evidence has been found of fiber loss from these filters when transported in shockproof containers (Schneider et al. 1996).

For assessing potential risk of deposition of airborne SVFs on eyes or skin, a sampler should efficiently sample thick fibers as it has been shown that the deposition velocity of airborne particles on eyes and skin increases with increasing particle size (Schneider and Stockholm 1981, Schneider et al. 1994). Stationary sampling with open-faced filter cassettes for 37-mm-diameter filters with aluminum cowl pointing upward and with a sampling flow rate of 20 L/min was used to sample SVF with $D < 20 \mu\text{m}$ with a theoretical sampling efficiency of 100 ± 10 percent (Schneider 1986).

Dust fall sampling can be used as a proxy for air sampling. However, only a weak correlation between dust accumulation on undisturbed horizontal furniture surfaces and airborne dust concentrations was found by Kildesø et al. (1999). Dust fall sampling over extended periods of time has been performed with small open PVC containers (Aurand et al. 1983) or small plastic sheets covered with an adhesive (Schultz and Ober 1986, Umweltbundesamt 1994).

Dust fall samplers sample at a rate R

$$R = S v C(\infty) \quad (39.6)$$

where S = sampling area

v = deposition velocity

$C(\infty)$ = concentration at some distance from surface

The sampling rate can readily exceed the sampling rate obtainable by filter sampling for large fibers, and it occurs when the deposition velocity is greater than the face velocity at filter surface.

Cholak and Schafer (1971) developed a simple method for monitoring erosion of SVF material in air-supply ducts. They suspended 2-in.-wide adhesive tape strips in ventilation ducts near the exit with sticky side facing the wind to sample fibers. Shapiro and Goldenberg (1993) measured deposition rates of SVF on pipe walls for turbulent flow conditions. SVF was sampled onto adhesive tape placed flush on vertical and horizontal parts of the pipe. Empirical equations were obtained of deposition velocity as a function of fiber concentration in the turbulent core, fiber size, and turbulence. Given these equations, tape samplers mounted in duct walls for prolonged periods of time could be used to quantify the contribution to average room air concentrations of SVF from episodic releases from HVAC systems.

Direct-Reading Methods. Direct-reading instruments could be of some use to detect presence and activity periods of sources. However, direct-reading methods are not specific for SVF. As an example for a mass monitor Table 39.1 shows that 1000 SVF/m^3 would represent a mass of only $1.4 \mu\text{g/m}^3$, which is only a small fraction of the total dust concentration typically found indoors. Fiber monitors designed to separate fibers from other particles cannot distinguish between fiber types. Tables 39.6 and 39.7 show that SVF constitute only a small fraction of fibers present.

Surfaces. Quantitative sampling and analysis of dust deposited on a surface can be used to identify potential sources for resuspension and the risk for skin contamination. Surface sampling can also be used to determine of dust fall rate if the time since the last surface cleaning is known and the surface is undisturbed. Surface sampling was introduced as an integral part of a SVF measurement strategy by Schneider because it was considered that measurement of airborne concentrations alone would have little relation to the potential for skin and eye irritation from such fibers (Schneider 1986).

Surface concentration on surfaces receiving particles by routes other than by air and being disturbed by room occupants is likely to exhibit large gradients (Schneider et al. 1990b). Sampling strategies for surface dust are described in Chap. 64.

Common methods for sampling surface dust are based on wiping, vacuuming, and lifting with adhesive tape. Wipe sampling is much less efficient than using adhesive tapes (Wheeler and Stancliffe 1998) and it may cause fibers to break, thereby distorting the fiber number and size distribution. Conventional vacuum cleaners are suitable for sampling large quantities of floor dust. Quantitative evaluation of surface contamination by this method is, however, hampered by lack of standardization of the vacuuming procedure and by difficulties in recovering quantitatively the collected dust from the filter bag, especially if only little dust has been collected. A special vacuum cleaner for sampling dust from floors has been developed by Roberts et al. (1992). Dust is separated in a stainless-steel cyclone and collected in a glass container. Sampling efficiency from carpets was reported to be about 70 percent for carpets soiled according to the ASTM F608-89 method. Only 0.2 percent of the test dust passed the cyclone. As an example, Gynzelberg et al. (1994) used this sampler to collect floor dust in a reproducible way to detect relative differences between buildings. Presence of dust components, including SVF, was determined by polarized light microscopy.

There are various modifications of a procedure known as the *microvacuuming technique*. Corrigan and Blehm (1997) have tested one version for sampling SVF. It consisted of a vacuum pump operating at 16 L/min, a filter holder, and a 25-mm-diameter filter with 50 mm cowl giving a face velocity of 69 cm/s. Using tape sampling as a reference, it was found that this microvacuuming method was not efficient in removing SVF from painted metal surfaces. This was the only surface type studied, and it was seen as an ideal surface for fiber collection. They were careful in keeping a 0.25-in. distance between the sampling nozzle and the surface and concluded that different vacuuming techniques such as scraping the surface with the nozzle would influence collection efficiency.

A simple sampling method is to lift the dust layer off a surface with adhesive tape (Nichols 1985, Corrigan and Blehm 1997). Ryan and colleagues (1997) compared asbestos fiber concentrations determined by SEM on 3M Scotch 810 Magic Tape lifts of asbestos-contaminated painted drywall and on excised parts of the drywall. They estimated that the sampling efficiency to asbestos fibers longer than 5 μm was of the order of 40 percent.

Schneider (1986) introduced gelatin foils originally developed for forensic purposes (BVDA fingerprint lifters) for sampling SVF from nontextile room surfaces. The foils have excellent sticking properties and can follow minor curvatures. The optical properties are very good as the gelatin surface regains its smoothness after sampling, and the gelatin is optically isotropic (but shows fluorescence). The sampled dust can be quantified by optical microscopy or SEM. The foils were also used for sampling SVF from skin, demonstrating that SVF on surfaces were transferred to the fingertips on contact.

Analysis

Fiber shape is an important determinant in assessing the potential for health hazard, and microscopy must be used for quantification. Phase-contrast optical microscopy (PCOM) has been the method of choice for SVF at industrial concentrations (WHO 1996). In indoor environments SVF are a minority in the fiber population and PCOM will greatly overestimate SVF concentration. Various methods can be used to exclude fibers that are definitely not SVF. Low-temperature ashing of the filter and sample followed by redispersion and filtering or, if collected on pre-gold-coated filters, etching in a low-temperature asher (VDI 1994), will remove organic SVF look-alikes. Etching may leave a skeleton of inorganic material, which, however, can be distinguished from SVF by its morphology. SVF are optically isotropic. Any fiber lighting up under crossed polars in a polarization microscope

(PLM) can be excluded as being non-SVF. A PCOM can be used as a PLM if it has a rotating stage and can be fitted with polarizer and analyzer. Alternatively, a PLM microscope can be fitted with PCOM optics.

Electron microscopy (EM) offers the advantage that energy-dispersive x-ray analysis (EDXA) can give semiquantitative information on elemental composition of fibers. Transmission electron microscopy (TEM) with selected-area electron diffraction (SAED) can be used to exclude any crystalline fibers having the same elemental composition as SVF.

Morphological criteria can be useful for excluding non-SVF. The criteria are that SVF should have parallel edges (Draeger et al. 1998, Rödelasperger et al. 1998) and have ends with three distinct features: (1) the edge will be a clean break with the fracture occurring perpendicular to the fiber length, (2) the end will exhibit a notch-type break, or (3) the end will taper similar to that of a sharpened pencil (Switala et al. 1998).

Optical Microscopy. WHO (1996) and NIOSH (1994) specify how to set up and operate a PCOM for fiber analysis. It is also specified which fiber sizes to include and how fibers not completely within a counting field are counted. NIOSH (1994) recommends the “B” counting rules for SVF. The size criteria are $D < 3 \mu\text{m}$, $L < 5 \mu\text{m}$, $L:D \geq 5:1$, which is different from a WHO fiber regarding the aspect ratio. TIMA (1991) found by analysis of 268 samples from installation of insulation mats and blowing wool and from manufacturing plants that going from a 3:1 to the 5:1 aspect criteria as the only change, would reduce the fiber count by only 3 percent.

Rules are also given for counting (1) fibers attached to particles, (2) split fibers, and (3) fiber bundles. The NIOSH B rules and WHO rules (WHO 1996) are only marginally different on points 1 and 3 but differ on 2, which, however, does not apply for SVF. Miller and colleagues (1995) found that the B rules gave slightly fewer fibers than the previously used “A” rules when using PCOM on air samples from living spaces before and after installation of SVF insulation. Obviously these rules act on all fiber types included by the PCOM method, not only SVF. No difference was found using A and B rules in SEM analysis. The variability caused by factors such as low number of fibers detected and interference from non-SVF is thus likely to be more important than minor differences in counting rules.

As the fiber diameter becomes smaller than the limit of resolution of the microscope ($0.5 \mu\text{m}$), the width of the fiber image does not become smaller but only fainter, with corresponding decrease in probability of detection. The lower limit of visibility in a PCOM at $40\times$ magnification is approximately $0.25 \mu\text{m}$ (NIOSH 1994). A comparison of PCOM counts with TEM of superfine SVF showed that the PCOM method does not miss WHO fibers (Rood and Streeter 1988).

Optical properties such as strain in the glass and edge effects may become visible if a SVF is observed in a PLM with crossed polars. A microscopist should become familiar with such effects by observing pure SVF. PLM cannot distinguish between optical properties and thus between fiber types for $D < 1 \mu\text{m}$. Using SEM, Umweltbundesamt (1994) found that on average out of every 100 SVF in indoor air with $D < 3 \mu\text{m}$, 21 had $D < 1 \mu\text{m}$. “Other inorganic” (as defined in the next paragraph) fibers with $D < 1 \mu\text{m}$ would typically be 200. The parallel edge criterion was not used, but still, for $D < 1 \mu\text{m}$, significant interference from non-SVF mineral fibers should be expected.

Electron Microscopy. Many studies to assess the mineral fiber content in air have used transmission electron microscopy, with the main objective of characterizing asbestos concentrations. Scanning electron microscopy does not have the same capability of detecting very thin fibers and to determine crystal structures of fibers. On the other hand, sample preparation is simple and constitutes a compromise between amount of information obtainable by analysis and analytic resources available. A SEM method for workplaces has been developed (WHO/EURO 1985), and this method has been used for

indoor environments, too. The VDI guideline 3492 (VDI 1994) has been designed especially for indoor environments. It uses the WHO size criteria but with a $L \leq 100 \mu\text{m}$ limit added. It specifies in detail how fibers analyzed by SEM/EDXA should be categorized into asbestos, calcium sulfate (gypsum), and “other inorganic” fibers. The filters are etched in a low-temperature ash to remove organics. SVF, which belong to the “other inorganic” fibers, have many look-alikes regarding elemental composition. They are generated from natural rocks and soils, volcanic eruptions, coal burning, waste burning, mortar, cement, concrete, lightweight building blocks, limestone, and calcium silicates industrial minerals (Table 39.5). Consequently, VDI (1994) introduced the concept of characterizing product fibers. Bulk samples of SVF materials are to be taken at the site of measurement and EDXA spectra of thin fibers from the sample are to be recorded. EDXA spectra of fibers in an air sample should then be compared with these spectra, and if they fulfill a set of preestablished criteria, they should be classified as product (SVF) fibers.

Morphology (parallel edges) as a characteristic of SVF is not used (VDI 1994). However, Draeger et al. (1998) found that the parallel-edge criterion should be used as an inclusion criterion for SVF in SEM/EDXA analysis. A SEM analysis was made of fibers sampled during simulation of SVF insulation wool installation. In this study 92 percent of the fibers determined to be SVF according to VDI 3492 (VDI 1994) had parallel edges. For fibers generated from 12- to 21-year-old SVF materials, only 1.4 percent did not fulfill the parallel-edge criterion. Rödelsperger et al. (1998) found that among fibers generated in a vibration test of new insulation mats having elemental composition as SVF, 88 to 90 percent had parallel edges. Old mats taken from a building released fibers which were not SVF. Measurements in buildings showed that the percentage of fibers with elemental composition as SVF having parallel edges was about 20 percent, increasing to 90 percent in cases with increased emissions of SVF. Thus, criteria other than elemental composition must be used to identify SVF, and it can be reasonably stated that fibers can be SVF only if they conform to both the elemental composition and the parallel-edge criterion.

Even though tests can show that a SEM can detect fibers with diameters below $0.1 \mu\text{m}$, there is a gradual decrease in probability of actually detecting fibers as their diameter reduces from $0.3 \mu\text{m}$, with the ability to accurately characterize smaller fiber diameters depending on the quality and display mode of the SEM (Kauffer et al. 1993).

The analytic advantages of electron microscopy as compared with optical microscopy are counterbalanced by the more complex sample preparation and higher limit of detection in terms of fiber numbers determined for a given amount of microscope time spent.

Foils. Analysis of fibers on tape samples can be analyzed by PCOM/PLM (Nichols 1985). Schneider et al. (1990a) analyzed SVF collected on gelatin foils. A PLM with a 20 $\times$ objective was used and the image was projected onto a digitizer for ease of observation, size measurement, and data handling. Using the WHO PCOM method as a reference, about 70 percent of all fibers were seen. All fibers with $D > 3 \mu\text{m}$ or with $L > 50 \mu\text{m}$ were seen.

Results below Detection Limit. The number of fibers obtained by error-free counting of a given specimen area follows a Poisson distribution. For four fibers counted, the 95 percent confidence interval is 1.1 to 10 (VDI 1994). Thus the total number of fibers actually counted or the 95 percent Poisson confidence interval should always be stated. PCOM and, more frequently, SEM analyses often result in a large number of samples with very few or no fibers detected. Rather than calculating the concentration for each sample and averaging using various rules for including results below the detection limit, the results should be pooled. Pooling should be done using

$$C = \frac{\sum_i N_i}{\sum_i V_i} \quad (39.7)$$

where C = concentration

i = filter number

N_i = number of fibers counted on filter area A_i

V_i = air volume filtered through the same filter area A_i

Poisson confidence intervals can then be calculated for $\sum N_i$ (VDI 1994). The V_i should be of the same order of magnitude.

39.3 RESULTS

Air

Several studies of SVF concentrations in the indoor environment have been published. They are summarized below.

Schneider (1986) measured SVF in air and on surfaces in two groups of buildings. One was a random sample of 11 schools with mechanical ventilation selected at random. In each school two classrooms were monitored for three consecutive days using stationary samplers. The other group consisted of four kindergartens, one school, and one office where measurements were requested by the labor inspectors because of indoor air problems suspected to be caused by SVF. One to two rooms were monitored per building, taking one sample per room. Surface samples were taken with gelatin foils from regularly cleaned surfaces and from occasionally cleaned surfaces. Samples were analyzed for SVF and non-SVF by PLM (Table 39.6). The results show that compared to a random sample, rooms in "problem" buildings had 40 times higher concentrations of SVF with $D < 3 \mu\text{m}$ in air and SVF with $D > 3 \mu\text{m}$ were present at high concentrations. These buildings were more dusty in general, and the concentration of non-SVF was also increased.

Rindel and colleagues (1987) measured SVF in air and on surfaces in 24 kindergartens selected at random in the same geographic area. To be included, the kindergartens had to be built in the 1970s, have no mechanical ventilation, and have no wall-to-wall carpeting. The buildings were divided into one group (10) with SVF products with water-soluble binder, one group (6) with resin binder, and one control group (8) with no readily visible SVF. Two air samples were taken in each of two rooms per building using stationary samplers. Surface samples were taken with gelatin foils from regularly cleaned surfaces and from occasionally cleaned surfaces. Samples were analyzed for SVF and non-SVF by PLM (Table 39.6). For airborne SVF, $D < 3 \mu\text{m}$, no statistically significant difference was found between the three groups of institutions, but SVF with $D > 3 \mu\text{m}$ were found more often in the institutions with SVF materials than in the control group. No differences were found for SVF on surfaces. Health investigations were made using a questionnaire, daily registration of symptoms, and clinical investigations.

In the Danish Town Hall study (Skov et al. 1990), 14 town halls were investigated. The exposure characterization included measurement of SVF in air. Samples were analyzed for SVF and non-SVF by PLM (Table 39.6). Health investigations were made using a questionnaire.

Schneider et al. (1990a) studied a sample of rooms with SVF ceiling boards of types covering the market and building habits in Denmark, selected among nurseries, kindergartens, schools, and offices in the Copenhagen area. Rooms having physically damaged boards or notable indoor climate problems were excluded. Two air samples were taken in each room. Surface samples were taken with gelatin foils from regularly cleaned surfaces and from occasionally cleaned surfaces. Samples were analyzed for SVF and non-SVF by PLM (Tables 39.6 and 39.9).

Schumm et al. (1994) measured SVF concentration in air for 67 different applications of SVF in buildings in Germany. The sites were selected to cover a range of building constructions, installation methods, product properties, and uses. Measurement strategy and analysis followed a draft VDI 3492 (VDI 1994), but “simulation of the conditions of use” simulated normal conditions not worst-case conditions. The results are summarized in Table 39.7.

Following the VDI 3492 guidelines, Umweltbundesamt (1994) made 134 measurements in 24 buildings with visible SVF insulation in Germany. The buildings were selected to cover a broad range of construction methods, product types, and ages, and the measurements included situations of extreme use and of high velocities (Table 39.7).

Rödelsperger et al. (1998) measured SVF in 47 buildings described as representative samples, that is, there was no special influence on the installed SVF materials. The VDI 3492 (VDI 1994) method was used. They found an arithmetic mean of 656 SVF/m^3 , which was reduced to 136 SVF/m^3 if the parallel-edge criterion was included (Table 39.7). Thus the results by Schumm and colleagues (1994) and Umweltbundesamt (1994) may have overestimated the product SVF by a factor of 4. Regarding “other mineral” fibers excluding gypsum the results of Rödelsperger and colleagues (1998) and Umweltbundesamt (1994) are in good agreement. Both found that the airborne concentrations of “other mineral” fibers, excluding gypsum were one order of magnitude higher than SVF.

Thriene and colleagues (1996) investigated an office because of a request following health complaints. The building had suspended ceilings made of grooved, unsealed, and partially frayed SVF ceiling boards. Six rooms were measured (Table 39.7) and fibers analyzed using the VDI 3492 method.

Dodgson et al. (1987) measured airborne SVF concentrations in the living spaces associated with installation of new SVF (five houses) and with disturbance of existing SVF insulation (five houses). Four stationary samples were taken for each occasion. Filters were analyzed using the WHO/EURO (1985) SEM method. The results are summarized in Table 39.8. Levels 24 h and 7 days after installation were not distinguishable from levels before installation.

Van der Wal and Tempelman (1987) conducted a small study to determine the extent to which SVF penetrate into the living spaces of houses being insulated by blowing wool into

Day after installation	14	2×10^3 product fibers	6×10^3		

the external wall cavity. In each of eight houses two rooms in the living spaces were measured using stationary samplers. Filters were analyzed using PLM (Table 39.8). During the experiments, ventilation was prevented as much as possible. The fiber concentrations were still above background the day after installation, but it was postulated that good ventilation would have decreased concentrations to background level.

Jaffrey (1990) measured airborne SVF concentrations in the living spaces of 12 dwellings during and after installation of insulation. Stationary samples, duration 4 h, were taken and analyzed by TEM/EDXA. Concentration of fibers $D < 3 \mu\text{m}$ and $5 < L < 100 \mu\text{m}$ were generally below 6000 SVF/m^3 . Up to $20,000 \text{ SVF/m}^3$ were found when SVF were blown. Follow-up measurements within a week after insulation were below 1000 SVF/m^3 . Minor and major disturbance of existing loft insulation did not cause any measurable contamination of living spaces (Jaffrey 1990). Total inorganic fibers (all diameters) were in the range < 1000 to 9000 fibers/m^3 (geometric mean of their data was 2340 f/m^3).

Miller and colleagues (1995) measured airborne SVF concentrations before and after installation of SVF insulation in newly constructed houses. Filters were analyzed by PCOM (NIOSH 1994) and by SEM (WHO/EURO 1985) (Table 39.6). It was concluded that there was little if any difference between pre- and postinstallation concentrations for PCOM counted fibers and that the SEM results also indicated that if there was an increase, it was small.

A small-scale study on selected sampling sites in Europe evaluated personal exposure to respirable inorganic and organic fibers during normal human activities (Schneider et al. 1996). Four groups—schoolchildren in suburban Paris, retired persons in a rural area of Denmark, and office workers and taxi drivers from the city area Düsseldorf/Neuss—were monitored over 24 h 4 times during one year. Personal sampling pumps were used to collect airborne dust. The VDI 3492 method was used but without etching to retain organic fibers. This limited study ranked lifetime exposure to fibers in the following way: organic fibers $>$ other inorganic fibers $>$ fibers with elemental composition similar to SVF $>$ SVF. Selected results are summarized in Table 39.6.

In a survey of 22 buildings for asbestos contamination using SEM analysis (Altree-Williams and Preston 1985) levels of mineral fibers were found in the range < 1000 to $13,000 \text{ WHO f/m}^3$. Organic fiber concentrations ranged from < 1000 to $63,000 \text{ WHO f/m}^3$.

Esmen and colleagues (1980) tested entrainment of fibers from glass fiber air filters. The resulting concentration in living spaces was estimated to be of the order 103 f/m^3 , decreasing and becoming indistinguishable from ambient level within one day after installation.

Working (grinding, cutting, drilling) of fiber-reinforced plastic did not generate glass fibers with smaller diameters than the original fibers, but some of these original coarse fibers were found in the airborne dust (Antonsson and Runmark 1987).

Schneider and colleagues (1996) reviewed outdoor measurements. Only SEM data were included in order to allow direct comparison of results. The results ranged from 100 to $8000 \text{ inorganic (other than asbestos and gypsum) WHO f/m}^3$. Their own measurements of outdoor background concentrations in Germany, France, and Denmark gave results ranging from 260 to $3500 \text{ inorganic (other than asbestos and gypsum) WHO f/m}^3$. Organic fibers ranged from below 260 to 3700 WHO f/m^3 . Umweltbundesamt (1994) found in the ambient air around their indoor measuring sites $300 \text{ SVF WHO f/m}^3$, respectively $1400 \text{ other inorganic WHO f/m}^3$ (median) in winter and 290 f/m^3 , respectively 2150 f/m^3 in summer (only fibers with $L < 100 \mu\text{m}$ were counted). According to Rödelsperger and colleagues (1998), the SVF concentration in outdoor air would be half if the parallel-edge criterion were included.

Surfaces

Deposition rate of SVF (as determined by PLM) in public buildings have been reported to be in the range 0.5 to $1.5 \text{ SVF/(cm}^2 \cdot \text{day)}$ (Schneider 1986) and $1.7/(\text{cm}^2 \cdot \text{day})$ (Schumm et al. 1994).

More than half of the SVF found on surfaces have $D > 3 \mu\text{m}$ (Table 39.1). Surface concentration measurements are reviewed in Table 39.9. Very high surface concentrations were found in “problem” buildings, but as expected the concentrations depend to a large extent on the cleaning frequency. The variability of surface concentrations has been studied by Vallarino (1998) in 20 buildings. Four rooms were sampled in each building, and in each room samples were taken from three area types determined by the level of contact by room occupants; constant, if occupants would readily come into contact (e.g., desk or table immediately adjacent to chairs); frequent (e.g., shelves and table not adjacent to chairs, and seldom (e.g., top of bookcases and high shelves). An analysis of variance including level of contact, room, and building showed that level of contact was by far the greatest source of variability. Fibers other than SVF were also counted, and it was found that most fibers were organic; 85 percent of all samples had organic fiber concentrations at or below 3.9 f/cm^2 . SVF concentrations were slightly correlated ($r = .38$ for log-transformed data) to the surface dust concentration measured as percentage area covered by dust.

Skin and Eye

Alsbrink and colleagues (1983) demonstrated that SVF accumulated in the eyes of persons working in rooms with SVF ceiling boards. However, the fiber number in the eyes or concentration in the air was not determined. To get an estimate of the rate of deposition the results given by Schneider and Stolkholm (1981) can be used. They studied deposition and accumulation of airborne SVF in eyes of workers handling SVF. It was shown that the deposition velocity to the eye increases as the fiber diameter increases. A correlation between the airborne fiber concentration and the accumulation rate of fibers in the eyes were determined. From this relation it can be estimated that over an 8-h exposure to SVF with $D > 3 \mu\text{m}$ at a concentration of 1000 SVF/m^3 , three SVF fibers would accumulate in one eye. Thus at 100 SVF/m^3 or less airborne fibers with $D > 3 \mu\text{m}$, this exposure route is negligible compared with the risk of introducing fibers by fingers having touched an infrequently cleaned surface. To support this hypothesis, Schneider (1986) sampled dust from the fingertips of employees in a day care center before and after a simulated task consisting in picking textile toys from various shelves. Three persons picked up 1.5 to 4 SVF/cm^2 on their fingertips, and one person, touching a very dusty surface, 82 SVF/cm^2 .

Concentration Modifiers

Because of differences in strategies and measurement methods, it is difficult to compare results across studies. Furthermore, the individual results are very variable and there are insufficient data to determine the apportionment of the overall variability to the variance components between days, between rooms, and between buildings. Within individual studies of suitable size it is possible to derive generally applicable information on the relative effect of various external factors on SVF concentration.

When grouping their results into low, medium, and high concentrations of SVF, $D < 3 \mu\text{m}$, ceiling boards with no surface treatment and an old type of board with water-soluble binder were placed in the high group (Schneider et al. 1990a).

In the study of the 67 different applications by Schumm and colleagues (1994), it was found that, in general, concentrations only exceeded 100 f/m^3 if

- There was visible damage or visibly leaky vapor barrier.
- The material was in bad condition.

‡Contact level: constant.

§Contact level: seldom.

- Poor construction methods had been used (e.g., ceiling tiles not mounted properly).
- There were obvious routes along which SVF could pass from the attic to living spaces.

Of particular relevance are the indications that living space concentrations of SVF were not necessarily higher in buildings with open-mounted SVF and that the use of the building had greater influence. This indicates that choice of SVF insulation materials should depend on the intended use of the building.

An investigation of airborne SVF concentrations in 24 buildings by Umweltbundesamt (1994) showed

- No difference between old (<10 years) or new SVF material
- No difference between buildings with visible or covered SVF products
- No increase in concentration caused by a single drawing of cables or mounting a switch
- That carpets may act as reservoirs for SVF
- That if a sandwich construction allowed a pumping effect, fiber concentrations were increased

Rödelsperger and colleagues (1998) could not identify installation situations with an inherent increased potential for fiber release. Increased SVF concentrations were only found if maintenance or structural work had taken place.

39.4 EFFECTS

Irritation of Upper Airways, Skin, and Eye

SVF exposure during handling of SVF may cause respiratory tract, skin, and eye irritation (IPCS 1988). Skin irritation is caused by fibers with diameters exceeding 5 μm (Heisel and Hunt 1968). There is anecdotal evidence that buildings may be contaminated by SVF of sizes and in quantities sufficient to cause skin irritation. Skin symptoms have been reported among employees working in offices contaminated by SVF from faulty construction (Verbeck et al. 1981), or from torn, encapsulated insulation batts (Farkas 1983). The symptoms disappeared after the ceilings were sealed with plastic foil. Koh and Khoo (1995) found transient skin and eye irritation among laboratory personnel during repair of SVF insulated pipes in the ceiling, and Sim and Echt (1996) linked skin irritation among laboratory workers to nearby SVF insulation work.

Alsbrink and colleagues (1983) compared 39 persons working in rooms with SVF ceiling boards with water-soluble binder with a control group. SVF were found in the mucus thread in the eyes of the exposed but not in the control group. The exposed group had increased prevalence of symptoms and signs of eye irritation. Coating the ceiling boards reduced both symptoms and signs.

Thriene and colleagues (1996) found extensive skin, eye, and airway irritation using a questionnaire among persons working in an office building with suspended ceilings made of grooved, unsealed, and partially frayed SVF ceiling boards. Concentrations ranged from 1000 to 3500 SVF/m³ ($D < 3 \mu\text{m}$) and 100 to 300 SVF/m³ ($D > 3 \mu\text{m}$) as determined by the VDI 3492 method.

An example of gross contamination of a home by SVF from an air-handling system lined with SVF has been reported. Respiratory symptoms were so severe that the family members had to abandon their house (Newball and Brahim 1976).

In the kindergarten study by Rindel and colleagues (1987), it was found that eye and skin symptoms were reported more frequently in the SVF containing kindergartens than in the control group. While there were no differences in SVF concentrations between the three

groups SVF were detected less frequently in the control group. It was concluded that the found levels (below 200 f/m³) hardly could explain the reported symptoms and signs.

In the Danish Town Hall study (Skov et al. 1990) SVF did not show up as an explanatory factor for the registered symptoms. Airborne SVF concentrations reported in that study were low (Table 39.6).

Nonmalignant Chronic Respiratory Effects

An update of the U.S. stone and slag wool worker cohort found no consistent evidence of an association between nonmalignant respiratory diseases (excluding influenza and pneumonia) and SVF exposure (Marsh et al. 1996). For European SVF production workers, no increase in mortality from bronchitis, emphysema, or asthma was found (Sali et al. 1999). A review of epidemiologic evidence on morbidity following exposure to SVF did not reveal persuasive evidence that SVF exposure at industrial concentrations is a risk factor in chronic airway obstruction (Weil and Hughes 1996).

Lung Cancer and Mesothelioma

The International Agency for Research on Cancer classified SVF insulation wool as a class 2B carcinogen (possibly carcinogenic to humans). The classification was based on sufficient (glass) limited (stone) evidence for the carcinogenicity in experimental animals and limited (stone/slag) or inadequate (glass) evidence for the carcinogenicity in humans. Textile fibers (continuous filaments) were not classified (IARC 1988).

Despite the divergence of views among EU member states as reflected during 10 years of discussion, EU has published in 1997 EU Directive 97/69/EEC on classification of SVF. According to this directive, SVF of the wool type is classified as carcinogenic, category 3 “possibly carcinogenic.” The classification as a carcinogen need not apply if it can be shown that the SVF comply with one of four animal tests in which two measure clearance rates of fibers longer than 20 μm . SVF wool is also classified as irritating to the skin. It should be noted that skin irritation of cured SVF is a mechanical reaction and not damaging in the way that chemical irritants may be.

Regarding exposure levels in the indoor environment, there is general agreement that risk of chronic lung disease is negligible. The International Program on Chemical Safety reviewed cancer and other health risks of SVF in 1988 and concluded “that the possible risk of lung cancer among the general public is very low, if there is any at all, and should not be a cause of concern if the current low levels of exposure continue” (IPCS 1988). Lockey and Ross (1994) concluded that “the risk of any long-term health-related problems to occupants from SVF used in residential and occupational application is nil.” After reviewing also more recent the evidence of SVF and cancer, Infante and colleagues (1994) concluded that there is “a presumably negligible risk” to consumers from home/institutional exposures.

From these risk assessments it can be concluded that for indoor air, the first effect endpoints to be addressed are upper airway, skin, and eye irritation. SVF constitute only a small fraction of the total fiber exposure (Schneider et al. 1996), and this should be included in any risk assessment.

39.5 GUIDELINES

There are no concentration guidelines for SVF relevant to indoor air by national or international bodies. With the caveat that SVF concentrations have been measured using dif-

ferent strategies and analytic methods, the data support the following tentative recommendation for handling indoor air problems in buildings containing SVF:

- If the overall level of airborne concentrations is below 100 WHO SVF/m³ and surface concentrations on regularly cleaned surfaces are below 0.2 SVF/cm² and infrequently cleaned surfaces below 3 SVF/cm², look for causes other than SVF if there are indoor environment complaints.
- If the overall level of airborne concentrations exceeds 200 WHO SVF/m³, it is likely that SVF sources have been agitated during the measurements. Include source control on the building management program.
- If SVF concentrations on occasionally cleaned surfaces exceed 10 f/cm², consider increasing cleaning frequencies and/or improving cleaning methods.
- If the overall level of airborne SVF with $D > 3 \mu\text{m}$ is above 100 SVF/m³, then SVF are a likely cause (sole or contributing) if occupants experience irritation of upper airways, skin, or eyes. Eliminate the secondary sources by thorough cleaning.

The relevance of this tentative recommendation would have to be confirmed by targeted field studies.

In any assessment of SVF in the indoor environment, the concentration of other mineral fibers and organic fibers should be determined. Figure 39.1 shows an air sample from a school where measurements were requested because of suspected SVF problems.

39.6 PREVENTION

Installation of SVF Materials

Construction work may leave behind SVF, which, during a short period after construction is completed, may increase SVF concentrations above background (Thriene et al. 1996, Umweltbundesamt 1994, Rödelsperger et al. 1998) (see also Table 39.8). It is recommended that occupants have a building thoroughly cleaned before moving in. An alternative strategy advocated by Flatheim (1996) is to also minimize contamination during construction. SVF containing materials with surfaces facing the indoor air should not release fibers. This can be obtained, for instance, by surface treatment, covering, encapsulating, or sealing the material (Danish Building Regulations for Small Houses).

Testing of Products

The Danish Society of Indoor Climate has issued a set of criteria by which manufacturers can provide their building products with The Indoor Climate Label setting limits for off-gassing. Their *Product Standard for Ceiling and Wall Systems*, 2d ed. October 1997, has included a limit for particle release, specifying that particle release shall be less than 2 mg/m² as measured by a given test. In this test method, test objects are placed on the top of a box and vibrated by pink noise emitted from loudspeakers placed in the side of the box. Released particles are allowed to settle onto a glass plate on the box floor from where they are sampled and quantified. While originally developed for measuring release of SVF from ceiling boards (Nordtest 1989), no specifications are given yet for SVF release.

With an early version of the method (Nordtest 1989), Christensen et al. (1988) determined fiber release from ceiling boards with resin and with water-soluble binder. The test results were generally below 0.5 f/cm², but boards with water-soluble binder had a tendency to give off more fibers. Ceiling boards taken from existing buildings gave off 10

times more fibers. Extensive water damage of ceiling boards with water-soluble binder may cause deterioration of the boards. However, ceiling boards with water-soluble binder aged over 4 weeks by exposing them to high (90%) and low (35%) relative humidity 4 times per day did not consistently release more fibers than boards stored at 50% RH.

Buttner and Stetzenbach (1996) tested the shedding of fibers from newly installed rigid 1-in. fiberglass ductboard (rectangular 13×20 cm, duct velocity 2.8 m/s) and the dispersal into the air of an experimental room ($4 \times 4 \times 2.2$ m high) operated at a nominal air exchange rate of 5 h^{-1} . Using both SEM and optical microscopy, they found that SVF concentrations in the room air were lower than in the outdoor air. This supports earlier findings by others (Balzer et al. 1971, Cholak and Schafer 1971).

Building Operation and Maintenance

Many building investigations have documented biocontamination of SVF duct material in HVAC systems. Thus there is a need to determine the conditions for which SVF can be used. Foarde and colleagues (1995) conducted a systematic study of the influence of moisture, soil, and temperature on the growth of *Penicillium chrysogenum* on SVF. Four new materials (one of which contained a biocide) and one used material (<5 years) were tested. High relative humidity (97% RH) alone supported growth on one new material. If combined with initial wetting another material also supported growth. Soiling with HVAC dust supported growth at 97% RH for all, including the one with a biocide. Soiling caused growth on one material at significantly lower relative humidity. Low temperature (12°C as compared with 23°C) delayed but did not prevent growth. These results indicate that to prevent growth of microorganisms on SVF materials, they must be kept clean and dry. This will also hold true for SVF insulation material stored at construction sites prior to installation.

It is an open question whether cleaning of airducts can improve the indoor air quality (Kulp 1995). Cleaning of ventilation ducts lined with SVF could cause a transient increase in SVF concentration in the room air. Measurements indicate that it is possible to clean ventilation ducts lined with SVF without increasing SVF concentrations in rooms after cleaning. Care must be taken in selecting the proper cleaning methods (NAIMA 1995).

Ceiling boards will become soiled with time because of diffusional deposition of particles on the surface. Pressure waves will force air through the boards, which act as a filter. This increases the soiling rate. If it is decided to paint the ceiling boards, one should avoid filling the pores with paint, as this greatly reduces the sound absorption, and not to compromise the fire protection.

Once SVF have been introduced into the indoor environment, there are only two ways of removing them: by ventilation and by cleaning. Thriene and colleagues (1996) found short-term reduction in airborne SVF concentration ($D > 3 \text{ }\mu\text{m}$) by a factor of 10 after cleaning a contaminated office. In the field study by Schneider and colleagues (1990), ventilation (natural vs. mechanical exhaust) and cleaning (poor, medium, and good as judged from the hours spent on cleaning) was correlated with airborne SVF concentrations ($D < 3$ and $> 3 \text{ }\mu\text{m}$, respectively). The only significant correlations with airborne SVF concentrations were

- Ventilation and SVF with $D < 3 \text{ }\mu\text{m}$
- Cleaning and SVF with $D > 3 \text{ }\mu\text{m}$

This indicates that both ventilation and cleaning are needed to control airborne concentrations of SVF of all diameters. For surfaces it is obvious that cleaning is needed to control surface concentrations. As a starting point dust fall rates in the range 0.2 to $2 \text{ SVF}/(\text{cm}^2 \cdot \text{day})$ (Chap. 64) can be used to estimate the cleaning frequencies needed to control surface contamination below a given level.

40.1 INTRODUCTION

Overview

Radon [radon-222 (^{222}Rd)], a carcinogen present in indoor air, has emerged as a controversial public health problem since 1980 or so. However, the story of radon as a cause of lung cancer is far longer, beginning in the late nineteenth century with the identification of high rates of cancer in miners working in the Erz Mountains of eastern Europe. By the early twentieth century, levels of radon in mines in this region were measured and found to be quite high and it was soon hypothesized that radon was the cause of the unusually high rates of lung cancer. Although not uniformly accepted initially, as the findings of epidemiologic studies of underground miners were reported from the 1950s on, there was soon substantial evidence showing that radon was a cause of lung cancer (Samet 1989, NRC 1999). In fact, the concern about radon in the air of homes was initially driven by the strong evidence that radon causes lung cancer in underground miners.

Radon is a noble and inert gas resulting from the decay of naturally occurring uranium-238 (^{238}U). With a half-life of >3 days, radon diffuses through rock and soil after it forms. In mines, it enters the air from the ore or is brought into the mine dissolved in water. In homes, the principal source is soil gas, which penetrates through cracks or sumps or around a concrete slab. Because ^{238}U is universally present in the earth, radon is a ubiquitous indoor

air pollutant, and it is also present in outdoor air. Infrequently, building materials or water may also contribute significantly to indoor concentrations.

Radon is an alpha emitter which decays with a half-life of 3.5 days to a short-lived series of progeny (Fig. 40.1) (USDHHS 1995). Unlike radon, the progeny are solid, and form into small molecular clusters or attach to aerosols in the air after their formation. The inhaled particulate progeny may be deposited in the lung on the epithelium, the surface that lines the airways of the lung; radon, by contrast, is largely exhaled, although some radon is absorbed through the lung. Radon itself is not responsible for the critical dose of radioactivity delivered to the lung that causes cancer. While radon was initially considered to be the direct cause of the lung cancer in miners, Bale (1980) and Harley (NRC 1999) recognized in the early 1950s that alpha emissions from radon progeny and not from radon itself were responsible for the critical dose of radiation delivered to the lung. Alpha decays of two radioisotopes in the decay chain, polonium-218 and polonium-214 (^{218}Po and ^{214}Po) (Fig. 40.1), deliver the energy to target cells in the respiratory epithelium that is considered to cause radon-associated lung cancer (NRC 1991). Alpha particles, equivalent to a helium nucleus, are charged and have a high mass. Although their range of penetration into tissues is limited, they are highly effective at damaging the genetic material of cells. As reviewed in the report of the Biological Effects of Ionizing Radiation (BEIR) VI Committee (NRC 1999), passage of even a single alpha particle through a cell can cause permanent genetic change.

Evidence on radon and lung cancer risk is now available from about 20 different epidemiologic studies of underground miners, including 11 studies that provide quantitative information on the exposure-response relationship between exposure to radon progeny and lung cancer risk (NRC 1999, Lubin et al. 1995). Although radon progeny are now a well-recognized occupational carcinogen, radon has again become a topic of controversy because it has been found to be a ubiquitous indoor air pollutant in homes, and recommended control strategies in the United States and other countries include testing of most homes and mitigation of those exceeding guideline levels (Cole 1993).

FIGURE 40.1 Decay pathway from ^{226}Ra to ^{210}Pb by year, day, minute, and second.

Radon was found to be present in indoor air as early as the 1950s, but the potential health implications received little notice until the late 1970s and early 1980s. The problem first received the greatest attention in Scandinavia, but homes with radon levels of concern have now been identified in other countries of Europe and in North America. Housing surveys show that radon is ubiquitous and that concentrations tend to follow a lognormal distribution (Fig. 40.2). Policies are now in place in many countries to manage the lung cancer risk associated with indoor radon. These policies involve the identification and mitigation of homes with concentrations above guideline values and the use of construction techniques that reduce radon concentrations. Since these policies potentially extend to almost all residential housing, their scientific base has been challenged, as has their cost-effectiveness.

Although risk management for indoor radon remains controversial, the evidence on radon and lung cancer is now very extensive. Initially, research was driven by the need to characterize the risks faced by underground miners in order to set exposure limits that would have acceptable risks. This work emphasized epidemiologic approaches, but ani-

FIGURE 40.2 Distribution of radon concentration in U.S. homes based on the National Residential Radon Survey.

mal studies were also conducted to confirm the hazard and to address the modifying effects of such factors as the presence of ore dust and diesel exhaust, cigarette smoking, and dose rate. More recently, research has reflected the need to understand better the risks posed to the general population by indoor radon. Epidemiologic studies have been conducted to assess directly the general population's risk of lung cancer from indoor radon; laboratory studies using molecular and cellular approaches have been carried out to better understand the mechanism of radon carcinogenesis and thereby to address key uncertainties in assessment of the risks of indoor radon. Since the midtwentieth century, risk models have been developed for the purpose of risk assessment and risk management. Key reports have come from the International Commission for Radiological Protection (ICRP), the National Council for Radiation Protection and Measurements (NCRP), and the Biological Effects of Ionizing Radiation Committees of the U.S. National Research Council.

This chapter provides an overview of the current evidence on the lung cancer risk associated with indoor radon, emphasizing the epidemiologic findings and the most recent risk models proposed by the BEIR VI Committee of the U.S. National Research Council (NRC 1988). This report provides the most recent comprehensive summary of the evidence on radon and lung cancer. The chapter also addresses policies to manage the problem of indoor radon and mitigation approaches.

Concentration and Exposure

The units used to describe concentration of radon and its progeny and exposure to radon progeny have their origins in the uranium mining industry. The units traditionally used in the United States are not in the SI system (International System of Units), but have been maintained and will be used in this chapter. For describing concentrations and exposures in mines, the concentration has been expressed historically as working levels (WLs), where one WL is any combination of radon progeny in one liter of air that ultimately releases 1.3×10^5 MeV of alpha energy during decay (Holaday et al. 1957). Exposure to one WL for 170 hours provides one working-level month (WLM) of exposure. Because most persons spend much more than 170 h at home each month, a concentration of one WL in a residence results in an exposure much greater than one WLM on a monthly basis, approximately 3 WLM under typical occupancy conditions. In the United States, indoor concentration of radon is described in units of picocuries per liter (pCi/L), a measure of radioactivity. Translation of pCi/L of radon into WL of radon progeny requires an assumption as to the equilibrium between radon and its progeny; assuming 50 percent equilibrium, 200 pCi/L of radon is equivalent in concentration to one WL. In most countries besides the United States, SI units are used. Concentration is expressed as becquerels per cubic meter (Bq/m^3), where 1 pCi/L equals $37 \text{ Bq}/\text{m}^3$. Cumulative exposure in SI units is expressed in joule-hours per cubic meter, and one WLM is $3.5 \times 10^{-3} \text{ Jh}/\text{m}^3$.

40.2 MEASUREMENT OF INDOOR RADON

A variety of methods have been used historically to measure concentrations of radon and radon progeny. Practical and inexpensive methods were needed to make measurements in the underground uranium mines; these methods have been the basis for the measurement technology applied to indoor radon (Fortmann 1994). Continuous sampling methods were evolved for use in underground mines, primarily for measuring the concentration of radon progeny.

However, integrated methods have generally been used for measuring the concentration of radon in homes. These methods involve the counting of alpha-particle emissions. Three

general types of devices are available: alpha-track detectors, activated-carbon monitors, and electrets (Fortmann 1994). All of these devices are passive, relatively inexpensive, and simple to use. The alpha-track detectors employ a film that is etched by the passage of alpha particles, and the tracks are then counted to estimate concentration. CR-39 is the most widely used film material at present. Alpha-track detectors have a filter to exclude radon progeny and dust. Alpha-track detectors are usually left in place for at least one month and for as long as 12 months.

Activated-carbon monitors are used for short-term measurements, typically a few days to a week. The charcoal adsorbs the radon and gamma rays emitted by the subsequently formed progeny are counted by gamma detection instruments. A variety of factors influence performance of activated-charcoal monitors, but their accuracy has been found to be adequate for screening protocols (Fortmann 1994). Electrets have been used for short-term and long-term measurements. These devices measure change in charge of the electret as the indicator of integrated radon concentration.

Measurement protocols have been developed for use in homes and in schools and other buildings (Roca-Battista and Magno 1994). Elements of these protocols include the type of sampler, the duration of the measurement, the conditions of building use during the measurement, and the locations to be monitored. The protocols need to properly account for the temporal variation of radon concentrations in homes (or other buildings) that is driven by weather, season, and patterns of building use and operations.

The principal protocols now in use for homes in the United States were developed by the U.S. Environmental Protection Agency (USEPA), which has advocated the use of short-term screening protocols to test for the need for mitigation. The protocol calls for closed-house conditions and placement of the monitor in the lowest, lived-in area. The measurement should be taken for at least 2 and no more than 90 days. Follow-up testing is recommended if the screening measurement exceeds the guideline value of 4 pCi/L (150 Bq/m³). USEPA also gives guidance on quality assurance and calibration facilities have been provided by the U.S. Department of Energy. Protocols are also available for longer-term measurements (USEPA 1992c). In applying the protocols, decisions as to the need for mitigation are needed to acknowledge the imprecision of the measuring devices and the inherent variability of radon concentrations (Harley 1990).

40.3 SOURCES OF EXPOSURE TO INDOOR RADON

Penetration of radon-contaminated soil gas is the principal source of the radon found in homes (Nero 1988). Soil gas contains radon formed from the ²³⁸U decay series, as in mines. The presence of a home establishes a net pressure gradient for flow of the soil gas into the home through such openings as cracks in the foundation, sump holes, and other portals (see Fig. 40.3). The rate of infiltration of soil gas into the home varies with the strength of the “stack effect” and also with the interaction of wind with the walls and roof. Sextro (1994) provides a detailed treatment of the entry of soil gas into homes. Other potential sources include building materials that are rich in radium, such as the alum shale-based materials used in Sweden, wallboard made with phosphogypsum with a high concentration of radium, and water and natural gas having high radon concentrations. Water from deep drinking wells may contain radon at high concentrations, and at exceptionally high concentrations, offgassing of radon from water may contribute substantially to indoor concentrations. Public water supplies are not likely to be of concern as a source of indoor radon under most circumstances.

Data for the United States show that the concentration of radon in homes follows a nearly lognormal distribution with most homes having values near the median of

FIGURE 40.3 Radon entry routes into homes.

approximately 1 pCi/L (37 Bq/m³) (Fig. 40.2) (USEPA 1992b). However, some homes have much higher levels, ranging to over 1000 pCi/L (37,000 Bq/m³). There is substantial heterogeneity of radon concentrations in homes across regions with some regions having few homes with high levels and others, such as the Reading Prong area in the northeastern United States, having many homes with high levels. Even within regions and communities there is substantial variation in concentrations. This heterogeneity reflects both soil and housing characteristics (Schumann et al. 1994, Koontz 1994). Relevant soil characteristics include the radium content and distribution, porosity, permeability to gas movement, and moisture (Schumann et al. 1994). Some types of rocks are more likely to cause radon problems, including black shales, lignite, and coal, some sandstones, granites, granitic metamorphic rocks, and glacial deposits. Homes with basements have the greatest potential for higher concentrations. The heterogeneity of indoor concentrations is a barrier in developing risk management approaches. We still lack accurate techniques for predicting homes most likely to have high radon concentrations, so that testing of individual homes is needed to identify those with unacceptable levels.

40.4 CONCENTRATIONS OF INDOOR RADON

Table 40.1 shows radon concentrations taken from national surveys of dwellings where either the median or the geometric mean were provided. Units are shown as pCi/L, and the majority of data are taken from the 1993 UNSCEAR report, *Sources and Effects of Ionizing Radiation* (United Nations Scientific Committee on the Effects of Atomic

Radiation 1993). Other data are taken from individual reports of national surveys from Italy (Bochicchio et al. 1996), Sweden (Pershagen et al. 1994), and Germany (Steindorf et al. 1995). The values range from well below 1 pCi/L to nearly 2 pCi/L. The range varies widely across the countries.

40.5 RESPIRATORY DOSIMETRY OF RADON

The relation between exposure to radon progeny and dose of alpha energy delivered to target cells in the respiratory epithelium is complex and dependent on both biological and physical factors (Table 40.2) (Dwyer et al. 1992). An understanding of this relation is central to extending risks observed in underground miners to the risks to the general population from indoor radon. The physical and biological factors determining the exposure-dose relationship differ for exposures in these two settings, and this source of uncertainty in risk assessment for indoor radon has been examined using dosimetric models of the lung (Lubin et al. 1995). The most recent comprehensive assessment of exposure-dose relations was carried out by the Radon Dose Panel convened by the National Research Council (NRC 1991) and updated by the BEIR VI Committee. Although increasingly sophisticated models of lung dosimetry have been developed and the extent of information on key model parameters continues to grow, gaps in the evidence on key issues continue to constrain

TABLE 40.2 Physical and Biological Factors Influencing the Dose to Target Cells in the Respiratory Tract from Radon Exposure

interpretation of these models, including persistent uncertainty as to the specific cells that give rise to lung cancer.

Using computer models of the lung, it is possible to calculate estimates of the dose of alpha energy delivered to target cells and to assess the impact of variation of model parameters on the estimated dose. Doses in mining and indoor environments can be compared, and the impact of indoor environmental characteristics, such as aerosol size characteristics, can be assessed. The range of published dose estimates is broad, reflecting assumptions concerning the form of the model and values of model parameters (NRC 1991, Nazaroff and Nero 1988). The values span from about 0.8 rad/WLM (0.8 mGy/WLM) to about 10 rad/WLM (100 mGy/WLM). These absorbed dose factors can be converted to tissue dose equivalents by assuming a quality factor and then used to assess risk by applying risk coefficients derived from epidemiologic studies of populations exposed to low-linear-energy-transfer (LET) radiation, as in the dosimetric approaches used in the past to estimate radon risks.

However, the model findings have been principally applied to compare exposure-dose relations for the circumstances of exposure in homes and in mines. The comparative relationship has been summarized by the *K factor*, a unitless quantity calculated as the quotient of the ratio of exposure to dose in homes to the same ratio in mines. The *K factor* has been used to adjust for differing dosimetry in homes and mines in estimating the risk of exposure in homes. A number of analyses have been reported on the value of the *K factor* (NRC 1991). In the 1991 report of the Radon Dose Panel of the National Research Council, estimates of the *K factor* tended to be somewhat below 1, regardless of age and sex and the putative target cell (NRC 1991). The *K factor* values changed little with the more recent analysis of the BEIR VI Committee, which used the latest dosimetric models and parameter values. The BEIR VI Committee assumed a value of 1 in its risk assessment.

40.6 EPIDEMIOLOGIC STUDIES OF RADON AND LUNG CANCER

Studies of Miners

The early information of lung cancer and radon progeny exposure came from case series and relatively informal epidemiologic studies based on the metal miners in the Erz Mountain region of Germany and Czechoslovakia (NRC 1988, Lorenz 1944).

Nevertheless, this initial evidence was strongly indicative of a causal association between radon and lung cancer, although some were skeptical (Lorenz 1944). Subsequently, however, the findings of cohort studies of underground miners convincingly established that radon caused lung cancer in humans.

The findings of the first large-scale epidemiologic study on lung cancer in underground miners in the United States were reported in the late 1950s and early 1960s. By the early 1960s, this study, a prospective cohort study of over 3000 underground uranium miners from the Colorado Plateau conducted by the U.S. Public Health Service, convincingly showed excess lung cancer, well beyond that predicted by mortality rates for the general population (Wagoner et al. 1964). The risk of lung cancer in the miners was shown to rise with increasing exposure to radon progeny and to be synergistically increased by smoking. Findings from a study of Czechoslovakian miners, first reported in the 1970s, were similar (Sevc et al. 1976). On the basis of the findings of these and several other studies as well as the historically documented excess lung cancer in the miners of Schneeberg and Joachimsthal, radon was generally considered to be a cause of lung cancer by the 1970s (NRC 1980, Lundin et al. 1971, Holaday 1969).

During the 1980s and the early 1990s, the findings of additional cohort studies of underground miners all incorporating estimates of radon progeny exposure were published, and the information on exposures to radon progeny of the Newfoundland fluorspar miners was updated (Lubin et al. 1994). These reports confirmed the excess risk of lung cancer observed in the previous studies and expanded the database for developing models of the relationship between radon progeny exposure and lung cancer risk (Table 40.3). The estimates of the lung cancer risk associated with exposure to radon progeny were relatively consistent among the studies, covering a range of about 10. The more recent cohorts include three groups of Canadian uranium miners (Muller et al. 1984; Howe et al. 1986, 1987); Chinese tin miners (Xuan et al. 1993), notable for the large population of exposed miners and the number first exposed as children; Swedish iron miners (Radford and Renard St. Clair 1984); New Mexico uranium miners (Samet et al. 1991); Australian uranium miners from the Radium Hill mine (Woodward 1991); and French uranium miners (Tirmarche et al. 1993). The new studies added

to the literature on radon progeny and lung cancer, contributing estimates of the exposure-disease relationship between radon progeny exposure and lung cancer risk, and new evidence on key uncertainties in regard to the lung cancer risk associated with radon. A pooled database that combines the data from the earlier and more recent cohorts has been the basis for developing the most recent risk models for radon and lung cancer.

Studies of the General Population

To reduce the uncertainties associated with extrapolating risks from the studies of underground miners to the general population, epidemiologic studies of ecologic and case-control design have been undertaken in the general population. Ecologic studies are descriptive, comparing incidence or mortality rates for lung cancer for persons in specific geographic units with estimates of radon exposure for these units. The case-control studies involve comparison of the estimated exposures for persons with lung cancer with those of comparable but unaffected controls. The ecologic studies, which use readily available data on lung cancer mortality, were conducted to determine whether patterns of lung cancer occurrence were consistent with the hypothesis that indoor radon causes lung cancer. The case-control studies have been implemented to address the risk of lung cancer directly, and thereby remove the uncertainties inherent in extrapolating risks from underground miners to the general population.

In ecologic studies, the units of analysis are groups, usually defined by geography. Methodological problems limit the usefulness of ecologic studies (Piantadosi et al. 1988, Greenland and Morgenstern 1989, Greenland and Robins 1994, Stidley and Samet 1993), and these studies are generally considered to be appropriate for developing hypotheses on exposure-disease associations and not for quantitative risk estimation. Stidley and Samet (1993) provide a detailed review of the results and methods of 15 ecologic studies of lung cancer and indoor radon exposure published through 1992. A few additional studies have been subsequently reported and are listed in the BEIR VI report (NRC 1999). Exposure classifications used in these studies included surrogate measures such as the geologic characteristics of an area, and estimates based on measurements of current indoor radon levels in samples of homes. Confounding, by factors such as cigarette smoking, cannot be adequately controlled using ecological methods, and regression approaches at the ecological level are not satisfactory for estimating risks (NRC 1999, Greenland and Morgenstern 1989). Consequently, the BEIR VI Committee cautions against using the evidence from ecological studies, noting the availability of data from more appropriate designs.

In the case-control studies, exposures to indoor radon of lung cancer cases are compared with those of controls. Information on cigarette smoking and other factors can be obtained by interview. In some of the early studies, exposures were indirectly estimated based on surrogates such as type of residential construction or residence location (NRC 1988). In the more recent studies, exposures to indoor radon have been estimated by making longer-term measurements of radon concentration in as many of the current and previous residences of the cases and controls as possible (U.S. Department of Energy 1991, Neuberger 1992). Several of the studies have been restricted to nonsmokers or long-term former smokers in order to estimate the lung cancer risk in this group as precisely as possible.

Results have now been reported for a number of case-control studies having relatively large sample sizes and incorporating measurements of radon concentrations (Table 40.4). The BEIR VI report includes a complete summary. The findings of the studies have been summarized using metaanalysis (NRC 1999, Lubin and Boice 1997). Pooling of the evidence from these studies has been proposed as a basis for increasing statistical power and to assess modification of radon risk by such factors as smoking (U.S. Department of Energy 1991). At this time, separate data poolings are planned for case-control studies from Europe

TABLE 40.4 Summary of Results from Case-Control Studies of Residential Radon Exposure

Study	Cases	Controls	Radon level, pCiL ⁻¹ (median/mean)	Comment
Finland I	238	415	40% > 4.7 20% > 7.4	Results show only a modest suggestion of an overall trend with increasing radon level, but all relative risks exceeded 1
Finland II	517	517	Cases, 2.8 (mean); controls, 2.6 (mean)	Results show no overall trend; residential occupancy less than 12 h/day
Israel	35	35	1.0 (mean)	Study has few cases; radon concentrations are very low; no conclusions can be drawn
Missouri	538	1183	Cases, 1.8 (mean); controls, 1.8 (mean)	Results show no overall trend with increasing radon level; suggestive trends were found when analyses restricted to adenocarcinoma cases or in-person interviews
New Jersey	480	442	Cases, 0.5 (median); controls, 0.5 (median)	Significant exposure-response trend, but mean exposures very low and results influenced strongly by highest exposure category with 5 cases and 1 control
Port Hope	27	49	Cases, 2.7* (mean); controls, 0.5* (mean)	Nonsignificant excess relative risk with or without adjustment for smoking
Shenyang	308	356	Cases, 2.8 (median); controls, 2.9 (median)	Results show no increasing RR with increasing radon level, overall and within categories of indoor air pollution
Stockholm	201	378	Cases, 3.1 (median); controls, 2.9 (median)	Results suggest positive increase, but cautious interpretation indicated because trend depends on cut points and disappears after adjustment for occupancy or with BEIR IV weighting
Sweden	1218	2576	1.5 (median)	RRs increase significantly with increasing radon level; RR patterns similar by histologic type and homogeneous across categories for never-smoker, ex-smoker, and number of cigarettes per day
Winnipeg	738	738	Cases, 3.1 (mean); controls, 3.4 (mean)	Results show no increasing RR with increasing radon level, as measured in living area or in basement

*Estimated cumulative radon-progeny exposure to WLM.

and from North America, followed by a pooling of all available evidence. Findings should be reported in the year 2000.

A recently reported metaanalysis included the eight studies with 200 or more lung cancer cases included in Table 40.4 (Lubin and Boice 1997). A loglinear model for relative risk was fit to the data for each study and the estimates from the individual studies were then pooled. The fitted relative risk at 150 Bq/m³ was 1.14 [95 percent CI (confidence interval) 1.0 to 1.3]. In a comparative analysis conducted by the BEIR VI Committee, this risk estimate was shown to be consistent with an estimate based on the data from the studies of miners.

40.7 ANIMAL STUDIES OF RADON AND LUNG CANCER

Animal studies on the respiratory effects of radon were initiated early in the twentieth century to determine if radon was carcinogenic but were later implemented to assess experimentally factors modifying the risk of radon (Nazaroff and Nero 1988). Although the human evidence on the carcinogenicity of radon has been compelling, the animal studies have provided confirmatory data and enabled assessment of aspects of exposure, such as exposure rate and the presence of other agents, which cannot be readily addressed with epidemiologic methods. The animal studies have also provided quantitative risk coefficients. Of the modern studies, the largest experiments were conducted at the Pacific Northwest Laboratory (PNL) in Washington State and at the laboratory of the Compagnie Generale des Matieres Nucleaires (COGEMA) in France. The animal studies have been described in detail (NRC 1991, Nazaroff and Nero 1988, Monchaux et al. 1994).

The COGEMA and PNL studies complement the epidemiologic data. Their findings confirm that radon decay products cause lung cancer, although the cancers produced in animal models are not fully analogous to human lung cancer in location or histopathology. Risk coefficients derived from animal and human data are remarkably close.

40.8 RISK ASSESSMENT FOR RADON AND LUNG CANCER

General Approach and Historical Perspective

The risks of radon have been assessed with two general approaches: the dosimetric and the epidemiologic. The dosimetric approach relies on a model to estimate the dose of alpha energy delivered to the respiratory tract; lung cancer risk is then estimated by applying a quality factor, generally assumed to be 20 for alpha particles, to the risk coefficients obtained from populations exposed to low-linear-energy-transfer (LET) radiation, such as in the atomic bomb survivors. The ICRP followed this approach in its early risk models.

The epidemiologic approach involves extrapolation of the risks observed in miners to lower exposures for the purpose of estimating either the safety of occupational exposure limits or the risk of indoor radon. Use of the epidemiologic approach requires assumptions concerning the shape of the dose-response relationship, the effect of the exposure rate, the effects of potential modifying factors such as cigarette smoking, and the consequences of factors affecting the delivered dose. Nevertheless, the epidemiologic approach has been the basis for most current risk assessments because of the rich evidence from studies of

underground miners. Extensive reviews of risk models for radon and lung cancer are provided in the BEIR IV (NRC 1988) and BEIR VI reports (NRC 1999).

The BEIR IV Model

The 1988 *Report of the Biological Effects of Ionizing Radiation* (BEIR) IV Alpha Committee reviewed the principal risk assessments published through 1987 and added its own, based on analyses of four studies of underground miners. These early risk models were based primarily on risk coefficients derived from one or a few of the then extant studies of underground miners.

The model developed by the BEIR IV Committee (NRC 1988) has been used as the basis for some of the more recent risk assessments of indoor radon conducted by USEPA and other agencies. Data from four cohorts—Malmberget, Sweden iron miners; Colorado Plateau uranium miners; Beaverlodge, Canada uranium miners; and Ontario, Canada uranium miners—were analyzed to develop the model.

The Committee recommended the following relative risk model, termed the *time-since-exposure* model for $r(a)$, the age-specific lung cancer mortality rate:

$$r(a) = r_0(a) [1 + 0.025 \gamma(a) (W_1 + 0.5 W_2)]$$

where $r_0(a)$ = age-specific background lung cancer mortality rate

$\gamma(a)$ = 1.2 when age $a < 55$ years, 1.0 when age $a = 55$ to 64 years, 0.4 when $a \geq 65$ years

W_1 = WLM received 5 to 15 years before age a

W_2 = WLM incurred ≥ 15 years before age a

This model inherently assumes that the effects of other factors determining lung cancer risk, such as cigarette smoking, are multiplicative with those of radon progeny exposure.

The National Cancer Institute Model

With the publication of additional studies and the opportunity to work with the team investigating the Czechoslovakian uranium miners, the U.S. National Cancer Institute and the original investigators analyzed pooled data from 11 studies of underground miners (see Table 40.3) (Lubin et al. 1994). The cohorts included uranium, tin, iron, and fluorspar miners; all had data on exposure to radon progeny, six studies had some data on cigarette smoking, and only a few studies had information on exposures other than radon progeny. The pooled data set included over 2700 lung cancer deaths among 68,000 miners followed for nearly 1.2 million person-years of observation. A full description of the analysis has been published as a National Cancer Institute monograph (Lubin et al. 1994) and the data from the same cohorts, with some updating, were used by the BEIR VI Committee.

As in the BEIR IV analysis, excess relative risk (ERR) was linearly related to cumulative exposure to radon progeny. The ERR gives an estimate of the increase in relative risk per change in unit of exposure to radon progeny. In the analysis of the pooled data, the ERR was found to vary significantly with other factors; it decreased with attained age, time since exposure, and time after cessation of exposure but was not affected significantly by age at first exposure. Over a wide range of total cumulative exposures to radon progeny, lung cancer risk increased as exposure rate declined. This finding of an exposure rate effect in the pooled analysis confirms the pattern reported from the Colorado Plateau study (Hornung and Meinhardt 1987) and supports the prior hypothesis of an inverse dose-rate effect

(Darby and Doll 1990). The inverse exposure rate has potentially significant implications for risk estimation at typical indoor levels using the miner studies.

Information on tobacco use was available from six of the cohorts. The combined data were consistent with a relationship between additive and multiplicative for the joint effect of smoking and exposure to radon progeny. Over 50,000 person-years, including 64 lung cancer deaths, were accrued by miners who were identified as never smokers. In this group, there was a linear exposure-response trend which was about threefold greater than observed in the smokers.

Two sets of models were preferred by the report's authors; the sets differ in being either categorical or contiguous in the parameterization of the variables. Each includes one model incorporating radon progeny exposure during three time-since-exposure windows and variables for effect modification by attained age and exposure rate and one model similarly incorporating exposure in the same windows and variables for attained age and duration of exposure. The selected exposure windows were 5 to 14 years, 15 to 24 years, and 25 or more years before the attained age. The models are similar to the BEIR IV model with an additional term for either rate or duration of exposure.

The BEIR VI Model

The BEIR VI Committee used the pooled data set and the analysis of the National Cancer Institute as a starting point for developing its risk models (NRC 1999). The Committee's final models had the same form as those developed by the National Cancer Institute group, including a term for exposure rate. The Committee offered two preferred risk models, one representing exposure rate by duration of exposure and the other by average concentration during exposure. A model was also developed on the basis of those with exposures below various cutoffs in ranges considered most relevant to indoor radon risks.

The BEIR IV and VI Committees' Risk Assessments

Although the BEIR IV report did not offer quantitative estimates of the numbers of lung cancer cases attributable to radon, it offered a general approach for doing so. Using the BEIR IV model and assuming equivalent exposure-dose relationships in homes and mines as recommended by the BEIR IV Committee, Lubin and Boice (1989) calculated the proportion of lung cancer deaths attributable to radon exposure of residents of single-family homes in the United States. They assumed a lognormal exposure distribution with a mean of approximately 1 pCi/L (Nero et al. 1986) and estimated that 14 percent of lung cancer deaths, approximately 13,300 deaths annually, were attributable to radon. The new model based on the 11 cohorts of underground miners has also been used to estimate the numbers of lung cancer deaths attributable to radon (Lubin et al. 1994). The assumptions with regard to dosimetry and exposure were comparable to those made by the USEPA in its 1992 report (USEPA 1992b). The new model predicted 14,400 lung cancer deaths for 1993 among residents of single-family homes in the United States.

The BEIR VI report (NRC 1999) provides risk estimates for various exposure scenarios and also makes projections of the burden of lung cancer in the United States attributable to radon progeny. These estimates are provided in Table 40.5, which includes the figures for the total population and for smokers and never smokers separately. The estimates for smokers and never smokers are based on the assumption of a submultiplicative combined effect of smoking and radon progeny. Estimates based on the BEIR IV model are included in the tables, along with estimates based on fitting a constant relative risk model to the data at exposures less than 50 WLM. The BEIR VI report also includes a quantitative uncertainty analysis.

Table 40.5 Estimated Attributable Risk (AR*) for Lung Cancer Death from Domestic Exposure to Radon Using 1985-1989 U.S. Population Mortality Rates Based on Selected Risk Models

Model	Population	Ever-smokers	Never-smokers
<i>Males</i>			
Committee's preferred models			
Exposure-age-concentration	0.141	0.125	0.258
Exposure-age-duration	0.099	0.087	0.189
Other models			
CRR† (<50WLM)	0.109	0.096	0.209
BEIR IV	0.082	0.071	0.158
<i>Females</i>			
Committee's preferred model			
Exposure-age-concentration	0.153	0.137	0.269
Exposure-age-duration	0.108	0.096	0.197
Other models			
CRR† (<50WLM)	0.114	0.101	0.209
BEIR IV	0.087	0.077	0.163

*AR = the risk of lung cancer death attributed to radon in populations exposed to radon divided by the total risk of lung cancer death in a population.
†Based on a submultiplicative relationship between tobacco and radon.
‡CRR = constant relative risk.

These estimates confirm that radon progeny should be considered as a significant cause of lung cancer in the United States. The attributable risks are higher on a percentage basis for never smokers than smokers, reflecting the submultiplicative interaction between smoking and radon progeny. Of course, the numbers of attributable cancer deaths are far higher in smokers than in never smokers. Of the radon-attributed lung cancer deaths, only a minority can be prevented by current risk management strategies as the total number attributed can, in theory, be prevented only by lowering levels of radon progeny indoors to the outdoor values. For the United States, about one-third of the lung cancer deaths are attributed to concentrations above the current USEPA guidelines.

40.9 RADON CONTROL STRATEGIES

Radon control strategies have been developed in relation to existing and new housing. For existing housing, control programs are directed at identifying homes with levels above guideline values for acceptability and taking steps to lower the concentration. For new construction, preventive strategies are used at construction sites to reduce the potential for high levels. This chapter focuses principally on the approaches recommended in the United States by the USEPA; full details are provided in the agency's technical publications (USEPA 1992c).

The general program of the U.S. Environmental Protection Agency is described in its documents for the public, *A Citizen's Guide to Radon* (USEPA 1986, 1992c), *Model Standards and Techniques for Control of Radon in New Residential Buildings* (USEPA 1994a), *Radon Mitigation Standards* (USEPA 1994b), *Radon Resistant New Construction in Homes* (USEPA 1995). For existing housing, USEPA has called for voluntary testing of essentially all single-family residences and mitigation if the annual average concentration is above 4 pCi/L. Because homes with unacceptably high concentrations cannot be accu-

rately predicted, USEPA recommends testing of all homes, even in areas where few homes above the guideline have been identified. The recommended protocols involve either two sequential short-term tests or one short-term test followed by a long-term test for confirmation (Page 1994).

For homes requiring radon mitigation, there are a variety of control approaches, depending on the type of housing and the source of the radon (Leovic and Roth 1994). The methods for reducing radon can be grouped as those for preventing the entry of radon and those for reducing the concentration of radon within the building. For preventing radon entry from soil, techniques include soil depressurization, sealing, building pressurization, and source removal. Active soil depressurization methods use a fan to create a negative pressure in the soil beneath a building and thus divert the flow of radon to the outdoors. Sealing of entry routes, such as basement sumps, is a second strategy for preventing radon entry. Building pressurization can also be used to reverse the flow of soil gas into the home. If materials are the source of radon, then removal may be warranted. Radon in water can be removed by passage through an activated-carbon unit or by aeration of the water before it is brought into the building. To remove radon after entry, ventilation and air cleaning represent the two principal approaches. Ventilation may be costly and ineffective for extremely high levels, and air cleaning has not received widespread application. The evaluation of a building with an elevated radon concentration should be carried out by an experienced diagnostician, preferably one who has been certified by USEPA or a state agency.

In areas with the potential for high radon levels, construction techniques are available to add features that render buildings relatively radon-resistant or that permit easy mitigation (Leovic and Roth 1994). For homes, these techniques include the installation of a soil depressurization system during construction. If needed, the system can be implemented following construction by the addition of a fan. Passive systems for depressurization may also be built into homes. Sealing of entry routes during construction can also reduce radon entry. For schools and other buildings, the HVAC system can also be designed to reduce radon entry.

40.10 SUMMARY

The story of radon and lung cancer continues. Over 100 years after underground miners were found to be at risk for thoracic malignancy, we have identified radon and its progeny as the cause, quantitatively characterized the risk, and gained substantial understanding of the mechanisms. Nevertheless, the subject of radon and lung cancer is again controversial because of the problem of indoor radon. Risk assessments based on the studies of miners indicate that indoor radon should be considered a public health problem and the emerging evidence from the case-control studies is confirmatory. Fortunately, radon concentrations can be measured accurately and inexpensively, and effective mitigation techniques are available.

41.1 DEFINITION

To prevent transmission of HIV and hepatitis B virus infection, health care workers now wear protective gloves when they have contact with patients, human blood, or other secretions. The most effective gloves are made from natural rubber, and rubber proteins are quite allergenic. These allergens, carried on starch powder grains, become airborne in rooms where powdered gloves are donned and discarded. As a result, not only the wearers but also others working nearby are exposed to airborne rubber allergens.

41.2 SOURCES

Natural rubber is a plant product derived from the cytosol, or latex, of the tree *Hevea brasiliensis*.¹ About 90 percent of harvested raw rubber is processed by acid coagulation at pH 4.5 to 4.8 into dry sheets or crumbled particles for manufacture of extruded rubber products (rubber thread or tubing); compression, transfer, or injection-molded goods (rubber seals or washers); or pneumatic tires for vehicles.² About 10 percent of harvested rubber is not coagulated, but is ammoniated and used mostly to manufacture rubber gloves and other “dipped” products, such as condoms and balloons.³

The functional unit in latex is a rubber particle, a spherical droplet of *cis*-1,4-polyisoprene that is coated with a layer of protein, lipid, and phospholipid that provides structural integrity. Proteins constitute 1.7 percent of the rubber, or 15 mg/mL in raw latex. About 60 percent of the protein is intimately associated with the rubber, and 40 percent is in the latex cytosol. Some of the major rubber proteins are listed in Table 41.1.⁴⁻¹⁷ The cytosol contains most of the enzymes necessary for the conversion of sucrose into *cis*-1,4-polyisoprene.

TABLE 41.1 Physicochemical and Functional Properties of Selected Rubber Proteins and Allergens

Hevains	Serine proteases from serum (Hevain a = 69 kDa, $pI = 4.3$; Hevain b = 58 kDa) or lutoids (Hevain 1 = 80 kDa) ^{4,5}
Hevein	4.7 kDa lectin-like protein that binds chitin and aids in latex coagulation via interaction with <i>N</i> -acetyl-D-glucosamine and a 22-kDa glycoprotein receptor on the surface of rubber particles ^{6,7}
Hevamine	Lutoid-derived 29-kDa basic protein with lysozyme/chitinase activity ^{8,9}
Prenyltransferase	70-kDa homodimeric protein (monomer = 38 kDa) that catalyzes polymerization of isopentenyl pyrophosphate into <i>cis</i> -1,4-polyisoprene ¹⁰
Unknown protein	23-kDa protein to which individuals with myelodysplasia preferentially produce IgE antibody; 45% homology with rubber elongation factor ¹¹
Rubber elongation factor	
Hev b 1	58-kDa homotetrameric protein (monomer = 14.6 kDa) that envelops larger rubber particles and facilitates action of prenyltransferase enzymes to produce rubber chains ^{12,13}
Hev b 2	β -1,3-Glucanase ¹⁴
Hev b 3	24-kDa protein that envelops smaller rubber particles and to which individuals with myelodysplasia preferentially produce IgE antibody; protein fragments and aggregates when frozen ¹⁵
Hev b 4	A component of the microhelix protein complex ¹⁴
Hev b 5	Acidic protein ($pI = 3.5^{16}$ or 3.89^{17}) of 16 ¹⁶ to 17.4 kDa ¹⁷ that shows a high degree of homology with an acidic protein from kiwi fruit

Organelles called “lutoids” contain hevamines, proteins with chitinase and lysozyme properties, and hevein, a fungitoxic protein with considerable structural homology with wheat germ agglutinin and other plant lectins.¹⁸ Some protein is lost on centrifugation of raw latex, and some protein hydrolysis occurs when ammonia is added.¹⁹

Although traces of latex allergen have been reported in rubber tire dust and molded rubber, dipped rubber products are responsible for most of the allergic reactions to natural rubber latex. The majority of the factories producing gloves are in Southeast Asia, where *Hevea brasiliensis* grows. The manufacturing process of rubber gloves is illustrated in Fig. 41.1.²⁰ Into the raw, ammoniated latex are compounded several low-molecular-weight accelerators, antioxidants, and secondary preservatives. Gloves are produced by coating porcelain formers with a coagulant compound, then dipping the porcelain former into the compounded latex. The coagulation is completed by oven heating, after which the bead roll at the proximal end of the glove is created. The coagulated glove then passes through leaching tanks to remove water-soluble protein and excess additives, after which the glove is cured by *vulcanization*, a heat-catalyzed process in which the rubber molecules are crosslinked in the presence of the sulfur-containing accelerators. Finally, the gloves are powdered using either a wet slurry or a dry process and stripped from the formers. Powder-free gloves are passed through a final chlorination wash, which makes the glove surface more slippery, and may elute or denature much of the remaining allergen.

The majority of latex allergens are heat-stable proteins present in both raw latex and in extracts of finished rubber products, rather than “neoantigens” introduced by the manufacturing process.^{21–23} Small amounts of 11- and 26-kDa allergens not present in the raw latex have been reported in some glove extracts.²⁴ Casein is compounded into a few brands of surgical and household gloves, and may be responsible for glove-related reactions in milk-sensitive persons.²⁵ Latex antigens can be leached from rubber gloves by normal skin moisture, and subsequently adsorbed onto cornstarch powder inside the

FIGURE 41.1 Natural rubber glove manufacturing process: (1) natural latex-containing protein is harvested from *Hevea brasiliensis* rubber trees; (2) autocoagulation of natural latex is prevented by addition of ammonia; (3) natural latex is centrifuged and concentrated from 30 to 60 percent solids—removal of serum phase reduces concentration of water-soluble proteins; (4) processing and attributes of the finished device depend on the addition of many chemicals to the natural latex (compounding)—accelerators and antioxidants cause many cases of contact dermatitis of the hands; (5) porcelain formers attached to a continuous chain are cleaned to remove debris from the previous cycle; (6) formers are dipped in an emulsion to apply cornstarch as a releasing agent and a compound that coagulates liquid natural latex on contact; (7) releasing agent and coagulant are oven dried; (8) formers dip into natural latex and a uniform film is deposited; (9) the coagulant and heat convert the natural latex from liquid to solid; (10) rotating brushes contact the rotating formers and a cuff is rolled onto the glove; (11) formers pass through warm water baths to remove water-soluble protein and excess additives; (12) crosslinking of the polyisoprene polymers is catalyzed by heat and requires an accelerator; (13) cornstarch is applied to the outer surface of the natural rubber latex glove as a detacking agent; (14) the gloves are stripped from the porcelain formers. (From C. P. Hamann. 1993. *Am. J. Contact Dermatitis* 4; used with permission.)

gloves.²⁶ However, considerable amounts of latex allergens are adsorbed to powder on gloves that have not been worn.^{27–30} Presumably the rubber proteins have become adsorbed onto the starch during manufacture of the gloves. When powdered gloves are donned or discarded, the cornstarch particles with adsorbed latex allergens become airborne and can sensitize nearby persons by inhalation or can evoke symptoms in previously sensitized persons.²³ Residual rubber allergens in latex gloves can be eliminated by treatment with potassium hydroxide,³¹ but the effect of this treatment on the barrier properties of the gloves has not been reported.

Isolation and characterization of latex allergens has been complicated by variations in the source material used (nonammoniated latex, ammoniated latex, or extracts of finished rubber products); in the selection of latex-sensitive persons who are skin-tested or who

provide IgE (immunoglobulin E) antibody-containing serum for allergen identification; and in the stability or lability of individual rubber proteins (Table 41.1). European investigators have identified rubber elongation factor (REF) (Hev b 1) as a major rubber allergen.³² Positive wheal-and-flare skin test reactions were induced in the majority of rubber-sensitized persons by REF doses of 4 ng, and positive nasal and bronchial challenge tests were induced by REF concentrations of 400 to 4000 ng/mL. Two groups of investigators have independently identified an acidic protein in latex serum (Hev b 5) to which the majority of both latex-sensitive health care workers and individuals with myelodysplasia produce specific IgE antibodies.^{16,17} Most latex-sensitive persons produce IgE antibodies to several proteins in natural rubber, but on Western blots the pattern of reactivity to this array of molecules differs from patient to patient. Rubber proteins from the tree *Parthenium argentatum* do not cross-react with proteins from *Hevea brasiliensis*.³³

41.3 CLINICAL MANIFESTATIONS

Irritant Contact Dermatitis

The most common reaction to rubber gloves is the development of dry, irritated areas on the skin, especially on the hands. These reactions are not immunologic, but are due to the irritant effects of repeated hand washing, use of detergents and sanitizers, or the addition of powders to the gloves.

Allergic Contact Dermatitis

Contact dermatitis is most commonly produced by rubber gloves, shoes, sports equipment, and medical devices; it appears 1 or 2 days after contact with the offending product. The dermatitis is a cell-mediated delayed-type hypersensitivity reaction to low-molecular-weight accelerators and antioxidants contained in the rubber product.^{34–39} It is unrelated to immediate hypersensitivity from IgE antibodies.

Contact Urticaria

Contact urticaria on the hands is the most common early manifestation of IgE-mediated rubber allergy, occurring in 60 to 80 percent of latex-sensitive health care workers.^{35,37,39–47} Symptoms appear within 10 to 15 min after donning gloves and include redness, itching, and wheal-and-flare reactions at the site of glove contact. Contact urticaria may be preceded by irritant contact dermatitis or a cell-mediated contact dermatitis.

Rhinitis and Asthma

Inhalation of latex allergen-coated cornstarch particles from powdered gloves can evoke rhinitis and asthma in latex-sensitive persons.^{23,37,42,44,47,48} These reactions have been described not only in health care workers but also in workers employed in a rubber glove manufacturing facility.⁴⁹ The majority of latex-sensitive individuals are atopic, with personal histories of seasonal allergic rhinitis due to pollens or allergic asthma due to house dust mites or animal danders. However, of the 29 health care workers with latex-induced occupational asthma reported by Hunt et al.,⁴² 14 had no preceding history of asthma, suggesting that latex-induced

wheezing may occur as an isolated phenomenon. Latex-induced occupational asthma may be severe enough to cause some individuals to discontinue work.⁴⁷

Anaphylaxis

Latex-sensitive persons can experience anaphylaxis in a variety of medical care situations, including contact with *rubber bladder catheters*, rubber balloon catheters used for barium enemas, or during surgery, childbirth, or dental procedures.^{21,50-56} Approximately 7 percent of intraoperative anaphylaxis is associated with allergy to latex.⁵⁷ Anaphylaxis may also be triggered by toy balloons or condoms. In this context it is important to realize that reports using the term *anaphylaxis* often include patients with mild disseminated allergic reactions such as erythema or urticaria as well as those with life-threatening hypotension or airway obstruction.

Myelodysplasia Patients

Individuals with spina bifida are at increased risk of latex sensitization as a consequence of undergoing repeated neurologic, urologic, and orthopedic surgical procedures, or by early, repeated contact with rubber bladder catheters and rubber gloves during removal of fecal impactions. Anaphylaxis is a common result of the sensitization.⁵⁸⁻⁶¹ The reported prevalence of latex sensitivity in myelodysplasia patients has varied widely, from 18 to 64 percent. As compared with latex-sensitive health care workers, latex-sensitive individuals with myelodysplasia preferentially produce IgE antibodies to Hev b 1, Hev b 3, and a 23-kDa protein that exhibits 45 percent homology to Hev b 1.^{11,15,62}

Epidemiology

There are limited data on the frequency of latex sensitization in the general population. In 453 consecutive children seen in a university hospital allergy clinic, only 10 of 326 atopic children (3 percent) had a positive skin test to latex.⁶³ Ownby and colleagues measured latex-specific IgE antibodies in 1000 volunteer blood donors selected to minimize inclusion of health care workers.⁶⁴ Elevated specific IgE antibodies were present in 6.5 percent; males were twice as likely to be sensitized as females. The prevalence of latex-specific IgE was not associated with age or race. The same group of investigators also administered questionnaires and measured latex-specific IgE antibodies in 996 ambulatory surgical patients, of whom 6.7 percent had latex-specific IgE antibodies, but none had systemic allergic reactions.⁶⁵

Health care workers, particularly those who are atopic and who use rubber gloves regularly, are at increased risk of sensitization to natural rubber latex. In questionnaire-only surveys, up to 53 percent of responding health care workers⁶⁶ report some type of reaction to rubber gloves. In surveys involving both questionnaires and either latex skin testing or immunoassays for latex-specific IgE antibodies, 5⁴⁰ to 17 percent of various hospital employee groups were latex-sensitive.^{23,35,37,42,44,46,48,67-76} The variation of reported prevalence is the result of different skin test materials, small sample size, and selected populations.

The frequency of respiratory allergy among dentists and dental workers may be higher than in hospital employees.^{38,46,48,77-83}

Since 1990 we have evaluated over 350 employees at our medical center whose clinical histories and laboratory findings indicated sensitization to latex.^{23,42} Risk factors for sensitization included frequent use of disposable rubber gloves, presence of prior atopic disease,

and prior or current hand dermatitis. The peak onset of symptoms occurred in late 1989 and early 1990 and did not correlate with any peak in glove usage at our institution; usage has continued to rise. Most sensitized employees (77 percent) reported contact urticaria from gloves, and over 50 percent also experienced allergic rhinitis, conjunctivitis, or asthma when working in areas of high glove use. Sixteen episodes of rubber-induced anaphylaxis occurred in 12 employees. In all of these episodes the exposure was substantial and obvious, most often the vehicle was gloves, balloons, or other dipped rubber products.

41.4 MEASUREMENT OF ANTIBODIES

Skin testing with natural rubber latex is the diagnostic procedure of choice in Europe and Canada, where commercial extracts have been available for this purpose. In the United States, there are no licensed commercial latex extracts available for diagnostic use. Allergists frequently perform puncture skin testing with extracts of finished rubber products, usually latex medical gloves, but these gloves vary widely in their allergen contents,^{25,84,85} and systemic reactions have been reported with use of these unstandardized preparations.⁸⁶ Skin testing with glove extracts, ammoniated latex, or nonammoniated latex, all standardized on their protein contents, is safe and efficient.⁸⁷ In a subsequent multicenter trial of this reagent in 121 latex-allergic and 178 non-latex-allergic patients, skin puncture tests at a concentration of 100 $\mu\text{g/mL}$ yielded a 96 percent sensitivity and 100 percent specificity. The sensitivity increased to 100 percent with no loss of specificity when the concentration was increased to 1000 $\mu\text{g/mL}$.⁸⁸ This reagent may soon be licensed in the United States.

Rubber-specific IgE antibodies may also be demonstrated by several varieties of solid-phase immunoassays similar to the tests for IgE antibodies to other allergens. Reagents for these assays are marketed commercially, and the test is available through diagnostic reference laboratories. Depending somewhat on the criteria of the selection of the normal reference, the optimum sensitivity is 97 to 100 percent, and specificity is 83 to 86 percent.⁸⁹ When both skin tests and immunoassays are performed in the same patient groups, only 50 to 90 percent of skin test-positive persons have latex-specific IgE antibodies measurable by immunoassay. The source of the allergen material used for these assays is somewhat controversial. Glove extracts would provide a source most like the actual exposure, but gloves vary greatly in concentration of the allergen, and it may not be possible to prepare sequential batches of the reagent that are comparable. For this reason, extracts from the unprocessed latex may be preferable. In one collaborative study, solid-phase allergens prepared in different laboratories from two nonammoniated latex samples, two ammoniated latex samples, and three latex rubber gloves produced concordant results,⁹⁰ indicating that the glove extracts used in this particular study contained as complete a repertoire of allergens as the raw latex preparations.

41.5 MEASUREMENT OF ALLERGEN CONCENTRATION IN GLOVES

The allergen content of various latex products can be assayed by competitive solid-phase assays using either human IgE antibody, obtained by pooling high-titered serum from several allergic donors, or IgG antibody, from rabbits immunized with the rubber proteins.⁹¹ Results of the two assays correlate well. Unfortunately, however, a simple protein assay by a modified Lowry method is not sufficiently sensitive, and does not correlate well with the allergen content. In the human IgE-based assay, a weighed amount of glove rubber is

extracted in buffered saline. The allergen content of the sample is assayed by a competitive immunoassay. The antigen preparation for adsorption on the solid phase and for construction of the standard curve is prepared from a concentrated extract of allergenic rubber examination gloves. The protein concentration of this reference extract is measured by the bicinchonic acid assay. In turn, for validation, this reference glove extract is compared to an FDA nonammoniated raw latex standard extract (lot E-5) by parallel line inhibition assay and by IgE immunoblotting. The results can be expressed either as allergy units or as a protein concentration. Fifty microliters of a pool of sera from latex-allergic individuals that contain high titers of IgE is mixed with the test sample. The allergens in the test sample combine with this IgE antibody and prevent its attachment to the solid phase. After washing, the amount of IgE bound to the solid phase is determined by a radioiodinated, enzyme-linked or fluorescein-labeled anti-IgE. Concentration of the allergen in the samples is calculated by logistic regression.^{91,92} The allergen content of different lots of latex gloves varies over at least a 500-fold range. Powdered gloves consistently contain 10- to 100-fold more allergen than do nonpowdered gloves (Fig. 41.2).

41.6 MEASUREMENT OF ALLERGEN CONCENTRATION IN AIR

Air Sampling

Either area or personal breathing zone samplers are suitable. Area sampling (3 L/s) allows estimation of the average concentration in a room over a suitable period. Personal breathing zone sampling (4 L/min) allows estimation of individual exposure while performing particular tasks. Because large samples are collected, the lower limit of detection of the

FIGURE 41.2 Latex allergen contents of 71 lots of rubber medical gloves, all of which were extracted in an identical fashion. Latex allergens are expressed in allergy units (AU) per milliliter, based on a latex reference extract obtained from the FDA Center for Biologics Evaluation and Research (100,000 AU/mL). [From J.W. Yunginger et al., *J. Allergy Clin. Immunol.* 93: 836–842 (1994)].

amount of the allergen in the air by area sampling is more sensitive than by personal breathing zone sampling. For optimum sensitivity the sample should be collected on a polytetrafluoroethylene (Teflon) filter that allows extraction into no more than 1 mL of buffer. The immunochemical assay of the sample is the same as described for the measurement of gloves. Distribution of the particle size of airborne latex allergens is determined by an Andersen cascade impactor attached to an area sampler.⁹³

41.7 POPULATIONS AFFECTED

Hospitals and clinics may contain high levels of latex aeroallergens.⁹³ In our medical center, latex aeroallergen levels were highest (range = 14 to 208 ng/m³) in work areas where powdered rubber gloves were frequently worn (Table 41.2), and lowest (range = 0.3 to 1.8 ng/m³) in work areas where powder-free or synthetic gloves were in use. Latex allergen was airborne only when there was activity in the work area. The level became undetectable on weekends, when no one was working. It was interesting that operating rooms had concentrations in the higher ranges, even though some had functioning laminar flow ventilation systems (Table 41.3). Rapid disappearance of the allergen from the air is consistent with the relatively large size of the latex-carrying particles. Two-thirds of the total is carried on particles greater than 14 μ m mean mass aerodynamic diameter (Table 41.4). Less than 20 percent is on particles smaller than 4 μ m.

TABLE 41.2 Latex Aeroallergen Levels in Various Areas within Mayo Medical Center

Air samples	Aeroallergen level, ng/m ³

<2	0.3	6.5

* D_{p50} = particle size cutoffs in micrometers at 50 percent collection efficiency for spherical particles with unit mass density at 25°C and 760 mmHg.

Latex allergen concentrations in personal breathing zone samplers were highly variable, ranging from 8 to 974 ng/m³ in areas where powdered gloves were frequently used. Our medical center phased out the use of high-allergen latex gloves,⁹⁴ and follow-up studies in the same work areas showed that latex aeroallergen levels had fallen to <3 ng/m³.

To confirm that powdered rubber gloves were the major contributor to latex aeroallergen levels, we conducted a 52-day, prospective, multiple crossover study in a single operating room, during which either high- or low-allergen gloves were used, and latex aeroallergen levels were monitored daily.⁹⁵ Latex aeroallergen levels during low-allergen glove-use days (range = 0.1 to 3.5 ng/m³) were significantly lower than on high-allergen glove-use days (range = 2.2 to 56 ng/m³) (Fig. 41.3). On designated high-allergen glove-use days, latex aeroallergen levels were strongly correlated with the total number of gloves used. Gloves themselves are not necessarily the immediate source of airborne allergen. Large quantities of latex allergen can be recovered from used anesthesia scrub suits, used laboratory coats, and laboratory surfaces and other sources of settled dust.

Considering the high frequency of allergic reactions among dentists and dental office workers, it is not surprising that dental offices, too, often contain concentrations of latex aeroallergen that are similar to other health care delivery areas.⁹⁶

41.8 STANDARDS OF EXPOSURE

There has been no mechanism for setting official standards for airborne latex allergen exposure. One reason is that the reference standard can be considered approximate only.

FIGURE 41.3 Mean latex aeroallergen levels in one operating room during a 12-h sampling period for each of 52 study days, and types of gloves used (high allergen or low allergen) on surgical days. [From D.K. Heilman et al., *J Allergy Immunol.* 98:325–330 (1996).]

Its protein content is that of a crude preparation containing a mixture of many different natural rubber allergenic proteins. The relative proportions of these proteins may (and probably does) vary between different sources of the allergen. Solid-phase IgE inhibition assays also depend on the relative reactivity of the IgE antibody to these various allergens in the serum pool. Two-site assays using IgG antibodies from rabbits or other immunized animals are feasible, and assays employing monoclonal antibodies to one or more of the specific rubber allergens are useful for special purposes. Despite these reservations, reasonably accurate quantitative comparisons are not difficult when appropriate technical considerations are observed. We have found the assay quite useful for comparing allergen levels at various sites and at different times. Thus, this solid-phase inhibition assay format represents the best practical quantitative method that is currently available, and it allows valid practical conclusions about concentrations that elicit symptoms in sensitive persons.

The concentration of allergen in the air measured in various locations in medical centers varies more than a 1000-fold. Typical concentrations in areas where sensitive workers report mild to moderately severe respiratory symptoms range from approximately 10 to 1000 ng/m.^{3,93} In pilot studies involving latex-sensitive health care workers who underwent inhalation challenge tests with high-allergen-content glove powder under conditions similar to those encountered in their workplace, four of nine volunteers had reproducible FEV₁ decreases of ≥ 20 percent at cumulative inhaled latex aeroallergen doses ranging from 100 ng to 1500 ng over a 1-h time period.⁹⁷ It is reasonable to conclude that concentrations of 1 to 10 ng/m³ are unlikely to elicit symptoms in most workers sensitive to latex, although exquisitely sensitive persons may have mild symptoms from prolonged exposure to these concentrations. From results of a study using a similar assay system, Baur and his colleagues suggested that a level of 0.6 ng/m³ can possibly elicit symptoms in previously sensitized persons, dictating surveillance.⁹⁸ Because the lower limit of detection of airborne allergen using area samplers is less than 1.0 ng/m³, a concentration of less than 10 ng/m³ represents a readily achievable and verifiable target to control exposure.

41.9 METHODS OF CONTROL

Recommendations for control have focused on two quite separate issues: prevention of intraoperative anaphylactic reactions in highly sensitive patients (typically children with myelodysplasia) and reduction of airborne exposure. It is only the second that is relevant to this chapter. The National Institute for Occupational Safety and Health (NIOSH) has published recommendations that form a consensus for reducing the problem.⁹⁹ Powdered natural rubber gloves are the primary source of airborne latex allergen in the workplace. Substitution of polyethylene or vinyl gloves may be appropriate for uses where the risk of transmission of infection is minimal, but these synthetic elastomer gloves do not have the high barrier protection of natural rubber and are not universally satisfactory substitutes. The most practical method of control, then, is to use only powder-free latex gloves. There are examples of powdered gloves that contain relatively small amounts of allergen, as well as examples of powder-free gloves that can generate small amounts of aeroallergen when they are donned and discarded. Therefore, the most foolproof alternative would be to use only gloves that have been assayed and found to contain only small concentrations of allergen. Unfortunately, this alternative is not readily available. NIOSH recommends measuring the total protein concentration as a useful indicator of exposure.⁹⁹ We consider total protein assays insufficiently sensitive to provide reliable guidance, because the Lowry assay results are below the limit of detection in many gloves that contain substantial amounts of allergen by radioimmunoassay.⁹¹ Immunochemical assays for latex allergens that are both sensitive and specific are available only to immunochemists with access to specific antibodies and reference standards.

A second important aspect of control is recommendations to sensitized workers. These recommendations should be individualized and personalized to meet each specific situation. Sensitized individuals should, of course, avoid wearing high-allergen-content latex gloves or working in areas where others wear these gloves. Until high-allergen-content gloves are replaced in all health care sites, these patients should take low-allergen gloves with them for personal medical examinations and dental procedures. They should avoid condoms and balloons (both toy balloons and natural rubber balloon medical devices). Because of the risk of anaphylaxis, if suprathreshold amounts of allergen are encountered during surgical operations, latex-sensitive persons should wear a Medical Alert (trademark) bracelet and inform their physicians of the allergy. On the other hand, it is important not to impose restrictions that do more harm than good. Overly rigorous interpretation of the latex-free concept makes regular employment and pursuit of a career difficult, if not impossible. In contrast to dipped products made from liquid rubber, molded products made from dry rubber generally have low levels of extractable allergen and do not produce positive skin tests in latex-sensitive persons.¹⁰⁰

41.10 SUMMARY

Allergy to natural rubber latex is an important source of occupational disease in health care workers. Disposable rubber gloves are the major allergen reservoir. Because powdered gloves have 10 to 100 times more allergen than do powder-free gloves, they are the main source of the airborne allergen that causes rhinitis and asthma. Rubber protein carried on the starch powder is the cause of respiratory reactions. Sensitized workers are at risk of anaphylactic reactions if exposed to a sufficient amount of latex allergen. Assays are available to measure the allergen in the air. Exposure can be controlled by substituting low-allergen-content gloves, primarily powder-free gloves.

42.1 INTRODUCTION

Endotoxins are proinflammatory substances present in gram-negative bacteria (GNB). Inhalation of airborne endotoxin has been associated with workplace-related illnesses (Flaherty et al. 1984; Heederik et al. 1991; Schwartz et al. 1995b; Milton et al. 1995, 1996b), and suspected of playing a role in the development of nonspecific building-related symptoms, sometimes referred to as *sick building syndrome* (Gyntelberg et al. 1994, Teeuw et al. 1994) and of contributing to the severity of asthma (Michel et al. 1991, 1996).

GNB have a thin cell wall of peptidoglycan and an outer membrane in which endotoxin is present. Conversely, gram-positive bacteria (GPB) have a thick cell wall composed of peptidoglycan, but no outer cell membrane, and therefore, no endotoxin. Endotoxin is shed from the outer membrane of GNB as membrane fragments of growing or dying GNB. When endotoxin is purified from GNB, it consists of a family of molecules termed *lipopolysaccharides* (LPS). In the environmental literature, the acronym LPS is used for purified preparations while the term *endotoxin* is used to denote the naturally occurring material (Jacobs 1989). LPS is composed of lipids and carbohydrates. Figure 42.1 shows the location of endotoxin on the outer membrane of *Escherichia coli*. The lipid portion, lipid A, is primarily responsible for the inflammatory or toxic properties of LPS. All lipid A's with toxic activity have certain structural similarities, although their structure can vary widely among bacteria species. On the other hand, the structure of the polysaccharide portion of LPS varies among serotypes within species (Sonesson et al. 1994).

FIGURE 42.1 Endotoxins are located on the outer membrane of gram-negative bacteria [From E. T. Rietschel and H. Brade, 1992, *Bacterial endotoxins*, *Sci. Am.* (Aug.), pp. 54–61.]

The potency of endotoxin is measured by comparing the biological activity of the sample to that of a reference standard. The most common biological assay is the *Limulus ameobocyte lysate* (LAL) assay, which utilizes the ameobocyte cells of the *Limulus polyphemus* (horseshoe crab). The U.S. reference standard is a LPS purified from *E. coli* O113:H10:K. The current preparation (1998) is known as EC6 [United States Pharmacopoeia (USP) convention,

Rockville, MD, lot G]. Results are reported in *endotoxin units* with reference to the biological activity of the reference standard. By convention, 1 EU is equivalent to 0.1 ng of the reference standard endotoxin. It must be emphasized that endotoxin measurements are based on a biological assay for biological activity or potency and do not represent a measure of the concentration of a single chemical substance (*U.S. Pharmacopeia* 1995).

42.2 SOURCES OF ENDOTOXIN

Endotoxin is an integral component of GNB and, therefore, endotoxin levels are related to the occurrence of GNB. Levels of GNB, in turn, are influenced by environmental conditions such as substrate availability, humidity, and temperature. Since these conditions are available outdoors, GNB and, therefore, endotoxin are ubiquitous outdoors. High levels of endotoxin have been detected in numerous settings, especially where organic dust is present, such as in agricultural and related industries. In particular, airborne endotoxin has been correlated with workplace illness in swine barns (Heederik et al. 1994), cotton mills (Kennedy et al. 1987), grain-handling areas (Schwartz et al. 1995b), and vegetable fiber processing plants (Rylander and Morey 1982). High airborne endotoxin levels ($\geq 1 \times 10^4$ EU/m³) have also been observed in a variety of industrial settings where recirculated industrial wastewater or other water-based fluids (e.g., metalworking fluid) contaminated with GNB are aerosolized (Milton et al. 1995, 1996a; Sprince et al. 1997).

In nonindustrial settings, airborne endotoxin has been suggested as a cause of nonspecific building-related symptoms (Gyntelberg et al. 1994, Teeuw et al. 1994) and has been detected in settled dust and bioaerosols in homes and offices (Rylander et al. 1989, Teeuw et al. 1994). One confirmed source of indoor endotoxin is contaminated humidifiers, which can cause high background levels of airborne endotoxin in homes and offices. Cold-water humidifier systems can become contaminated with GNB (Tyndall et al. 1995). In steam humidification, GNB contamination can occur in the duct system, if water condenses on the walls of the ducts (Teeuw et al. 1994). Airborne endotoxin levels have also been shown to be higher than outdoor background levels after severe water damage and other as yet poorly defined conditions (Milton 1996).

42.3 HEALTH EFFECTS OF ENDOTOXIN

Acute Effects

High exposure to airborne endotoxin causes systemic symptoms, while elevated, but more moderate exposure levels found in a wide range of industrial and some nonindustrial environments (>50 EU/m³) can cause significant effects on pulmonary function. Experimental cotton dust exposures show a strong dose-response relationship between endotoxin and acute airflow obstruction with thresholds of 90 to 330 EU/m³ (Rylander et al. 1985, Castellan et al. 1987). Figure 42.2 from Castellan et al. (1987) demonstrates the dose-response relationship between endotoxin and acute airflow obstruction. One epidemiologic study of animal feed handlers detected acute airflow obstruction at endotoxin levels similar to the experimental levels (300 to 400 EU/m³) (Smid et al. 1994). In another epidemiological study of workers at a fiberglass manufacturing plant, endotoxin levels of 45 to 150 EU/m³ induced acute responses (Milton et al. 1996b). The latter study included chemical analysis of the air samples as well as the LAL assay. The chemical analysis found no evidence that the biological methods underestimated the LPS in the samples (Walters et al.

FIGURE 42.2 Proportion of subjects in exposed group with an individual decrease in forced expiratory volume (FEV_1) in one second of ≥ 5 percent versus log airborne endotoxin concentration. Data are from 108 sessions of exposure to cotton dust, each involving 24 to 35 subjects. Exposure concentrations were determined from air samples collected by vertical elutriators. (From R. M. Castellan, S. A. Olenchock, K. B. Kinsley, and J. L. Hankinson. 1987. *Inhaled endotoxin and decreased spirometric values: An exposure-response relation for cotton dust*. *New Engl. J. Med.* **317**: 605–610. Copyright © 1987 Massachusetts Medical Society. All rights reserved.)

1994). Section 42.5 discusses the variability of the LAL assay, which is used most often to quantify endotoxin levels.

A cold-water humidification system at a textile processing plant was implicated in the lowest endotoxin exposure associated with acute airflow obstruction. Workers exposed to the humidification mist had a personal geometric mean endotoxin exposure of 64 pg/m^3 . Workers unexposed to the cold-water humidification had geometric mean exposures of 18 pg/m^3 (steam humidification) and 19 pg/m^3 (no humidification). Exposed workers had significantly lower lung function on the first workday of the week than did the unexposed workers (Kateman et al. 1990). The endotoxin levels in the exposed group are well below levels associated with health effects published by the same investigators (Smid et al. 1994), which indicates that there might have been measurement problems or that another exposure associated with endotoxin actually caused airflow obstruction in the exposed workers.

Chronic Effects

Pulmonary function and respiratory effects resulting from chronic endotoxin exposure have been indicated from various cross-sectional studies (Thelin et al. 1984, Kennedy et al. 1987,

Donham et al. 1989, Smid et al. 1992, Milton et al. 1995, Schwartz et al. 1995b). Table 42.1 contains summaries of a selected number of the cross-sectional studies. In the earliest study from which a quantitative exposure-response relationship could be determined, an apparent threshold of $1 \mu\text{g}/\text{m}^3$ (approximately $10,000 \text{ EU}/\text{m}^3$) was reported for chronic effects (Thelin et al. 1984). More recent studies described thresholds for chronic effects, such as decreased lung function, at 10 to $400 \text{ EU}/\text{m}^3$ (Kennedy et al. 1987, Smid et al. 1992) and any exposure below $100 \text{ EU}/\text{m}^3$, but above background (Schwartz et al. 1995b). In these studies, however, the effects observed from chronic exposure varied. Kennedy et al. reported that chronic endotoxin exposure leads to an increased risk of pulmonary abnormalities, but not acute airflow obstruction, while Schwartz et al. demonstrated that chronic exposure leads to enhanced bronchial reactivity and acute airflow obstruction.

Chronic endotoxin exposure and lung function have been studied in four prospective studies summarized in Table 42.2. Two of these studies detected an association between endotoxin and accelerated loss of lung function (Schwartz et al. 1995a, Vogelzang et al. 1998), while the other two studies found no strong association (Christiani et al. 1994, 1999; Heederik et al. 1994). A summary of these studies is located in Table 42.2, which is a subset of all the longitudinal studies that have been performed. In the longitudinal study by Vogelzang et al., the cohort of pig farmers showed a mean decline of FEV_1 of $73 \text{ mL}/\text{year}$, which was significantly associated with endotoxin exposure (see Fig. 42.3). The contradictory results may be explained by exposure misclassification. Exposure misclassification may be due to a lack of standardized measurement methods and reagents; thus results in a bias toward the null—thus, true—associations may not be seen. Longitudinal studies that rely on repeated measurement of endotoxin over many years such as one of the two negative studies (Christiani et al. 1994) may be especially susceptible to this sort of measurement error.

Low-Dose Effects

In nonindustrial, nonagriculture settings, levels of endotoxin will rarely be as pronounced as those addressed in the preceding discussion. In these settings, levels of airborne endotoxin are similar or only slightly above normal outdoor background levels except when

TABLE 42.1 Cross-Sectional Studies of Chronic Endotoxin Exposure

Study population	Results	Reference
Poultry farm workers	Decreased FEV_1 over the workday	Thelin et al. (1984)
Cotton textile workers in China	Decreased FEV_1 baseline	Kennedy et al. (1987)
Pig farmers in Sweden	Decreased baseline FEV_1 in a dose-dependent way	Donham et al. (1989)
Animal feed workers in the Netherlands	Decreased FEV_1	Smid et al. (1992)
Fiberglass manufacturing plant employees in Ohio	Flulike illness and depressed diffusion capacity (intermittent exposure); asthmatic illness and decreased FEV_1/FVC ratio (daily exposure)	Milton et al. (1995)
Grain handlers in Iowa	Enhanced bronchial reactivity and acute airflow obstruction	Schwartz et al. (1995b)

TABLE 42.2 Longitudinal Studies of Chronic Endotoxin Exposure

Study population	Results	Reference
Pig farmers in Iowa	Accelerated decline in FEV_1 and FEF_{25-75}	Schwartz et al. (1995a)
Pig farmers in the Netherlands	Annual decline in FEV_1	Vogelzang et al. (1998)
Cotton textile workers in China	Decline in FEV_1 associated with cotton dust, not endotoxin exposure	Christiani et al. (1994, 1999)
Pig farm workers in the Netherlands	Decreased FEV_1 within subgroup of farmers only	Heederik et al. (1991)

FIGURE 42.3 Predicted association between log-transformed endotoxin exposure and annual rate of decline of FEV_1 (with standard error), corrected for age, baseline FEV_1 , and pack-years of smoking. Based on 171 pig farmers. (P. F. J. Vogelzang, J. W. J. van der Gulden, H. Folgering, J. J. Kolk, D. Heederik, L. Preller, M. J. M. Tielen, and C. P. van Schayck. 1998. Endotoxin exposure as a major determinant of lung function decline in pig farmers. *Am. J. Resp. Crit. Care Med.* **157**: 15–18.)

heavily contaminated ultrasonic or cool-mist humidifiers are in use. These low-level exposures have been associated with increased severity of asthma and nonspecific building-related symptoms (Rylander et al. 1989, Michel et al. 1991, Gyntelberg et al. 1994, Teeuw et al. 1994).

Michel et al. (1991) conducted a 4-month longitudinal study in homes of persons with asthma. They found that asthma severity increased when endotoxin in settled house dust was above the median level (1.1 ng/mg). They found no association between endotoxin levels and dust mite concentrations. In a subsequent study conducted in homes of asthmatics, Michel et al. (1996) found that endotoxin in settled house dust increased the severity of asthma, but only when the home also was contaminated with high levels of dust-mite antigen. In a study of asthmatic children, endotoxin in settled house dust was not associated

with daily peak expiratory flow (PEF) after adjusting for the dust-mite allergen and the presence of pets (Douwes et al. 1998). Pets were associated with higher endotoxin levels in living-room floor samples.

In a study of 19 Dutch government buildings (Teeuw et al. 1994), buildings were grouped as either "healthy" or "sick" on the basis of mean symptom prevalence ($<15\%$ = "healthy"; $>15\%$ = "sick") gathered from interviewing 1355 office workers. Among the symptoms that were included in the questionnaire were headaches, lethargy, dry eyes, itchy eyes, stuffy nose, dry throat, sore throat, and dry skin. The investigators reported higher levels of airborne endotoxin in mechanically ventilated "sick" buildings than in mechanically or naturally ventilated "healthy" buildings. Similarly, levels of airborne culturable GNB were higher in "sick" buildings. The concentration of airborne endotoxin was reported as 6 to 7 times higher in "sick" buildings than in the "healthy" buildings (254 vs. 46 ng/m³). The mean levels of endotoxin were the lowest in naturally ventilated buildings (35 ng/m³) (Teeuw et al. 1994). The levels in naturally ventilated buildings, however, were 100-fold higher than would have been expected based on data from other laboratories. Additionally, the levels in "problem" buildings are similar to levels reported in dusty agricultural settings in the same region (Smid et al. 1992). Although the researchers reported utilizing some appropriate controls, these endotoxin levels might be overestimates due to the presence of $\beta(1, 3)$ -D-Glucan (cell wall components of mold) or other interferent compounds. The reaction is a well-known problem with the type of LAL used in the Dutch government building study (Roslansky and Novitsky 1991).

Twelve buildings from the earlier Danish Town Hall Study were the focal point of the second large epidemiological study that implicated endotoxin in nonspecific building-related symptoms (Gyntelberg et al. 1994). The study tested for many parameters in carpet dust which might be associated with general health symptoms. Culturable GNB as a percentage of total culturable bacteria (range: 20 to 80 percent total culturable bacteria) were found to have the strongest association with symptoms. The most highly associated symptoms included fatigue, heavyheadedness, and throat irritation. There was no association, however, between symptoms and endotoxin level in the dust. Although airborne levels were not measured, the authors did speculate that airborne endotoxin levels would be more strongly correlated with culturable GNB than with endotoxin levels in dust. The mean endotoxin level in the dust samples from the Danish Town Hall Study was 20 EU/g (2 ng/g), which is 500 times lower than levels Michel et al. (1991, 1996) reported in dust from homes. Michel's data are in general agreement with two additional studies (Douwes et al. 1995, Milton et al. 1997) which reported similar endotoxin levels in house dust, and were similar to dust endotoxin levels reported in offices in the United States (Hines et al. 1997).

42.4 SAMPLING METHODS

Filter media are usually used to collect endotoxin aerosols because they allow for long collection times and are easy to use. Occasionally, all-glass impingers are used, but they may underestimate endotoxin levels because of their low collection efficiency for submicron particles in which a large fraction of endotoxin is normally present (Olenchock et al. 1983).

Filter Type

Because the assay to analyze samples for endotoxin (LAL assay) is a comparative bioassay, endotoxin activity levels can be altered by factors such as the type of filter. Therefore, several authors have reported attempts to examine the effect of filter medium on endotoxin

measurements made with LAL assays, many leading to contradictory results (Milton et al. 1990, Sonesson et al. 1990, Gordon 1992, Douwes et al. 1995, Milton and Johnson 1995). Cellulose mixed ester, Teflon, and especially PVC have all been shown to inhibit or inactivate endotoxin activity (Milton et al. 1990), while in a later study, Milton and Johnson demonstrated that polycarbonate capillary pore membrane filters were the only filters which did not reduce endotoxin activity of LPS and whole GNB suspensions during incubation with filter media.

Aerosol type affected the extraction efficiency of the filters in one study (Gordon 1992) where filters were extracted in a hot-water bath. In comparison experiments with LPS-spiked metalworking fluid, cellulose acetate filters gave the highest endotoxin yields when compared to other filter types, while in LPS-spiked saline aerosols, glass filler filters gave a threefold higher endotoxin activity than did cellulose acetate (Gordon 1992). Douwes et al. (1995), however, found that glass filter, Teflon, and polycarbonate gave similar endotoxin yields when filters were extracted in 0.05% Tween-20. These results suggest that one should be very careful in selecting a filter, and it might be necessary to match the filter used for sampling with the type of aerosol that is being sampled.

In a cross-validation study, Walters et al. (1994) found that air sampling on polycarbonate capillary pore membrane filters and extraction by sonication in 0.05 M potassium phosphate, 0.01% triethylamine, pH 7.5 buffer gave optimal yields of LPS as well as endotoxin bioactivity. They concluded that this combination of filter media and extraction method should be considered the standard for environmental studies until other methods have been documented as effective with additional cross-validation studies (see also the next two paragraphs, on extraction media and method).

Extraction Media

For the *Limulus* assay, endotoxin is extracted from filters with an aqueous extraction medium. Most laboratories commonly use pyrogen-free water, while some use buffers such as tris and phosphate triethylamine (pH 7.5) or dispersing agents such as Tween-20, Tween-80, or saponin. Douwes et al. (1998) reported that endotoxin activity was 7 times higher in 0.05% Tween-20 extracts than in extracts prepared in pyrogen-free water alone; 0.05% Tween-20, however, can inhibit the activity of U.S. reference standard EC6, while simultaneously only mildly inhibiting other LPS preparations and environmental endotoxin extracts, resulting in up to 15-fold differences in the estimated potency of a single preparation on *E. coli* O55:B5 LPS (Milton, unpublished data). The use of Tween-20, therefore, cannot be recommended for use with LAL assays.

Extraction Method

The most common methods of filter extraction are sonication and rocking in the extraction medium. LPS is fairly heat stable and ubiquitous in the laboratory. Therefore, care should be taken to use labware that is newly manufactured free of endotoxin or that has been appropriately heated to destroy endotoxin (e.g., at 270°F for 30 min).

Sample Storage

Generally, environmental samples for endotoxin analysis should not be frozen, especially once they have been extracted. The literature differs on the proper handling of unextracted

samples, however, freeze-thaw cycles significantly reduce endotoxin activity in house dust samples (Douwes et al. 1995, Milton et al. 1997).

42.5 METHODS OF ANALYSIS

Biological Assays

The most common method of analysis for endotoxin is the *Limulus* ameocyte lysate assay. The LAL assay is used because it is easy, fast, and sensitive to a very broad range (1 pg/mL to 10 ng/mL). The lysate contains an enzyme (serine protease) that is specifically activated by endotoxin, which, in turn, activates a cascade of additional enzymes (also serine proteases). The cascade allows for an amplification of end products which is responsible for the ease with which low endotoxin levels can be detected. β (1, 3) D-Glucan, a compound found in fungi, some plant cell walls, and certain cellulose materials, can activate LAL via an alternate pathway. This pathway can be inhibited by the addition of a particular detergent (zwittergent) or removed by chromatographic purification followed by recombining only the desired LAL components (Roslansky and Novitsky 1991, Obayashi et al. 1985).

The LAL assay is a comparative toxicity bioassay, not an analytic assay. This means that measured endotoxin activity level can be altered by factors other than the actual LPS concentration, including filter choice, filter extraction method, extraction buffer, and type of glassware (Finney 1978). LAL is also sensitive to interference by a variety of chemicals, proteins, and other agents (Novitsky et al. 1986, Remillard et al. 1987). This makes it extremely difficult to interpret results, especially when comparing samples collected on different filter media, samples containing different types of environmental contaminants, and samples extracted and assayed with different extraction media.

Hollander et al. (1993) used the kinetic LAL method to quantify the endotoxin concentration in various occupational settings. The authors found that there was inhibition and enhancement of the LAL assay. These results were thought to have resulted from aspects of the particular industry; for example, vitamins, antibiotics, and minerals found in the animal feed industry were thought to inhibit the assay. Therefore, the lack of inhibition or enhancement must be assured before a valid measurement can be performed (Hollander et al. 1993). Milton et al. (1992, 1997) have demonstrated that routine use of the parallel-line assay method can effectively detect and often correct such interference. Figure 42.4 from Milton et al. (1997) shows the results of both inhibition and enhancement, as well as an assay with no evidence of interference.

A major source of variability is the LAL reagents themselves. Saraf et al. (1997) found significant differences in endotoxin measurements made with kinetic chromogenic LAL preparations from three different manufacturers. Two of the lysates produced comparable results, but the third manufacturer's lysate yielded 100- to 1000-fold lower estimates of endotoxin potency for most samples. LAL preparations vary not only from manufacturer to manufacturer but also possibly within lots of LAL from the same manufacturer. House dust samples stored at -20°C and assayed using lysate from the same manufacturer, where the lysate was produced in different years, showed an average 3.5-fold increase in endotoxin potency over the course of the storage. Most of the difference in potency was due to differences in sensitivity between two different lots of lysate (Milton et al. 1997).

The problem seems to be that current manufacturing practice does not control for the sensitivity of LAL to environmental endotoxins. This circumstance is expected to improve (BioWhittaker, Inc. personal communication). Because of this situation, interlaboratory

FIGURE 42.4 Endotoxin in duplicate extracts of house dust samples. Linear regressions of aliquot 2 on aliquot 1 are shown. (From D. K. Milton, D. K. Johnson, and J.-H. Park. 1997. *Environmental endotoxin measurement: Interference and sources of variation in the Limulus assay of house dust*. *Am. Indust. Hyg. Assoc. J.* 58: 861–867. Copyright 1997, American Industrial Hygiene Association.)

differences in endotoxin measurements and the inability to find exposure-response relationships in some longitudinal studies may be attributable largely to differences in LAL lots.

Chemical Assays

LPS can also be detected in environmental samples with chemical methods. These methods take advantage of the fact that there are chemical markers that are characteristic of LPS. Of these markers, 3-hydroxy fatty acids are the most commonly employed. Of the methods available, *gas chromatography–mass spectrometry* (GC-MS) is the most specific and utilized most frequently (Maitra et al. 1978, Parker et al. 1982, Sonesson et al. 1990, Mielniczuk et al. 1993).

Mielniczuk et al. (1993) describe a method in which GS-MS is utilized to analyze 2- and 3-hydroxy fatty acids as methyl-trimethylsilyl and methyl-pentafluorobenzoyl derivatives in the electron-impact and chemical ionization/negative-ion modes, respectively. Both 2- and 3-hydroxy fatty acids were detected in organic dust collected from an office building's ventilation system. Their method separates the 2-hydroxy fatty acids (which occur widely in nature from non-bacterial origin, and therefore might lead to overestimation of LPS) and 3-hydroxy fatty acids. This method can be applied for the measurement of airborne endotoxin.

Assays for 3-hydroxy fatty acids have advantages and disadvantages over the LAL assay. The main advantages are that GC-MS is not subject to the variability that plagues the bioassays, and GC-MS can characterize the organisms present in a sample by their unique combination of 3-hydroxy fatty acids. Additionally, different types of 3-hydroxy fatty acids may be related to the biological potency of the LPS (Saraf et al. 1997). Therefore, it may be possible to estimate biological potency (endotoxin exposure) from LPS measurements using GC-MS. The main disadvantages of GC-MS include an approximately 1000-fold lower sensitivity compared with the LAL assay and an inability to distinguish biologically active and inactive forms of LPS.

42.6 CONTROL METHODS

Exposure Limits

The Dutch Expert Committee on Occupational Standards has proposed the health-based recommended occupational exposure limit of 50 EU/m³ or approximately 5 ng/m³ (Health Council of the Netherlands: DECOS 1998). This limit is based on personal inhalable dust exposure, measured as an 8-h time-weighted average (TWA). However, it may be premature to make recommendations of this kind regarding low-level endotoxin exposure due to the lack of a standard protocol of analyzing samples and the inherent variability of the LAL reagents used in the assay.

The American Council of Government Industrial Hygienists (ACGIH 1999) has proposed a practical alternative to a limit value such as the Dutch Committee's occupational exposure limit. ACGIH's approach for limiting endotoxin exposure is to use relative limit values (RLVs). The RLV makes use of an appropriate background endotoxin level and the presence of symptoms to determine an action level. When symptoms associated with endotoxin exposure are present (e.g., fatigue, malaise, cough, chest tightness, and acute airflow obstruction) and endotoxin levels exceed 10 times background levels, action should be taken to reduce endotoxin exposure. Therefore, 10 times background is proposed as a RLV action level in the presence of respiratory symptoms. In environments where the potential exists for endotoxin exposure but there are no complaints of respiratory symptoms, endotoxin levels should not exceed 30 times the background level. Thus, 30 times background is a maximum RLV in the absence of symptoms.

Remediation

Although obvious in many industrial and agricultural environments, the source of endotoxin exposure may be less apparent in office and home settings. Cool-mist, ultrasonic, and recirculated spray humidifiers should be considered potential sources of high-level endotoxin exposure. Containing any other sources of water intrusion or condensation may also be useful in lowering endotoxin levels indoors. Otherwise, little is known about endotoxin sources in office building and homes, although pets, especially dogs, are associated with elevated endotoxin levels (Douwes et al. 1995, Park 1999). If a source is found, the best ways to minimize exposure to endotoxin are either to eliminate contamination of GNB, limit aerosolization of materials contaminated with GNB, or contain operations that may generate aerosols. Equipping exposed workers with personal protective equipment can be utilized as a last resort. Eliminating GNB contamination is more difficult than it might seem. Biocides are generally ineffective at controlling contamination and may be important sensitizers or adjuvants themselves (Preller et al. 1995), and when they do work, may permit growth of fungi and GPB with equally or more serious health effects (Burge and Muilenberg 1995).

CHAPTER 43

ALLERGENS DERIVED FROM ARTHROPODS AND DOMESTIC ANIMALS

43.1 INTRODUCTION

Domestic houses vary enormously in their construction and furnishings as well as in the behavior of the occupants. As a result, a wide range of foreign proteins can be present airborne and in the dust of houses. Not surprisingly, these proteins are potent antigens and can induce immune responses in the inhabitants of the house. The importance of house dust as a cause of allergic disease has been obvious for many years, but attempts to purify allergens from house dust were initially unsuccessful. As late as 1980, house dust extracts made from the contents of vacuum cleaner bags were widely used for skin testing and immunotherapy. Since the late 1970s, many of the relevant proteins in house dust have been purified, cloned, and sequenced (Third International Workshop 1997). In addition, monoclonal (or conventional) antibodies have been produced which can be used to measure the quantity of these proteins present both airborne and in dust samples (Luczynska et al. 1990, Arruda et al. 1997). The most important sources of allergens within houses are domestic animals (cats and dogs), mites of the genus *Dermatophagoides*, and the German cockroach. However, there are hundreds of possible sources, including a wide range of other animals that can be present as pets or pests; fungi (see Chap. 45); many other insects including beetles, crickets and flies, as well as spiders and other mites (Table 43.1). In some cases these other animals can be the dominant source of foreign proteins within a house, such as pet mice, gerbils, rabbits, and ferrets. Such animals as silverfish and spiders also produce proteins but are not generally thought to produce sufficient antigen to pose a problem. This chapter focuses on those antigen sources for which information is available, and on the antigens present in houses and their relevance to human disease.

TABLE 43.1 Indoor Sources of Environmental Allergens

Dust mites	Mammals
<i>Dermatophagoides pteronyssinus</i>	Cats: <i>Felis domesticus</i>
<i>Dermatophagoides farinae</i>	Dogs: <i>Canis familiaris</i>
<i>Euroglyphus maynei</i>	Rabbits: <i>Leporidae</i>
<i>Blomia tropicalis</i>	Rodents
Storage mites	Pets: Mice, gerbils, guinea pigs, chinchillas, etc.
<i>Lepidoglyphus destructor</i>	Pests: Mice (<i>Mus musculus</i>),* rats (<i>Rattus rattus</i>)
Tarsonimidae	
Insects	Pollen
Cockroaches	Derived from outside
<i>Blattella germanica</i> (German)	
<i>Periplaneta americana</i> (American)	
<i>Blatta orientalis</i> (Oriental)	Sundry
Other: Crickets, flies, beetles, fleas, moths, midges	Horsehair in furniture, kapok
	Food dropped by inhabitants
	Spiders, silverfish, etc.
Fungi*	
Inside: Multiple species including <i>Penicillium</i> , <i>Aspergillus</i> , <i>Cladosporium</i> (growing on surfaces of rotting wood)	
Outside: Entry with incoming air multiple species, <i>Alternaria</i>	

*Many small rodents become indoor pests, including many different species of "mice."

For each source, the chapter will consider evidence available about immunochemistry, techniques for measurement, the form in which the proteins become airborne, the evidence for disease relationships, and proposed thresholds for exposure. The evidence is most complete for dust mites, cats, and the German cockroach and strongly suggests that the particles on which these proteins become airborne make a great difference in the quantity that becomes airborne, the way in which they contribute to symptoms, and their distribution in the community. Because of these differences, the way in which thresholds are defined may also have to be different. Thus cat and dog allergens become airborne on small particles which fall slowly, tend to stick to walls and clothing, and tend to become widely distributed in the community. For these allergens significant exposure may occur outside the house and reservoir dust may be a poor index to airborne levels. By contrast, dust-mite antigens are present predominantly on larger particles which become airborne only locally and transiently and are not transferred easily. Here reservoir measurements in the individual houses are the best available approach to defining exposure.

The first approach to purification was to carry out conventional protein purification starting with a crude extract of cat pelt (Ohman et al. 1974) or dust-mite culture (Chapman and Platts-Mills 1980). These purifications were monitored by skin testing or the direct radioallergosorbent test (RAST) technique. The objective was to identify major allergens which could be used to study immune responses and as a marker to measure exposure. Initially, assay was dependant on producing conventional antibodies and only very limited sequence data were available. The field has progressed rapidly, largely because of three technical advances: monoclonal antibodies; cloning and sequencing of proteins; and production of recombinant proteins. Immunoassays started with radioallergosorbent test

inhibition, which is difficult to standardize and cannot be expressed in absolute units. Once purified proteins were available, the advantages of measuring a single representative allergen became obvious. Techniques rapidly developed using the Mancini technique (cat), inhibition radioimmunoassays (RIAs), and then two site monoclonal antibody-based assays for mite, cat, dog, and cockroach proteins. Immunoassays have made it possible to standardize extracts, measure exposure, and also evaluate techniques proposed for controlling exposure in domestic houses.

43.2 DUST MITES

Mites were first recognized in bedding dust by Dekker in 1928 [see Dekker (1971)]; however, the first evidence about their role as a source of allergens and as a cause of asthma came from Voorhorst et al. in 1967. Those studies defined the relationship of mites to humidity and their distribution in houses and provided for the first time estimates of the number of mites that created a risk for sensitization and symptoms (i.e., 100 per gram of dust) (Voorhorst et al. 1967). The group in Holland also developed the techniques to grow dust mites so that it became possible to make skin test reagents and in vitro assays and, in due course, to allow purification of allergens. Skin testing has provided abundant evidence that sensitization is associated with asthma in many different countries; relative risks for asthma range from 4 to >12 when comparing sensitized to nonsensitized individuals (Smith et al. 1969, Miyamoto et al. 1968, Sears et al. 1989, Sporik et al. 1990).

The most important mites in domestic houses are from the genus *Dermatophagoides*, and these are also the best defined. However, many other species can occur in houses. These include *Euroglyphus maynei*, Cheyletid mites which are predators, *Blomia tropicalis*, which is found mostly in tropical and subtropical areas, and the storage mites. Storage mites are so called because they are well recognized as a cause of soiling in stored food. The main species include *Lepidoglyphus destructor*, *Acarus siro*, and *Tyrophagus putrescentior* (see Fig. 43.1). These mites may be important in houses but are better recognized in agricultural settings and are one of the causes of barn asthma (Van Hage-Hamsten et al. 1985).

The first immunoassays for mite antigens were by RAST inhibition, and it was possible to provide quantitative measurements (Tovey and Vandenberg 1979). Measurements of this kind in arbitrary units cannot be used to propose standards and can provide only limited evidence about the relationship between exposure and either sensitization or disease. Conventional purification of allergens is critically dependent on the availability of sufficient quantities of materials. Purification of pollens commonly starts with 1 kg of material, the first studies on mite used 50 g of culture, but by the late 1970s, 400 g of culture was available. The first purification of mite antigen identified a protein of MW (molecular weight) 24,000 daltons (Der p 1) which could be radiolabeled with ¹²⁵I (Chapman and Platts-Mills 1980). Measurements of Der p 1 by RIA were extremely sensitive and could be quantitated by reference to a standard curve. The units used were arbitrary until it was possible to purify sufficient allergen to make a weight estimate. By 1983 there was sufficient agreement to establish a WHO International Standard with both international unitage and an estimate of the content of Der p 1 in micrograms (12.5 µg/ampule) (Ford et al. 1985). The international standard (NIBSC 82/518) remains the reference for measurements of mite allergen, regardless of the assay. The first monoclonal antibodies were developed in 1984, and they were shown to define three distinct epitopes on Der p 1 (Table 43.2); an *epitope* is that part of the surface of a molecule to which an antibody binds. Using two monoclonal antibodies, it was possible to perform a two-site immunometric assay. Initially,

* All mites found in house dust are collectively referred to as domestic mites.

The term "dust mites" is generally restricted to *Dermatophagoides* and *Euroglyphus*.

§ Cheyletidae includes predator mites which are commonly found in houses with high numbers of pyroglyphid mites.

FIGURE 43.1 Classification of arthropods.

these assays used a radiolabeled second antibody and subsequently, an enzyme-labeled second antibody (Chapman et al. 1987, Luczynska et al. 1989). Providing assays that are sensitive, specific, and simple to carry out has made it possible to measure mite allergens in dust samples from houses in many different countries and has revealed a wide range of exposure from <0.4 to $>500 \mu\text{g Der p 1}$ (or Der f 1) per gram of dust.

Airborne Mite Proteins

Measurement of dust mite allergens in the air has established several findings:

There is no (or extremely little) allergen airborne in undisturbed conditions. Using an assay that was specially adjusted to be highly sensitive, Yasueda and his colleagues in Japan (Yasueda et al. 1990) have reported the presence of 0.05 to 0.1 ng Der p 1 per cubic meter in undisturbed rooms. The results from other groups have been consistently negative: $<1.0 \text{ ng/m}^3$.

Mite allergen is found airborne during vigorous disturbance but generally falls within a few minutes. Thus mite allergen becomes airborne locally and transiently.

The particles carrying airborne mite allergen appear to be 10–20 microns in diameter and electron microscopy has demonstrated that the particles carrying Der p 1 are mite fecal pellets (Tovey et al. 1981, De Blay et al. 1992).

Calculation of the number of particles airborne suggested that during disturbance 200 particles could be inhaled per hour. However, from the size of fecal pellets one would predict that only 10 percent would enter the lungs. The overall number entering the lungs per day would be only 50 to 200 (Platts-Mills et al. 1984). This is critical because this form of exposure may give rise to chronic inflammation while the patient is unaware of any acute triggering. The small number of particles and their transient presence in the air means that accurate measurement of the quantity inhaled is very difficult. To solve this problem, Tovey and his colleagues in Sydney have developed nasal traps which monitor and identify particles entering the nose (DeLucca et al. 1999).

Thresholds for Exposure to Mite Allergens

Given the complexity of airborne measurement, the only practical method for measuring exposure is to assay the mite allergen in reservoir dust within the house [see Third International Workshop report (1997)]. The most widely used index of exposure is the concentration of mite allergen in micrograms per gram of house dust. Perhaps surprisingly, there is an excellent relationship between this concentration and sensitization. Obviously,

TABLE 43.2 Properties of Allergens Derived from House Dust Mites

Source	Allergen*	Molecular weight, kDa	Function†	Sequence‡
<i>Dermatophagoides</i> spp.				
Group 1§	(Der p 1, Der f 1)	25	Cysteine protease	cDNA
Group 2§	(Der p 2, Der f 2)	14	(Epididymal protein)	cDNA

*Revised nomenclature proposed by the WHO/IUIS subcommittee. See www.allergen.org.

†Based on sequence similarity searches of protein and nucleic acid databases. In most cases the allergen function has been confirmed by testing for biologic activity (e.g., enzymatic activity). Allergens in parentheses show structural homology, but the functional activity has not been confirmed or established.

‡Method given for full sequence determination, where available. However, protein sequences are incomplete; usually N-terminal or internal peptide sequences have been determined.

§Allergens for which monoclonal antibodies are available and are suitable for immunoassay purposes.

there is a wide range of genetic susceptibility; nonetheless, one can state that exposure to $\geq 2 \mu\text{g/g}$ dust creates a risk of sensitization [see *Dust Mite Allergens and Asthma* (1992)]. The distinction between genetically atopic individuals and the remainder of the population has been defined by Kuehr and his colleagues in Freiburg (Kuehr et al. 1994). They confirmed the value of $\sim 2 \mu\text{g}$ for atopic individuals and estimated that the threshold value for sensitization of nonatopic individuals was $50 \mu\text{g}$ group 1 mite allergen per gram. However, there is no simple definition of genetically at-risk individuals since the genetic studies have defined a progressively larger number of genes that can influence sensitization and asthma. The threshold of $2 \mu\text{g}$ mite allergen per gram of dust has proved very useful in studying different communities. In countries or geographic areas where less than 10 percent of the houses have this concentration of mite allergen in their dust, mite sensitization is unusual, and there is no significant association between mite allergy and asthma (Sporik et al. 1995, Ingram et al. 1995, Ronmark et al. 1998).

43.3 THE GERMAN COCKROACH: BLATTELLA GERMANICA

The fact that insects can be a source of immunologically foreign proteins was well known because of experience in laboratories using insects, such as grasshoppers, for experimental purposes. The awareness of cockroaches as allergens started in the 1960s when Bernton and Brown reported that many asthmatic patients in New York were sensitized to these pests. Subsequently a high prevalence of sensitization was reported from Kansas City and Boston (Hulett and Dockhorn 1979, Twarog et al. 1976). In Chicago, Kang and her colleagues demonstrated sensitization, bronchial provocation, and immunotherapy as treatment for asthma using German cockroach extracts (Kang et al. 1993). The significance of cockroach allergens among inner-city populations in the United States was confirmed in a series of case-control studies on patients presenting to emergency rooms (Pollart et al. 1989, Gelber et al. 1993, Call et al. 1992). Most recently, cockroach sensitization was shown to be an important risk factor for hospitalization in a cohort of children [the National Inner-City Asthma Study (NICAS)] with asthma in cities in the Northeast (Rosenstreich et al. 1997).

Purification of allergens from the German cockroach started with traditional immunochemistry (Twarog et al. 1976, Pollart et al. 1991). More recently DNA libraries have been established for both *Blattella germanica* and *Periplaneta americana*, and allergens have been identified, cloned, sequenced, and expressed as recombinant proteins (Arruda et al. 1997, Helm et al. 1996, Pomes et al. 1998) (Table 43.3). These studies have provided protein, monoclonal antibodies, and immunoassays. In common with many other allergens, the

TABLE 43.3 Allergens of Cockroach Species

Source	Allergen	Molecular weight, kDa	Function	Sequence
<i>Blattella germanica</i>	Bla g 1*	20–25	Unknown	cDNA

	Per a 3*	72–78	Arylphorin	cDNA

*Allergens for which monoclonal antibodies are available and are suitable for immunoassay purposes. Footnotes the same as for Table 43.2.

cockroach allergens are homologous with proteins derived from other species, and many of these proteins are enzymes (Tables 43.2 and 43.3).

The fact that many allergens are enzymes has given rise to considerable speculation about the relevance of enzymatic activity to the effect of these allergens on the lung. It has been suggested that enzymes (mite or cockroach) could play a primary role in irritating or inflaming the respiratory tract or that enzymatic activity could play a role in inducing immune responses (Stewart and Thompson 1996). Despite very interesting evidence that Der p 1 can cleave both CD 23 and CD 25 on the surface of lymphocytes, it remains unclear whether this activity can occur *in vivo* (Platts-Mills et al. 1998). Perhaps more important, there is currently very little evidence that exposure to mite or cockroach allergens can have a significant effect on the respiratory tract of nonallergic individuals (Van der Heide et al. 1997). In fact, in all the studies showing an association between allergen exposure and asthma, the effect has been apparent only for patients who have specific IgE antibodies. Monitoring T-cell responses *in vitro* is too difficult to be used in epidemiologic studies.

Measurement of cockroach allergens in house dust has demonstrated high levels throughout houses that are badly infested. In most studies the highest concentration of Bla g 1 or Bla g 2 has been found in the kitchen (Gelber et al. 1993, Call et al. 1992). However, it is not clear which site of exposure is most important, particularly for children. In the National Inner City Asthma Study report they found that Bla g 2 in the children's bedrooms correlated with severity (Rosenstreich et al. 1997).

Cockroach allergen is generally not measurable in the air if conditions are undisturbed but becomes airborne during disturbance such as vacuum cleaning (De Blay et al. 1997, Mollet et al. 1997). The form of the particles carrying airborne Bla g 2 or Bla g 1 is not known; however, the particles behave aerodynamically as if they were large (i.e., $\geq 5 \mu\text{m}$ in diameter). Analysis of the quantities of cockroach allergen Per a 1 within the body of the American cockroach has confirmed that this protein is produced in the gut and is present in the feces (Pomes et al. 1998).

Cockroach allergen has been found in schools in Baltimore (Sarpong et al. 1996). This allergen could reflect infestation of the schools or passive transfer on children's clothing. However, in other studies no cockroach allergen was found in the schools despite the fact that one-third of the children were living in infested housing (Perzanowski et al. 1999). At present, the evidence for cockroach allergens is less complete than for dust-mite or animal allergen. It appears that cockroach allergens are carried on particles that are airborne only transiently and are not sufficiently sticky to be transferred on clothing. Thus the presence of significant roach allergen in a building or house is generally thought to reflect roach infestation.

Positive skin tests or serum assays for IgE antibodies to cockroach allergen have been found commonly among individuals with asthma. By contrast, very few patients present to allergy clinics or primary-care clinics with perennial rhinitis related to cockroach sensitivity. This is in contrast to dust-mite-allergic individuals, who often complain of rhinitis. The reason for this distinction is not clear but the result is that very few cockroach allergic individuals are aware of being allergic to roaches. It is likely that quiet breathing is the best way to inhale large particles from bedding or sofas. If so, the primary inhalation of both mite and cockroach allergens may be while sleeping, and the process may not be apparent to patients. In keeping with this theory, there is probably no such thing as a typical allergic history for the relevance of cockroaches to asthma.

43.4 ANIMAL DANDER ALLERGENS

The importance of cats as a cause of allergic symptoms has been obvious to patients and their physicians for many years. Indeed, a history that symptoms of rhinitis or asthma get

worse on entering a house with a cat is one of the more reliable forms of allergic history. In addition, patients are often aware that they become worse near a cat, particularly if they touch the cat. In many different case-control and population-based studies, there has been a strong association between sensitization to cats and asthma (Sears et al. 1989, Pollart et al. 1989, Gelber et al. 1993, Sporik et al. 1995, Squillace et al. 1997). This association is dependent on the presence of cats in the houses of that town or community but not in the individual patient's house. In some studies, there was actually a negative association between the presence of a cat in the house and sensitization to cat allergens. This probably reflects two phenomena: that allergic families often choose not to have cats in their houses and that cat allergen becomes so widespread in the community that all genetically predisposed individuals are exposed to sufficient allergen to become sensitized.

The major allergen from cats was first purified by Ohman and his colleagues in 1974 and was designated Cat 1. When the IUIS (International Union of Immunological Societies) terminology was introduced in 1982, the allergen was designated *Felis domesticus* 1 or Fel d 1, using the first three letters of the genus and the first letter of the species for the abbreviation (Table 43.4). Using conventional polyclonal antibodies, it was possible to measure Fel d 1 in extracts derived from cat pelt using the Mancini technique. In 1984 Aalberse established a monoclonal antibody to Fel d 1 which made it possible to purify larger quantities of the native protein. This, in turn, led to the production of monoclonal antibodies directed against multiple epitopes and the development of immunoassays (Chapman et al. 1988). Purification and protein sequencing also led to cloning and sequencing of the full protein (Morgenstern et al. 1991). Although other allergens have been defined for cats, Fel d 1 is the most important. Indeed, Fel d 1 is one of the most dominant allergens that have been characterized. The protein has two polypeptide chains and is normally present as a dimer. It has been demonstrated that IgE antibodies can react with individual chains but not with shorter peptides. By contrast, T cells will respond in vitro to fragments of the molecule. The dog allergen Can f 1 has also been cloned, and monoclonal antibodies for this protein have been used to develop sensitive immunoassays (Ingram et al. 1995, Custovic et al. 1997). The cat allergen Fel d 1 has weak sequence homology with uteroglobin, but it has no known enzymatic activity, and its function in the cat is unknown. Early studies showed that this protein was present in saliva and suggested that the allergen might be transferred to the fur by licking. Subsequent studies established that the real source of allergen on the fur was protein coming directly through the skin, probably from the sebaceous glands (Charpin et al. 1993). Attempts have been made to reduce cat allergen production by castration of male cats.

Airborne Animal Allergens

The first studies on airborne cat allergen suggested that it might be present on particles small enough to be inhaled (Findlay et al. 1983). When more sensitive assays were developed, it was established that cat allergen is present in the air of most cat-inhabited houses. Furthermore, almost one-third of airborne cat allergen is carried on particles less than 5 μm in diameter (Luczynska et al. 1990, De Blay et al. 1991). The nature of the particles carrying airborne cat allergen has not been established; however using a micromancini technique, Tovey and Sieber have identified particles that carry Fel d 1. The importance of these airborne particles to symptoms is strongly suggested by the fact that many allergic individuals report onset of symptoms (rhinitis, conjunctivitis, or wheezing) within 20 min of entering a cat-inhabited house. In addition, the quantity of cat allergen found airborne in houses is similar to the quantities of allergen necessary to induce symptoms in a bronchial challenge (Van Metre et al. 1986, Luczynska et al. 1990).

TABLE 43.4 Allergens Derived from Mammals Present in Domestic Houses

Source	Allergen	Molecular weight, kDa	Function	Sequence
<i>Felis domesticus</i>	Fel d 1*	36	(Uteroglobulin)	PCR
<i>Canis familiaris</i>	Can f 1*	25	Taste perception	cDNA
	Can f 2	27	Calycin	cDNA
<i>Mus musculus</i>	Mus m 1	19	Calycin	cDNA
<i>Rattus norvegicus</i>	Rat n 1*	19	Calycin	cDNA

*Allergens for which monoclonal antibodies are available and are suitable for immunoassay purposes. Footnotes the same as for Table 43.2.

The particles carrying cat allergen appear to be very sticky, so that large quantities of allergen are found on clothing, walls, and furniture as well as on carpets and bedding. This behavior of the particles is an important method for transferring allergen to houses without cats; in addition, this widespread distribution complicates any analysis of how cat allergen becomes airborne. The significance of this passively transferred allergen is strongly suggested by several findings:

Many children who do not have a cat in their own house become allergic to cats.

Analysis of dust samples from houses without a cat (and also from schools) has shown values of 2 μg to as high as 80 μg Fel d 1 per gram. These values are similar to the concentrations of dust-mite allergen that are sufficient to cause sensitization.

Some allergic individuals experience increased symptoms in schools where cat allergen is present only because of passive transfer.

The studies that have been done on the dog allergen Can f 1 suggest that it is distributed in the same way as cat allergen. Specifically, Can f 1 is airborne in undisturbed conditions, the particles behave as if they are sticky, and this allergen may accumulate in houses or schools in which there are no animals (Custovic et al. 1997).

43.5 RATS AS A SOURCE OF AIRBORNE ALLERGEN: LABORATORY ANIMALS AND PESTS

Rats, mice, rabbits, gerbils, and guinea pigs all tend to have proteinuria, and urinary proteins can become potent allergens. The allergen in rat urine, Rat n 1, is present in very high concentration in the urine of male rats and can accumulate in the bedding of rat cages (Platts-Mills et al. 1986). Not surprisingly, the quantity that becomes airborne is dependent on the nature of the bedding and also how dry it is. As the bedding dries out, increasing quantities can become airborne. The particle size is highly variable, but the average size as measured with a cascade impactor is $\sim 7 \mu\text{m}$. Furthermore, the falling properties are in keeping with this size. Mice are an important pest in many major cities, and they have been shown to contribute to the allergen load in city apartments (Swanson et al. 1985). There is a need for more studies on the relationship between rodent antigens and allergic disease in inner cities. However, all rodents that have been studied have been found to produce proteins which can induce allergic disease.

43.6 MEASURES USED TO DECREASE ALLERGEN CONCENTRATION IN DOMESTIC BUILDINGS

Reducing exposure to allergens has been an important aspect of the treatment of allergic diseases for many years. Reducing dust mite and other indoor allergens is recommended for the treatment of asthma in allergic patients (Third International Workshop Report 1997, NAEPP Guidelines 1997). These recommendations were based on the evidence that allergens play a significant role in bronchial inflammation, that removing patients from their houses will consistently produce an improvement in symptoms, and that asthma severity and symptoms can be reduced in controlled trials of avoidance measures in patients' homes (Ehnert et al. 1992, Walshaw and Evans 1986, Murray and Ferguson 1983, Halken et al. 1997). Understanding the form in which allergens are distributed in a house and become airborne has provided the basis for improving avoidance measures. Indeed, many of the measures that were recommended previously had no effect, including air filtration to decrease dust mite exposure [see Nelson et al. (1988)]. Most importantly, it is clear that the measures used are allergen-specific (Table 43.5). The specific measures recommended to control dust mites are aimed primarily at controlling sites of dust mite growth: (1) covering pillows, mattresses, and comforters; (2) reducing carpets, upholstered furniture, and drapes; and (3) controlling humidity.

Given the evidence about the ways in which cat allergen becomes airborne and is distributed in the community, it is not surprising that the measures proposed to reduce cat (or dog) allergen are different. The first approach is to remove the animal from the house; however, this needs to be followed by aggressive cleaning because carpets, sofas, and other items represent a major reservoir for animal dander allergens (Wood et al. 1989). When the animal stays in the house, reducing airborne allergen has been achieved only by using a combination of measures, such as reducing reservoirs (carpets, sofas, etc.), routine cleaning, washing the cat, and air filtration (De Blay et al. 1991, Avner et al. 1997, Wood 1997). However, there are only preliminary reports of controlled trials for avoidance of cat allergens in the treatment of asthma.

TABLE 43.5 Recommendations Regarding Avoidance Measures for Indoor Allergens

Cats and dogs
Keep animals outside
Remove reservoirs or clean weekly*
Air filtration
Wash animal weekly to reduce allergen going into reservoirs or becoming airborne
Mites
Barriers for mattresses, pillows, comforters†
Hot-wash bedding weekly
Carpets: remove, keep dry, clean weekly*
Acaricides or tannic acid
Control humidity in house
Cockroaches
Obsessional cleaning to remove food sources
Bait stations or boric acid distributed at sites of cockroach debris
Reduce reservoirs of allergens and sites where cockroaches can breed

*Vacuum cleaning with double-thickness bag or filter.

†Covers made of plastic or semipermeable fabrics.

For patients living in poverty, any intervention in the lifestyle may be difficult because of cost and other reasons. Several groups have tried to control cockroach allergen without success. Specifically, the measures proposed did not decrease the quantity of allergen in the house. However, in the South and in the Pacific Northwest many patients living in poverty have significant exposure to mite allergens (Call et al. 1992). Two controlled trials on patients with asthma living in poverty have achieved both reduction of dust-mite allergen and clinical benefit (Carter et al. 1998, Shapiro et al. 1999). These results suggest that significant benefit can be achieved in this population provided the recommendations are adequately explained and are effective. For cockroach allergen, further research is needed to develop effective measures to control allergen. For the many other allergens that can accumulate in houses, there is currently too little information, but the principles are to control the source, reduce the reservoirs within the house, and finally for allergens that remain air-borne to apply air filtration.

43.7 CONCLUSIONS

Approximately one-quarter of the population are allergic to one or more of the common indoor allergens. Among children and young adults with asthma, this proportion may be as high as 80 percent. Although it is not clear why asthma is increasing, it is clear that the increase affects predominantly allergic patients (Crater and Platts-Mills 1998). There are three types of hypotheses to explain the increase: (1) exposure has increased because of changes in houses and increased time spent indoors; (2) changes in diet, immunization, viral infections, or some other aspect of lifestyle have altered immune responsiveness so that more children are becoming allergic with the same exposure; and (3) some unidentified aspect of lifestyle, such as diet or sedentary existence, has increased the tendency to wheeze among allergic individuals. However, it is obvious that exposure to relevant allergens plays a central role in the disease. Furthermore, it is clear that children are spending an increasing amount of time indoors, and it is therefore not surprising that the indoor allergens are those that are most strongly associated with asthma.

Our current understanding of indoor allergens has been achieved by means of traditional immunochemistry, monoclonal antibodies, and molecular biology. Using sensitive immunoassays, it has been possible to define the distribution of allergens in the house. This has provided the basis for designing avoidance measures and has also led to the proposal of thresholds. The concept of a threshold for exposure in relation to allergic disease is not the same as threshold measurements for a toxic gas. First, for most allergens the measurement is only an indirect assessment of exposure; also, allergens are not inherently toxic, so their inflammatory effects are dependent on an immune response; and finally, for some allergens exposure may be taking place at multiple different places (both within the house and elsewhere) and the relative importance of different sites is not easily determined. The best established threshold measurement is that for dust mites (Platts-Mills et al. 1987, Third International Workshop 1997). The measurement proposed was for the maximum *concentration* of mite allergen in dust samples collected from the house. Clearly this is not a measurement of the allergen entering the respiratory tract, but it appears to be the best index of exposure. The value that has been tested most widely is 2 μg group I mite allergen per gram of dust. However, this value is best described as the threshold for sensitization of genetically predisposed individuals. The situation for allergens derived from animal dander is less clear. It has not been shown within a community that the concentration of cat (or dog) allergen within the individual child's house correlates with the risk of sensitization. In addition, the concentration of allergen in dust may be a poor index of exposure within the house.

Thus, at present it is easier to say that in a community where most of the homes have animals, animal dander will be widely distributed in all the houses and also in the schools. In a community where the majority of houses have $\geq 8 \mu\text{g}$ *Fel d 1*/g of dust, then sensitization of atopic individuals will be common and in addition sensitization will correlate with asthma. Threshold measurements for cockroach allergen are not well defined. However, it is clear that in a population where none of the houses are infested (*Bla g 2* $< 1 \mu\text{g/g}$ dust), sensitization is rare and unrelated to asthma (Squillace et al. 1997).

Since the midtwentieth century there have been dramatic changes in lifestyle in which the indoor environment both at work and at home is increasingly dominant. Thus, it is not surprising that exposure to proteins found inside the house has been increasingly recognized as a major health problem. In addition, it is clear that some conditions are definitely harmful, such as carpets and sofas in a warm humid climate or animals kept inside houses with very low ventilation rates. On the other hand, it is unlikely that the increase in asthma is due primarily to changes in conditions in houses. Thus, the alternative explanation is that changes in lifestyle have created a situation where we have to take the indoor environment increasingly seriously. Overall, it is clear that understanding the role of indoor allergens and the immune response they elicit as well as methods of designing and managing houses to control exposure is likely to be increasingly recognized as an important part of health care.

CHAPTER 44

POLLEN IN INDOOR AIR: SOURCES, EXPOSURES, AND HEALTH EFFECTS

Michael L. Muilenberg, M.S.

Department of Environmental Health

Harvard School of Public Health

Boston, Massachusetts

44.1 INTRODUCTION

Pollen is an essential component in the life cycle of flowering plants. Any farmer, forester, beekeeper, or naturalist will attest that, without the movement of pollen from one plant to another, neither the plant kingdom, nor humans, would survive. At the same time, pollen can cause discomfort and sometimes debilitating symptoms in those whose immune systems act inappropriately to pollen grains which come into contact with their mucosal membranes (eyes and respiratory system, in particular). While pollen-induced diseases may not be attributable to building design or operation, the impact of the subjects' pollen (or other) allergies should be taken into account when assessing the health of any study population.

44.2 POLLEN AND FLOWER: DESCRIPTION AND FUNCTION

The Biology of Flowering

The pollen grain is a specialized "capsule" that protects the male gametophyte (which will give rise to the "sperm") as it is transported from the anther where it was produced, to a receptive stigma, where pollen tube formation can occur, leading to fertilization of the egg by the sperm. This journey can take a number of different forms depending on the type of flower producing the pollen. The pollen grain can travel via *active transport*; that is, by insect, beetle, bird, bat, or other animal. Flowers and pollen utilizing this type of transport are typically called *entomophilous*, especially if an insect is the transport vector, or more generally, *zoophilous*. Of more importance to us are the *passively transported*, or

anemophilous, grains that are carried via air currents. Such airborne grains are the most likely to come into contact with one's nasal mucosa and cause allergic symptoms. There are gradations between these two types of pollen transport; *amphiphilous* pollen can be dispersed by wind and/or insects.

The obvious differences in the flower morphology between entomophilous and anemophilous plants are discussed after the basic design of the flower is presented. The flower is essentially the plant reproductive organ and hence is made up of male and/or female parts. The male portion of the flower, called the *stamen*, includes a slender stalk that supports the pollen-producing anthers. The female part of a flower, called the *carpel*, consists of the *ovule(s)* which, when fertilized, will become the seed. The carpel also has a pollen-receptive structure, called a *stigma*, that is attached to the ovule by an elongated *style*. In addition, flowers frequently include sterile parts, such as *petals*, which are often colorful to attract pollinators, and green *sepals* located below the petals.

Depending on the species, flowers can contain from a few, up to dozens of stamens and from one to many carpels. They might also contain only male parts (*staminate* flowers), only female parts (*carpellate* flowers), or both types of structures (called *perfect* flowers). To complete this picture, both types of imperfect flowers (staminate and carpellate) can be on the same plant or on separate plants.

As entomophilous plants have evolved to attract insects to their flowers and anemophilous flowers have evolved using the wind to carry their pollen to other flowers, it is not surprising that these two flower types usually have a very different appearance. Entomophilous flowers commonly have larger showy petals to attract insects or birds, or large white petals to attract bats or moths. They often also produce nectar to entice and "reward" animals that visit the flower. Such flowers are almost always "perfect" with the anthers and stigmas arranged so that pollen collected on a visit to one flower will come into contact with the stigma of the next flower visited, thereby increasing the chances of successful pollination. On the other hand, anemophilous flowers generally have very reduced petals and sepals; these structures offer no reproductive advantage since attracting pollinators is not necessary. Having small, or absent, petals and sepals reduces the chance of interference with the windborne transport of pollen. These flowers have also evolved strategies to get their pollen grains into the wind. Some have long anther filaments that extend the anthers away from the flower further into the windstream. Similarly, longer styles increase the probability of contact with windborne pollen. Plants depending on wind for pollination are more likely to have separate staminate and carpellate flowers. Finally, because anemophilous plants use an undirected approach (air currents) to get their pollen to the flower of a same-species plant, they often produce many grains per plant to compensate for the extremely large percentage of grains that never make it to a receptive flower. Pollination via animal vectors is somewhat more directed in the sense that an insect picking up pollen during a flower visit has a reasonable chance of visiting a flower of the same species at its next stop. This might explain why many anemophilous plants that are associated with allergies produce more pollen grains than the "average" entomophilous plant.

As there are differences between the flowers that produce entomophilous and anemophilous pollen, so there are differences between the pollen grains produced by the two flower types. Anemophilous pollen generally tends to be smaller (less than $\sim 50\text{ }\mu\text{m}$ in diameter) in comparison to entomophilous pollen, although there is significant size overlap between both types. Several notable exceptions to the size difference include pollen from trees in the pine family (including firs and spruces) which are all larger than $50\text{ }\mu\text{m}$ yet strictly wind-pollinated. The texture or ornamentation of the outer pollen wall also varies between insectborne and windborne grains. Entomophilous grains tend to have a more elaborately ornamented outer wall and are often "sticky" compared to the relatively smooth anemophilous grains.

Pollen Morphology

Pollen grains are formed in the anther from a pollen “mother” cell, which then divides meiotically to produce a tetrad of haploid cells. The tetrahedral arrangement of these cells that develop into the pollen grains is important. In some plants this *tetrad* remains intact and develops into a *compound* grain having four parts. Examples of plants producing pollen grains in tetrads include broad-leaved cattail (*Typha latifolia*), and woodrush (*Luzula*). In some plant types such as acacia (*Acacia*) and mimosa (*Albizia*) trees, the immature tetrads further divide, resulting in a mature compound grain of 8 or 16 components called a *polyad*. In most plants the tetrad separates when the grains mature, and the pollen grains are released singly (*monads*).

The wall of the mature pollen grain is divided into distinct layers. The inner layer, composed of cellulose, is called the *intine*. The outer layer, or *exine*, is composed of a unique, very resistant polymer called *sporopollenin* and small quantities of polysaccharides. The intine can vary in thickness between different plant types, but the often elaborate sculpturing of the exine is what makes pollen grains of different plant types most distinctive. The exine has two main layers consisting of the unsculptured *nexine*, and the *sexine*, which can be spiny, granular, warty, reticulate, striate, or essentially absent.

Another striking feature of most pollen grains is the presence of apertures. *Apertures* are areas where the exine is thin or absent and that are not part of the previously mentioned sculpturing pattern. When apertures are elongate they are called furrows or *colpi*. Circular to oval-shaped apertures are called pores or *pori*. A number of aperture combinations are possible: no apertures (*inaperturate*), two pores (*diporate*), one furrow (*monocolpate*), three furrows (*tricolpate*), or three furrows with pores in the middle of each furrow (*tricolporate*). Pollen grains in the grass family (Poaceae) are *monoporate* and they all have a cap (or *operculum*) of exine material in the center of the pore (Fig. 44.1a). Birch (*Betula*) grains are *triporate*, and the intine under each pore is thickened into a lens shape (Fig. 44.1b). The pollen of red oaks (*Quercus rubra* group) are *tricolporate* with a coarsely granular exine (Fig. 44.1c). Grains of the pine family (Pinaceae) are often classified as *monocolpate* with the furrow having large, air-filled bladders, on each side (Fig. 44.1d). One can refer to pollen identification manuals for more information on the pollen morphology of specific plant types (Basset et al. 1978, Lewis et al. 1983, Moore et al. 1991).

44.3 POLLEN ECOLOGY

Geographic Distribution

Climate, especially temperature and moisture availability, has a major impact on the distribution of plants and their airborne pollen. Black spruce (*Picea mariana*) and paper birch (*Betula papyrifera*), both of which produce anemophilous pollen, are examples of cold-climate trees. Neither tree will grow naturally in warm areas where average July temperatures exceed about 21°C. Paper birch trees will tolerate cold climates where average July temperatures are as low as 12°C. Black spruce can be found in slightly colder areas with average July temperature as low as 10°C (Smith 1974, p. 177). Therefore, these trees are most abundant in New England, the northern tier of states, and in Canada. Olive trees (*Olea*), on the other hand, will not tolerate cold temperatures and consequently grow in southern California and the Southwest, where they contribute significant amounts of pollen to the air.

Moisture availability also has a major influence on plant distribution. This is obvious when looking at a map of vegetation or ecoregion zones in the United States (Fig. 44.2). The zones have somewhat more of a north/south banding arrangement due to moisture gra-

FIGURE 44.1 Photomicrographs of representative pollen types: (a) grass (Poaceae)—note the operculum in the pore center of the grain on the right (arrow) and the operculum broken off from pore membrane of the grain on the right (arrow); (b) birch (*Betula*); (c) red oak (*Quercus rubra*) showing a surface view on the top (note granular surface) and cross section on the bottom; (d) pine family types include pine, fir, spruce (*Pinus*, *Aibes*, *Picea*)—note the air bladders (arrows) giving the grain a “Mickey Mouse cap” appearance. (All photos by the author.)

FIGURE 44.2 Ecoregions divisions map of North America. Note especially the north-south arrangement of ecoregions in the western coastal and central plains areas of the United States and Canada. [Adapted from Bailey (1997).]

dients (precipitation and water evaporation) than an east/west banding pattern which one would expect if temperature were the major influence. This pattern is especially apparent through the Western Coastal and Central Plains states. Seasonal cycles of precipitation are a very important factor in plant distribution. Rainfall distributed evenly through the year will support a very different flora than will seasonal precipitation with long dry periods. A number of other factors including light, soil type, wind, microclimate, and land use patterns by humans, all have an impact on plant distribution. A set of maps showing the distribution of specific plants producing airborne pollen can be found in Lewis et al. (1983).

Seasonality

Most plants in temperate areas release pollen over only a few weeks each year. In warmer climates the flowering season of specific plant types can be longer but seasonal

cycles are still evident. The approximate period of pollen shedding is quite predictable and is controlled by factors such as temperature, day length, and/or water availability. The difference in pollen seasons is illustrated by a graph of mean birch tree (*Betulaceae*) pollen recoveries from four U.S. cities over a 5-year period (Fig. 44.3). The graph shows that peak pollen periods in the warm central Florida climate were between mid-February and early March. Birch pollen recovery in Seattle peaked in early April, and pollen in the upper Midwest and Northeast (Michigan and New York) did not peak until late April and early May. Similarly, reflecting regional climatic differences, grass pollen recoveries from three of these same cities are highest in Florida from March through May, in Michigan from late April through June, and in Seattle from late May to mid-July (Fig. 44.4).

Early spring flowering plants in temperate areas are strongly influenced by temperature. Flowering onset and dispersal of pollen varies up to 3 weeks before or after the mean date depending on the arrival of warm dry weather (Frenguelli et al. 1991). For example, various tree pollen start dates recorded in Oklahoma varied by over 30 days between different years (Levetin 1998). Yearly variation in the beginning of the pollen shedding is illustrated in a graph that shows how the onset of birch pollen season in Seattle varied over a 2-week period within 5 years (Fig. 44.5).

Conversely, the onset of cocklebur (*Xanthium*) pollen shedding is influenced by day length (or actually, darkness). Cocklebur requires at least 8.3 h of darkness for flowering to begin (Salisbury 1971, p. 86). Therefore, the beginning of the pollen season is on or about the same date each year. Ragweed (*Ambrosia artemisiifolia*) exhibits a similar photoperiodicity and requires about 14.5 h of daylight for flowering onset. In any one year, ragweed flowering onset and pollen shedding are generally only a few days away from the mean. The small variation in the start of ragweed pollen shedding is often attributable to local weather patterns, particularly humidity and temperature (Bianchi et al. 1959).

FIGURE 44.3 Birch family pollen concentrations from four cities. Concentrations are 3-day running averages of 5-year averages. [Data from AAAAI (1999) and supplied by Dr. M. Jelks, Sarasota, FL; Dr. J. McDonald, Kalamazoo, MI; Dr. F. S. Virant, Seattle, WA; and Dr. K. Geraci-Ciardullo, Westchester County, NY.]

FIGURE 44.4 Grass pollen concentrations during 1998 from three cities. Only a portion of the grass season is presented. [Data from AAAAI (1999) and supplied by Dr. M. Jelks, Sarasota, FL; Dr. J. McDonald, Kalamazoo, MI; and Dr. F. S. Virant, Seattle, WA.]

FIGURE 44.5 Cumulative percentage of birch pollen recoveries in Seattle, WA over 5 years. Note the 2-week difference in the beginning of the pollen season, often defined at 10 percent of the annual recovery. [Data from AAAAI (1999) and supplied by Dr. F. S. Virant (Seattle, WA).]

Circadian Cycles and the Influence of Weather

Weather and ambient conditions have a large impact on pollen release and dispersal which often results in more or less distinctive circadian patterns of airborne pollen concentration. Typically, anemophilous pollen is shed during warm, dry weather (Dingle et al. 1959, Käpylä 1984). Ragweed pollen maturation occurs only when overnight temperatures exceed about 10°C, and release occurs when relative humidity is below RH ~70 percent (Solomon 1988). Therefore, ragweed pollen is typically shed during early to midmorning hours, but dispersal will not occur without some air turbulence. A lack of sufficient air movement can delay the dispersal of pollen until later in the day. It is important to realize that pollen release by a flower and its dispersal by air currents does not always coincide in time. Higher wind speeds do not necessarily result in higher airborne pollen concentrations. Location of pollen sources, dilution, and increased impaction with subsequent removal from the airstream, must also be considered when evaluating the effects of wind (Emberlin and Norris-Hill 1996). For example, Urticaceae (nettle and pellitory) pollen is typically recovered at midday in Spain but in early evening in England. Such a difference in recovery time could be due to biological factors (different species), weather patterns and air movement, or a difference in distance between the pollen source and samplers at the different locations.

Any rainfall that occurs before the flower releases its pollen will inhibit pollen shedding as the result of increased humidity. Rainfall effectively washes out or “scrubs” pollen from the air (Dingle and Gatz 1966), thereby abruptly reducing concentrations of pollen already airborne. Thus, there is a strong negative correlation between rainfall and airborne pollen concentrations.

A number of researchers are working on predictive models of pollen concentrations. Using ragweed pollen concentrations in Michigan, Stark et al. (1997) developed a model using rainfall, wind speed, temperature, and time from start of the season. Models for other pollen types have also been proposed, including daily mugwort (*Artemisia vulgaris*) concentrations (Wolf et al. 1998), onset of ash (*Fraxinus excelsior*) pollen season (Peeters 1998), and grass pollen and hayfever severity (Schäppi et al. 1998), among many others.

44.4 INDOOR POLLEN

Pollen Sources

The overwhelming source of pollen indoors is outdoor air. One mode of transport is via air currents through open windows, doors, “cracks” or gaps in outer walls, and air intakes. The tightness of the structure and the type of ventilation will affect the relative importance of each of these routes. Modern office buildings that are very tight and use high-efficiency filters on their air intakes would be expected to have essentially no airborne pollen carried into the building through “gaps.” Maintenance of the ventilation system is important to ensure that filters fit tightly, thereby minimizing the penetration into the building of pollen and other particles.

Pollen entry into buildings by humans and pets could possibly be a more important route of entry than the airborne route. Carriage on clothing has been shown to be a significant source of fungal spores in residences, particularly in farm homes (Pasanen et al. 1989). Outdoor activities bringing one into contact with flowering weeds or grasses could potentially result in the accumulation of pollen grains on clothing or in pet hair that could easily be carried indoors and dispersed.

In unusual situations, indoor sources might also contribute to the indoor pollen load. Greenhouses are an obvious example. Although probably not a significant source, indoor plantings in homes or offices could contribute to airborne pollen concentrations. Most indoor plants that flower have showy flowers that are strictly insect-pollinated, and pollen

from such plants could become airborne only under violent disturbance and would quickly settle out of the air (Burge et al. 1982).

Indoor/Outdoor Relationships

Air samples taken inside and out of Texas mobile homes indicated that indoor pollen concentrations averaged about half that found outdoors with a higher indoor/outdoor ratio in the summer (Sterling and Lewis 1998). This seasonal difference could be attributed to multiple factors such as seasonality of pollen production, different home ventilation strategies, or patterns of occupant movement. In 51 homes in Tucson, Arizona, airborne pollen concentrations detected by Rotorod samplers were found to be about 20 times lower than those immediately outside the home using the same sampler type, and a few hundred times lower than concentrations in regional centers using Hirst-type pollen samplers (Lebowitz et al. 1982). Only 16 percent of the sampled homes had detectable airborne pollen, and these homes had a mean concentration of 1.2 gr/m^3 (grains per cubic meter) of air, whereas outdoor concentrations routinely reach 100 gr/m^3 and peak at over 1000 gr/m^3 depending on type. These indoor recoveries frequently corresponded to peak pollen production times outdoors.

In Sofia, Bulgaria, studies using settle slides showed that peak numbers of deposited pollen grains in naturally ventilated interiors were about 20 times lower than those found outdoors. In homes where the windows remained closed for a larger percentage of the day, this ratio was much larger. During the spring, in one home the windows remained closed most of the day, resulting in indoor deposition numbers that were 200 times less than those outdoors. In most cases, peak deposition days indoors closely matched those of outdoors (Yankova 1991).

For years, air conditioning has been suggested as an effective means for reducing the penetration of outdoor bioaerosols into interiors. Solomon et al. (1980a) sampled 20 homes and 10 paired outpatient clinic rooms (air-conditioned and naturally ventilated), and found pollen concentrations in air-conditioned rooms to be about 5 percent that in naturally ventilated rooms.

Pollen in Dust

Dustborne pollen concentrations, determined by microscopic examination of swept and vacuum-collected dust in seven naturally ventilated Tucson homes, averaged $5.8 \times 10^5 \text{ gr/g}$ of dust. Minimum and maximum concentrations were 178 gr/g dust and $5.5 \times 10^6 \text{ gr/g}$, respectively (O'Rourke and Lebowitz 1984). It was suggested that because airborne concentrations are so low in these homes, even during peak seasons, pollen is more likely brought inside on the feet of occupants and pets than via atmospheric transport.

A Finnish study indicated that birch pollen allergen activity in outdoor dust averaged 10 times higher than in indoor residential dust and that urban homes might have slightly higher dustborne allergen concentrations than rural homes. The authors proposed that pollen allergen (birch pollen antigen in this case) is a better indicator of exposure than pollen grains because grains can be devoid of allergenic activity. Birch allergen concentrations indoors also peaked about 3 weeks after the atmospheric pollen peak outdoors, which was presented as evidence of pollen and allergen being carried into the home on shoes and clothing, rather than via airborne routes (Yli-Panula and Rantio-Lehtimäki 1995). Because these studies indicate that pollen penetration into homes is greatest via carriage on shoes and clothing rather than via air transport, it is assumed that under cer-

tain circumstances in tight buildings, dustborne pollen and their allergens could potentially contribute to allergy symptoms.

44.5 POLLEN SAMPLING

Air Sampling

Pollen can be collected from air in a number of ways. The two most commonly used sampler types that enable one to determine airborne concentrations (volumetric collections) are *rotating arm impactors* and *Hirst-type suction slit impactors*. Before these samplers became popular (during 1960 to 1970), settle sampling was the most common collection method. Typically, settle samplers simply consisted of an adhesive-coated glass microscope slide with some type of support. The slide would be set indoors or outdoors for time periods ranging from hours to days. Adhesives included oils (e.g., immersion oil), petroleum jelly, glycerin jelly, or grease. After exposure, pollen grains that landed on the slide were counted microscopically and reported as gr/cm^2 . The *Durham sampler*, a popular version of settle sampler, consisted of a slide stage with a clip and a rain shield which enabled sampling during adverse weather conditions. A major drawback to the use of settle samplers is that recoveries cannot be reliably translated into airborne concentrations. There is also a significant bias toward larger particles because of their higher settling velocity. Settling rates also are influenced by wind speed and turbulence. Unless one is interested in determining how many grains settle onto a surface, this method is not recommended.

It should be noted that there are settle (or *sedimentation*) samplers used by palynologists who are interested in how pollen settles out of the air and how this relates to surrounding vegetation, weather patterns, and other factors. Settle samplers are not likely to be used by indoor air specialists; however, knowledge of their existence might prove useful. The Tauber traps, and their look-alikes, are one type of commonly used sedimentation sampler. This sampler consists of a cylindrical container, 10 cm tall and 10 cm in diameter, that sits on a base. The cylinder has an aerodynamically shaped “collar” or cover (15-cm diameter) with a 5-cm-diameter opening that sits atop the cylinder. Pollen is deposited into the cylinder through the opening during rainy and dry weather (Tauber 1974). Glycerol, sometimes with preservatives added, is added to the container to retain the particles in the sampler. The solution is removed periodically and centrifuged. The recovered pellet is treated with acids to dissolve organic matter and sand, and the pollen is acetolyzed (see section on pollen analysis below). Pollen deposition is reported as $\text{grains}/\text{cm}^2$ per time.

Rotating-arm impactors use narrow, opaque bars wrapped with clear plastic tape or, more commonly, adhesive-coated clear plastic rods, which are spun through the air about a central axis. Airborne particles with sufficient inertia are unable to follow the airstreams around the rods (or bars) and are impacted onto the adhesive-coated leading edge of the rod. Most commonly silicone grease is used as the adhesive [see study by Solomon et al. (1980b)]. The collected particles can be stained and viewed directly with a light microscope by either placing the clear rod under the microscope in a manufacturer-supplied clear plastic stage mount or removing the tape from the bars, mounting it on a glass slide and viewing it microscopically. Typically, a stain (e.g., Calberla’s stain; see Appendix at end of this chapter for formula) is used in the mountant to highlight the pollen grains and make it easier to discern their micromorphology.

The Rotorod sampler (Sampling Technologies Inc., Minnetonka MN; see Appendix), probably the most commonly used rotating-arm impactor, uses plastic collecting rods having a width of about 1.6 mm which efficiently collects particles down to around 15 μm in diameter. Therefore, this sampler efficiently collects all except the smallest airborne pollen

types. Generally the Rotorod is operated intermittently for 15 to 60 s at every 10-min interval for a 24-h period resulting in 24-h average concentrations. The timer is easily adjusted to allow for continuous sampling for shorter periods if desired.

Hirst-type samplers are slit impactors. These instruments pull air through a narrow slit (typically 2×14 mm) behind which is positioned an impaction surface coated with an adhesive (Fig. 44.6). The impaction surface can be either a slide that moves past the slit at a rate of 2 mm/h, or a drum, with clear, adhesive-coated tape wrapped around its circumference, that rotates the impaction surface under the intake slit also at 2 mm/h. Intake air is forced to make a right-angle turn over the impaction surface. Particles with sufficient inertia leave the airstream and impact on the collection surface. A number of adhesives have been used with Hirst-type samplers, including petroleum jelly, petroleum jelly/paraffin mixes, silicone grease, and stopcock grease (e.g., Lubriseal, Thomas Scientific, Swedesboro, NJ). When using samplers in very warm climates it is important to select an adhesive with a high melting point (e.g., some type of silicone grease). See also the guide to sampling pollen and spores by the British Aerobiology Federation (available from Burkard Mfg. Co.; see Appendix), which gives more specific instructions on Hirst-type sampler operation.

Hirst-type samplers using the "slide head" collect particles over a 24-h period while those using the drum can be operated for 7 days before the impaction surface needs to be changed. These samplers have a cutpoint below $5 \mu\text{m}$, thus enabling essentially all pollen types to be efficiently collected. Hirst-type samplers also allow recoveries to be analyzed by time of day with a minimum time discrimination of approximately 2 h. Because pollen release and dispersal have rather pronounced periodicity, determination of pollen concentrations for time intervals of 2 or 4 h can be very important in defining human exposures.

The most commonly used Hirst-type samplers in the United States are the Burkard spore-trap samplers (Fig. 44.6) (Burkard Manufacturing Co., Ltd., Rickmansworth, England; see Appendix). The Kramer-Collins [G-R Electric Mfg. Co., Manhattan, KS (Kramer et al. 1976)] sampler operates on the same principle as the Burkard. In Europe, the Lanzoni Sampler (Lanzoni, Bologna, Italy; see Appendix) is also popular. Portable models allowing time discrimination in indoor environments are available from Burkard and Lanzoni and from Allergenco (Allergenco Air Sampler MK3, San Antonio TX; see Appendix).

Filtration samplers are used by some researchers to collect pollen, but they are far less common than the previously mentioned impaction devices. Filtration can be *active*, that is, using a pump to move air through the filter; or *passive*, depending on air currents to move particles into the filter. Because of their relatively large size, pollen grains are very easy to collect with a variety of filter types. Studies of submicron allergen-containing particles have used fiberglass filters and high-volume pumps as well as other types of membrane filters (cellulose esters, synthetics, etc.) (Busse et al. 1972, Solomon et al. 1983). Cour traps are passive filtration samplers using two 5-layered gauze filters with an exposed surface area of 400 cm^2 . The filters can be exposed for a number of days or weeks. After the desired length of sampling time, the filters and other organic material are dissolved in a series of acid baths, and the pollen is acetylated, stained, and viewed microscopically. Airflow (wind speed) can be recorded next to the sampler to estimate the volume of air sampled, allowing pollen concentration estimates to be calculated. When this sampler was compared with a Hirst-type sampler (Burkard), the Cour trap was shown to collect pollen less efficiently, but it recovered more types of pollen than did the Burkard (Tomás et al. 1997). The Cour traps have a simple design and do not require power to operate, although sample processing and analysis are time-consuming and complex. They are used for routine pollen monitoring in outdoor environments only.

The locations of airborne pollen samplers can have a significant impact on the recovery. Of most concern is the proximity of the sampler to sources. When deciding on a location for a long-term sampler, it is ideal to avoid setting the sampler within approximately 50 (to 100) m of any anemophilous plants, but, in practice, this is seldom possible. Noting the types of nearby plants that could unduly influence recoveries might help explain any unusually anomalous

FIGURE 44.6 Burkard recording spore sampler, a Hirst-type sampler: (a) full view of the sampler; (b) lid assembly; the impaction surface which would subtend the intake orifice when placed in the sampler. (Drawings by Anna Clark.)

results. To lessen the impact of local sources, a common practice is to elevate the sampler to a rooftop two to four stories high. Recoveries from an elevated sampler will be more representative of a larger geographic area. On the other hand, results from rooftop samplers have been criticized as not being representative of real exposures because the samplers should be in the breathing zone of humans (instead of birds). Differences between rooftop and ground-level day-to-day pollen recoveries have been shown to be significant, especially for weed pollen, but also for tree pollen, with counts most often higher at ground level than at rooftop level (Rantio-Lehtimäki et al. 1991). Galán et al. (1995) found little difference in pollen concentrations or significant events (onset or peak concentration) between samplers at heights 1.5 and 15 m. Some claim that these differences average out over time (Raynor et al. 1973). The guidelines of the American Academy of Allergy Asthma and Immunology Pollen and Spore Network state that samplers must be at least one story (about 5 m) above grade.

Dust Sampling

It has been shown that pollen concentrations in dust can be significant; over one million grains per gram of dust have been reported (O'Rourke and Lebowitz 1984). Because pollen in indoor air would be expected to quickly settle as a result of less turbulent air movements compared to outdoors, "house dust" might serve as a sink as well as a secondary reservoir of outdoor-source pollen. It is possible to sample and analyze dust to determine how much pollen has been carried indoors and/or settled out of the air; however, to determine the potential for reaerosolization and exposure, such sampling is generally done only for research purposes.

Pollen Analysis

Light microscopy is the most common means of identifying and counting pollen grains. Typically, magnifications of 400 $\times$ are required for counting and identification. Some grains might require 1000 $\times$ (oil immersion) magnification to view some of the finer and less obvious morphological features. Using a good-quality microscope with a binocular head, 10 $\times$, 40 $\times$, and 100 $\times$ objectives, 10 $\times$ wide-field eyepieces, and a mechanical stage with vernier scale, is important for reliable counting and identification of pollen. Phase contrast, while a very useful option, is not essential.

Pollen types are differentiated using a number of characteristics including size, shape, number of components or units, types of apertures (furrows or pores), and surface ornamentation (see section on pollen morphology, above). Most often, grains are stained for optimal viewing. Stains are usually incorporated in the mountants used to prepare air sampler recoveries. Calberla's solution (see Appendix) uses basic fuchsin stain. Glycerin jellies often contain phenosafranin stain or basic fuchsin (see formulas in Appendix), although a number of other stains can be used.

Preparing air sample recoveries for microscopic viewing is a relatively easy task because the grains are usually an obvious, although rarely a predominant, fraction of the airborne particulate load. On the other hand, when preparing soil or dust for pollen analysis, the pollen grains are an extremely small fraction of the total particulate. The pollen grains must be concentrated and the other particulate matter removed. The organic matter and soil particles are usually dissolved using very strong acids in a procedure called *acetolysis*, which does not significantly affect the very resistant pollen exine. Refer to Moore et al. (1991, Chap. 4) for a more detailed treatment of this procedure.

While morphological differentiation of pollen grains by light microscopy is by far the most common analytical method, the use of fluorescent-labeled antibodies shows promise for some applications. Studies in Tucson showed that particles detected by fluorescent-

labeled antigrass antibodies exceeded pollen counts in many cases (Schumacher et al. 1988). Takahashi et al. (1993) used fluorescent antibodies to detect Japanese cedar pollen and found it to be faster than conventional methods and amenable to automatic counting methods. Showing relationships between health outcomes and airborne allergen concentrations as determined by labeled antibodies, rather than pollen concentrations, might prove to be a better method. When using labeled antibodies, the agent itself (allergenic protein) is actually being detected, rather than a particle with which the agent is often (but not always) associated. Fluorescent antibodies for pollen detection are currently being used only for research purposes and are not available for general monitoring.

44.6 HEALTH EFFECTS

The most significant health effects attributable to pollen exposures are hypersensitivity diseases such as hayfever, asthma, and, rarely, allergic dermatitis. Hayfever, or rhinoconjunctivitis, is by far the most common pollen-induced disease. When pollen grains or components of the grains contact the mucosal linings of the nose, eyes, or oral cavity, the water-soluble allergens from the pollen come into contact with mast cells, resulting in the release of histamine and other substances (leukotrienes, cytokines, etc.) in sensitive individuals. Subsequent symptoms can include nasal congestion; itching or burning sensation in the nose, throat, and eyes; watery to mucoid nasal discharge; and swelling of the mucous membranes—all of which can vary from very mild to severe, depending on the level of sensitivity of the individual and level of exposure. Table 44.1 lists the frequency of sensitivity, evaluated by skin-prick test, to a few select pollen types.

There are few reliable reports correlating the onset of symptoms with specific airborne pollen concentrations. One group found that grass-sensitive patients showed allergic rhinitis symptoms when mean daily grass pollen concentrations reached about 50 gr/m³ of air (Davies and Smith 1973). Although there is a demand for these dose-response relationships, they will probably be long in coming. It appears that allergen exposure required to elicit symptoms varies greatly between individuals (Cookingham and Solomon 1995). In addition, an individual's exposure threshold can vary depending on recent exposures. A certain concentration necessary to elicit symptoms in the middle of a pollen season might be different from that required to elicit symptoms early in the pollen season.

Asthma is a hypersensitivity of the airways to a variety of agents, leading to increased resistance to airflow. Wheezing and difficult breathing (dyspnea) are typical symptoms, although additional criteria are frequently used for diagnosis. Pollen-induced asthma is now widely accepted, yet how these large (>15- μ m) allergen-carrying particles penetrate deeply enough into the airways to trigger asthmatic responses has not yet been completely resolved. Pollen allergen has been shown to be associated with airborne particles smaller than the actual pollen grains themselves (Busse et al. 1972). These small particles might be flower or pollen fragments or other rafts containing the allergenic proteins that have leached off of pollen grains. Penetration of small, sometimes submicronic, particles into the lower airways is one explanation for post-season hayfever and possibly asthma (Habenicht et al. 1984).

44.7 SUMMARY

Pollen is a major factor in outdoor-related rhinoconjunctivitis (hayfever) and allergic asthma symptoms but plays only a minor role in indoor-related disease. However, the

TABLE 44.1 Examples of Pollen Sensitization Rates^a

Pollen agent	Population tested	Percentage of positive skin-prick test reactions	
		Total cohort, ^b %	Atopics, ^c %
Olive pollen ^d	Italians	17	23

^aAs measured by frequency of skin-prick test positive reactions.^bTotal cohort indicates a population not selected on the basis of allergy status.^cAtopics indicates those having hypersensitivity diseases with a familial tendency.^dData from Larese Filon et al. (1998).^eData from Sears et al. (1989).^fData from Rachmiel et al. (1996).^gData from Kasti et al. (1997).^hData from Hartel et al. (1997).

potential contribution of indoor pollen exposure to allergy-type symptoms in naturally ventilated buildings should not be ignored. The real importance of pollen to indoor air quality lies in the significant percentage of the population that is hypersensitive to the large variety of airborne pollen types. The effect these hypersensitivity diseases can have on a subject's (or a patient's) health status, whether they are indoors or out, should be considered.

APPENDIX

Formulas

Calberla's Stain

5 mL glycerol

10 mL 95% ethanol

15 mL distilled water

2 drops (approx.) of saturated, aqueous solution of basic fuchsin

Glycerin Jelly

20 g gelatin

70 mL distilled water

60 mL glycerin

1.2 g phenol

Boil water. Measure 70 mL and add to gelatin. Boil again and mix. Add glycerin and phenol and mix. Add a few drops of saturated stain (to desired intensity). Pour in storage bottles and cool.

CHAPTER 45

THE FUNGI

Harriet A. Burge, Ph.D.

*Department of Environmental Health
Harvard School of Public Health
Boston, Massachusetts*

45.1 INTRODUCTION

The fungi are among the most important and least understood of the indoor air pollutants. They are ubiquitous in the human environment. Their spores are abundant in air, on surfaces, in dust, and in water. They can cause human diseases and are extremely important as plant pathogens. They are consumed in food (mushrooms, tempeh, blue cheese), and their metabolites are used in medicine (antibiotics, antitumor agents, immunosuppressants). Several different terms are used to designate fungal growth, or types of fungi. The most widely used of these are listed in Table 45.1. This chapter provides an overview of the nature of the fungi, their ecology (focusing on indoor growth), approaches for investigation, health effects, and control.

45.2 NATURE OF THE FUNGI

This section offers a brief summary of the general nature of the fungi, especially as the information may be useful in the indoor air quality. The reader is strongly urged to read *The Fifth Kingdom* (Kendrick 1992) for an in-depth treatment of the subject.

Place among the Kingdoms of Life

The fungi are neither plants nor animals. Most occupy a kingdom of their own, called “*the fungi*.” A few “fungi” are related to primitive unicellular organisms now grouped in the kingdom Protista along with some unicellular animals and plants. Genetic and biochemical analyses indicate that the fungi are more closely related to animals than to plants (Kendrick 1992).

TABLE 45.1 Common Terms Used for Fungi

Indoor fungi	Mold	Any visible growth on surfaces
	Mildew	Fungi as they appear on fabrics
Edible fungi	Mushrooms	Basidiomycete fruiting bodies
	Truffles, morels	Ascomycete fruiting bodies
Plant pathogens	Wood rot	Basidiomycetes that degrade lignin in wood
	Powdery mildew	Ascomycete pathogens (e.g., the white powder on infected rose leaves)
	Rusts, smuts	Basidiomycete pathogens usually with grasses as the primary host (e.g., wheat rust, corn smut)
Morphological designations	Brackets	Basidiomycetes that form shelflike fruiting bodies on trees (e.g., <i>Ganoderma</i>)
	Cup fungi	Ascomycetes that produce large cup-shaped fruiting bodies
	Yeasts	Ascomycetes and Basidiomycetes that are unicellular
Common bioaerosols that are not fungi	Pollen	The male reproductive unit of flowering plants
	Moss and fern spores	Reproductive units of these primitive plants
	Slime molds	A group of organisms of uncertain position in the kingdoms of life; probably more animal than fungal

Morphology and Chemistry

Fungi are (primarily) filamentous microorganisms. Fungal filaments (hyphae) in mass are called *mycelia*. A mycelium functions to absorb water and exude enzymes that facilitate digestion of organic materials. Mycelia form visible fungal colonies often called “mold” as well as large fruiting bodies (e.g., mushrooms). Specialized structures for reproduction are formed from differentiated hyphae. The majority of fungi reproduce by spores formed from these specialized structures. Fungi produce spores (conidia) when adverse conditions are encountered, such as nutrient depletion, desiccation, a rise in the concentration of waste products, or a rise in reserve energy (Kendrick 1992). Fungal spores are generally designed for airborne dispersal and are either hydrophobic (for dispersal in dry weather) or hydrophilic (for dispersal in wet weather).

Chemistry and Metabolism

Structural Components. The major structural component of the cell wall of most fungi is an acetylglucosamine polymer (chitin). Cell walls also contain (1 → 3)-β-D-glucans or mannans that form the matrix in which the chitin is embedded. In addition, the cell wall surface may be coated with hydrophobic waxes and/or mucopolysaccharides that are hydrophilic and confer some antigenic specificity to the cell (Douwes et al. 1999). Fungal cell walls may also contain *melanin*, a brown pigment that protects the cells from ultraviolet light. Other pigments may also be present either in the cells themselves, or in cellular exudates. The membrane sterol in fungal cells is ergosterol.

Enzymes and Metabolites. In addition to these structural components, a variety of metabolites are produced by the fungi and are released into the environment. These include water, CO₂, ethanol, organic acids, enzymes, volatile organic compounds (VOCs) and nonvolatile toxins.

Water and CO₂ are normal products of aerobic respiration. Ethanol and the organic acids are fermentation products, and are enormously important in food preservation (e.g., converting sugar solutions into alcoholic beverages, and milk into yogurt and cheeses). The fungi digest food externally by releasing enzymes into the substrate to break down complex carbon and nitrogen sources. For example, some fungi produce amylase to degrade starch, cellulase to degrade cellulose-containing plant materials, or ligninases to degrade wood and wood products. The fungi also produce proteases, some of which are probably important allergens. Also of particular interest to the IAQ practitioner are the volatile organic compounds and mycotoxins produced by fungi.

Fungal volatile organic compounds may play a role in building related symptoms. The most commonly recovered are eight- and nine-carbon aldehydes and ketones (Borjesson et al. 1990, 1992). These are the compounds that produce the odors commonly associated with fungal growth. In one study, a mixed fungal population produced many volatiles with strong odors, including 2-ethyl hexanol, cyclohexane, and benzene (Ezeonu et al. 1994). Fungal volatiles may or may not be produced by a specific fungal strain depending primarily on environmental factors. Some volatiles are only produced when nutrients are limiting as would occur on some building materials (Bjorman and Kristensson 1992).

Mycotoxins are products of metabolism in specific fungi that accumulate either in substrates or in the fungus itself, or both (Rodricks et al. 1977, Shank 1981). Table 45.2 lists the common classes of mycotoxins. Similar to the case for volatile organic compounds, mycotoxins may not be produced under all environmental conditions, and the presence of a fungus in a particular environment cannot be assumed to indicate the presence of the mycotoxins (Nikulin et al. 1994, Rao et al. 1997). Mycotoxins may also be implicated in fungus-associated symptoms (see discussion below).

Growth Requirements

Most fungi use complex nonliving organic material for food, require water and oxygen, and have temperature optima within the human comfort range. Many require some light for initiation of sporulation. The environmental factors controlling fungal growth are interactive. For example, the optimum temperature for growth of a fungus may be 22°C on one culture medium but 18°C on another. Likewise, growth might occur at a low water activity at 22°C but not at 18°C.

Food sources for fungi are ubiquitous. Most fungi can utilize monosaccharides and disaccharides as carbon sources, as is evidenced by their ready growth on ripe fruit. Others use cellulose, lignin, keratin, and even some kinds of paint and plastics. The cellulases allow fungi (e.g., *Chaetomium globosum*, *Stachybotrys chartarum*) to degrade paper and other cotton products. The wood-rotting fungi are those that produce ligninases (e.g., *Merulius lacrymans*). The keratinophilic fungi can use human skin scales, and, in fact, human skin for food (e.g., *Wallemia sebi*, *Trichophyton* species).

Water contributes a significant portion of the total hyphal weight. Furthermore, water is necessary for the hydrolysis of organic materials and is the medium through which solutes are transported in and out of the cell (Kendrick 1992). The water requirement of a microorganism is defined as the water activity A_w . Water activity is the ratio of the water vapor pressure of a certain substance (i.e., growth medium or substrate) to the vapor pressure of pure water at a given temperature. Water activity is measured by enclosing the substance in a chamber at a given temperature and allowing it to come to equilibrium with the surrounding air. Then, the relative humidity within the chamber is measured with a psychrometer or hygrometer.

TABLE 45.2 Some Common Fungi, Mycotoxins, and Health Effects from Ingestion, Dermal, or Inhalation Exposure

Fungus	Mycotoxin	Carcin.	Mutagen	Other effects
<i>Alternaria alternata</i> , <i>Phoma sorghina</i>	Tenuazoic acid			Nephrotoxic, hepatotoxic, hemorrhagic
<i>Aspergillus clavatus</i>	Patulin			Inhibits protein synthesis
<i>Aspergillus flavus</i> , <i>A. parasiticus</i>	<i>Aflatoxins</i>	X	X	<i>Hepatotoxic</i>
<i>Aspergillus fumigatus</i>	Fumitremorgens Gliotoxin			Tremorgenic Cytotoxic
<i>Aspergillus ochraceus</i> , <i>Penicillium viridicatum</i> , <i>P. verrucosum</i>	Ochratoxin A	X		Nephrotoxic, hepatotoxic
<i>Aspergillus nidulans</i> , <i>A. versicolor</i> , <i>Cochliobolus sativus</i>	Sterigmatocystin	X		Hepatotoxic
<i>Cladosporium</i> sp.	Epicladosporic acid	X		Immunosuppressive
<i>Cladosporium cladosporioides</i>	Cladosporin, emodin			Antibiotics
<i>Fusarium poae</i> , <i>F. sporotrichioides</i>	T-2 toxin	X		Hemorrhagic, immunosuppressive, causes nausea and vomiting

<i>Penicillium crustosum</i>	Roquefortine C			
<i>Penicillium griseofulvum</i> , <i>P. viridicatum</i>	Griseofulvin	X		Teratogenic, hepatotoxic
<i>Penicillium expansum</i>	Patulin, Roquefortine C, Citrinin	X		Nephrotoxic
<i>Pithomyces chartarum</i>	Sporidesmin Phylloerythrin			Hepatotoxic Causes photosensitization and eczema
<i>Stachybotrys chartarum</i> (atra)	Satratoxins, verrucarins, rotridins			Inflammatory, immunosuppressive, causes dermatitis, hemotoxic, hemorrhagic

Sources: Derived from Kendrick (1992), Arafat and Musa (1995), and Osborne et al., (1996).

Most microorganisms require a substrate A_w in excess of 95% for growth. Although many fungi can grow at lower A_w , optimal growth occurs only when A_w is high. As the A_w falls below the optimum, growth rate gradually decreases to the point where no growth occurs. A few fungi have A_w optima below 0.9 (e.g., some *Aspergillus* species, some yeasts).

An indoor temperature range of 18 to 24°C is optimal for the growth of most fungi, although the breadth of the temperature range tolerated by different fungi varies considerably. A few fungi have temperature optima above 30°C (e.g., *Aspergillus fumigatus*), although most environmental fungi do not grow above 30°C. Fungal spores have optimal temperature ranges for germination that may be different from those for mycelial growth optima (Ayerst 1969). Spores are more heat-resistant than mycelia and generally survive longer at both ends of the temperature scale. However, other factors such as presence of appropriate substrates, absence of fungal inhibitors, and availability of water ultimately determine whether a fungus will be able to survive in a certain environment.

Classification and Nomenclature

Fungi produce both asexual (clone) and sexual spores. Most fungi of IAQ interest use asexual spores as the primary means for reproduction, and the powdery spores seen on fruits, walls, moldy leather, and other surfaces are examples of these asexual spores. Most of these same fungi also produce sexual spores at some stage in their life cycles. Fungi are classified into large groups by the way they produce sexual spores [see Kendrick (1992)]. The fungi important in indoor air mostly fall into the class Ascomycetes, with a few Basidiomycetes and Zygomycetes also of some importance. When the sexual stage is known, the fungus is named using a binomial representing that stage (e.g., *Eurotium repens*). The asexual stage of *Eurotium repens* is named *Aspergillus repens*. According to the rules of nomenclature, the official name is *E. repens*. However, because *Aspergillus* has been used for so many years and is often the only stage seen, the fungus is most often called *Aspergillus repens*. Both of these names have been used in indoor air-related publications. Most of the fungi important for indoor air quality fall into this same category; that is, they are asexual stages of Ascomycetes for which the asexual rather than the sexual names are used. Accuracy in naming fungi also may be a problem. Fungi are named according to strict rules of botanical nomenclature (International Code of Botanical Nomenclature 1994). Mycologists may argue about these rules, but they do follow them to the best of their ability. However, nonmycologists seldom take the time to accurately trace the names of specific fungi. Thus some confusing errors have entered the allergy and indoor air quality literature. Table 45.3 lists some common indoor fungi, the class to which they belong, and the nature of potential nomenclatural confusion.

Fungal Aerosols (General)

Particles that become airborne from fungal growth include spores (the unit of most fungal exposure), fragments of the filamentous body of the fungus, and fragments of decomposed substrate material. Fungal spores range in size from about 1 to >100 μm , and are found in many different shapes. The simplest are smooth spheres; the most complex are large multicellular branching structures. Most fungal spores are near unit density or less.

Asexual spores may be passively dispersed on disturbance by wind, water, or animals (Aylor and Sutton 1992, Aylor and Waggoner 1980). In the case of *Alternaria* and some other large-spored fungi, quick changes in relative humidity acting in concert with certain light wavelengths trigger spore release (Ingold 1971). Many ascospores are forcibly launched from inside tubelike asci when water pressure causes the cells to swell and burst.

TABLE 45.3 Some Examples of Nomenclatural Confusions

Class	Sexual name	Asexual name	Common but inappropriate names
Zygomycetes		<i>Rhizopus</i> <i>Mucor</i>	
Ascomycetes	<i>Nectria</i> (e.g.)	<i>Acremonium</i>	<i>Cephalosporium</i>
	<i>Pleospora</i> , <i>Leptosphaeria</i>	<i>Alternaria</i>	
	<i>Eurotium amstelodami</i>	<i>Aspergillus amstelodami</i>	<i>Aspergillus glaucus</i>
	<i>Emicella nidulans</i>	<i>Aspergillus nidulans</i>	
	<i>Sartorya fischeri</i>	<i>Aspergillus fumigatus</i>	
	<i>Botryotinia fuckeliana</i>	<i>Botrytis cinerea</i>	
		<i>Candida albicans</i>	<i>Monilia albicans</i>
	<i>Mycosphaerella</i>	<i>Cladosporium sphaerospermum</i>	<i>Hormodendrum hordei</i>
	<i>Filobasidiella</i>	<i>Cryptococcus</i>	
	Unknown	<i>Epicoccum nigrum</i>	<i>Epicoccum purpurascens</i>
	<i>Gibberella fujikuroi</i>	<i>Fusarium moniliforme</i>	
	<i>Emmonsella capsulata</i>	<i>Histoplasma capsulatum</i>	
	<i>Talaromyces</i> xx	<i>Paecilomyces</i>	
	<i>Eupenicillium</i>	<i>Penicillium</i>	
	Unnamed	<i>Saccharomyces</i>	
	<i>Melanopsamma pomiformis</i>	<i>Stachybotrys chartarum</i>	<i>Stachybotrys atra</i>
Basidiomycetes	<i>None</i>	<i>Merulius lacrymans</i>	
	???	<i>Sporobolomyces</i>	

Some (e.g., those of *Eurotium repens*) are released when the fruiting body is crushed or disintegrates and the asci burst. Basidiospores also are released by a poorly understood mechanism in response to sudden increases in osmotic pressure within the spore-bearing structure.

The fungal aerosol both indoors and out is complex, consisting of a mixture of spores, mycelia, and other materials from several or many different kinds of fungi, as well as non-fungal particles. Fungal aerosol compositions and concentrations vary dramatically over time in response to environmental changes. Air movements, sudden changes in humidity, and release of new spore types from maturing sources are a few of the factors that affect fungal aerosols. Also, active disturbance of substrate material may dramatically change both the composition and concentration of fungal aerosols.

45.3 AIRBORNE FUNGI IN THE INDOOR ENVIRONMENT

The indoor fungal aerosol is composed of particles penetrating from outdoors, particles reaerosolized from settled dust, and particles released from growth on indoor materials.

Outdoor Sources of Fungi

Fungi are ubiquitous in the outdoor environment. Many are plant pathogens, invading plant tissues, and causing disease. Others decay dead organic material such as dead wood, leaves, and synthetic materials made from organic compounds (e.g., cloth, paper, plastics, leather). Of particular importance are agricultural substrates. Field crops that are harvested after the plant dies become giant incubators for fungi. Spores are released in visible clouds during harvesting operations (Burge et al. 1991). The terms *soil fungi* and *phyloplane fungi* have come into common use in the IAQ community. A complex community of fungi occupies soil, with a composition dependent on water and nutrient availability, pH, and many other factors. Often species of *Penicillium* and *Aspergillus* dominate soil populations. Actinomycetes (filamentous bacteria—not fungi) are also abundant in soil. *Phylloplane* fungi are those that commonly occupy leaf surfaces, although they may be found on many other outdoor materials (e.g., wood, soil, building surfaces). Dead leaf populations are usually dominated by *Cladosporium* species, although many other fungi can be locally abundant. Living leaves may support the growth of plant pathogens as well as nonpathogenic commensals (e.g., *Sporobolomyces*).

Fungal spores form the largest and most consistently present component of the outdoor bioaerosol. Concentrations vary seasonally, with lowest levels occurring during periods of snow. While rain may initially wash dry spores from the air, wet (hydrophilic) spores that are released in response to the rain immediately replace these.

Outdoor fungal aerosols are usually dominated by phylloplane fungi, ascospores, and basidiospores, and concentrations vary spatially and temporally. Some kinds of spores are cosmopolitan in outdoor air (e.g., *Cladosporium cladosporioides*). Others produced by fungi with more fastidious nutritional requirements are only locally abundant (e.g., the corn pathogen *Helminthosporium maydis*). Temporal variation occurs with respect to both concentrations of continuously present taxa (e.g., *Cladosporium cladosporioides*) and the overall composition of the aerosol. Both diurnal and seasonal variations occur. For example, *Alternaria* spores are present in the air on dry days throughout the growing season, but gradually increase in concentration from spring through fall. They are also at their highest concentrations in the afternoon. Basidiospores (mushroom spores), on the other hand, are also abundant throughout the growing season, but concentrations vary with the season depending

on the kind of mushroom; thus basidiospore totals tend to be less consistently seasonal (Fig. 45.1). Diurnally, basidiospores are usually most common early in the morning.

The American Academy of Allergy, Asthma, and Immunology (AAAAI) maintains a network of spore-counting stations across the country that collect daily data on spore (and pollen) levels for reporting to the news media, and to a central station for analysis (AAAAI 1999). This network consists of volunteers who use specified samplers (Burkard spore traps) and submit to quality assurance procedures that include testing and certification of spore-counting and identification ability. The counters at each station then count a standardized list of individual spore types, plus all others, creating a total spore count. All stations submit all their data to the central station (at Harvard School of Public Health) for analysis. Many also report to news media. These reports are often either printed in the next day's paper, or broadcast with the weather. Note that reported counts are always from the day before the sample was collected.

Indoor/Outdoor Relationships

How the outdoor aerosol penetrates interior spaces depends primarily on available pathways. Figure 45.2 compares *Cladosporium* concentrations in a centrally air-conditioned home, a naturally ventilated home with room air conditioning, and outdoors. In this summer study, the *Cladosporium* concentration indoors was controlled by that outdoors, but

FIGURE 45.1 Seasonal distribution of some common fungal spores measured with a Burkard spore trap on a rooftop in Ann Arbor, MI over one year.

FIGURE 45.2 Diurnal variation in *Cladosporium* concentrations outdoors and in two Topeka, KS houses averaged over one week (Burkard recording spore trap samples).

levels were consistently lower indoors than out. There was little hour-to-hour variability, and levels in centrally air-conditioned homes were always lower than those in naturally ventilated homes. Li and Kendrick (1996) reports similar data.

Other studies indicate a similar pattern of penetration for large buildings [e.g., Burge (1999)]. This publication demonstrates the problems associated with interpretation of indoor/outdoor ratios. These ratios are strongly dependent on the absolute concentrations being measured. Very low ratios (indicating little outdoor penetration) tend to occur when the outdoor aerosol concentration is high. On the other hand, high ratios (>1), often considered to indicate indoor growth, occur only when outdoor concentrations are low. It should also be obvious that, when studying penetration, indoor/outdoor ratios can be considered only with consideration of individual fungal types. On the other hand, if the hypothesis being tested is that total exposure to fungi is related to the outcome, then totals can be considered.

The Indoor Aerosol

Indoor Sources. Although there is a clear connection between fungal contamination of indoor environments and human health and comfort, relatively little is known about the dynamics of indoor microbial populations. Fungi clearly can grow on building substrates (Burman and Kristensson 1992, Gallup et al. 1987, Pasanen et al. 1993). Factors that might

influence the kinds of fungi that can grow on particular materials include the nature of the material and the dynamics of water availability, temperature, and light (Su et al. 1992b). The actual composition of the fungal community at any point in time may also depend on the kinds of fungi available as inoculum, and interactions between the fungi (and possibly other organisms) within the ecosystem.

The specificity of species-substrate interactions has only been suggested, and no studies evaluate the role of competition in controlling indoor fungal populations. Temperature and water relations have been discussed above. The interaction among all of these factors is important to consider. For example, water and temperature requirements are likely to be influenced by nutrient availability (Flannigan 1993). Although it is assumed that relative humidity in the air is a good indicator for the likely presence of microorganisms on interior surfaces, the relationship between relative humidity and water availability is unknown for many indoor materials.

In addition to controlling the species composition of fungal populations, the nature of substrates, water availability, temperature, competition, and other factors play a role in the kinds of secondary metabolites that are produced by specific fungi. Clearly, some recognized mycotoxins and volatile organic compounds are produced by fungi only under specific environmental conditions.

Water is probably the most important factor controlling overall indoor fungal growth, since food sources are ubiquitous (Kendrick 1992). The kinds of fungi that are able to colonize indoor materials are generally (1) those with broad nutritional requirements (e.g., *Cladosporium sphaerospermum*), (2) those that are able to colonize very dry environments [e.g., members of the genus *Eurotium* (i.e., the *Aspergillus glaucus* group)], or (3) organisms that readily degrade the cellulose and lignin present in many indoor materials (e.g., *Chaetomium globosum*, *Stachybotrys chartarum*, *Merulius lacrymans*).

Dust. House dust is never sterile and always contains fungi. Reported concentrations have ranged from about 5000 g^{-1} to more than $5,000,000 \text{ g}^{-1}$ of dust (Burge et al. 1993) (Fig. 45.3). Many have settled from air after having penetrated from outdoors. Others are growing on organic material in the dust. Yeasts, Coelomycetes, and *Aureobasidium*, none of which are abundant in indoor air, usually dominate dust populations. The common outdoor fungi *Alternaria*, *Epicoccum*, and *Cladosporium herbarum* are also abundant in dust. Occasionally, xerophilic fungi [e.g., *Eurotium* (*Aspergillus*) *amstelodami*, *Wallemia sebi*] will find a suitable amplification environment in dust, and become dominant. However, when water activity in the dust becomes very high (>0.9), rapid growth of mesophilic or xerotolerant fungi may occur, leading to moldy odors and to drastic changes in dust populations. Often *Aspergillus* and *Penicillium* species will become dominant. Little data are available on changes over time in dust fungal populations.

Surfaces. Surface fungal growth may be the first sign of moisture problems in buildings. Fungal colonies may develop to a visible state in as little as one week (Pasanen et al. 1992). The appearance of surface fungal growth depends on the material on which the fungi are growing, the distribution of moisture in the material, and the type of fungi present. Fungal colonies usually start from a single spore and spread radially, forming circles of growth. Growth of fungi with melanin in the hyphal walls becomes visible soon after growth begins (e.g., *Alternaria*, *Cladosporium*). On the other hand, completely colorless fungi may never be visible (e.g., *Acremonium*). Many fungi have colorless mycelium but pigmented spores (e.g., *Stachybotrys*, *Penicillium*, *Aspergillus*). For these, growth becomes visible only when spores have become abundant.

Water. Standing and moving water also support growth of some kinds of fungi. Types and concentrations depend on nutrients, temperature, oxygen concentration, pH, and other factors. *Fusarium* and *Acremonium* species are frequently recovered from water reservoirs of humidifiers. Some yeastlike fungi (e.g., *Sporobolomyces*, *Rhodotorula*) may also multiply in water (Solomon 1974). Many fungi occupy surfaces in direct contact with the water,

FIGURE 45.3 Dust levels of several fungal taxa from samples collected across the United States and cultured on MEA agar.

especially those at the air/water interface. These wet surface populations, called *biofilms*, are complex communities of fungi, bacteria, protozoa, and algae embedded in a mucopolysaccharide matrix (Ford 1993).

Aerosolization from Indoor Sources. The presence of fungi on surfaces or in dust or water is often considered de facto evidence of human exposure to fungal aerosols, including spores and other particles containing fungal materials. This is certainly true for any volatile compounds produced by the fungi. However, the rates, time course, and nature of these releases are unknown, and the effects of ambient relative humidity and temperature on emission rates have not been studied (Sprecher and Hanssen 1982). Estimating the likelihood of exposure to spores and other particles (e.g., hyphal and substrate fragments) is more complex, and the presence of fungi does not necessarily mean that aerosols are being produced. On the other hand, the apparent absence of visible or measurable indoor growth does not ensure absence of exposure.

Dust. It is becoming increasingly common to collect dust samples as surrogates for human exposure to bioeffluents (Burge et al. 1993, Chew et al. 1996, Fischer et al. 1988, Gravesen and Skov 1988). This practice has been based (primarily) on the fact that dust-mite allergen levels appear to correlate with sensitization (Platts-Mills and deWeck 1989). However, the relationship between dust content and human exposure to allergens was not studied until the mid-1990s. Chew et al. (1996) report some preliminary analysis of data relating levels of fungi in house dust and in simultaneously collected air samples. These data indicate that concentrations of culturable fungi in dust do not relate to air levels, but that the presence of some specific fungi in dust is an indication of their presence in air. Further studies that include long-term air sampling are necessary to accurately document dust/air relationships for fungi.

Surfaces. Fungal spores are designed for airborne dispersal from surface growth. For many fungi, including most of the common ones that occupy indoor surfaces, air movement is sufficient to produce spore aerosols. Spore release from mature surface fungal colonies has been shown to vary with air speed and between different taxa, with the liberation of *Cladosporium* conidia requiring about twice the air speed as spores of *Penicillium* or *Aspergillus* (Pasanen et al. 1991). This may explain why *Cladosporium* is often the dominant fungus in dust while *Penicillium* or *Aspergillus* may dominate air samples. Similarly, *Cladosporium* may grow abundantly on surfaces (e.g., within the ventilation system) yet *Cladosporium* concentrations may not be elevated in air (Burge 1999). On the other hand, many fungi require more active disturbance for spore release (e.g., vibration of the substrate, mechanical abrasion, raindrop action). Fungi in this group often have sticky spore surfaces (e.g., *Fusarium*, *Acremonium*, *Stachybotrys*).

The Basidiomycetes actively discharge spores. Most basidiospores that are found in indoor air have penetrated from outdoors. However, a few are wood-rotting fungi that invade very wet wood in buildings and produce spore-releasing fruiting bodies (e.g., *Merulius lacrymans*).

It is possible that mycotoxins could be released from surfaces in forms other than intact spores. Demolition of fungus-contaminated material could result in the release of small particles of substrate material into which the toxins have diffused. However, to date, no reported studies document such releases.

Water Reservoirs as Sources for Fungal Aerosols. Most of the fungi that grow in standing water are released in droplets (Ingold 1971). These droplets may be formed from the action of water drops (or other things) that fall into the water (e.g., in drip pans), or purposeful mechanical action may be used to produce water aerosols that also include spores (e.g., spray humidifiers, fountains, misters). A few wet-spored fungi that may live either in standing water or along the edge are Basidiomycetes and have forcible discharge mechanisms so that agitation is not necessary (e.g., *Sporobolomyces*).

Nature of Indoor Fungal Aerosols. Indoor fungal aerosols are always complex mixtures. These mixtures contain many types of spores, fungal fragments, and particles of growth substrate. Other kinds of biological and nonbiological air pollutants may also be present in varying quantities. Possible synergism or antagonism within these complex mixtures, with respect to either sampling effects or human health has not been studied.

Fungal spores range in size from about 1 μm to more than 100 μm . Although people who study air pollution often consider “respirable” spores (e.g., those <10 μm) to be important, it should be noted that many allergens are borne on much larger particles (e.g., dust-mite and pollen allergens) and the so-called nonrespirable fraction must be included in fungal aerosol studies.

Many investigators have used culture plate impactors to assess airborne fungi, and, of these, the Andersen two-stage and six-stage samplers provide particle size information. However, very little data are available on the particle size distribution of indoor fungal aerosols. There are a limited amount of particle size data from one study in a hospital where third- and sixth-stage Andersen samples were incubated at 37°C for thermotolerant fungi (Solomon et al. 1978). A summary of these results is presented in Table 45.4. In a second study, fungal aerosols in a large building were collected with a two-stage Andersen sampler (unpublished data). These data are also presented in Table 45.4. Note that each stage collects nearly all particles larger than the d_{50} , while smaller particles pass on to the next stage or are lost.

Prevalence Patterns for Indoor-Source Fungal Aerosols. Asexual stages of Ascomycetes are among the most prevalent airborne fungi in indoor environments. Indoor source aerosols tend to be dominated by the readily released spores of *Aspergillus* and *Penicillium* species, although many different fungi have been dominant in individual localities.

TABLE 45.4 Cascade Impactor Data for Some Common Indoor Microorganisms

% recovery				
Taxon	Total recoveries	3rd stage	6th stage	<i>p</i>
Yeast/bacteria	873	83	17	0.01
<i>Aspergillus fumigatus</i>	123	16	84	0.01
<i>Aspergillus niger</i>	142	87	13	0.01
<i>Paecilomyces</i> sp.	80	30	70	0.05

Concentrations of both total and specific fungi in residential and office settings vary widely from study to study. Some of this variation is related to the types of indoor environments chosen for study (e.g., mechanically ventilated, air-conditioned, naturally ventilated), the climatic region in which the study was done, and variations in sample collection methods (e.g., type of sampler, analytic approach, conditions during sampling). This makes it impossible to compare actual concentrations among different studies, and is one of the reasons why even the most general numeric guidelines are not feasible at this time.

45.4 FUNGI AS AGENTS OF DISEASE

Fungi may act as agents of infection; they produce allergens, and are notorious for the production of toxic substances.

Infections

Some fungi can invade human tissue and cause infection. Of these, only a few can affect normal healthy people, and for these few, exposure sources are almost always outdoors. For example, histoplasmosis and coccidioidomycoses are fungal infectious diseases that result from outdoor exposures to *Histoplasma capsulatum* (a fungus that contaminates damp soil enriched with bird droppings) and *Coccidioides immitis* (a fungus that grows in desert soils).

Most fungal infections are “opportunistic” in that only people with compromised immune systems are susceptible (Rippon 1988). For these fungi, the greater the amount of immune system damage, the lower is the dose of the fungus required to cause infection. Thus, a relatively normal person (e.g., a heavy smoker with no other health problems) might contract cryptococcosis when heavily exposed while removing pigeon droppings harboring *Cryptococcus neoformans* from an attic, while a nonsmoking person might not. On the other hand, a transplant patient on immunosuppressive therapy might require only a few spores of the same fungus to initiate infection.

Aspergillus fumigatus is the best known of the opportunistic human pathogenic fungi. It is important to remember that intense exposure to *Aspergillus fumigatus* aerosols is common, especially in farmers and others who routinely handle composted material. While such exposure may lead to acute or even chronic allergic respiratory disease, it almost never leads to infection unless the exposed person is seriously immunocompromised. Such people should avoid all fungal exposure, including that occurring outdoors.

Hypersensitivity Diseases

Airborne fungal proteins are commonly implicated as agents of hypersensitivity diseases (hayfever, asthma, hypersensitivity pneumonitis) (Lehrer et al. 1983, Lopez and Salvaggio 1985, Lopez and Salvaggio 1987, Salvaggio 1987, Salvaggio and Aukrust 1981). The fungal components that lead to allergic disease were not studied until the 1990s. The allergens of fungi are probably digestive enzymes that are released as the spore germinates. Other spore components (of unknown function) may also be allergenic. Only very few fungal allergens (out of possibly hundreds of thousands) have been characterized and named: (e.g., *Alt a 1*, *Cla h 1*, and *Asp f 1* from *Alternaria alternata*, *Cladosporium herbarum*, and *Aspergillus fumigatus*, respectively).

Hayfever and Asthma. The rate of positive skin tests (a measure of sensitivity) to fungal allergens ranges from about 10 percent to in excess of 60 percent of subjects tested with the rate depending on the populations tested, the allergen extracts used, and the method of testing (Pope et al. 1993). About 40 percent of inner-city asthmatic children tested had a positive skin test to the only fungal extracts used (*Alternaria* and *Penicillium*) (Eggleston et al. 1998). Immediate skin sensitivity to *Cladosporium* or *Alternaria* extracts was reported as more prevalent in damp dwellings (9.3 vs. 3.9 percent), and related to the presence of current asthma [odds ratio (OR) = 3.4; 95 percent confidence interval (CI) = 1.4 to 8.5] (Norback et al. 1999). In addition, evidence is increasing that sensitivity to fungi and subsequent exposure is a risk for dying of asthma (Targonski et al. 1995). Regional differences in skin test responses to fungal allergens have not been specifically reported.

Allergic symptoms related to indoor fungal aerosols have been reported frequently (e.g., Gallup et al. 1987, Kozak et al. 1980, Roby and Sneller 1979, Sneller and Roby 1979, Tarlo et al. 1988), and there is epidemiologic evidence that exposure to culturable airborne fungi is a risk factor for symptoms of asthma. In general, symptoms tend to be related to concentrations (in air or dust) of specific fungi rather than total fungal concentrations and to actual fungal measurements rather than observed or reported dampness (Garrett et al. 1998).

Many studies have used reported dampness as a surrogate for exposure to fungi. In homes of Chicago Head Start children, self-reported dampness or mold growth in the previous year was associated with self-reported diagnosis of asthma (Slezak et al. 1998). Williamson et al. (1997) report significant differences between current and previously reported dampness in homes of asthmatic and control subjects. Dampness and asthma were also associated in a study reported by Yazicioglu et al. (1998) (OR = 2.61, 95 percent CI = 1.13 to 6.81). Dampness has also been shown to be independent of dust-mite allergen as a predictor for asthma (Nicolai et al. 1998).

Finally, symptoms of respiratory disease, including those of asthma, have been studied in relation to airborne levels of specific fungi in homes (Flannigan et al. 1990, Strachan et al. 1990, Su et al. 1992a).

A number of studies have documented that conditions known to promote fungal growth in homes (i.e., dampness, water damage) are closely related to nonspecific respiratory symptoms in resident children (Brunekreef et al. 1989, Dales et al. 1990, Martin et al. 1987). In these studies, it is not clear that the symptoms are related to asthma, but may actually be nonspecific inflammation related to exposure to fungi (Larsen et al. 1996).

Allergic Fungal Sinusitis. Some people with allergies develop fungal colonies in their sinuses. This colonization results in further nasal inflammation and secretions, and the sinuses become filled with a mass of fungal hyphae mixed with very thick secretions (Morpeth et al. 1996). The role of exposure to fungi is not clear in this disease (Chrzanowski et al. 1997). Obviously, fungal spores enter the nose and sinuses of everyone

who breathes, and the types of fungi that usually cause this disease are relatively common in outdoor air. In spite of this, only a small fraction of allergic individuals develop the disease. The fact that the disease appears to be more common in warm humid climates where the causative fungi are most abundant argues for some role for intensity of exposure. However, other factors than exposure are most likely involved as well.

Hypersensitivity Pneumonitis (Synonym: Allergic Alveolitis). *Hypersensitivity pneumonitis* is another type of disease that may result from exposure to fungal allergens. Generally, for this disease to result, intense exposures are necessary over a relatively short period of time. Many cases are related to exposure to thermophilic bacteria (i.e., actinomycetes) (Fink et al. 1971). However, cases involving *Aspergillus* (Vincken and Roels 1984), *Penicillium* (Assendelft et al. 1985), *Alternaria* (Dykewicz et al. 1988), and a few other fungi have been reported. Most outbreaks have been associated with occupational and composting exposures (Brown et al. 1995). However, *Penicillium* growing in the ventilation system of a large building was the culprit in one case. The disease may be seriously underdiagnosed. When fever, chills, chest tightness, and other flulike symptoms that are associated with a specific environment are observed, hypersensitivity pneumonitis is one disease to consider.

Toxicoses

It is clear that not all dampness-related illness is associated with exposure to allergens. Possible associations between nonspecific respiratory symptoms and dampness have been discussed above. Inflammatory agents produced by fungi, including glucans, mycotoxins, and volatile organic compounds, may mediate some of these effects. These compounds may also play a role in the symptoms associated with allergic disease. Symptoms characteristic of allergic rhinitis and asthma result from inflammation, at least in part. β -Glucans and many mycotoxins, as well as many volatile products of fungal metabolism, are known to act as irritants, and exposure could lead to mucous membrane inflammation. Exposure to indoor fungi may also increase the risk of (nonfungal) respiratory infections (Pirhonen et al. 1996).

Glucans. The glucans are present in most common fungi with the exception of the Zygomycetes (Albersheim and Valent 1978). These compounds have been shown (under experimental conditions) to cause inflammation. Extrapolating from these laboratory studies, some investigators have hypothesized that dustborne glucans contribute to indoor air problems such as are described as the sick building syndrome (Rylander et al. 1989, 1998). The macromolecules reported by Gravesen and Skov (1988) might also be glucans. However, it is difficult to defend this hypothesis in view of the mass of fungal material (the majority containing glucans) that is commonly present in both outdoor and indoor air.

Mycotoxins. These compounds could become abundant in indoor environments if source fungi colonize indoor substrates and the resulting aerosols are confined. Table 45.2, which briefly reviews the classes of common mycotoxins, also lists some of their known health effects. Many of the fungi listed in Table 45.2 are commonly found in building interiors. However, to date, no published data unequivocally document a relationship between airborne mycotoxin and disease, except in industrial/farming environments where very high levels can be present (Baxter et al. 1981, Sorenson 1990, Sorenson et al. 1984). Croft et al. (1986) provide the most convincing case study, in which massive exposure to *Stachybotrys chartarum* (and probably other fungi) was investigated as a cause for several symptoms in occupants of a home. More recently, investigators along with physicians reported an out-

break of hemosiderosis in infants. Their principal hypothesis was that exposure to *Stachybotrys chartarum* spores with their associated mycotoxins was the cause (Etzel et al. 1998, Montana et al. 1997). However, more recently, the CDC sought outside peer review for these studies and determined that the relationship was weak and other causes were at least as likely (Anonymous 2000). Studies involving exposures to *Stachybotrys chartarum* in laboratory animals have demonstrated that a large number of spores must reach the lower airways to result in symptoms, and that such exposures are unlikely (Burge 1999, Rao et al. 2000). Current knowledge about the role of *S. chartarum* in disease is reviewed by Sudakin (2000). On the other hand, it is often assumed that common fungi that are not clearly recognized as “toxigenic” are safe (i.e., do not release toxic substances). In view of the very broad range of common fungi that have been shown to produce mycotoxins and the important role of fungal exposure in allergic disease, this seems to be an unwarranted assumption.

Volatile Organic Compounds. In addition to glucans and mycotoxins, the VOCs that fungi emit could have toxic effects when they accumulate in indoor environments. Rates of emission, concentrations in indoor environments, and dose-response relationships are unknown for these compounds. It is clear that odiferous fungal VOCs lead to complaints. The connection between fungal VOCs and health effects (including mucous membrane irritation and other building-related symptoms) in indoor environments is ambiguous, although the possibility that they contribute to poor indoor air quality is gaining acceptance (Mattheis and Roberts 1992, Wilkins and Larsen 1995).

45.5 METHODS FOR ASSESSING THE FUNGAL STATUS OF BUILDINGS

Assessment of the fungal status of buildings may involve questioning occupants, visual examination of building components, and collecting and analyzing samples. Each of these approaches yields a different kind of information. In the questionnaire approach, untrained observers report on past factors that might indicate fungal growth (e.g., floods, leaks, periods of elevated humidity, extreme crowding, no or low rates of fresh air ventilation). Occupants might also report sites where they consider fungi are growing, as well as the presence of odors. Questioning occupants may indicate the possibility of fungal contamination, and reveal why the complaints occurred. Walkthroughs allow trained investigators to look for current conditions indicative of fungal growth and for the growth itself. Environmental measurements for CO₂, relative humidity, and temperature might be made as indicators of ventilation and overall environmental conditions. This step can confirm the presence of fungal growth or conditions likely to lead to such growth. Note that observation of growth is not proof of exposure to hazardous agents, but probably would prompt recommendations for remediation. Trained investigators may collect materials that appear moldy for verification, and materials that might have hidden fungal growth (e.g., dust, water). These investigators also could perform air sampling that, if properly done, could document exposure.

Walkthrough Observations

The fastest, easiest and often the most reliable approach to evaluating buildings for fungal growth is to visually examine the building and pay attention to odors. Walkthrough observations fall into four categories: (1) searching for conditions that lead to dampness or water intrusion, (2) searching for sources commonly associated with fungal growth, (3) searching

for visible evidence of fungal growth, and (4) noting odors. Such inspections must be thorough, consistent, and based on experience and knowledge of where fungi grow, what conditions lead to fungal growth, and what fungal growth looks and smells like.

Consistency is obtained by developing checklists that are used for every new investigation. An example of such a checklist is presented in Table 45.5. This type of table allows relative classification of building conditions, where each condition is ranked between 1 (excellent) and 5 (poor). Each site is also described, as is any visible growth that is seen. The list is designed for use both in large buildings, and in single residences. One could easily separate the two to create two shorter lists. Table 45.6 offers some hints for evaluating the potential for fungal growth using sensory observation.

TABLE 45.5 Checklist for Visual Observation of a Building

Conditions		Amounts of microbial growth	
0 = absent		0 = absent	
1 = excellent		1 = very little (a few spots)	
2 = good		2 = some (~25% of surface)	
3 = fair		3 = moderate (~50% of surface)	
4 = poor		4 = extensive (~75% of surface)	
5 = terrible		5 = extreme (all of surface)	
Site	Conditions	Sample?	
Landscaping	Design (appropriate for limiting water intrusion and dampness)		
	Maintenance		
	Comments:		
Walls	Type (describe):		
	Condition		
Windows	Type (describe):		
	Condition		
Roof	Flat (1), pitched (2)		
	Type (describe):		
Attic	Condition		
	Type (describe):		
Fans	Condition of fans (mechanical)		
	Visible fungal growth on fans?		

TABLE 45.5 Checklist for Visual Observation of a Building (*Continued*)

Site	Conditions	Sample?
Filtration	Type of filtration (describe):	
	Loading (approximate) of filters	
	Visible fungal growth on filters	
	Physical condition of filters	
Chillers	Condition of chiller(s) (cooling coils)	
	Visible fungal growth on coils	
	Describe fungal growth:	
	Condition of drip pans	
	Perceivable microbial growth in drip pans	
	Describe microbial growth:	
Humidifiers (central)	Condition of central humidifier	
	Perceivable microbial growth in humidifier	
	Describe microbial growth:	
Ductwork	Type of ductwork (describe):	
	Condition of ductwork (physical)	
	Visible fungal growth on ductwork surfaces	
	Describe fungal growth:	
Plenum	Condition of plenum if present	
	Condition of air handlers in the plenum	
	Visible microbial growth in plenum air handlers	
	Describe microbial growth:	
	Condition of humidifier(s) in plenum	
	Visible microbial growth in plenum humidifiers?	
	Describe microbial growth:	
Diffusers	Condition of diffuser linings	
	Visible growth on diffuser linings	
	Describe microbial growth:	
	Visible discoloration around diffusers?	
Occupied space Ceiling	Type of ceiling (describe):	

TABLE 45.5 Checklist for Visual Observation of a Building (*Continued*)

Site	Conditions	Sample?
	Condition of ceiling	
	Visible water damage to ceiling	
	Visible fungal growth on occupied space side of ceiling?	
	Visible fungal growth on back of ceiling?	
	Describe fungal growth:	
Windows	Condition of window frames	
	Visible water damage to windows or frames	
	Visible fungal growth on windows or frames	
	Describe fungal growth:	
Walls	Type of wall and surface (describe):	
	Visible water damage to walls	
	Visible fungal growth on walls	
	Describe fungal growth:	
Flooring	Type of flooring (describe):	
	Condition of flooring	
	Visible fungal growth on flooring	
	Describe fungal growth:	
Furniture	Dustiness of hard surfaces	
	Condition of furniture	
	Water damage to furniture	
	Visible fungal growth on furniture	
	Describe fungal growth:	
Humidifiers	Console humidifiers (describe type and number):	
	Condition of humidifiers	
	Perceivable microbial growth in humidifiers

Other sources	Condition of any aquariums	
	Condition of any house plants	
	Any odors	
	Musty, fungal, or microbial odors	

TABLE 45.5 Checklist for Visual Observation of a Building (*Continued*)

Site	Conditions	Sample?
	Describe odors:	
Basement	Type of basement (describe)	
	Condition of basement	
	Evidence of water intrusion	
	Visible fungal growth	
	Describe fungal growth:	
	Odors	
	Describe odors:	

Correlations have been made between observed dampness, odors, and culturable spore levels in homes (Dales et al. 1997, Fischer et al. 1988, Grant et al. 1989, Li and Kendrick 1995, Platt et al. 1989). Other correlates with fungal levels include the presence of pets, having an unfinished basement, lack of central air conditioning, and decreased use of air conditioning (Dekoster and Thorne 1995).

Sampling

Collection of samples for analysis is often a part of investigations of fungal problems in buildings. However, samples should never be collected without first considering the reasons for sampling, what will be done with the data, and how analysis will be performed. Table 45.7 presents four major reasons for fungal sampling, and examples of the kinds of hypotheses that are tested, data requirements, and how data can be interpreted. Several organizations have published guidelines for the development of sampling strategies. The most recent of these is the ACGIH publication on assessment and control of bioaerosols (ACGIH 1999).

Sampling Strategy. *Sampling strategy* involves developing hypotheses, and then designing a plan that will allow testing of the hypotheses. Figure 45.4 is a flowchart describing the processes involved in developing a sampling strategy beginning with the nature of complaints. Bold type indicates given information. Italics indicate hypotheses; bold-bordered squares present components of the sampling strategy.

Given data can be derived from the initial call, from questioning occupants either casually or formally using a questionnaire, or from data derived from an epidemiologic study. In the latter case, for example, the nature of the complaint may be asthma, and the distribution of complaints one of the study outcomes. Thus, sites would be in homes of potentially asthmatic subjects, and the remainder of the flow chart could be followed within each home. An example of how the chart might be used in a large building outbreak of HP is presented in Table 45.8.

TABLE 45.6 Some Hints for Detecting Fungal Sources by Sensory Observation

Dampness/water	Fungal sources	Visible fungi	Odors
Shrubs and trees close to foundation	Dead plant material close to building	Circular spots of discoloration	Mushroom odors
Building in damp places and inadequate drainage	Lots of dust, especially in high-humidity spaces	Blue “dust” on filters or brownish green dust on insulation	Cheesy odors (like blue cheese, camembert)
Gaps in roof and/or walls	Presence of dead organic material (hay, straw, wood)	Black, brown, greenish, blue, pink, yellow mixes of discoloration on surfaces	Bread- or beerlike odors in the absence of any baking or beer or wine making
Crawlspaces	Root cellars	Tiny blackish green dots on fabric	“Musty” odors
Inadequate ventilation	Humidifiers, fish tanks with bubblers	Any powdery spots on fruits or vegetables	Fresh soil-like odors indoors
Inadequate insulation			
Showers, humidifiers, cooking, fountains, fish tanks, large numbers of plants, etc.			

TABLE 45.7 Reasons for Sampling

Reason for sampling	Hypotheses	Data requirements	Data interpretation
Confirming the identity of visible fungal growth	This child is having severe asthma attacks at school that are caused by mold growing on her classroom wall	Genus and species of the fungus (fungi); skin test data for the child	Relate the kinds of fungi recovered to positive skin tests in the child; if fungi and skin tests match, an association is likely—if not, need further study
Confirming release of aerosols from reservoirs	Organisms growing on this wall are forming aerosols	Colony or spore identifications from samples of the reservoir material Colony or spore identifications from air samples with no disturbance Control colony or spore counts from environment with no wall growth	Same organism is present on the wall and in the air, and not in the control environment
	Organisms growing on this wall may form aerosols under some conditions of disturbance	Colony or spore identifications from samples of the reservoir material Colony or spore identifications from air samples with no disturbance Colony or spore identifications from air with logical disturbance of the wall	Same organism is present on the wall and in the air, and concentrations increase when the wall is disturbed

Evaluating suspected reservoirs for fungal growth	This humidifier contains viable fungi	Colony observation from culture of the humidifier fluid	Yes or no
	This humidifier contains <i>Fusarium moniliforme</i>	Colony identifications from culture of humidifier fluid	Yes or no
	This humidifier contains high levels of <i>Sporobolomyces</i>	Colony counts and identification from culture of humidifier fluid	<i>Sporobolomyces</i> is/is not present Counts are higher than some specific guideline or standard
	Clearance sampling after removing flooded moldy carpet (with no background data from before the flood)	Colony or spore identifications and counts from air samples before the carpet is removed, during removal, and after renovation is complete Colony or spore identifications and counts from surface dust (e.g., from shelves) before, during, and after renovation	Samples during removal have higher concentrations of specific fungi than before removal Airborne and surface dust concentrations of specific fungi are higher during removal and lower after carpet removal than before

FIGURE 45.4 Flowchart describing processes for developing sampling strategies.

It is essential that the expected agents and the best approach for their analysis be considered before choosing a sample collector. Where several analytic approaches are available, expected concentrations and required limits of detection must be carefully considered. If only one approach is available, then thought must be given to whether the approach will allow testing of your hypothesis. If not, then there is no point in collecting the samples.

Generally the type of collector depends on equipment available in an investigator's lab. For most fungal agents, most common collectors can be used with suitable modification. The principal considerations are the particle sizes in the aerosol, the nature of the agents so that the collection process doesn't damage the sample, and the physical nature of the sample required (e.g., culturable spores, particulate or dissolved antigens or toxins). The example in Table 45.8 uses a spore trap rather than a cultural impactor because (1) spores need not be alive to have an effect and (2) the available culture plate impactors would be overloaded if conditions were appropriate for HP.

Probably the most difficult step in this process is estimating the expected concentrations and variability in space and time, and establishing required limits of detection. A mass of background data is currently being collected for some environments, but this database is currently inadequate to guide inexperienced investigators. Estimates of variability are even more difficult to make, and, again, experience may be the only real source for this information. Many epidemiologic studies (as well as investigators of individual buildings) use data from only one sampling event, and often, only one or two very brief sample collection periods (i.e., 1 to 5 min) to characterize indoor aerosols. Figure 45.5 documents variability for two homes in levels of *Penicillium* that presumably were derived from indoor sources. In this unpublished study, patterns for other homes were entirely different, indicating that (as many have suspected) short-term air samples are rarely representative of airborne exposure to the fungi. A study of aerosols in a small bakery further demonstrates this extreme variability in fungal concentrations and gives some indication of the number of samples necessary to accurately document changing fungal levels over time (Levy et al. 1999). Buttner and Stetzenbach (1993) report experimental data on the strong effects of human activity on fungal aerosols, and Lehtonen et al. (1993) confirm this source of variability in homes.

At any rate, single samples are almost never appropriate, and for nearly all studies, duplicates at two time periods and at least two sites will be required (a total of eight samples). Since, for most studies, outdoors must be one of the sites, this protocol provides for only one sampling site indoors, which is rarely sufficient. It is helpful to construct a chart

TABLE 45.8 Development of Air Sampling Protocol for Outbreak of Hypersensitivity Pneumonitis

Nature of complaints	▪ Chest tightness, fever, chills, associated with building occupancy ▪ Clinical testing —→ Hypersensitivity pneumonitis
Distribution of complaints	▪ 30 people in eight offices; >100 people in >30 offices with no complaints ▪ Collect samples in eight complaint and eight control offices
Agents	▪ Bioaerosols associated with HP are actinomycetes, small-spored fungi, and endotoxin
Expected variability	▪ High; logarithmic distribution ▪ Instantaneous: Replicates (≥ 2/site/time) ▪ Over time: Sampling events: ≥ 3/site
Expected concentrations	▪ High: need upper LOD $\geq 10,000$ spores/m³
Analytical method	▪ No need for viability data: spore counts or antigen assays appropriate ▪ Spore counts only approach currently available; could be analyzed on site ▪ Microscopy; sampling handling easy
Type of collector	▪ Spore traps have high cutpoints, easier to use, or use ▪ Filters collect small particles, harder to analyze
Volume of air/sample	▪ ~28 liters (1 cubic foot)
Minimum # air samples	▪ $(8 + 8) * 2 * 3 = 16 * 6 = 96$
Interpretation: hypothesis supported if:	▪ Very small spores typical of fungi or actinomycetes consistently present (>50% of samples) in symptomatic offices; less prevalent in control offices ▪ Same spore type present in at least one symptomatic sample at concentrations $\geq 10,000$ spores/m³; no concentration this high in controls
Conclusions if hypothesis supported	▪ Symptoms may be related to small spore aerosol
Next steps	▪ Culture sample to identify organism ▪ Look for reservoir(s) visually, and using reservoir sampling ▪ Possibly do precipitin or ELISA tests to confirm connection between exposure and disease

FIGURE 45.5 Diurnal variation in *Penicillium* concentrations outdoors and in two Topeka, KS houses averaged over one week (Burkard recording spore trap samples).

such as that in Table 45.9 during strategy development, so that you are continuously aware of the magnitude of the task ahead, and the possible expense. This table doesn't account for overhead, dealing with clients on the phone, office help, or other factors.

Data Interpretation. Data interpretation is often the most difficult step in an investigation. If there are clear and obvious conditions that are likely to lead to the reported complaints, the situation is relatively easy, although it is never safe to say in an unqualified way that this agent or condition "caused" the complaints. There are too many possible causes for all complaints to make this possible. Likewise, one can never really say that this agent is not causing the complaints because sampling protocols are never good enough to prove the negative case. For example, in an experimental study, counts of *Penicillium* in air were relatively low despite moderate to heavy surface contamination (Buttner and Stetzenbach 1993).

In between is the large gray area where we all wish there were clear guidelines. Many have been reported (Rao et al. 1996), but in practice, none of them can be defended without extensive qualification. The ability to make the appropriate qualifications comes only with experience, and even the most experienced of investigators often fail. The following guidelines are the author's own, and are presented as a starting place. They are continually evolving and are *not* to be considered "official" in any way. These guidelines also do not imply any health outcome. The presence of even relatively concentrated fungal aerosols may not lead to any symptoms or disease. Likewise, the absence of these conditions does

TABLE 45.9 Guidelines for Charting the Practicalities of Sampling

Sites	Replicates	Time periods	# Samples, <i>N</i>	Cost, \$*
2	2	2	8	800
3	2	2	12	1200
4	2	3	24	2000
4	3	3	36	2600
18	2	4	144	9000

*\$50/sample for analysis, \$100/h investigator time.

not imply the absence of disease risk, only that such risk is less likely than if the conditions were not present. Note that the air guidelines require at least 16 samples for even the smallest task: duplicates at two sites and four time periods.

Data that may indicate that excessive fungal growth is present are

1. Visible fungal colonies in the space that are obvious with a casual inspection
2. Strong, consistently present fungal (moldy) odors
3. Dust cultures with concentrations of total fungi above the 75th percentile for the type of environment, and with a single fungus accounting for more than half the total count
4. Air samples with total fungal concentrations consistently (i.e., measured on at least four different occasions with replicates for each site—at least eight samples/site)
 - a. Greater than 200 colony-forming units(cfu)/m³ of air or 500 spores/m³
 - b. At least one order of magnitude (i.e., 10 times) higher than a noncomplaint control environment with similar ventilation characteristics sampled at the same time
 - c. A single fungus accounting for at least half of the total in the complaint environment
5. Air samples where concentrations of specific fungi consistently (measured on at least four occasions with replicates at each site—at least eight samples/site)
 - a. Exceeding those outdoors by at least an order of magnitude (10×)
 - b. With both the indoor and outdoor samples collected simultaneously and representing the same total quantity of air (e.g., if eight 1-min samples are collected indoors, then eight 1-min samples also must be collected outdoors).

45.6 CONTROLLING FUNGAL EXPOSURE IN BUILDINGS

Exposure to fungal agents in buildings results from penetration of the ever-present outdoor aerosol either directly or on the clothing of building occupants, and from aerosolization from indoor sources. Building occupants could also carry and release fungi from their homes or from outdoor activities such as raking leaves, mowing, and composting activities (Brown et al. 1995). These pathways for exposure require different approaches for control. Direct penetration of aerosols is best prevented by design, and by filtration, and exposure from this source can be reduced using air-cleaning techniques. Aerosols released from occupants are difficult to control directly, but clean-air ventilation should provide dilution, and air cleaning may help to lower concentrations. Exposure to aerosols from indoor sources should be addressed primarily by source control.

It should be noted that the benefits of fungal control with respect to improvement in symptoms has not been studied systematically (Peat et al. 1998), although many case studies document improvement in symptoms following extensive remediation.

Preventing Exposure to Aerosols

As discussed above, outdoor fungal aerosol particles are relatively large (1 to 100 μm , average $\sim 5 \mu\text{m}$). Fungal particles behave physically in the same way as any other particle of similar aerodynamic properties, and particles in this size range are readily trapped by appropriately efficient filters, impact on surfaces in ventilation systems, and settle relatively quickly in still air. Air in a closed building with mechanical ventilation is likely to have only very low levels of outdoor fungal aerosols (Burge 1999). Note that, in spite of these effects, indoor aerosols in clean buildings do parallel those outdoors, but at a low level. In naturally ventilated houses, even with window air conditioners, indoor levels are likely to be close to those outdoors. Whether most of the particle removal in mechanically ventilated buildings is from filtration or from impaction on surfaces in the ventilation system is not clear. Even buildings with inefficient filters appear to be relatively free of outdoor aerosols. Clearly, however, efficient filtration does trap particles in this size range, and should serve to prevent buildup of particles within the ventilation system.

Although rarely considered, another source for outdoor aerosols is carriage by building occupants. In environments where maintaining extremely low fungal concentrations is essential, a protocol could be designed where occupants and visitors either don garments that prevent release of spores from clothing and hair or are “cleaned” of such particles.

Air cleaning within the occupied space is another approach for preventing outdoor aerosol exposure, especially when efficient filtration has already been used as a primary control approach, and when no indoor sources are present. Air cleaners are unlikely to significantly reduce exposure, for example, during the growing season in a house with all the windows open (Fox 1994), and clinical studies seldom indicate improvements in patient’s symptoms with the use of air cleaners (Nelson and Skufca 1991).

Source Control

Source control involves removing fungi and possibly removing the substrate on which the fungi were growing. Source control is possible only if the conditions that allowed the growth to occur are discovered and corrected. Thus, the leaky roof must be fixed, the floodwaters removed, the humidity controlled, condensation prevented, and so on. Note that these all involve limiting access to water (Lstiburek and Carmody 1993). Once these conditions are corrected, one can begin removing growth that has occurred. Four categories of sources can be considered:

1. Growth on the surface of impervious materials
2. Growth in dust
3. Growth on permeable materials where the materials themselves have not been damaged
4. Growth on permeable materials where the material has been damaged

Growth on impervious surfaces (e.g., metals, enameled walls, varnished or heavily waxed wood, vinyl, ceramic materials) can be removed using detergents and water. Generally, biocides are not necessary since viability is rarely a condition required for health effects, and (assuming that you have changed underlying conditions) the remaining spores should have inadequate water on which to grow. On hard materials such as bathroom tile, where water is inevitable, long-lasting biocides may delay, but not prevent, return of the growth.

As mentioned above, dust always contains some fungi. If growth has occurred in surface dust (which often occurs in very warm, damp environments), the dust along with the fungi can be removed with detergent and water (washable surfaces), a damp cloth (surfaces that won't be damaged by such treatment), or using furniture polish or oil (on wood). If the dust is on or in porous materials (e.g., carpet, filter material, books), the dust and spores can be removed with a vacuum with a good filter (one that can trap 1 μm particles). In some cases, fungi grow into permeable materials without causing significant damage (e.g., fiberglass insulation and filter material). In these cases one has two choices: either remove the surface growth or (if necessary) use an encapsulant to ensure that residual material will not be released, or remove the substrate completely. Which approach to take depends on the extent of growth, the nature of the complaints, and the chances of the growth recurring. In cases where there is a small chance that regrowth might occur, biocides that have residual activity could be used. These are far from foolproof, and if growth does occur again and the water source cannot be eliminated, removal will be necessary.

Whenever the colonized material has been damaged (i.e., the properties necessary for its use have changed), the material must be removed and/or discarded. Moldy clothing (cotton, wool, leather) can only rarely be adequately cleaned. Ceiling tiles, wallpapers, cotton, wool, linen, or jute carpeting or furniture can rarely be rescued. Gypsum board that is supporting extensive surface growth and cellulose insulation also must be removed. Concentrations of fungal aerosols increase during removal activities, and such removals should include measures to contain the aerosols (Rautiala et al. 1996). Respiratory protection is strongly advised during removal.

Fungus-contaminated materials can be deposited in regular landfills. Remember that it is these same fungi that naturally degrade materials in such places.

Prevention

Prevention of fungal exposures in buildings requires that buildings be purposely designed and operated to minimize available moisture (Lstiburek and Carmody 1993). Providing adequate outdoor air ventilation (filtered) throughout the year will help keep the indoor environment dry in winter and may dilute indoor aerosols and reduce exposure. One study has reported differences in bronchial obstruction in occupants of low- and high-ventilation-rate environments with respect to dampness indicators. In the low-air-exchange space, the likelihood of bronchial obstruction was greater than in the high-air-exchange group (Oie et al. 1999).

In some cases, dehumidification is necessary to keep water content of materials low enough to prevent fungal growth (e.g., in basements, and in very humid environments). Careful consideration of the position of any barrier to moisture transport in and out of a building is another requirement. Finally, persistent condensation must be controlled.

To prevent the growth of fungi and other microorganisms on filters and other porous materials, biocidal impregnants have been developed that are designed to kill cells that contact the filter material. Most cells (including fungal spores) that come into direct contact with recommended biocides are probably damaged or killed. However, some experimental evidence indicates that currently available immobilized biocides will not kill *Mycobacterium tuberculosis* that impacts on treated filter fibers (Ko et al. 1998). There remain several other practical questions with regard to their use. First, it should be emphasized that spores (and other microorganisms) that pass through filters are not affected by the biocide. Direct contact with filter fibers is essential for the biocide to work. Thus, the biocides act only to prevent growth on the filter (or other material). Another significant question is whether the biocide is effective once a dust cake has built up, and how much dust does it take to block the biocide.

CHAPTER 46

TOXIGENIC FUNGI IN THE INDOOR ENVIRONMENT

Carol Y. Rao, Sc.D.

*Division of Respiratory Disease Studies, Field Studies Branch
National Institute for Occupational Safety and Health
Morgantown, West Virginia*

46.1 INTRODUCTION

Intense scientific and public scrutiny has focused on hazards associated with exposure to fungi, especially in enclosed environments. Fungi are well known as agents of infection (e.g., histoplasmosis, aspergillosis), allergic disease (e.g., asthma, hypersensitivity pneumonitis), and toxicoses (e.g., tremorgenicity, aflatoxicoses, ergotism) (Baxter et al. 1981, Brown et al. 1998, Burge 1985, Dvorackova 1976, Garrett et al. 1998, Juchet et al. 1998, Land et al. 1987, Robertson et al. 1987). Fungi also produce malodorous volatile organic compounds that may cause physical irritation (Pasanen et al. 1998, Walinder et al. 1998). The fungal cell wall is composed primarily of chitin fibrils embedded in a matrix of β -(1 $\rightarrow$ 3)-D-glucans. Glucan exposure may exacerbate the infectious, allergic, and toxic reactions to fungi (Burge 1989, Flannigan et al. 1991, Rylander et al. 1992). Exposure to mycotoxins in indoor air has become of particular concern because of the potential for both acute and chronic health effects (Flannigan 1987, Hendry and Cole 1993, Jarvis 1990, Miller et al. 1988, Morey 1993, Sorenson 1990, Tobin et al. 1987). The potent health effects elicited in laboratory animals and information from anecdotal case studies have fueled the anxiety. This chapter discusses mycotoxins in general and the fungal species *Stachybotrys chartarum* (syn. *S. atra*) in particular. Although other toxin-pro-

ducing species of fungi can also be found in the indoor environment (Tobin et al. 1987), *S. chartarum* has been the most public, because of the severity of the reported symptoms and the population affected.

46.2 MYCOTOXINS

Throughout history, mycotoxins have played an important role in human and animal health. With its distinctive and grisly symptoms (gangrene, limbs falling off, convulsions, and death), *ergotism*, also known as “Saint Anthony’s fire,” has been documented as far back as 430 B.C. Ergotism is caused by ingestion of rye products contaminated with a fungus (*Claviceps purpurea*) that produces *ergot alkaloids*, potent mycotoxins affecting the smooth muscles and the central nervous system. However, the pivotal event in the recognition of mycotoxins as a serious cause of animal and human disease occurred in the 1960s with an outbreak of “turkey X disease” in England. The common factor was that affected livestock had been fed Brazilian peanut meal which had been highly contaminated with the fungus *Aspergillus flavus*. Using modern analytic methods, scientists isolated a series of toxins from the meal, which were subsequently named *aflatoxins*. Aflatoxins were shown to be acutely toxic and highly carcinogenic to laboratory animals.

Mycotoxins are secondary metabolites that are derived from a few precursors formed during metabolism (Betina 1989, Jarvis 1989). They have no molecular features in common, and chemical structures range from the simple monilliformin ($C_4H_2O_3$) to complex polypeptides with molecular weights over 2000 daltons (Bu’lock 1980). Mycotoxins are not volatile (Hendry and Cole 1993, Pasanen et al. 1993). It is commonly believed that not all mycotoxins have been identified yet, since more are being discovered as analytic methods are developed.

Mycotoxins are natural products usually produced in response to environmental stimuli only by specific groups of organisms and only during part of their life cycle (Kendrick 1992). The toxins apparently are not necessary for fungal growth, and their exact function has not been clearly established (Bennett and Deutsch 1985, Demain 1989, Lillehoj 1982). They may play a role in regulating competition with other organisms since many mycotoxins inhibit the growth of surrounding microorganisms in culture (Bean and MacFall 1982, Butt and Ghaffar 1972, Janzen 1977, Northolt and Bullerman 1982, Wicklow 1981, Williams et al. 1989).

Particular mycotoxins can be produced by more than one fungal species, or even fungal genus, and conversely, a fungal species typically can produce more than one mycotoxin (Table 46.1). Often, a mycotoxin can elicit more than one type of toxic effect (e.g., antiviral, antibacterial, antifungal, immunosuppressive, carcinogenic, mutagenic, cytotoxic, teratogenic, and neurotoxic), and the degree of toxicity (relative potency) varies greatly.

46.3 EXPOSURE ASSESSMENT

Production of Mycotoxins in the Indoor Environment

Some species of fungi can produce mycotoxins on various building substrates (Larsen and Frisvad 1994, Nielsen et al. 1998, Nikulin et al. 1994). Although the majority of individual strains of toxigenic fungal species are genetically capable of toxin production, factors controlling the expression of this potential are not well understood (Lillehoj 1982, Tantaoui-Elaraki

TABLE 46.1 Some Mycotoxins and Associated Effects, Fungal Species, and Occurrences

Mycotoxin	Health effects*	Some toxin-producing fungal species	Known occurrences
Aflatoxins	Carcinogenic, mutagenic, acute toxicity	<i>Aspergillus flavus</i> , <i>A. parasiticus</i>	Peanuts, beans, milk, grains
Citrinin	Nephrotoxicity	<i>Penicillium fellutanum</i> , <i>P. viridicatum</i> , <i>P. citrinum</i>	Rice
Ergot alkaloids	Gangrenous, convulsive, hallucinogenic	<i>Claviceps purpurea</i> , <i>C. paspali</i> , <i>C. fusiformis</i>	Rye
Fumonisin	Carcinogenic	<i>Fusarium moniliforme</i>	Corn
Ochratoxins	Nephrotoxicity, carcinogen	<i>Aspergillus ochraceus</i> , <i>Penicillium viridicatum</i>	Barley, oats, rice, coffee
Patulin	Antibacterial, carcinogenic, mutagenic, neurotoxicity	<i>Penicillium expansum</i> , <i>P. urticae</i> , <i>P. patulum</i> , <i>P. roquefortii</i> , <i>Aspergillus clavatus</i>	Apples, pears
Penitrem A	Tremorgenic	<i>Penicillium cyclopium</i>	Grains, grasses
Sporidesmin	Hepatotoxicity	<i>Pithomyces chartarum</i>	Forage grasses
Sterigmatocystin	Carcinogenic	<i>Aspergillus versicolor</i> , <i>A. flavus</i> , <i>A. amstelodami</i> , <i>A. nidulans</i> , <i>Chaetomium theilavioideum</i>	Rice, corn
Tenuazonic acid	Nephrotoxicity, hepatotoxicity	<i>Alternaria alternata</i>	Apples, tomatoes
Trichothecenes: T-2 Toxin, Roridins, Satratoxins, Verrucarins, Verrucarols, Trichoverrols, Deoxynivalenol	Emetic, hemorrhagic, acute toxicity, alimentary toxic, aleukia, skin necrotization, neurotoxicity	<i>Fusarium poae</i> , <i>F. sporotrichioides</i> , <i>Stachybotrys chartarum</i> , <i>Myrothecium roridum</i> , <i>M. verrucaria</i> , <i>Trichoderma viride</i> , <i>Dendrodochium toxicum</i> , <i>Cephalosporium crotocinigenum</i> , <i>Cylindrocarpon</i> sp., <i>Memnoniella echinata</i>	Corn, hay, rice, wheat, wallpaper
Zearalenone	Estrogenic	<i>Fusarium graminearum</i> , <i>F. oxysporum</i> , <i>F. solani</i>	Corn

*Documented in animals and/or humans via ingestion, inhalation or dermal contact.

Sources: Busby and Wogan (1970), Hawksworth et al. (1995), Kendrick (1992), Smith et al. (1995), Udagawa et al. (1979), Ueno (1983), Vesonder and Horn (1985).

1992). Mycotoxin production is highly dependent on fungal species and strain, environmental conditions (e.g., temperature cycling, water activity, light, presence of other microorganisms), and growth substrate (Bennett and Deutsch 1985, Bennett et al. 1981, Buckle and Sanders 1990, Butt and Ghaffar 1972, El-Kady and Moubasher 1982, Faraj et al. 1991, Joffee and Lisker 1969, Northolt and Bullerman 1982). Thus, growth of toxigenic fungal species in an indoor environment will not necessarily indicate whether mycotoxins are present. An isolate may produce high levels of toxin in its natural state but yield only low levels in the laboratory. Conversely, an isolate may produce high levels in the laboratory, but not in the field. In addition, some toxigenic isolates can lose (or gain) the ability of mycotoxin production over time under artificial culture conditions (Mayne et al. 1971, Tantaoui-Elaraki 1992). Therefore, the identification of a fungus as a “toxigenic species” is a guide to the type of mycotoxins that might be produced, but does not establish the presence of those toxins. Verification of toxins remains a matter for analytic chemistry (Bu’lock 1980).

Exposure to Mycotoxins

Toxigenic fungi can accumulate mycotoxins in the fungal spores and the fungal filamentous structure (mycelia) and can excrete mycotoxins into the growth substrate. Mycotoxins have not been shown to be volatile (Pasanen et al. 1993). Toxin partitioning between the spores, mycelia and growth substrate is highly dependent on fungal species and strain and environmental conditions (Palmgren and Lee 1986, Sorenson et al. 1987, Wicklow and Shotwell 1982). The primary routes of indoor environmental exposure for mycotoxins are most likely dermal and inhalational. Significant exposures probably occur when fungal spores, fungal mycelia, and contaminated growth substrate are aerosolized, especially as a result of handling of moldy material.

Analytic Methods for Detecting Mycotoxins

The currently available analytic methods were designed for agricultural products, and the crossover to uses in the indoor environment may be problematic in some instances (e.g., air samples with low concentration and low bulk). Analytic methods include analytical chemistry techniques, immunoassays and bioassays (e.g., tissue culture, cell culture, lethality testing in animals) (Table 46.2) (Babich and Gorenfreund 1991, Chu et al. 1984, Gilbert 1993, Krishnamurthy et al. 1989, Panigrahi 1993, Visconti et al. 1991). Extraction using organic solvent and mechanical disruption of samples, sample purification to prevent interference from other compounds, detection and determination, and chemical confirmation are the routine in mycotoxin analyses (Scott 1995).

Analytic Chemistry Methods. The necessary reference standards, equipment (which can be very costly), and technical expertise required for analytic chemistry analyses may not be available to most bioaerosol laboratories, which somewhat limits the use of these techniques. Also, the results from these methods seldom give a complete description of the toxic capabilities of the fungus. Many mycotoxins are still unidentified (therefore no reference standard is available), and even less is known about the effects of mycotoxin mixtures (fungi often produce more than one mycotoxin at a time).

Immunologic Methods. Immunoaffinity chromatography is a relatively new technology that uses highly specific antibodies to separate mycotoxins from a sample (as opposed to organic solvent fractionation and cleanup). The commercially available assay kits are sensitive, rapid, and easy to use. However, commercial assays exist for only a few agriculturally

TABLE 46.2 Methods to Detect, Identify, and/or Quantify Mycotoxins

Method	Assay	Advantages	Disadvantages
Analytic chemistry techniques	Thin-layer chromatography (TLC)	Relatively simple	Insensitive Susceptible to interference compounds Qualitative
	High-performance liquid chromatography (HPLC)	Quantitative	Specialized equipment
	Tandem mass spectrometry (MS/MS)	Identification	and expertise Reference standards
	Gas chromatography, liquid chromatography or supercritical fluid chromatography in combination with mass spectrometry (GC/MS, LC/MS, and SFC/MS)		
Immunoassays	Enzyme-linked immunosorbent assay (ELISA)	Quantitative	Commercial kits available only for some mycotoxins
	Radioimmunoassay (RIA)	Specific Sensitive Relatively simple	
Bioassay	Toxicity testing	Simple	Nonspecific
	Lethality	Rapid	Qualitative
	Functional changes		
	Morphological changes Mutation		

significant mycotoxins (i.e., aflatoxin, ochratoxin, zearalone, T-2, deoxynivalenol, and fumonisins). The accuracy of some of the kits are comparable to HPLC analysis (Dorner and Cole 1989).

Biological Assays. As the detection of many mycotoxins by analytic chemistry methods is not adequate at present and the feasibility of testing for all known mycotoxins chemically is not practical, biological assays have been employed as a detection (qualitative) method (Buckle and Sanders 1990, Robb et al. 1990). Biological assays have been developed for detection of mycotoxins in food and feed using terrestrial animals (e.g., chick embryo, rabbit skin, insects), aquatic animals (e.g., brine shrimp, trout), organ and tissue culture (e.g., fibroblasts, liver cells, lung cells, fetal cells, tracheal explants), microorganisms (e.g., yeasts, bacteria, other fungi), or plants (e.g., seeds) (Abbas and Shier 1984, Babich and Gorenfreund 1991, Madhyastha et al. 1994, Panigrahi 1993). Although there have been attempts to increase the quantitative capability of bioassays (by different cleanup methods), the most feasible purpose is primarily as a qualitative screening method.

Indoor Concentrations and Normal Ranges

Fungi are a common contaminant in the indoor environment. It is the amplification of fungi and dissemination of fungal spores in high concentrations that are unusual. Most fungal species found in the indoor environment have no intrinsic ejection mechanism for spore dispersal, and aerosolization of spores from a surface is determined mostly by physical, not

biological, constraints. Aerosolization is highly dependent on water content of the substrate and physical disturbance (Ward et al. 1995, Wilkins et al. 1998). Thus, aerosolization usually occurs only when surfaces or reservoirs supporting growth are mechanically disturbed (e.g., remediation work).

Virtually all reported data on fungal concentrations in air are based on culture of air samples. Therefore, recovery is dependent on the culturability of the spores, which is probably independent of toxin content of the spores. Neither fungal growth on a surface nor the presence of airborne culturable spores is a reliable indicator of toxin presence.

Given these limitations, there are several published guidelines intended to limit exposures to toxigenic fungi in the indoor environment (Rao et al. 1996). Acceptable levels of fungi range from "presence not acceptable" to less than 1000 colony forming units (CFU/m³) (Eastern New York Occupational Health Program 1995, Nathanson 1993, World Health Organization 1988). In addition, environmental controls have also been recommended in order to decrease the probability of fungal amplification (e.g., moisture control) (American Society of Heating, Refrigerating, and Air-Conditioning Engineers 1999, Maroni et al. 1995, Standards Australia 1989, U.S. Environmental Protection Agency 1993).

46.4 HEALTH EFFECTS FROM MYCOTOXIN EXPOSURES

Route of Exposure: Inhalational

The most commonly encountered mycotoxins have health effects that include carcinogenicity, induction of tremors, or damage to the immune system or major organs (Table 46.1) (Corrier 1991, Hendry and Cole 1993). Most documented cases of human mycotoxicosis have appeared in rural or agricultural settings as a result of ingestion of contaminated food and/or from skin contact (Akkmeteli 1977). In vitro testing of human skin indicates slow absorption that would not be likely to lead to systemic effects. However, risk of systemic toxicity increases in the presence of high toxin concentration, prolonged dermal exposures, and vehicles that enhance penetration (such as an organic solvent) (Kemppainen et al. 1988/89). Most risk of systemic effects associated with exposure to aerosolized toxin-containing particles is thought to occur through inhalation exposure (Creasia et al. 1990, Jarvis et al. 1989). However, evidence that relates disease to the inhalation of mycotoxins is limited. Some anecdotal human data have indicated that acute, high-level inhalation of mycotoxins can have serious health effects (Dvorackova 1976, Dvorackova and Pichova 1986, Hintikka 1978, Land et al. 1987, Samsonov 1960). Data are limited on chronic, low-level inhalation exposures.

Aflatoxins are produced by *Aspergillus parasiticus* and *A. flavus*. The International Agency for Research on Cancer (IARC) has classified aflatoxins as a group 1 (i.e., sufficient evidence) human carcinogen based primarily on ingestion exposures (International Agency for Research on Cancer 1993). Epidemiologic studies correlate aflatoxin exposures in farming and food processing settings to various forms of cancer (Baxter et al. 1981, Burg et al. 1981, Hayes et al. 1984, Olsen et al. 1988). Anecdotal evidence has linked the presence of *Aspergillus flavus* in the environs or the presence of *A. flavus* precipitins in patient serum to neoplastic diseases, interstitial lung diseases, and leukemia (Aleksandrowicz and Smyk 1973, Dobrowolski and Smyk 1993, Loughheed et al. 1995, Wray et al. 1982). However, because of the issues in assessing airborne exposure, a definitive inhalational causal relationship has yet to be established (Akkmeteli 1977, Smith et al. 1995). The development of detection methods for aflatoxin adducts in blood and urine has been useful in characterizing dietary exposures (Scholl et al. 1995, Strickland and Groopman 1995).

Some surveys of “cytotoxic spores” in domestic environments used fungal spores cultured on laboratory media (which probably is not indicative of toxin presence in the natural environment) to characterize exposure. No connection was made to any health effects (Lewis et al. 1994, Smith et al. 1992). In order to correlate specific mycotoxin exposure to indoor air quality problems, identification and evaluation of health effects from exposure to mycotoxins in indoor air are essential.

Experimental Evidence of Mycotoxin-Related Health Effects

Laboratory studies have indicated that inhalation of mycotoxins can elicit adverse health effects (Bunner 1987, Creasia et al. 1987, DiPaolo et al. 1993, Sorenson et al. 1986, Thurman et al. 1988). T-2 toxin was 2 to 20 times more toxic when inhaled than when injected interperitoneally or applied dermally. However, the types of systemic effects were similar regardless of route of exposure (Creasia et al. 1987, 1990). T-2 toxin, patulin, penicillic acid, and aflatoxin can interfere with rat alveolar macrophage function and with normal immune responses in the lung (Gerberick et al. 1984, Jakab et al. 1994, Richards and Thurston 1975, Sorenson et al. 1986, Sorenson and Simpson 1986). This may help explain the opportunistic bacterial infections that are often associated with chronic trichothecene intoxication in livestock (Harrach et al. 1983, Schneider et al. 1979).

It has been hypothesized that mycotoxins associated with spores are likely to be absorbed via the respiratory epithelium and translocated to other sites, possibly producing systemic effects (Flannigan et al. 1991, Tobin et al. 1987). However, most laboratory studies focus on exposures to a single purified mycotoxin dissolved in a solvent, even though these exposures are unlikely to accurately characterize health effects of inhaled dry spores (Nikulín et al. 1997). Synergistic, additive, or antagonistic effects of multiple mycotoxin exposures may occur, depending on the combination of mycotoxins and the concentration ratios (Koshinsky and Khachatourians 1992, Madhyastha et al. 1994, Ohff et al. 1985, Schiefer et al. 1986, Thompson and Wannemacher 1986). Also, particulate association of mycotoxins may amplify adverse effects in the animal lungs, possibly as the result of an increase in respiratory tract retention of the mycotoxin (Coulombe et al. 1991).

Doses of mycotoxins that cause specific toxic effects vary with the mycotoxin, the experimental animal species, and the route of administration. Some of the trichothecene toxins (produced by species of *Fusarium*, *Acremonium*, *Trichoderma*, *Myrothecium*, *Stachybotrys*) are characterized by ingestion LD_{50} levels (lethal dose for 50 percent of exposed animals) well below 1 mg/kg body weight (Schiefer et al. 1989). Health effects of human exposure to nonmacrocytic trichothecenes have been documented in clinical cancer trials. Intravenous injection of anguidine or diacetoxyscirpenol in doses ranging from 0.2 to 6.0 mg/m² body surface area (0.005 to 0.154 mg/kg body weight) commonly resulted in nausea and vomiting. Central nervous system and gastrointestinal tract disturbances were less commonly observed (Goodwin et al. 1978).

46.5 STACHYBOTRYS CHARTARUM

The Fungus *Stachybotrys chartarum*

Species Description. The genus *Stachybotrys* is in the anamorph class Hyphomycetes and was first described by Corda in 1837 (Eppley 1977, Kendrick 1992). The genus is defined by the production of black phialospores produced successively and collecting in a mucilaginous mass at the apex of clustered, inflated phialides. There are approximately 50

species in the genus. *Stachybotrys chartarum* (syn. *S. atra*) is characterized by relatively large ovate spores with smooth to irregularly warty walls. The reported spore size range is 3 to 4×7 to $10 \mu\text{m}$ with extensive variation among different isolates (Korpinen and Uoti 1974, Malloch 1981, Moreau 1974).

Ecology. *Stachybotrys chartarum* is a cellulose-decaying fungus with a worldwide distribution. It has been found on soil, paper, vegetable debris, straw, grains, and wet building materials (Croft et al. 1986, Grant et al. 1989, Hunter et al. 1988, Moreau 1974). The fungus grows optimally at room temperatures when the relative humidity is $\text{RH} > 93\%$ (Forgacs 1972, Grant et al. 1989). Sunlight suppresses mycelial formation but increases spore formation (Bakai 1960).

Recovery in the Indoor Environment. *Stachybotrys* species grow slowly when cultured with other fungi. Although able to inhibit the growth of other fungi, *Actinomyces* and other bacteria, *S. chartarum* can compete with fungi such as *Penicillium* and *Aspergillus* only on specialized culture media (e.g., high cellulose, low sugar and nitrogen) (Butt and Ghaffar 1972, Hunter et al. 1988, Jarvis 1990, Tobin et al. 1987). In bulk samples, the number of *S. chartarum* colonies detected and the frequency of recovery (*S. chartarum* colonies/total fungal colonies recovered) on cellulose agar can be up to two orders of magnitude higher than on glucose agar (Abdel-Hafez and Shoreit 1985, Abdel-Hafez et al. 1986).

S. chartarum spores are hardy and can survive for long periods at temperatures as low as -40°C . It has been estimated that up to 90 percent of field-collected spores may not be culturable (Miller 1992). However, unpublished data from our laboratory indicate >90 percent germination of spores from fresh cultures.

The Mycotoxins of *Stachybotrys chartarum*

Background. *Stachybotrys* toxins are macrocyclic trichothecenes, a group of chemically related fungal metabolites produced by various species of *Fusarium*, *Trichothecium*, *Trichoderma*, *Acremonium* (= *Cephalosporium*), *Cylindrocarpon*, and *Myrothecium*, as well as *Stachybotrys* (Grove 1993; Jarvis et al. 1986, 1995; National Academy of Science 1983).

The Nature of Trichothecenes. *Trichothecenes* are sesquiterpene alcohols or esters, derived from a common tricyclic skeleton (trichothecane). The colorless, crystalline, optically active solids are sparingly soluble in water and soluble in all common organic solvents at room temperature (Nummi and Niku-Paavola 1977). The skeletal structure includes a six-member oxygen-containing ring, an epoxide group and an olefinic bond. Trichothecenes are classified into four types (A to D) according to their structural characteristics (Grove 1993, National Academy of Science 1983). Macrocyclic trichothecenes (type D) contain a macrocyclic ester or an ester-ether bridge. As of 1991, 172 trichothecenes have been isolated from natural sources, 67 of which are macrocyclic (type D) (Grove 1993).

The Nature of Trichothecenes Produced by *S. chartarum*. At least eight major macrocyclic trichothecenes have been identified from *S. chartarum* isolates: satratoxins F, G, and H; roridin E; verrucarins B and J; and trichoverrols A and B (Croft et al. 1986; Grove 1993; Harrach et al. 1982; Jarvis et al. 1986, 1995; Pohland 1977; Stack and Eppley 1980). However, it is likely that there are others yet undiscovered. For example, 5 g of *S. chartarum*-contaminated rice culture was lethal to a 40-kg ram. However, the rice culture contained less than 1 mg of total macrocyclic trichothecenes (Jarvis 1991). Given the much

higher LD₅₀ values reported for satratoxins H and G (Glavits 1988, Yoshizawa et al. 1986), it is likely that additional toxins produced by *S. chartarum* were present in the culture.

Not all strains of *S. chartarum* can produce mycotoxins in detectable amounts, at least in a laboratory setting (Korpinen and Uoti 1974, Ohff et al. 1985, Sorenson et al. 1987). In surveys of *S. chartarum* strains implicated in mycotoxicoses, not all strains were toxic in tissue culture assays (Korpinen and Uoti 1974) or produced detectable trichothecenes (Bata et al. 1988, Sorenson et al. 1987). Therefore, the presence of *S. chartarum* growth is not proof of toxin presence (Jarvis et al. 1986, Korpinen and Uoti 1974, Pasanen et al. 1993). Only rarely are other *Stachybotrys* species (*S. cylindrospora*, *S. albipes*, *S. kampalensis*, and *S. microspora*) reported to produce trichothecenes (Grove 1993, Jarvis et al. 1995).

Experimental Evidence of the Effects of *S. chartarum* Mycotoxins. Table 46.3 summarizes the experimental data on health effects of macrocyclic trichothecenes. Trichothecenes are potent inhibitors of protein and DNA synthesis. They interact with ribosomes (binding the ribosomal peptidyl transferase) and interfere with the initiation and elongation events (Murty et al. 1985, Ueno 1983). The biologically active structure is the epoxide group (Jarvis and Mazzola 1982, Ong 1982). All trichothecene mycotoxins are capable of inducing immunosuppression, skin necrotization, vomiting, leucocytosis, and leukopenia in experimental animals (Ueno 1983, Uruguchi and Yamazaki 1983). Macrocyclic trichothecenes are more toxic (more potent) than the type A or B trichothecenes (e.g., T-2, verrucarol, deoxynivalenol) (Jarvis and Mazzola 1982). The macrocyclic trichothecene esters (verrucarins and roridin derivatives) are the most toxic nonnitrogen natural products known (Bata et al. 1988, Bergmann et al. 1989, Eppley 1977, Glavits 1988, Jarvis and Mazzola 1982, Ong 1982, Pestka and Forsell 1988).

Aerosolization of Mycotoxin-Containing *S. chartarum* Spores. *S. chartarum* toxins can accumulate in spores, mycelia, and in the growth substrate. Because the spores are hydrophilic, they tend to agglomerate and are aerosolized most readily under dry conditions with physical agitation. In a chamber study, *S. chartarum* particles (aerosolized by acoustic vibration) consisted of 85 percent spores and 6 percent hyphal fragments (mass median aerodynamic diameter <5 µm). Satratoxin H was found in concentrations ranging from 6.8 to 12.7 ng/mg dust. Satratoxin G and trichoverrols A and B ranged from none detected (limit of detection = 50 ng) to 6.9 and 4.5 ng/mg dust, respectively (Pasanen et al. 1993, Sorenson et al. 1987). However, in situ studies have shown that few spores are released from surfaces under environmental conditions which are likely to occur under normal occupancy conditions (Wilkins et al. 1998).

Human/*Stachybotrys* Interactions

Background. *S. chartarum* has been associated with animal intoxication and occasionally with human mycotoxicoses (Forgacs 1972, Hintikka 1978). Stachybotryotoxicosis was first diagnosed as a high-mortality disease of farm horses. Susceptibility to the effects of exposure seemed to be independent of nutritional status and age. The duration of disease, from time of detection of febrile reaction to death of an untreated horse, was 1 to 3 days (Shulyumov et al. 1960). The most common histological features reported in livestock are necrosis, aplastic anemia, and mucosal hemorrhage (Hintikka 1978, Schneider et al. 1979).

Occupational Exposures. Documented cases of inhalation exposure and subsequent health effects are rare. Reactions from concurrent dermal contact are the most commonly reported exposures. Accidental cases of trichothecene poisoning have been documented from laboratory dermal exposures. Symptoms included severe skin irritation, numbness,

TABLE 46.3 Summary of Experimental Data on Effects of Macrocytic Trichothecenes

Toxin	Assay system	Mode of exposure	Measured outcomes	Results	Ref.
Verrucarin A	Mouse spleen cells	Cell culture	Interleukins	Low doses superinduces IL5; high doses inhibit all ILs	Ouyang et al. (1995)
Verrucarin A, Roridin A	Rat spleen lymphocytes	Cell culture	Protein synthesis inhibition	In vitro response not always accurate predictor of whole-animal lethality	Thompson and Wannemacher (1986)
<i>S. chartarum</i> extracts	Mammalian epithelial kidney cells	Cell culture	RNA concentrations	Reduction in RNA, inhibition of RNA synthesis	Bodon and Palyusik (1970)
Satratoxin G	Mice	Single inter-peritoneal injection	Histology, death	LD ₅₀ : 1.23 ± 0.08 mg/kg body weight	Yoshizawa et al. (1986)
Satratoxin H	Mice	Single inter-peritoneal injection	Histology, death	LD ₅₀ : 5.69 ± 0.43 mg/kg body weight	Yoshizawa et al. (1986)
Roridin A	Dogs	Single intra-venous injection	Cardiac measures	2 mg/kg: atrioventricular block, increased heart rate, hypotension	Bubien and Woods Jr. (1987)
<i>S. chartarum</i> spores	Mice	Single intra-nasal injections	Histology after 3 days	1 × 10 ⁶ spores/ 50 µL PBS: inflammatory lung injury	Nikulin et al. (1997)
<i>S. chartarum</i> spores	Rats	Intratracheal instillation	Bronchoalveolar lavage	Dose-effect relationship, effects mycotoxin-related	Rao et al. (2000)
<i>S. chartarum</i> spores	Guinea pigs	Single intra-nasal spray	Histology	Inflammation of large bronchi, alveoli; cytotoxicity in lung, heart, liver	Samsonov and Samsonov (1960)

loss of sensitivity, and skin peeling. Patients recovered without sequelae (National Academy of Science 1983). Handlers of *Stachybotrys*-contaminated straw have reported cough, rhinitis, burning sensation in the mouth and nasal passages, and cutaneous irritation at the point of toxin contact. Rash, dermatitis, exudate, catarrhal angina with painful pharyngitis, bloody exudate from nose, fever (rare), moderate to severe cough, and leukopenia have been reported in some cases. The disease (clinical symptoms) developed within 2 to 3 days of contact with an average duration of 3 weeks (Hintikka 1978).

Indoor Exposures. *S. chartarum* is considered by some to present a serious health threat for individuals in contaminated indoor environments (Eastern New York Occupational Health Program 1995, Etzel et al. 1998, Miller 1992). One relatively well-defined case involved a home with heavy infestation of *S. chartarum* (Croft et al. 1986). Water damage had occurred in the house over a period of several years. Extensive fungal growth was evident on the ceiling of an upstairs bedroom and in the air ducts, and *S. chartarum* spores were collected from room air samples. The variety of symptoms reported by the occupants of this house (headaches, sore throats, hair loss, flu symptoms, diarrhea, fatigue, dermatitis, and generalized malaise) was generally consistent with the nonspecific nature of indoor air quality complaints (Tobin et al. 1987). Cleanup workers experienced skin and respiratory irritation. Verrucarins B and J, satratoxin H, and trichoverrins A and B were isolated from bulk samples of contaminated ceiling tile and airduct dust. Extracts of these samples were injected per os (orally) into rats and mice. Within 24 hours, all animals had died. Histology demonstrated degeneration, necrosis, and hemorrhage within the brain, thymus, spleen, intestine, lung, heart, lymph nodes, liver, and kidney. After the home was thoroughly cleaned, the occupants no longer suffered symptoms.

A highly publicized outbreak of pulmonary hemosiderosis occurred in a cluster of cases involving newborn babies living in damp, moldy homes in Cleveland (CDC 1997). A case-control study indicated that residing in water-damaged buildings positively correlated with the case patients (Montana et al. 1997) and that cases were more likely to live in houses with *S. chartarum* in the air (Etzel et al. 1998). The presence of toxins in the air was not confirmed. However, in a reanalysis of the medical and sampling data, the Centers for Disease Control have concluded "the evidence...was not of sufficient quality to support an association between *S. chartarum* and acute idiopathic pulmonary hemosiderosis" (CDC 2000).

S. chartarum has also been blamed for nonspecific symptoms often associated with complaints of poor indoor air quality (Cooley et al. 1998, Johanning et al. 1996, Sudakin 1998). However, as in the Cleveland outbreak, the presence of mycotoxins has seldom been confirmed, and exposure has been inferred from the presence of *S. chartarum* in bulk samples. The causal link between detection and identification of a toxigenic species of fungus in nonagricultural indoor environments and adverse health effects has yet to be definitively proved.

46.6 RISK ASSESSMENT

The process of risk assessment entails four major steps: hazard identification, exposure assessment, dose-response analysis, and risk characterization. Risk assessment is a tool that enables the public health community to determine what substances are risks, to determine at what levels the substances become risks, and to rank the importance of such risks. One specific regulatory outcome of the risk assessment process is the establishment of standards and guidelines of safe human exposure levels (Calabrese 1996, Malsh et al. 1994, U.S. Environmental Protection Agency 1995).

Standards for Mycotoxin Exposures

Official exposure limits exist only for mycotoxin concentrations in food and only for the best-known toxins such as aflatoxin, ochratoxin, and deoxynivalenol (Stoloff et al. 1991, van Egmond 1995). Some guidelines set limits for toxigenic fungi recovered in air (cfu/m³), but the definition of “toxigenic” in these guidelines is ambiguous (Eastern New York Occupational Health Program 1995, Rao et al. 1996). Also, basing guidelines on culturable fungi may not be the best method of limiting risk of mycotoxin exposures since toxins can be found in nonviable particles (Miller 1992). For *S. chartarum* exposure, no official standards exist, but several different kinds of guidelines have been proposed. The presence of 10³ to 10⁴ *S. chartarum* spores/m³ has been proposed as a level to initiate building evacuation (Eastern New York Occupational Health Program 1995). The presence in air of 10³ *S. chartarum* spores/m³ of air was proposed as a guideline by Miller (1992) on the basis of extrapolation from the Canadian Acceptable Daily Intake of anguidine (a non-*S. chartarum* trichothecene). Using published data (Sorenson et al. 1987) on the amount of toxin in bulk samples of *S. chartarum* spores, Burge (1996) estimated periods of time (ranging from 0.1 to 1100 days) necessary to accumulate 1 ng satratoxin at different spore concentrations in air (Burge 1996). Le Bars and Le Bars (1985) estimated that inhalation of 3 to 5 mg of spores could cause symptoms if the fungal strain is highly toxigenic. None of these guidelines is based on a step-by-step risk assessment process. Such a process entails collection of data regarding prevalence of the fungus, production of toxins, source strength, aerosolization parameters, and inhalational health effects. These data are currently not available for *S. chartarum* or any other fungal species.

CHAPTER 47

TUBERCULOSIS

Edward A. Nardell, M.D.

*Harvard Medical School
The Cambridge Hospital
Cambridge, Massachusetts*

47.1 INTRODUCTION

According to the World Health Organization, tuberculosis (TB) kills more adults worldwide than does any other infectious disease (WHO 1996, 1998). Because this airborne infection is believed to be transmitted from person to person almost exclusively indoors, tuberculosis may qualify as the most deadly of all indoor air hazards. Although most tuberculosis occurs in the earth's poorest places, it is also a growing problem in many middle-income countries, and most high-income countries have experienced a resurgence of the disease. Geographic borders do not confine tuberculosis. Increasingly, tuberculosis cases in the United States and Europe are occurring among persons born in high-prevalence countries. Although tuberculosis among foreign-born persons has always contributed importantly to U.S. case rates, the decline among U.S.-born residents more recently has highlighted that contribution. Besides moving infected persons rapidly from country to country, air travel itself has been associated with tuberculosis transmission in the confines of the aircraft, although this is only one of many indoor public spaces where infection is possible (Kenyon et al. 1996). The rise in strains of multi-drug-resistant tuberculosis (MDR TB) raises new concerns. Outbreaks of these often deadly infections, first reported in hospitals in New York City and Miami, are now being reported in such diverse sites as prisons in Russia, coal mines and worker hostels in South Africa, and AIDS hospitals in Argentina (Pablos-Mendes et al. 1998, Ritacco et al. 1997).

This chapter has two principal goals: (1) to describe tuberculosis as an indoor air quality problem and (2) to provide the practitioner of indoor air quality the background needed to understand both the rationale and limitations of current TB infection control guidelines. The reader is referred to monographs on tuberculosis for a more comprehensive discussion of the disease and its control (Reichman 1999, Rom 1996). Although much of what is discussed is applicable to tuberculosis wherever it occurs, the emphasis here is on the problem under low-prevalence conditions in moderate to high-income countries where a greater proportion of resources can be allocated for infection control. In low-income countries, nearly all resources are required for diagnosing and treating new tuberculosis cases, an intervention that both relieves suffering and contributes importantly to infection control. Recommendations for practical and inexpensive interventions for low-income countries have been published (WHO 1999).

47.2 TUBERCULOSIS AS A DISEASE AND INDOOR HEALTH HAZARD

Descriptive Epidemiology

Tuberculosis is a historically important disease, and one that will continue to be a major cause of mortality and morbidity worldwide for many decades. It has been estimated that a third of the world's population is infected with its causative organism, *Mycobacterium tuberculosis*, although a much smaller fraction has the active form of the disease. Tuberculosis infection without active disease is not contagious, but at some time in their lives, a small fraction of persons reactivate their dormant focus of infection resulting in clinical disease transmission. As already noted, TB kills more adults than does any other single infectious disease, including HIV. These two infections cannot be entirely separated, however, since tuberculosis is one of the most important causes of death in HIV-infected persons in many parts of the world. In sub-Saharan Africa and increasingly in Asia, where TB was already epidemic, the disease is exploding in incidence as a result of coinfection with HIV. Coinfection with HIV greatly accelerates the rate of reactivation in those already TB-infected, and the rate of TB transmission. Conversely, tuberculosis disease accelerates the course of AIDS, resulting in premature death even if the tuberculosis is cured.

The tuberculosis burden of disease varies greatly around the world. By region, WHO estimates that Southeast Asia has over 3 million cases of active disease, more than 2 million in India alone (WHO 1998). Another 1.5 million cases are estimated for the western Pacific region, with over a million cases in China. Africa has an estimated 1.3 million cases, with 20% in Nigeria, the continent's most populous nation. The eastern Mediterranean region contributes over half a million cases, with more than a third of cases in Pakistan. Europe and the Americas account for just under half a million cases each, with over a third of the European cases in Russia, while Brazil accounts for 30 percent of cases in the Americas. The United States contributes an estimated 5 percent of cases in its region and about 0.3 percent of cases worldwide.

The United States now reports fewer than 10 TB cases per hundred thousand population—a low case rate by world standards. Some less populous states such as Wyoming have occasional years when no new cases are reported. After a 7-year resurgence, which began in 1985, case rates in most U.S. reporting jurisdictions have again been declining. Despite overall decreases, some reporting areas continue to experience increases, and some cities still have rates more than 3 times the national average. The causes of this great disparity in TB case rates are many, with socioeconomic deprivation considered most important.

Malnutrition, concomitant diseases, crowded living conditions, and poor access to good general health care and effective TB control programs all favor persisting or increasing TB in poor communities. Inherited (innate) immunity in those populations whose ancestors survived epidemic tuberculosis of the last several centuries has helped limit its propagation, but many populations, including central African, Polynesian, and Aboriginal peoples, appear to have less inherited protection. Despite many innate and intractable factors favoring the success of the tubercle bacillus, however, experience has shown that effective treatment programs can control the disease anywhere in the world, even when poverty, homelessness, substance abuse, and other barriers persist (Farmer and Nardell 1998).

In the United States, an infusion of resources in response to the resurgence of TB has rescued badly eroded public health tuberculosis programs after years of neglect. These funds have focused attention on completion of therapy as the single most important control measure. *Directly observed therapy* (DOT), where the ingestion of every dose of medication is observed by a nurse or outreach worker, has been shown to be both highly effective and cost-effective (Frieden et al. 1995). Also important has been the introduction of molecular techniques for fingerprinting tubercle bacilli, permitting a reassessment of the role of recent transmission relative to reactivation of disease acquired in the remote past. Since tubercle bacilli isolated from persons with TB in communities tend to have a variety of fingerprint patterns, cases with epidemiologic linkages whose organisms have the same pattern are assumed to have resulted from recent transmission. Data from New York City have suggested that approximately a third of cases during the peak of the resurgence may have resulted from recent transmission, predominantly in congregate settings such as shelters for the homeless, hospitals, jails, AIDS residential treatment centers, and, perhaps, in public places (Alland et al. 1994). Previously it was believed that almost all TB in the United States resulted from reactivation of remote infection. Awareness of the importance of transmission in congregate settings has focused attention on the role of environmental control, particularly the role of prompt case detection and treatment, isolation, air disinfection, and the use of particulate respirators.

Tuberculosis Propagation Cycle

Figure 47.1 illustrates the processes necessary for the propagation of *Mycobacterium tuberculosis* in humans, its preferred host. Most research since the late 1990s has focused on the pathogenesis phase of the cycle whereby the infecting organisms multiply in the host, causing various symptoms (discussed below), depending on the site and extent of disease, and highly dependent on the immune response of the host. The tissue destruction characteristic of tuberculosis disease is only indirectly caused by the infecting mycobacteria. Rather, it is an unwelcome consequence of the body's own immune responses as it attempts to destroy or at least localize the infection. As noted below, necrosis of lung tissue resulting in lung cavitation, and access of tubercle bacilli to the environment, is a critically important end stage of the immunopathogenic response. The details of the body's immune response to tubercle bacilli and the immunochemistry of the organism have been the subject of intense scrutiny for decades, although many unknowns remain. Less well understood is the aerobiology of tuberculosis, the other equally important phase of the propagation cycle.

To survive the death of their host and propagate, tubercle bacilli must reach the lungs, and incite lung cavitation, which connect to airways, providing access to new hosts in the environment. Cough stimulated by disease and secretions in the airways generate aerosols containing some viable tubercle bacilli, although many bacilli are thought to succumb to the rigors of the aerosolization process. The formation of respiratory droplets and droplet nuclei, the dried residua of droplets, is discussed in Chap. 11. As indicated in Fig. 47.1, after aerosolization, airborne droplet nuclei containing viable tubercle bacilli are subjected

FIGURE 47.1 Tuberculosis propagation—biomedical model showing the major biomedical factors that determine the ability of *Mycobacterium tuberculosis* to propagate in a population. (From E. A. Nardell. 1999. *Transmission*. In L. B. Reichman and E. S. Hershfield. *Tuberculosis: A Comprehensive Approach*, 2d ed. New York: Marcel Dekker.)

to a variety of environmental stresses as they travel from one host to the next. Under controlled laboratory conditions, Loudon found that the half-life of virulent mycobacteria in air was about 6 h. Under real-world conditions, temperature, humidity, oxidants, irradiation, and other environmental stresses are certain to influence viability of airborne organisms for better or worse. Although carefully studied in *Serratia* and other test bacteria, the effects of environmental stresses on the transport of tubercle bacilli have not been investigated.

Finally, to cause infection, viable airborne organisms must avert the defenses of the host's upper respiratory tract and land in the alveolar region of the lung where they are likely to be engulfed by resident alveolar macrophages. The initial contest between tubercle bacillus and macrophage is a critical early defense, but it is not considered part of the immune response, as it is somewhat nonspecific. It is believed that in many individuals, inherited innate resistance to tuberculosis allows potential infections to be aborted early, before replication within macrophages or monocytes results in an antigenic stimulus sufficient to stimulate specific immunity. Once stimulated, acquired cellular immunity activates alveolar macrophages which attempt to sterilize the site of infection and prevent spread. Delayed-type hypersensitivity, manifest by a positive tuberculin skin test (see discussion below), is stimulated along with cellular immunity, and contributes to the microbicidal process. Often, however, these processes do not succeed in sterilizing the initial focus of infection, permitting local progression, dissemination by way of the bloodstream, and possible future reactivation.

Clinical Presentation, Pathogenesis, and Diagnosis

Signs and Symptoms. The onset of pulmonary tuberculosis is usually indolent, and the symptoms nonspecific, similar to other respiratory ailments such as bronchitis and pneumonia. The symptoms may include fever, fatigue, malaise, weight loss, chronic

cough, and less often, hemoptysis (coughing up blood). Under low-prevalence conditions, health care providers may not consider the diagnosis of tuberculosis early on, treating the patient for weeks or months for other lung ailments before ordering the tests necessary to diagnose the disease. As tuberculosis becomes uncommon in populations, failure to consider the diagnosis initially may not be inappropriate (Nardell 1996). Physicians are trained to consider common diagnoses first, and not to order diagnostic tests routinely when a condition is known to be statistically unlikely. All diagnostic tests have the potential for false-positive results, and misleading results may predominate when tests are performed under low-risk conditions. For example, the tuberculin skin test has a high predictive value for true TB infection when performed in populations at high risk for the disease (e.g., close contacts of an infectious case), but the same test when performed in low-risk populations has a poor predictive value (i.e., a high proportion of false-positives results). Not performing tests for uncommon conditions avoids overdiagnosis, but risks underdiagnosis. Under low-prevalence conditions for tuberculosis, therefore, physicians are faced with the dilemma of under- or overdiagnosis, both of which have undesirable consequences. Physicians need to be aware of the risk factors for tuberculosis and consider the disease promptly, but only when it is appropriate to do so.

The Diagnosis of Tuberculosis. In a symptomatic patient, the diagnosis of pulmonary tuberculosis is often suspected on chest x ray, and confirmed by sputum acid-fast smear and culture, which can demonstrate the causative organism. Sputum microscopy to detect acid-fast staining organisms is relatively quick once sputum samples are obtained, but the test is only about 50 percent sensitive compared to culture, and not completely specific for tuberculosis. Much less virulent, but more common, environmental mycobacteria appear similar under the microscope. All tests based on sputum samples are only as good as the quality of the specimens submitted, and good-quality secretions from the lower respiratory tract can be difficult to obtain. Patients may not have much sputum, or may swallow it rather than cough it up. Culture is both more specific and more sensitive than sputum acid-fast stain, but current methods require 2 to 8 weeks' growth to obtain results. New, more rapid nucleic acid amplification tests (e.g., Roche's Amplicor test, Gen-Probe's MTD test) can detect *M. tuberculosis* in sputum in as little as one day, with great sensitivity and specificity (American Thoracic Society 1997). These tests have recently been approved for use on both acid-fast, smear-negative and smear-positive sputum specimens, but not for routine use on clinical specimens from other sources. As with all diagnostic tests, the potential exists for both false positive and false negative results. Nucleic acid from residual dead organisms in fully treated patients, for example, still amplifies and gives positive results using these tests, whereas dead organisms do not grow in culture. It is anticipated, however, that the performance of these powerful tests will improve as techniques are refined, and that rapid, highly sensitive, and specific tests for tuberculosis in clinical specimens will soon make the diagnosis both quick and easy for clinicians and patients.

The development of good diagnostic serological tests, which do not require sputum samples, would also greatly enhance the diagnosis of TB, especially in pediatric patients and persons with extrapulmonary disease, and in ruling out the disease in suspect cases in respiratory isolation rooms. Until such tests become routine, however, it will continue to be necessary to overisolate a relatively large number of patients with respiratory symptoms that could have tuberculosis to ensure that no TB-afflicted individuals have escaped detection.

In hospitals serving low-prevalence populations, informal estimates suggest that overisolation of patients without TB occurs often; as many as 100 or more patients without TB isolated for every patient with the disease. During the peak of the resurgence, hospitals in high-prevalence areas like New York City and in Atlanta reported overisolation ratios as low as 7:1 (Blumberg et al. 1995). Such comparatively low ratios were achieved because of the high prevalence of disease, and because of a well-trained hospital staff strongly motivated to consider the diagnosis and isolate every suspect case. Under low-prevalence

conditions, however, motivation for isolation is difficult to maintain when only rare cases turn out to have the disease, and where nosocomial infections are rare. Overisolation has important implications for those interested in indoor air safety. Every suspect patient requires the same resources as does a case of proven pulmonary tuberculosis. An isolation room must be available, sputum samples must be obtained and tested, air disinfection (usually ventilation) in rooms and corridors must be operating correctly, and persons entering and leaving the room must be properly equipped with fit-tested personal respirators. Because nonspecific respiratory symptoms are so common, low-prevalence institutions may require almost as many isolation rooms as do high-prevalence institutions, but most of the time they will be occupied by people without the disease, at least until sputum samples can be obtained and tested.

The Unsuspected Case. Because signs and symptoms of tuberculosis are nonspecific, current diagnostic tests are imperfect, and the disease is becoming increasingly uncommon in countries such as the United States, where the diagnosis is often delayed, and occasionally missed entirely (Mathur et al. 1994). Most outbreak reports in the literature have been due to cases of tuberculosis that were not diagnosed early (American Thoracic Society 1991, Hutton et al. 1990). While provider education can increase awareness of the disease, an index of suspicion out of proportion to the true prevalence of the disease leads to overdiagnosis, overisolation, and overtreatment, with negative consequences for patient care. As already noted, some degree of underdiagnosis and overdiagnosis is necessary. Our current infection control guidelines, however, assume that most, if not all, tuberculosis patients will be suspected and placed in respiratory isolation where environmental controls and respiratory protection can be applied. Unsuspected cases by definition will not be in isolation rooms, and respirators will not be in use. Environmental interventions to prevent transmission from unsuspected cases in general medical and surgical areas, emergency rooms, waiting rooms, and specialty areas, such as orthopedics and obstetrics, is an alternative approach to the problem of unsuspected cases (see Chap. 11).

TB Skin Test. Tuberculin skin testing detects infection (latent or active) and is a routine part of institutional infection control programs and clinical medicine. A minute dose [5 TU (toxin units)] of purified protein derivative (PPD) antigen is injected intradermally. Later, after 48 to 72 h, a positive reaction, indicating infection with *M. tuberculosis* or related species, is manifest as slight swelling of the skin (induration) caused by the migration of sensitized inflammatory cells (lymphocytes) into the injection site. The test is read by measuring the diameter (in millimeters) of the indurated area (not the redness) across the axis of the arm (not lengthwise along the arm). Considerable experience is needed in applying and reading tuberculin skin tests to achieve reproducible results. The test is not intended to be self-read by patients or health care workers. True TB infection, with or without active disease, results in a reaction that measures an average of approximately 16 mm (Nardell et al. 1999). In persons with risk factors for tuberculosis, reactions greater than 10 mm are generally considered positive. In the absence of clinical evidence of active disease, a positive tuberculin test indicates latent TB infection. Because of biologic variation, approximately 3 to 4 percent of persons with true TB infection (culture-proven disease) will have reactions between 1 and 9 mm, and others will not react at all because of a general or specific failure of the immune system (anergy). While a large reaction increases the certainty of true tuberculosis infection, possibly recently acquired, it does not indicate a greater likelihood of active disease. Patients are sometimes erroneously told that a positive skin test simply means “exposure” to tuberculosis. Within the limits of the test, a positive tuberculin (Mantoux, PPD) skin test means there has been *both* tuberculosis exposure *and* infection, resulting in sensitization of the immune system to components of the organism.

False-positive reactions can occur as a result of cross-reactivity with common environmental mycobacteria or immunization with bacillus Calmette-Guérin (BCG) vaccine. BCG

is almost universally used in low- and medium-income countries where TB is common, but rarely used in the United States, Canada, and many low-incidence countries in western Europe. However, cross-reactions with other antigens tend to produce smaller reactions than does true TB infection, especially compared to recently acquired TB infection, which tends to produce large reactions. For example, PPD reactions of 15 mm or more in adults is much more likely to be due to true TB infection than to environmental mycobacteria or BCG vaccination. This is especially true among persons who have lived among populations with a high TB prevalence, among close contacts of active cases, and among other high-risk categories. The stigma associated with TB in many cultures is so great that many persons who test positive for infection are anxious to attribute the skin test reaction to other, more socially acceptable explanations, such as BCG vaccination. The effect of BCG on skin test results has been recently reviewed (Brewer et al. 1995). Like cross-reactivity with environmental mycobacteria, BCG vaccination generally produces a smaller reaction than does true TB infection, and one that wanes relatively quickly. Most adults who were vaccinated with BCG will test PPD negative unless infected with TB.

Latent Infection and Active (Infectious) Disease. As already indicated, tuberculosis infection is not synonymous with active, potentially contagious disease. Under high-prevalence conditions, tuberculosis infection tends to occur early in life, where it usually causes a self-limited, relatively mild respiratory illness (primary tuberculosis). Recovery is usually complete with or without treatment. In young children or immunocompromised persons, primary disease can progress, and can be fatal if vital organs such as the brain become involved. Most who recover from primary tuberculosis are left with a normal or near-normal chest x ray, and a positive tuberculin test as the only evidence of prior infection. Latent infection persists, however, with an estimated 10 percent lifetime risk of reactivation to clinically active (and potentially contagious) tuberculosis in the normal host. Reactivation usually occurs in the absence of any clear explanation, but immunosuppression due to any cause can precipitate reactivation. In normal hosts, about half of the 10 percent lifetime risk of reactivation occurs in the first 2 years after infection, and the remaining half occurs over the remaining years of life. Persons infected with tuberculosis in childhood can carry latent, asymptomatic infection for a lifetime, developing active disease as the immune system weakens in advanced age. This long latency period provides an opportunity to detect and treat TB infection, thereby preventing reactivation.

The reactivation rate for HIV-infected persons is much greater (5 to 10 percent *per year*) than that for normal hosts (5 to 10 percent *over a lifetime*). Moreover, primary infection is more likely to progress immediately, or soon after TB infection. Because the risk of TB is so great in HIV-infected persons, PPD reactions of 5 mm or more are considered positive. Not all HIV-infected persons with 5 mm PPD reactions are TB-infected, but infection is intentionally overdiagnosed and overtreated in order to prevent the disease in these highly susceptible persons.

Treatment of Infection and Disease

Among the great medical advances of the twentieth century has been the discovery of antibiotics effective against TB and other infectious diseases (Ryan 1992). Among the great disappointments of our time, however, is the realization that antibiotics alone have not eradicated any human pathogens. Antibiotics work by blocking critical microbial functions, tipping the balance toward the host's defenses, resulting in cure. Soon after the discovery of streptomycin in 1946, however—the first antibiotic highly effective against tuberculosis—the ability of microorganisms to circumvent the action of antibiotics, that is, to become resistant, became apparent. In the case of tuberculosis, drug resistance occurs by

rare but predictable spontaneous genetic mutations among infecting organisms, which are then selected to predominate if drug-susceptible organisms are killed off by any one effective antibiotic. Because mutations are rare (about one mutation in a million organisms), large numbers of organisms are required for a statistical likelihood that resistance will occur. This condition is satisfied when lung cavities form in active TB, in which tubercle bacilli flourish, but not in inactive, latent infection, where tubercle bacilli are relatively few in number.

What happened to those patients who became resistant to streptomycin in the 1950s? Many died. But when other effective drugs became available, it was soon discovered that resistant cases responded, and more importantly, that treating with multiple drugs at the same time was an effective way to prevent drug resistance. Spontaneous mutations to individual drugs are independent events. Organisms resistant to one drug remain susceptible to one or more others. The standard of tuberculosis treatment of active disease today is to begin with four drugs, and continue with at least two through the duration of therapy. In latent infection, however, because the numbers of organisms present are far fewer than in active disease, the risk of spontaneous drug resistance is correspondingly less. For this reason a single antibiotic is effective treatment for latent infection without disease, without the risk of engendering drug resistance. Isoniazid has been the most thoroughly studied of the drugs used to treat latent infection, but rifampin and other agents have also been used.

Treatment of Latent Infection. When tuberculin skin test conversion occurs on the job, defined as a documented increase in induration of at least 10 mm, treatment may be recommended to prevent progression to active disease. The clinical indications and contraindications for treating latent infection are beyond the scope of this chapter. However, when indicated, treatment of latent TB infection is usually both safe and effective. Large field trials have shown that 9 months of isoniazid (INH) daily (or twice weekly at a higher dose) reduces the chance of reactivation of latent infection by more than 90 percent. Because completion rates of therapy for latent infection among asymptomatic persons are relatively low, 6 months of INH have been recommended as a practical alternative, even though it may be somewhat less effective than 9 months, in an effort to get more persons through therapy. The only serious side effect of INH is hepatic inflammation (hepatitis), but this is uncommon and almost always reversible when the drug is promptly stopped with the onset of symptoms. In rare instances, almost always when drug ingestion continued despite symptoms, isoniazid hepatitis has progressed to liver failure, resulting in death or requiring liver transplantation. There are other less serious side effects occasionally associated with INH treatment, such as rash or headache, and they sometimes require discontinuation of therapy. When isoniazid cannot be used, another effective drug, rifampin, has been substituted. There is some evidence that rifampin may be effective as a shorter regimen, perhaps in as little as 4 months. The shortest regimen currently recommended is 2 months of INH and pyrazinamide, although experience with this regimen in the United States is limited.

Although an estimated third of the world's population is infected with tuberculosis and would presumably benefit from treatment for latent infection to prevent reactivation, such treatment is generally unavailable. All resources are directed toward treatment of active disease in high-prevalence areas, especially communicable pulmonary tuberculosis, and that task remains tragically incomplete. Only among those populations where effective disease treatment has been well established has treatment of latent infection been considered a rational public health strategy. The exception may be populations coinfectd with TB and HIV, where the high reactivation rate and tuberculosis mortality may demand that extra resources be found to implement treatment of both infection and disease.

Treatment and Control of Active Disease. As already noted, the treatment of both active and latent TB infection is long. This is because of the inherently low replication rate of

tubercle bacilli compared to ordinary bacteria, and the fact that current antibiotics are ineffective against tubercle bacilli that are truly dormant and metabolically inactive. As discussed earlier, treatment of active TB disease requires multiple drugs to prevent drug resistance. Because of the length of therapy, and because patients often begin to feel better long before the infection is eradicated, they sometimes fail to complete their full course of treatment. Since incompletely treated TB presents the threat of transmission to the public, treatment of active TB requires monitoring, coordination, and often intervention by local and state health departments. Health departments bring a different perspective to the treatment of TB infection than that found in the private sector. Some of these differences are listed below.

- Provider responsibility for treatment completion

Services at no cost to the patient

Availability of incentives and enablers to encourage treatment completion

- Outreach services

Full supervision of treatment [directly observed treatment (DOT)]

Cultural and language-sensitive services

Investigation, testing, and treatment of patient contacts

Although tuberculosis treatment can be prescribed by the private practitioner, clinic, or health maintenance organization (HMO), providers without a public health perspective and resources are seldom able to assure completion of therapy or contact tracing. Treatment of latent infection, for example, is in the interest of the community as well as the individual, and should not be discouraged by requiring copayments for drugs or visits. However health delivery systems evolve, tuberculosis will require provision for specialized public health resources to monitor and assure completion of therapy.

Droplet Nuclei Transmission

The transmission and engineering control of tuberculosis is discussed in Chap. 11. Tuberculosis control in institutions entails a much broader approach than engineering control, and this is discussed briefly below.

47.3 TUBERCULOSIS INFECTION CONTROL RECOMMENDATIONS: OVERVIEW

The following comments are based on the recommendations current at the time of this writing, that is, the 1994 *CDC Guidelines*. However, OSHA has proposed a *Tuberculosis Standard*, which, if adopted, would supersede the 1994 guidelines. The draft standard, published in November 1997, was based on the CDC document, but modified for monitoring and enforcement purposes. The draft document was the subject of considerable debate and controversy, and at the time of this writing was under revision. Current CDC guidelines and OSHA enforcement standards for institutions are widely available in print and on the World Wide Web (at www.cdc.gov), and should be consulted as authoritative sources of information. The following comments are intended to give the reader an overview of institutional infection control, from the author's perspective, which may not be entirely consistent with current recommendations or requirements in this controversial field.

Risk Assessment

Each institution should evaluate its risk for TB transmission on the basis of information such as the presence of known or unsuspected TB cases, the rate of TB in the population using the facility, and evidence for or against transmission to employees or other occupants. Reevaluation should be annual, as populations and risk factors change. An individual should be held responsible for organizing the risk assessment, with the assistance of other staff. Such a group should be designated as the institution's official tuberculosis infection control committee, and charged with data gathering, assessment, reassessment, and the development of an infection control plan.

TB Infection Control Plan

All institutions considered at risk for TB transmission will be required to have a written infection control plan, endorsed annually or modified, based on the infection control committee's assessment of the data. In most institutions such a plan will have the following components: a plan for educating staff about tuberculosis, a method for identifying suspects with infectious tuberculosis and triaging them into appropriate isolation facilities, a plan for respiratory isolation (including air disinfection and negative pressure—considered in Chap. 11), a plan for respiratory protection, and a plan for periodic skin testing of employees and other occupants at risk.

Identifying Suspects: Triage. As discussed previously, it is the unsuspected person with pulmonary tuberculosis who poses the greatest risk to other institutional occupants. Also discussed was the difficulty in selecting those especially likely to have the disease from those with similar symptoms due to other causes. This is the most challenging aspect of the triage plan: raising awareness enough to identify and isolate cases early without isolating every person with a cough or chest x-ray infiltrate if they are not at high risk. Criteria for isolation need to be established, and periodically be reassessed, on the basis of the rate of overisolation. Just what constitutes an acceptable rate of overisolation is unclear.

Isolation Rooms, Air Disinfection, and Negative Pressure. (See Chap. 11.)

Respiratory Protection. Perhaps the most controversial of the components of tuberculosis infection control in institutions has been the requirements for respiratory protection. Within occupational medicine and industrial hygiene, respiratory protection is a well-established discipline based on considerable science. The application of these industrial principles to tuberculosis control in institutional setting, however, has been difficult. Based on the tiny particle size of droplet nuclei (1 to 3 μm diameter) and the fact that one droplet nucleus can, in theory, cause infection, high-level respiratory protection was originally recommended. It soon became apparent that for routine use in hospitals and other institutions, for encounters with countless patients who are at risk for tuberculosis, most of whom do not have the disease, powered air-purifying respirators (PAPRs) were impractical and of unproven necessity. Not only are such respirators expensive; they impede communication, and may increase other hazards, such as handling needles and other hazardous materials. Through a long process of give and take between the health care community, NIOSH, and respirator manufacturers, new classes of respirators were developed and certified for use in the health care setting. These so-called N-95 respirators look and feel to the wearer much like disposable industrial respirators, but have fit and filtration characteristics better suited for their intended use. Face seal leakage remains their major limitation, despite fit testing and fit checking. However, when used in well-ventilated isolation and procedure rooms, the

resulting combined protection has been estimated to be more than adequate for all except the most intensive exposures, as might be encountered during high-risk procedures (Fennelly and Nardell 1998). For high-risk procedures, however, and when caring for known or suspected drug-resistant disease, higher respiratory protection is warranted, including PAPRs which have the advantage of minimizing face-seal leakage.

Periodic Skin Testing of Employees. Baseline and periodic skin testing of institutional workers potentially exposed to tuberculosis has been recommended by CDC and required by OSHA. Depending on the risk estimate for the institution and specific work category, institutions are required to test at least annually, and as often as every 3 months. The goals of frequent testing are to (1) detect new infection in the employee promptly so that evaluation for disease and preventive therapy takes place before symptomatic, contagious disease occurs and (2) promptly identify transmission so that a contact investigation and treatment ensues, in a further effort at containment. Two-step baseline testing is necessary to minimize false-positive conversions resulting from boosting of waning hypersensitivity due to prior infection with tuberculosis, environmental mycobacteria, or BCG vaccination (see 1994 CDC Guidelines for details). However, the tuberculin skin test remains an imperfect diagnostic test, with especially poor performance under low-prevalence conditions for tuberculosis. Mandated testing of all potentially exposed institutionally employees in low-risk facilities is sure to result in a high percentage of false-positive results despite all precautions. This is especially true among employees from places where BCG is used, where environmental mycobacteria infection is common, and where TB infection occurs early in life.

If An Employee Becomes Infected with Tuberculosis. The indoor air quality professional may be among those consulted when an institutional worker becomes infected with tuberculosis. The assessment and control of bioaerosol hazards in general, and tuberculosis in particular, are covered in detail in a monograph by Nardell and Macher (1999). The investigating infection control practitioner will first need to be satisfied that the apparent skin test conversion most likely represents true TB infection, and not a false-positive reaction, as discussed above. The investigator will also consider the possibility of transmission outside the institution, in the community, or in another institutional setting. When there is a suspected source case associated with the workplace, it is reasonable to assume that infection occurred at work. After considering potential lapses in administrative control procedures, such as prompt isolation, the investigator may consider the possibility that environmental conditions contributed to transmission. However, the indoor air quality professional should be certain that the infection control staff has concluded that transmission probably occurred before launching an elaborate environmental investigation.

In hospitals, most transmission is believed to occur in emergency rooms, general medical care areas, and intensive care units—not isolation rooms. The investigator will want to know that mechanical ventilation systems were working to specifications at the time of potential exposure. If exposure in a negative-pressure isolation or procedure room was suspect, assessment of both directional airflow and air turnover rates will be necessary. In laboratories, the function of exhaust hoods must be examined. The proper function of air filters or ultraviolet air disinfection devices must also be assessed, including the possibility that they were turned off at the time of transmission. The selection, fit testing, and use of personal respiratory protection is unlikely to be the sole reason for transmission, but it must be considered. Again, failure to use any respiratory protection at all in the presence of an unsuspected TB case is probably a much more common error than is an improper choice of respirator or inadequate fit testing. Under the scrutiny of an investigation looking for probable causes for transmission, deficiencies will be found and cause and effect may be concluded. The problem is that equally close scrutiny of many other institutions that have not

experienced transmission would likely find comparable deficiencies (Nardell 1998). In many cases of institutional TB transmission it is not possible to determine a single correctable cause. Nor is it possible to guarantee the absence of transmission in the future. However, the diligent application of commonsense control strategies can greatly reduce the chance of transmission.

TUBERCULOSIS

CHAPTER 48

LEGIONELLA

Brenda E. Barry, Ph.D.

*Environmental Health & Engineering, Inc.
Newton, Massachusetts*

48.1 INTRODUCTION

Legionella bacteria dramatically emerged from obscurity when they were identified as the cause of a deadly pneumonia epidemic in Philadelphia, Pennsylvania in July 1976 (Fraser et al. 1977, Fraser and McDade 1979). Members of the American Legion's Pennsylvania Department and their families had gathered at the Bellevue-Stratford Hotel in Philadelphia for their 58th annual convention. Within days of the start of the convention, some participants began to experience cough and fever that developed into pneumonia. Days after the convention had ended and attendees had returned to their homes, cases of pneumonia continued to be reported to Pennsylvania health departments. A total of 182 conventioners and other individuals who had entered the hotel during the convention developed the mysterious pneumonia, and 29 died. Although possible causes for the pneumonia epidemic were unknown, the media quickly labeled the illness Legionnaires' disease, and an extensive investigation was begun to determine its source. Months of detective work involving investigators from the Centers for Disease Control and Prevention (CDC) and other researchers were required to isolate and identify the bacteria that were the cause of the serious and, potentially fatal, pneumonia (Fraser et al. 1977, McDade et al. 1977).

Current-day building ventilation equipment, such as cooling towers, and water from potable-water systems continue to provide sources for exposures to *Legionella* bacteria and to present risks for developing Legionnaires' disease. Estimates from the CDC indicate that 10,000 to 15,000 cases of Legionnaires' disease occur annually in the United States alone (Marston et al. 1993, Millar et al. 1997). However, these figures are regarded as underestimates of actual disease incidence because infections caused by *Legionella* bacteria can be identified only when specific clinical tests for the bacteria are conducted. Many sporadic single cases of pneumonia caused by *Legionella* bacteria likely go unrecognized without

the required testing. The CDC estimates do, however, pointedly demonstrate that exposures to *Legionella* bacteria and the illnesses they can cause are current and important public health issues for those who manage buildings, and, in particular, for those who manage hospitals. The goal of this chapter is to describe *Legionella* bacteria, the health concerns they present, how the bacteria can be identified, what to do if growth is detected, and what can be done to prevent or minimize their growth.

48.2 BACKGROUND ON LEGIONELLA BACTERIA

Epidemiology

Legionellosis is the general term for an infection caused by exposure to *Legionella* bacteria. This designation includes not only Legionnaires' disease but also a short-term flulike illness called Pontiac fever, named after Pontiac, Michigan, the site of the first recognized outbreak of this illness. Infections caused by *Legionella* bacteria occur primarily following inhalation of aerosolized bacteria from a contaminated-water source. Some evidence indicates that infections may occur from direct contact of contaminated water with surgical wounds or by aspiration of contaminated water by patients who have undergone head and neck surgery (Breiman 1993). No person-to-person transmission has yet been documented. Critical elements for disease incidence usually include a mechanism for aerosolizing water from a source that contains *Legionella* bacteria, a pathway for the aerosol to reach susceptible individuals, and then inhalation of the aerosol by those individuals. Infections may occur sporadically, occur as part of an outbreak, or be acquired during a hospitalization (nosocomial infection).

The detective work begun by the CDC in 1976 did not end with the discovery of the cause of Legionnaires' disease. Following identification of *Legionella* bacteria as the infectious agent in the 1976 Philadelphia epidemic, the CDC investigated the possibility that these bacteria were also the culprits in other unsolved infectious outbreaks (Fraser and McDade 1979). *Legionella* bacteria were subsequently identified as the cause of Pontiac fever. In July 1968, nearly all of the 100 employees in, ironically, the Oakland County Health Department in Pontiac, Michigan developed flulike symptoms that resolved within a few days. The CDC subsequently identified *Legionella* bacteria as the cause of this earlier outbreak through analyses of serum samples that had been frozen and saved from the infected employees. Additional archival research revealed that *Legionella* bacteria had been the cause of other mysterious respiratory infections prior to their discovery in 1976. It was determined that an organism similar to *Legionella* bacteria had been isolated in 1947 (McDade et al. 1979) and that an outbreak of Legionnaires' disease had occurred in a meat-packing plant in 1957 (Osterholm et al. 1983).

Exposures to *Legionella* bacteria in unusual settings and subsequent infections caused by the bacteria continue to be sources of newsworthy items. In 1989, 33 grocery store shoppers in Louisiana were hospitalized with Legionnaires' disease following exposures to *Legionella* bacteria from an ultrasonic mist machine located in the produce department (Mahoney et al. 1992). In 1994, an outbreak of Legionnaires' disease among passengers on a cruise ship was linked to exposures from contaminated whirlpool baths (CDC 1994a). In 1996, a whirlpool spa display in a home-improvement center in Virginia was identified as the source of exposure for 23 store customers who had developed Legionnaires' disease; 2 of the victims subsequently died (CDC 1997).

The course of a *Legionella* infection and its likely victims differ between Legionnaires' disease and Pontiac fever. Legionnaires' disease occurs more frequently in older individuals, in individuals with preexisting lung disease or poor health status, in cigarette smokers, and in individuals with weakened immune systems due to chemotherapy or serious infec-

tions (CDC 1994b). The disease is often initially diagnosed as an atypical pneumonia. Because a number of bacteria and viruses can cause atypical pneumonia (Cotran et al. 1994), *Legionella* bacteria cannot be identified as the specific cause of the pneumonia without clinical testing for the presence of the bacteria. The disease usually begins 2 to 10 days after an exposure to the bacteria. Once inhaled into the lungs, the bacteria are readily engulfed and then grow within cells of the human immune system, such as alveolar macrophages and monocytes. Because the *Legionella* bacteria are protected within these immune cells, other infection-fighting cells in the body, called polymorphonuclear leukocytes, cannot effectively kill them. Patient symptoms can include fever, nonproductive cough, malaise, muscle aches, headaches, and chest pain; symptoms are generally quite severe.

One test often used to determine the presence of *Legionella* bacteria in specimens collected from the respiratory tract or urine samples is the indirect immunofluorescent antibody (IFA) test. This test uses antibodies against the bacteria that are labeled with fluorescent dyes to detect the bacteria by light microscopy. The bacteria are labeled with the dyes by attachment of the antibodies to them. The most specific test is direct culture of *Legionella* bacteria from respiratory tract secretions. Once diagnosed, patients with Legionnaires' disease are usually treated with the antibiotic erythromycin, although the antibiotic rifampin can also be used. Unfortunately, once infected, an individual's probability of subsequently dying from Legionnaires' disease ranges between 5 and 30 percent (Millar et al. 1997). Those who do recover from Legionnaires' disease often require a long period of convalescence during which medical costs continue and potential income is lost.

In contrast, Pontiac fever usually affects young adults to middle-aged adults and may occur in more than 90 percent of exposed individuals. Usually within 1 to 10 days after an exposure, infected individuals can begin to experience fever, cough, muscle aches, headaches, and chest pain, but no sputum production. These individuals usually recover fully from their infection within 3 to 5 days without medical complications. As a result, without specific testing for the presence of the bacteria, individuals can develop and recover from what they may regard as a summer cold or short-term flu without knowing that exposures to *Legionella* bacteria were the underlying cause.

As noted previously, although the CDC estimates more than 10,000 cases of Legionnaires' disease occur annually in the United States, the number of individuals who develop Pontiac fever is likely larger and even more difficult to estimate. Estimates of total numbers of individuals who have had an exposure to *Legionella* bacteria at some point in their lifetime is conceivably in the millions. This estimate is based on results from blood tests from normal healthy adults using the IFA method that determined that 1 to 16 percent of the tested individuals had elevated antibody titers for the bacteria (CDC 1994b). These antibody titers indicate that some prior exposure to *Legionella* bacteria caused a response by the immune system that was sufficient to produce antibodies to the bacteria.

These figures concerning disease incidence caused by exposures to *Legionella* bacteria should raise awareness among building and hospital managers regarding potential liability claims from individuals who may develop *Legionella* infections following exposures. Lawsuits related to cases of Legionnaires' disease are often settled rapidly and quietly to avoid negative publicity for the suspected or identified building source (Freije 1996). However, these claims can often result in settlements involving five-figure and six-figure sums. Development of sound maintenance programs for cooling systems and potable-water systems in buildings and hospitals followed by their implementation in conjunction with regular water testing protocols can be cost-effective approaches that pay long-term dividends.

Microbiology

Since the initial discovery of the genus *Legionella* in the 1970s, much has been learned about these potentially pathogenic bacteria (Winn 1995). First, these bacteria are not rare

or unusual organisms; they are natural inhabitants of lakes, streams, and wet soils throughout the world. Although more than 39 different species have been identified in the genus *Legionella*, one species, *Legionella pneumophila*, has been most frequently identified as the cause of legionellosis, including the 1976 Philadelphia epidemic (Breiman 1993). Within the species *Legionella pneumophila*, 14 different subgroups, termed *serogroups*, have also been identified; a total of 60 serotypes have been identified within the *Legionella* genus to date. *Legionella pneumophila*, serogroups 1 and 6 have been most frequently linked with legionellosis (Marston et al. 1994). Although many *Legionella* species have not yet been clearly identified as causes of legionellosis, possibly because of their scarcity in the environment, at this point, all species should be regarded as possible human pathogens.

Microbiologists classify *Legionella* bacteria as gram-negative, based on their staining characteristics with the Gram stain (Winn 1995). They range in size from 1.5 to 5 μm in length and 0.3 to 0.9 μm in diameter. The initial difficulties encountered when isolating and identifying *Legionella* bacteria from victims of the 1976 Philadelphia epidemic were due to the specific growth requirements of these bacteria and to problems in detecting them by light microscopy on sections of lung tissue from infected individuals. Researchers quickly determined that traditional bacterial growth media did not support the growth of *Legionella* bacteria. The bacteria were eventually cultured on media containing the amino acid cysteine and iron salts. The medium currently recommended for culturing *Legionella* bacteria that contains these ingredients is buffered yeast charcoal extract (BYCE) agar (National Center for Infectious Diseases 1994); antibiotics can be added so that the media is more selective for *Legionella* growth. The problems with microscopic identification of the bacteria were resolved when the Gimenez method, a silver-staining technique, was successfully used to visualize the bacteria within tissue sections (McDade et al. 1977).

The growth and proliferation of *Legionella* bacteria in environments such as cooling towers and potable-water systems depend on the appropriate mix of environmental and nutrient conditions (Barbaree 1991). Although *Legionella* bacteria can multiply in water temperatures ranging from 68 to 122°F (20 to 50°C), optimal growth occurs between 95 and 115°F (35 and 46°C). These temperatures commonly occur outdoors in the summer and early fall when legionellosis outbreaks are more frequently reported. In addition, *Legionella* bacteria are resistant to killing by the chlorine levels normally present in municipal water systems. Scale, sediment, and biofilm in plumbing systems are other factors that can support growth of the bacteria (Freije 1996). Biofilm, more commonly referred to as slime, is an accumulation of microbial growth on surfaces that can occur within plumbing and cooling-tower system components. The presence of other microorganisms in the water source, such as amoebas and protozoa, also appears to be an important factor for the successful proliferation of *Legionella* bacteria. The bacteria can multiply intracellularly within these microorganisms in the same way as they do within macrophages and monocytes in human hosts (Winn 1995). Their growth within amoebas, protozoa, and human immune cells may also provide a shelter that protects the bacteria from chemical treatments and drug regimens used to kill them.

48.3 EXPOSURE TO LEGIONELLA BACTERIA

Sources

Although *Legionella* bacteria were discovered in the mid-1970s, their presence in building environments most likely coincided with earlier developments in building construction and ventilation technology. Equipment used to manage indoor environments in buildings, and specifically to provide cooling, has provided a number of artificial environments that can

support the growth and proliferation of *Legionella* bacteria (Barbaree 1991). Air-conditioning equipment, such as cooling towers and evaporative condensers, are examples of systems that can provide both the warm temperatures and the nutrient conditions required for *Legionella* growth (Freije 1996). Water circulating through cooling systems equipment is used to reject heat generated by cooling activities (Pannkoke 1996). The water serves as a transfer medium for removing heat from coolant materials, such as freons, that circulate in air-conditioning systems. The warm water is then piped to cooling towers where it is sprayed into the air, transferring the heat from the warm water to the air drawn into the cooling tower. In the absence of adequate chemical treatment to control the growth of bacteria, algae, and protozoa in the recirculated water, *Legionella* bacteria can grow and proliferate. Chemical approaches for controlling the growth of microorganisms are discussed in a later section.

Potable-water systems can also be sources for *Legionella* bacteria in indoor environments. Because *Legionella* bacteria normally inhabit freshwater environments, low levels of the bacteria can be present in the municipal water supply that is delivered to buildings. Once within domestic water systems, the bacteria may find niches for growth in hot-water heaters, showerheads, tap faucets, whirlpool baths, and hot tubs. Humidifiers and decorative fountains are other potential environments for bacterial growth.

Risks from exposure to *Legionella* bacteria from potable-water sources are a particularly important issue in health care environments, such as hospitals and nursing homes. This is because patients with preexisting diseases may be at increased risk for developing a nosocomial infection from exposures to *Legionella* bacteria (Freije 1996). Exposures to the bacteria can occur from not only the domestic water sources noted previously but also from water reservoirs in patient respiratory care equipment, such as nebulizers and ventilators. Sterile water rather than tap or distilled, nonsterile water should always be used in these devices. Large volume room-air humidifiers that may create aerosols of water contaminated with *Legionella* bacteria should also be avoided in health care environments.

Elements for an Exposure to *Legionella* Bacteria

Development of legionellosis requires three basic elements: a source of *Legionella* bacteria, a pathway to potentially exposed individuals, and inhalation of viable bacteria by those exposed individuals. These three basic elements are illustrated in Fig. 48.1. The requirement for all three elements to be present may help explain why outbreaks of Legionnaires' disease or Pontiac fever are not more common. For example, published reports indicate that up to 45 percent of all cooling towers contain measurable levels of *Legionella* bacteria (Shelton et al. 1994). However, few cooling towers are associated with outbreaks of Legionnaires' disease or Pontiac fever. The reason likely lies in the fact that one or more of the three exposure elements is deficient or missing, so that sufficient numbers of viable bacteria are not transported from a contaminated source and then inhaled by a susceptible host.

When a source of *Legionella* bacteria is identified in a building, building owners and occupants often raise concerns about the potential health risks for developing illnesses due to airborne exposures to the bacteria. Those managing the remediation efforts often must address these genuine health concerns from those potentially at risk. Discussion of the potential health risks should focus on evaluating the specific exposure scenario because the source, pathway, and exposure elements can vary for each situation (Barry et al. 1999).

The concentration of *Legionella* bacteria measured in the contaminated source is the first element; methods for determining this value are discussed in a subsequent section. For a source such as a cooling tower, estimation of the concentration of *Legionella* bacteria likely emitted from the tower should not be based solely on the bacterial concentration measured in the cooling tower water. It should also include water flow and airflow rates in the

FIGURE 48.1 This figure illustrates the three basic elements required for an infection caused by *Legionella* bacteria: a source of the bacteria, such as a cooling tower; a pathway to potentially exposed individuals; and an exposure of susceptible individuals to viable bacteria. Two types of potentially exposed individuals are shown: an office worker within a building and a hospital patient.

tower, and the percentage of aerosolized water that escapes from the cooling tower (tower drift). *Legionella* concentration in a potable-water source, such as a showerhead or faucet, can be determined from water samples collected from these sources.

The second element is the pathway. Variables in the pathway can significantly affect the number of airborne bacteria that an exposed individual might eventually inhale (exposure dose). For example, pathway variables that may affect the airborne *Legionella* concentration between a cooling-tower source and occupants of a building include distance from the tower, wind conditions, moisture level in the air, and the efficiency of filters in the ventilation system. Moisture level, measured as relative humidity, should also be considered because water evaporation can reduce bacterial viability by removing the protective water medium surrounding the bacteria. In contrast, a maintenance worker standing next to the same cooling tower is likely to receive a higher exposure dose during a comparable exposure period because the pathway is shorter and the bacterial aerosol from the tower is less diluted. Similarly, an individual is likely to receive a greater exposure dose while showering under a contaminated showerhead or sitting in a contaminated whirlpool bath because of the proximity to the source.

The third element is the characteristics of the individual who may be exposed to the bacteria. As noted previously, Legionnaires' disease is more likely to occur in older individuals and those with preexisting diseases or poor health status, whereas Pontiac fever usually affects young to middle-aged adults who recover fully without medical complications. Aerosol droplets containing *Legionella* that are less than 5 μm in size can be inhaled and easily reach the small airways and gas-exchange regions in the lungs. However, the number of inhaled bacteria necessary to cause a legionellosis is not yet known. The attack rate for Legionnaires' disease, that is, the percentage of individuals who develop the disease following an exposure to a source, is estimated to be approximately 4 percent. The fatality rate among those who do develop Legionnaires' disease is currently estimated at between 10 and 15 percent; however, the fatality rate for nosocomial infections in hospital patients may be as high as 30 to 50 percent (American Society for Testing and Materials 1997). In comparison, the attack rate for Pontiac fever is 95 percent, but the fatality rate is virtually zero.

48.4 METHODS FOR DETECTING LEGIONELLA BACTERIA

The reliability and validity of test methods used to detect and quantify *Legionella* bacteria in suspicious water samples are essential qualities for correct interpretation of the results and subsequent implementation of any necessary remediation procedures. Because *Legionella* bacteria have very specific growth requirements, only those laboratories with expertise in culturing and quantifying the bacteria should be used for sample analyses. An underestimated bacterial count due to improper growth media or conditions, insufficient culture period, or inadequate identification procedures could inadvertently mask potential health risks for exposed individuals.

Direct culture is the best method for evaluating the presence of *Legionella* bacteria in water samples obtained from cooling towers and potable hot-water sources. This is because it detects only viable bacteria that could cause legionellosis. An additional benefit of this test method is that its specificity is 100 percent. The primary drawback is the culture period of approximately 8 to 10 days that is required to obtain accurate results. This waiting period may prolong selection and implementation of the appropriate remediation activities and may increase apprehension among building owners and occupants about potential health risks resulting from exposures. However, if water testing is conducted as part of regular maintenance procedures, changes in *Legionella* concentrations can be detected during an early phase of proliferation and appropriate remedial actions can be implemented more rapidly to reduce both bacterial levels and possible health risks.

Two rapid screening methods are available for detecting the presence of the bacteria in water samples in less than one day:

1. *The direct fluorescent antibody (DFA) test.* This method uses fluorescein-labeled antibodies against *Legionella* bacteria and fluorescence light microscopy to detect the presence of the bacteria in water samples. The advantage of this method is that the results can be obtained within a few hours of testing. However, the positive predictive value of DFA has been categorized as unacceptably low (Winn 1995). False-positive results can occur as a result of cross-reactions of the fluorescent antibodies with bacteria other than *Legionella* and with residual organic matter that may be present in the water sample. This method may also overestimate the numbers of *Legionella* bacteria capable of causing legionellosis because it detects both viable bacteria, that is, those that can proliferate in a susceptible host, and nonviable bacteria that cannot. False-negative results may also occur if the antibodies used for the assay are old or cannot detect a specific *Legionella* species.

2. *The polymerase chain reaction (PCR).* This method detects selected regions of genetic material specific for *Legionella* bacteria and then amplifies and labels these regions for identification (Morris 1996, American Society for Testing and Materials 1997). Similar to the DFA technique, a drawback is that overestimates may occur because both viable and nonviable bacteria are detected. Some environmental samples may also contain compounds or materials that interfere with or inhibit the PCR test.

In summary, direct culture is the recommended method for evaluating the presence of *Legionella* bacteria in water samples despite the disadvantage of waiting for colony growth. No reliable correlation can be drawn between numbers of viable bacteria in water samples, which can be clearly detected by the direct culture method, and the numbers of *Legionella* bacteria detected by DFA and PCR methods.

Collection of air samples directly onto nutrient agar should also be mentioned as a sampling technique for environmental samples. However, this method is not generally recommended (Morris 1996). Air samples are usually collected for 3 to 5 minutes onto an

appropriate media, such as BYCE, using a sampling pump drawing air at a known volume. The drawbacks of air sampling include a short sampling period and wide variability in airborne concentrations of bacteria from the suspected source due to spatial and temporal factors. In addition, *Legionella* bacteria may be damaged on impact with the nutrient plate, resulting in reduced colony counts and an underestimate of actual airborne concentrations.

48.5 GUIDELINES FOR REMEDIATION OF LEGIONELLA BACTERIA

The guidelines summarized in Table 48.1 present sound and conservative remedial actions when *Legionella* bacteria are detected in water samples from various sources. The table is based on numbers of bacteria detected by direct culture assays for viable bacteria. The detected levels are reported as the number of bacteria that formed colonies on the media plate per milliliter of water sampled and are expressed as colony-forming units per milliliter (cfu/mL). This table, which has been modified from the original version developed by Shelton et al. (1993), summarizes potential health hazards and recommended remedial actions following detection of *Legionella* bacteria for two categories of sources: (1) cooling towers and evaporative condensers and (2) a variety of sources supplied by potable-water systems such as hot-water tanks, showerheads, sink faucets, whirlpool baths, hot tubs, humidifiers, and decorative fountains.

The recommendations listed in Table 48.1 are based on a dose-response relationship for risk of infection. This means that the likelihood of developing an infection from an exposure to *Legionella* bacteria from a specific source increases with the number of bacteria that an individual might inhale from that source (exposure dose). The investigators developed these guidelines empirically from measurements of concentrations of *Legionella* bacteria from a variety of selected sources and information about reported cases of legionellosis that had been associated with various types of contaminated sources. Development of the rankings of the action levels in Table 48.1 involved consideration of the three elements—source, pathway, and dose—discussed previously.

Because of their ubiquitous nature, *Legionella* bacteria can never be completely eliminated from cooling systems and potable-water sources. Growth and proliferation can occur in systems that receive excellent maintenance. Detection of low levels of bacteria, that is, less than approximately 50 to 100 cfu/mL, indicates that the identified source should be monitored further and that cleaning or chemical treatment of the source may be appropriate. Detection of levels greater than 100 cfu/mL requires implementation of more stringent procedures because of the increased possibility for a legionellosis outbreak.

The CDC has developed procedures for disinfection of potable-water systems and cooling towers that have been contaminated with *Legionella* bacteria (CDC 1994b). The procedures for potable-water systems involve a pulse (one-time) thermal disinfection. The water in the hot-water tanks is raised to greater than 150°F (65°C), and then each outlet is flushed for at least 5 min. The 1994 CDC document also describes procedures for disinfecting cooling towers and related equipment; these procedures were adapted from a protocol developed by the Wisconsin Department of Health and Social Services (1987). Freije (1996) has provided additional information concerning recommendations for decontamination procedures for health care facilities.

The CDC protocol for disinfection of cooling towers has four stages: preparation, chemical disinfection, mechanical cleaning, and final disinfection and restart. During preparation, personal protective equipment (PPE) must be worn by workers, and the tower is shut down except for water circulation. Containment should be constructed around the tower to prevent release of *Legionella* bacteria to the environment during the cleaning process. A

TABLE 48.1 Suggested Remedial Actions Following Detection of *Legionella* Bacteria in Water Samples from Various Sources

<i>Legionella</i> , cfu/mL of sample ^a	Recommended remedial action	
	Cooling-tower evaporative condensers	Potable-water sources
Detectable, but less than 1	1 ^b	2 ^c
1–9	2 ^c	3 ^d
10–99	3 ^d	4 ^e
100–999	4 ^e	5 ^f
Greater than 1000	5 ^f	5 ^f

^aColony-forming units per milliliter.

^bAction 1. Low level of concern. Review routine maintenance program recommended by manufacturer.

^cAction 2. Low level of concern, but the number of organisms detected indicates that the source is a potential growth site for *Legionella* bacteria. Implement action 1. Conduct follow-up testing.

^dAction 3. Low, but increased level of concern. Implement action 2. Review premises for possibility of direct and indirect exposures. Depending on review results, cleaning or biocide treatment of the equipment may be indicated.

^eAction 4. High level of concern. It is uncommon for samples to contain numbers of *Legionella* bacteria that fall into this category. Implement action 3. Cleaning or biocide treatment of the equipment is indicated.

^fAction 5. High level of concern and potential for causing an outbreak. It is very uncommon for samples to contain numbers of *Legionella* bacteria in this category. Immediate cleaning or biocide treatment of the equipment is definitely indicated.

rapid-release, chlorine-based disinfectant, such as sodium hypochlorite or calcium hypochlorite, is then added to system water to attain an initial free residual chlorine (FRC) concentration of approximately 50 parts per million (ppm). Additional chlorine disinfectant is added as needed to maintain an FRC level greater than or equal to 10 ppm for 24 h. The pH is adjusted to a range between 7.5 and 8.0, and a detergent, such as a dishwashing agent, is added shortly after initiation of the disinfection cycle to facilitate removal of buildup in the piping. FRC and pH are monitored at approximately 15-min intervals for the first 2 h and at 2-h intervals for the remainder of the 24-h disinfection cycle. The CDC protocol provides additional information regarding mechanical cleaning of the cooling tower following the disinfection process and the recommended restart procedures.

48.6 REDUCING RISKS FOR LEGIONELLA INFECTIONS

Maintenance Programs

The best approach for minimizing health risks from exposures to *Legionella* bacteria in cooling systems and potable-water systems is to implement sound maintenance programs that minimize the likelihood for bacterial growth and proliferation. Programs for these two categories of systems are discussed separately.

Cooling Towers. Two objectives of a comprehensive water treatment program for cooling towers are maintenance of maximum cooling efficiency and extension of equipment lifetime. Control of microbial growth in cooling-tower water with biocides and regular cleaning programs can achieve both of these objectives (Bentham and Broadbent 1995). Microorganisms can enter a cooling-tower system from the water supply, through the air intake, or during tower installation. As noted previously, bacteria and other microorganisms can then not only accumulate in the circulating water but also grow on surfaces and accumulate as a biofilm, more commonly referred to as slime. Selection of a chemical treatment program and treatment schedule for a cooling system should be tailored to match the particular demands and operation of that system. The evaluation process should yield an effective water treatment program that minimizes the growth of bacteria, fungi, protozoa, and algae.

Other water treatment chemicals can also be added to the water treatment program to minimize scale and corrosion on cooling system component surfaces. Scale, which is an accumulation of mineral deposits on surfaces, and corrosion can both contribute to microbial proliferation by providing additional surfaces for microbial growth. Biocide use enhances efficient operation of cooling systems by maximizing heat transfer and minimizing corrosion of components and degradation of other water treatment chemicals that control scale and inhibit corrosion (Elsmore 1986).

An effective program for preventing the growth of *Legionella* bacteria in cooling-tower systems also includes comprehensive cleaning of towers at least once, preferably twice, a year. Cleaning is recommended in the spring prior to full start-up and in the summer and fall when outbreaks due to *Legionella* growth are more likely to occur. Regular water sampling for the bacteria can be used to monitor changes in bacterial populations that could indicate the need for modifications in the biocide treatment protocol or cleaning of the tower. Maintenance personnel should wear personal protective equipment (PPE) while collecting samples; recommended PPE includes gloves, disposable clothing, and a respirator. Bottles treated with sodium thiosulfate to neutralize residual chlorine should be used for water sample collection. It should be noted that total bacteria counts (TBC), which are routinely performed to monitor biocide effectiveness, are not an accurate indicator of *Legionella* bacteria concentrations. *Legionella* concentrations do not necessarily correlate directly with TBC values. Proactive monitoring to assess biocide treatment efficacy should include collection of water samples that are specifically tested for the presence of *Legionella* bacteria.

Portable Water Systems. One of the first steps in the development of a sound maintenance program for potable-water systems should be a review of the system design and its components (Freije 1996). For example, dead legs in the plumbing lines should be removed because they can harbor stagnant water that may be a source of contamination for an entire system. Washers and gaskets made of natural rubber should be avoided because they can support the growth of *Legionella* bacteria. Faucets and showerheads with scale buildup should be replaced. Another component of a good maintenance program is regular cleaning for plumbing system components. This is because, in most cases, biocides and disinfectants cannot be used in domestic water systems because of the potential for human exposures to these harsh chemicals. Hot- and cold-water tanks should be drained at least once per year so that scale and sludge can be removed. Because hot-water tanks can be a particular point of *Legionella* contamination, water temperatures should be maintained above 140°F (60°C). Water from hot-water tanks should be able to reach 120°F (50°C) at faucets and showerheads after 1 minute of full flow to minimize the likelihood for *Legionella* growth. As noted for cooling-tower systems, a proactive water sampling program can be used to monitor the effectiveness of a maintenance program for minimizing *Legionella* concentrations in domestic water systems.

Chemical Treatment Programs for Cooling Systems. The two basic categories of biocides used in cooling-tower systems are oxidizing and nonoxidizing. Oxidizing compounds

include chlorine and bromine compounds. Examples of nonoxidizing biocides include quaternary ammonium compounds, thiocarbamates, and glutaraldehyde (Elsmore 1986).

Use of high concentrations of chlorine, termed hyperchlorination, can be an effective chemical treatment for eliminating *Legionella* bacteria in cooling systems. However, this approach can be costly because of the corrosive nature of chlorine and the subsequent damage to cooling system components. As a result, routine hyperchlorination is rarely used as a long-term strategy for controlling *Legionella* bacteria. Rather, this strategy is reserved for decontamination of cooling-tower systems that have high levels of *Legionella* bacteria (CDC 1994b).

Sodium hypochlorite (bleach) and sodium bromine compounds, particularly used in combination, can provide an effective treatment approach. This combination provides both chlorine and bromine as free halogen biocides to a cooling system. In general, continuous low-concentration treatment with an oxidizing biocide, such as sodium hypochlorite, is recommended for long-term control of microorganisms in cooling towers (Pope and Dziewulski 1992). Combined with a dispersant that acts as a detergent to minimize buildup within the system and proper pH control, these compounds can provide an effective biocidal system.

A brominated biocide, such as bromochlorodimethylhydantoin (BCD), is typically recommended for systems that operate under slightly more alkaline conditions ($\text{pH} > 8.0$). BCD is a broad-spectrum oxidizing biocide that contains both bromine and chlorine. Studies suggest that BCD can effectively control *Legionella* bacteria levels if it is used to maintain continuous levels of halogen (Bentham and Broadbent 1995). It may be necessary to utilize this chemical at concentrations that are higher than the manufacturer's recommended dosage (Fliermans and Harvey 1984, Pope and Dziewulski 1992). Proactive monitoring should be utilized to assess the effectiveness of this product because current literature indicates disagreement regarding effective concentrations. This diversity of opinion is likely due to a wide variety of site-specific characteristics.

Proper implementation of a water treatment protocol and a testing program to monitor its effectiveness are critical for a successful treatment program. However, no one program can be recommended for all cooling systems because of the wide variability in size, design, operation, and water quality (Bentham and Broadbent 1995). One strategy for increasing biocide effectiveness is to alternate use of biocide products. For example, glutaraldehyde, which is a nonoxidizing organic biocide, can be added to a system periodically as a secondary biocide. Use of an automated feed system for delivery of biocides and other water treatment chemicals to cooling towers is generally recommended. However, if a manual system is used for delivering any component of a water treatment program, such as glutaraldehyde, accurate recordkeeping of the treatment applications by maintenance personnel should be emphasized and enforced.

Design and Siting of Cooling Towers

Selection of a new cooling tower or replacement of an old model provides an opportunity to reduce the likelihood that it will become a future source of a legionellosis outbreak. Important factors that should be reviewed during the selection process are cooling-tower design, component materials, and the location selected for installation (American Society of Heating, Refrigerating, and Air-Conditioning Engineers 1996). Table 48.2 provides a summary of recommended selection and installation criteria for cooling towers.

The types of materials used for the construction of the cooling tower are an important factor. Although early cooling towers were constructed primarily of wood, current models use a variety of materials to resist corrosion, reduce maintenance, and promote long life (Pannkoke 1996). Galvanized steel, stainless steel, concrete, fiberglass, and plastics are common component materials.

TABLE 48.2 Selection and Installation Criteria for Cooling Towers

Selection criteria:

- Performance of drift eliminators
- Ease of access to tower interior, drift eliminators, and sump area
- Components made of durable, easy-to-clean materials
- Sufficient sump drainage
- Reliability

Installation criteria:

- Prevailing wind direction
- Location of existing air intakes
- Siting of towers as far away as possible from outdoor air intakes, operable windows, and public areas
- Relocation of existing air intakes that are less than 25 ft away
- Commissioning of tower to ensure proper operation
- Adherence to manufacturer's recommendations

The design and efficiency of the drift eliminators within a cooling tower should also be carefully evaluated (Freije 1996). The function of drift eliminators is to capture the water sprayed into the airstream during tower operation so that the possibility of droplets carrying *Legionella* bacteria exiting the tower is reduced. Many manufacturers have improved drift eliminator performance through design improvements (Broadbent 1993). High-efficiency drift eliminators are recommended. This factor can be evaluated with the drift eliminator efficiency rating, which is the percentage of water loss relative to the volume of water circulated through a tower. Older cooling towers can also benefit from these improvements in design by a retrofit with new drift eliminators.

Tower selection should include evaluation of a number of characteristics that could simplify maintenance procedures and minimize the growth of *Legionella* bacteria. The tower should provide easy access to drift eliminators and the sump area to permit inspection for water appearance and accumulations of microbial growth. The tower components should be made of durable and easy-to-clean materials, and the tower should allow uniform airflow. The sump area should have sufficient drainage to minimize accumulations of water and microbial growth. Once installed, the manufacturer's recommendations should be followed to ensure long service life for the tower.

The location selected for a new or replacement cooling tower is also an important factor that can reduce the potential for exposures to *Legionella* bacteria (Freije 1996). Direction of the prevailing winds and the location of air intakes for ventilation systems should be considered during site selection to minimize the possibility that aerosols from the tower enter the building (see Fig. 48.2). Cooling towers should be located as far away as possible from outdoor air intakes, operable windows, and public areas; 35 ft has been suggested as a minimal distance. The location of existing air intakes should also be reviewed and intakes relocated if the distance to the cooling tower is less than 25 ft.

48.7 SUMMARY

Legionella bacteria are not rare or unusual microorganisms; they are found in natural freshwater environments around the world. However, the human illnesses that can be caused by exposures to these bacteria merit serious attention by those who manage buildings, and, in particular, those who manage hospitals. Estimates from the CDC project

FIGURE 48.2 This photograph shows a cooling tower that is located too close to the air intakes of the hospital that it serves. This proximity increases the likelihood that airborne *Legionella* bacteria emitted in the drift from the cooling tower could enter the hospital ventilation system and reach susceptible individuals.

10,000 to 15,000 cases of Legionnaires' disease annually in the United States alone. The numbers of individuals who develop the flulike Pontiac fever are likely larger and even more difficult to estimate. It should be reiterated that these CDC figures are generally regarded as underestimates because infections caused by *Legionella* bacteria can be conclusively identified only when specific clinical tests for the presence of the bacteria are conducted. On the basis of blood tests for antibodies to *Legionella* bacteria in normal healthy adults, estimates of total numbers of individuals who have had an exposure to *Legionella* bacteria at some point in their lifetimes are conceivably in the millions. All of these facts clearly demonstrate that exposures to *Legionella* bacteria and the illnesses they cause are important public health issues.

Legionella bacteria can never be completely eliminated from building cooling systems and potable-water sources because they are ubiquitous in nature. Growth and proliferation of these bacteria can occur even in cooling systems and potable-water systems that receive excellent maintenance. Reducing the potential for exposures to *Legionella* bacteria can reduce the incidence of legionellosis and the likelihood of liability claims related to these infections. Developing sound maintenance programs for cooling systems and potable-water systems and then implementing them in conjunction with regular water testing protocols are cost-effective approaches that can pay long-term dividends.

ASSESSING IAQ

CHAPTER 49

STRATEGIES AND METHODOLOGIES TO INVESTIGATE BUILDINGS

Ed Light, CIH

*Building Dynamics, LLC
Reston, Virginia*

Tedd Nathanson, P.Eng.

*Indoor Air Quality Consultant
Ottawa, Ontario, Canada*

49.1 INTRODUCTION

The primary purpose of most IAQ investigations is to identify the cause of occupant complaints. Ideally, a reasonable explanation is developed as information is collected on complaints and building conditions. With increasing detail, the range of possibilities is reduced, focusing efforts on the most productive issues. Identifying or ruling out building environmental conditions as the underlying cause of occupant complaints provides an objective basis for recommending mitigation or other response measures. Many building IAQ complaints are not highly technical and can be handled by a nonexpert who understands the building operation and is attentive to the concerns of occupants. More complex cases may require multidisciplinary experts or teams for successful solutions.

Simply testing a building for compliance with numerical criteria seldom reveals the basis for IAQ complaints. Proposing and evaluating various cause-and-effect relationships for consistency with investigation findings provides a more realistic basis for drawing conclusions.

This section of the handbook will briefly discuss common types of IAQ investigations and then present procedures for basic complaint screening (Sec. 49.3) and strategies for conducting more detailed investigations (Secs. 49.4 and 49.5). Although technical considerations are important, communications between concerned occupants, building management, and IAQ investigators is often the most important factor in the actual resolution of complaints (see Sec. 49.6).

49.2 TYPES OF INVESTIGATIONS

Aside from research studies, building IAQ investigations can be generally categorized by purpose:

- To resolve health or comfort concerns
- To correct a problematic condition in the building (e.g., odors or discomfort)
- To improve or maintain IAQ in the absence of significant complaints (proactive)
- To commission a new facility (see Chap. 61).

A majority of IAQ investigations are in the first category (initiated by occupant concerns). When building occupants report that poor IAQ has made them ill, identification of underlying causes is difficult because:

- Symptoms are usually nonspecific (could overlap with many causes other than pollutant exposure)
- Building conditions vary over time and by location
- Reactions differ between individuals according to their sensitivity

At the outset of a complaint investigation, all plausible causes, both IAQ and non-IAQ, should be considered. An initial screening may rule out many factors on the basis of obvious inconsistencies with complaint patterns or building conditions. More detailed study may be needed to identify or rule out possible contributing factors. Common types of occupant health complaints are listed in Table 49.1.

A 1995 workshop of the American Thoracic Society recognized that management of IAQ complaints should consider both medical and building aspects (see Fig. 49.1).

While the remainder of this chapter will focus on strategies commonly used to investigate IAQ complaints, many of these same steps can also be used in building-driven or proactive studies.

49.3 INITIAL COMPLAINT SCREENING

Effective IAQ complaint surveys should start with informal interviews and general observations. More detailed data can be collected as a follow-up when necessary to understand and resolve occupant concerns. In general, IAQ complaints should first be screened by in-house personnel (typically the facility manager and building engineer), who briefly discuss concerns with occupants and perform a quick inspection. This initial assessment is a preliminary attempt to characterize the complaint and identify obvious causes. Although limited in scope, this exercise can often lead to a “commonsense” resolution of IAQ concerns. For example, many complaints can be resolved simply by HVAC adjustments, improved cleaning, or an explanation of building operations. A flow chart summarizing an initial complaint screen can be found in Fig. 49.2.

IAQ investigations commonly consider a variety of nonspecific symptom complaints, which could result from poor air quality but could also be due to other causes. Systematically compiled information on the timing, location, and category of health concerns may show a pattern consistent with building conditions, suggesting that symptoms may be related to poor IAQ. Lack of a consistent relationship may tend to rule out building-related illnesses (comfort and nuisance factors may still be driving the concerns).

TABLE 49.1 Common Types of Occupant Health Complaints

Ventilation-related complaints: Timing of symptoms is related to inadequate ventilation when no strong emission sources are present.

Source-related complaints: Timing of irritation or allergy symptoms is related to the presence of a specific source or contaminant.

Chemical or biological hypersensitivity: Some individuals report reactions to conditions that do not appear to affect most occupants.

Perceived IAQ problems: In cases where symptoms are unrelated to IAQ, it may be possible to identify other contributing factors such as thermal discomfort; nuisance odors; visible dust or stains; water- or foodborne illness; skin contact with toxic material; contagious illness; coincidental medical events such as cancer or miscarriage; symptoms that are psychological in origin and/or transmitted by sociological mechanisms such as stress.

FIGURE 49.1 Possible building-related discomfort, dissatisfaction, or symptom (directed to building management or personal physician). (Source: R. M. Menzies, McGill University, Montreal. Reprinted with permission.)

Initial steps to evaluate occupant symptom patterns include:

- Review any historical complaint records to see if similar concerns in the past were documented.
- Ask management for an overall characterization of reported complaints (who do they feel is concerned and why).

FIGURE 49.2 Simple complaint screening.

- Ask complainants and other nearby occupants to describe building environmental conditions and how they believe they are affected.
- Refer patients to a physician for diagnosis and treatment where potentially serious health problems are reported.

A preliminary review of building conditions can be accomplished as follows:

- Briefly check the HVAC system serving the complaint area to determine if it is operating as intended. This should identify obvious problems with thermal discomfort, underventilation, poor mechanical sanitation (e.g., accumulations of dirt, microbial growth, or stagnant water, which could become sources of airborne contaminants), or pathways for pollutant migration to occupied space. Where these deficiencies could be contributing to the complaint, corrections can often be made before considering a more thorough evaluation. An initial screening could also include a spot check of HVAC indicator measurements (e.g., temperature, relative humidity, and/or carbon dioxide).
- Check to determine if obvious pollutant sources are potentially influencing the complaint area. Also note any detectable odor, dampness, dust accumulations, or staining as possible indicators of contamination. Sources of odors reported by area occupants should also be identified, where possible (see Table 49.2).
- Compare the original uses of the complaint area and surrounding rooms with the present use. Has occupant density increased? Have work areas been rearranged or converted to other uses? Has new equipment, such as computers, printers, photocopiers, or humidifiers, been added? Has the HVAC system been reconfigured and rebalanced for these changes?
- Identify areas where remodeling, repair, or redecorating activities are in progress or have recently been completed. Check that proper control procedures are being used to isolate dust, paint fumes, and other offgassing contaminants related to the activity.

No pollutant sampling is recommended for the initial complaint assessment. Arbitrary measurement of background contaminants can lead to false positive conclusions. On the other hand, testing for intermittent or complex low-level exposures can lead to false negative conclusions.

Typical questions to ask during an initial complaint screen are listed in Table 49.3.

49.4 DETAILED ASSESSMENT

Where the initial screening is inconclusive or fails to resolve the problem, more formal investigation may be necessary. This should generally be conducted by personnel with specialized training in IAQ (a team approach or individual with multidisciplinary skills is recommended). Such an investigation should provide sufficient detail to identify complaint patterns (e.g., common timing of symptomology between occupants), HVAC deficiencies (e.g., outside air damper locked shut, wet surfaces promoting mold growth), and emission sources (e.g., a process responsible for detectable odor), with the primary objective being to determine the underlying cause for each type of complaint (see Fig. 49.3). While many deficiencies are identified in a typical IAQ investigation, some may not be related to the occupant complaints. Where this is the case, the investigation report should clearly distinguish unrelated deficiencies from those contributing to IAQ complaints.

TABLE 49.2 Odors as Problem Indicators in Office Buildings

Description	Problem	Complaints
Auto exhaust, diesel fumes	Carbon monoxide	Headaches, nausea, dizziness, tiredness
Body odor	Overcrowding, low ventilation rate (high carbon dioxide levels)	Headaches, tiredness, stuffiness
Musty smell	Microbial material, wet surfaces	Allergy symptoms
Chemical smell	Formaldehyde, pesticides, other chemicals	Eye, nose, and throat irritation
Solvent smell	VOCs	Odor, allergy symptoms, dizziness, headache
Wet cement, dusty, chalky smell	Particulates, humidification system	Dry eyes, respiratory problems, nose and throat irritation, skin irritation, coughing, sneezing
Sewage gas odor	Water traps dry in floor drains in washrooms or basement	Foul smell, dizziness

TABLE 49.3 Preliminary Questions for the Complainant

Where health is the primary concern:

- Describe your health problem (e.g., what, when, where).
- Does it seem to coincide with any building condition?
- Have you had any related allergies or similar reactions in the past?
- Have you discussed this with a physician?

Where a building condition is the primary concern:

- Describe the problem (e.g., odor, discomfort, mold growth).
- Where and when have you noticed the problem?
- What do you think is the cause of this problem?

FIGURE 49.3 Detailed complaint assessment.

The conclusions drawn from an IAQ complaint survey depend on initial problem definition and subsequent survey protocols. The scope of an IAQ survey must consider what factors are to be investigated and in how much detail. Where obvious problems are the likely cause of health complaints, a narrow scope of work, focusing only on these factors, may be sufficient. Many IAQ complaints, however, have no obvious cause and a more comprehensive evaluation is necessary.

Defining the spatial and temporal boundaries of an IAQ survey is critical. At a minimum, the survey should generally include:

- All occupied space with potentially similar complaints
- All suspect HVAC zones and sources of airborne contaminants potentially affecting that space
- A comparison space (similar area not initially identified with occupant complaints) selected as a control to suggest qualitative differences with the complaint areas

Typically, IAQ surveys document only a “snapshot” of building conditions. A more complete range of conditions, reflecting seasonal changes and near worst-case exposure scenarios, should also be considered before drawing conclusions from a cross-sectional building survey. Specific steps that can be taken during an IAQ investigation to help understand variations over time include:

- While inspecting the facility and interviewing operational personnel, identify *potential* sources and worst-case emission scenarios.
- When evaluating HVAC systems, define *potential* IAQ problems under various operating modes.
- If past environmental problems are suggested by interviewees or facility documentation, these should also be considered and evaluated as possible causes.
- Manipulate building activities or system operation to observe potentially problematic conditions for qualitative comparison (e.g., override HVAC controls to operate at minimum outside air; ensure a truck is idling in the loading dock during building inspection, operate all fume hood exhausts while HVAC supply shuts down after hours, cycle on kitchen exhaust fans).

A systematic investigation process should ideally begin with problem definition (characterizing occupant concerns). Next, HVAC systems should be studied to understand how the building operates and to identify potential deficiencies. Finally, potential emission sources are identified and prioritized. As the investigation proceeds, hypotheses (explanation of cause and effect) are suggested and tested for consistency with the findings. It should be expected that some preliminary hypotheses will be rejected and new hypotheses raised as work continues. What may start out as one unified complaint may ultimately be identified as multifactorial with a variety of underlying causes.

The investigator should review any documents available on the history of the building and its modifications. A person familiar with the building's HVAC system should accompany the investigator, and any persons required for access to the facility should be identified. Use of floor plans can expedite the documentation of inspection findings.

While an initial screening generally asks occupants only informal questions to help define the complaint, a formal investigation elicits information using a standardized approach to developing evidence on possible cause-and-effect relationships. One effective way to accomplish this is for investigators to interview both complainants and a representation of other occupants, with each interview structured to include the same basic questions. At a minimum, questions should request information on the individual's demographics (e.g., history in the building), sensitivity (e.g., allergies), concerns regarding building conditions (both IAQ and non-IAQ), and symptoms that they feel may relate to time spent in the building (e.g., seem to clear after leaving and reoccur when back in the facility). Questions in the structured interview format should be open, requiring the respondent to initiate descriptions of symptoms.

Overall analysis of the responses should look for possible trends, or the lack thereof, based on questions such as:

1. *Symptoms.* Are reported health problems consistent with building-related allergy or irritation? If nonspecific symptoms are reported, is an association with indoor air pollutants plausible? To what extent do the health problems reported by different individuals appear to be similar? Are only individuals with a history of hypersensitivity affected?
2. *Timing.* Is there consistency between complaints regarding when they started? When they are reported to be worse?
3. *Location.* Is there geographic clustering of complaints implying HVAC operations, contaminant sources, or other unusual occurrences?

Interviews may reveal patterns suggesting the underlying causes of symptoms (are they consistent with allergic reactions, irritation, nonspecific effects of air pollutant exposure or

to something other than IAQ?), timing (does onset or severity relate to any change in building conditions?), or location (do the affected areas implicate a particular HVAC zone, source, or pathway?). Pattern analysis should consider the possibility that there may be more than one building IAQ problem causing complaints or that health complaints may be related to something other than IAQ.

Self-reported building-related symptoms do not represent a medical diagnosis. Any suggestions of serious medical problems should be referred to a physician. Follow-up investigation may show that the underlying cause of symptoms is very different from that perceived by the occupant.

During discussions with building occupants, references to individual or organizational issues that might be responsible for stress-related symptoms (e.g., headaches, fatigue) or misperceptions of building IAQ (e.g., based on information reported in the media) should be noted. Individual concerns might involve family problems, lack of privacy, etc. Potential organizational problems could include conflicts with management or between staff, an unpopular move from another facility, communication problems, impending layoffs, and the like.

Questionnaires are another option for polling occupants. Although the questionnaire format is similar to the interview format, specific symptoms are often named (and suggested to respondents). Studies utilizing questionnaires must be carefully designed and administered for results to be considered representative (e.g., is there a bias in responders or nonresponders?).

Daily occupant diaries may be an option when there is sufficient time to compile this information. Affected and nonaffected (control) occupants can maintain a daily diary noting environmental conditions and their personal health status. Diaries can be completed while operational personnel compile a daily log of building activities and conditions. Correlation of the two may provide useful insight into the nature of complaints.

Pros and cons of the three options should be considered in selecting the instrument most suitable for a particular survey. All three options are limited by the accuracy of each individual's perception of personal health and building conditions and how well the respondents represent the population as a whole. Diaries rely less on memory, while questionnaires can poll more occupants in less time. Interviews may present fewer "leading" questions and allow for follow-up clarification. See Table 49.4 for a summary of options for characterizing complaints and see Secs. 49.2, 49.6, 49.7, and 49.8 for further discussion.

More-quantitative approaches for complaint characterization (e.g., statistical epidemiology, medical diagnosis) should not be attempted without qualified experts on the investigation team.

TABLE 49.4 Options for Characterizing Occupant Complaints

Methods	Pro	Con
Interview	Preferred choice in many situations	• Self-report • Recall?
Questionnaire	Poll large numbers of occupants	• Self-report • Administration bias? • Recall?
Daily diary	Daily recall	• Self-report
Medical evaluation	Conclusive opinion	• Time and cost

HVAC Evaluation

Understanding the design, operation, and maintenance of heating, ventilating, and air-conditioning (HVAC) systems is essential for resolving most IAQ problems. Key HVAC factors include ventilation, thermal comfort, mechanical sanitation (e.g., cleanliness of HVAC equipment), and pathways for contaminant movement. HVAC noise may be a non-IAQ factor in complaints.

While the initial complaint screening briefly considers whether HVAC systems were operating as intended, a more detailed follow-up evaluation takes a more comprehensive look at what factors might be influencing the complaint area. Specific investigation tasks that may be included at this stage are:

- Review HVAC documentation (e.g., design parameters, plans, balancing report, controls sequence, and how they differ from on-site conditions).
- Use information from occupant interviews to determine if there are intermittent or seasonal comfort complaints requiring evaluation.
- Interview the building engineer regarding system operation, preventive maintenance, and troubleshooting procedures (review available logs).
- Have facility managers demonstrate HVAC control system (e.g., contracted energy management services may modify control logic or setpoints on computerized HVAC systems, and facility managers may not be current regarding actual HVAC operation).
- Evaluate condition and performance of all HVAC components including air intakes, filtration systems, mixing plenums, fans, humidifiers, and ducts.
- Inspect HVAC equipment for general cleanliness and indicators of possible contamination (e.g., microbial growth, stagnant water, filter performance).
- Identify potential pathways for pollution migration such as a return air system or HVAC intake in the vicinity of a pollutant source.

In addition to the above tasks, simple indicators of HVAC performance are documented in most IAQ investigations for a preliminary assessment of ventilation, thermal comfort (including moisture and air distribution), and relative pressurization. Results may be sufficient to determine whether these factors are contributing to complaints and to recommend corrective measures, although more detailed follow-up (e.g., airflow measurements) may be needed to resolve some problems. Short-term measurement of HVAC indicators should be made in representative rooms within the study area while occupied (preferably after a few hours of peak occupancy). Information on building activities, relative occupancy, HVAC operating status, and weather conditions is essential to interpreting these results. Common HVAC indicators include:

Carbon dioxide. Nondispersive infrared meter or colorimetric detector tubes can provide a relative index of ventilation (assumes space is occupied for a sufficient period to approach equilibrium).

Temperature. Electronic sensor or thermometer can help evaluate conditions relative to the general comfort zone.

Relative humidity. Thermohygrometer or sling psychrometer addresses thermal comfort and potential for mold growth.

Air distribution. Smoke tubes used to visualize air currents help evaluate thermal comfort, ventilation, and contaminant pathways. Fundamental questions that may be answered by using these simple devices include:

- Are air supply diffusers and return vents functioning?
- Is air being distributed effectively within the room?
- Is air velocity experienced by occupants too low (stuffy) or excessive (drafty)?
- How does air move between potential sources and occupied areas?

For each deficiency with respect to ventilation, comfort, sanitation, or contaminant movement, the investigator should note when and where it can occur and what types of adverse effects are likely. See Table 49.5 for a summary of HVAC evaluation steps and see Secs. 49.3 and 49.4 for further discussion.

Source Inventory

In addition to the HVAC system, airborne contaminants originate from four basic categories. These are the occupants (including their activities and equipment), building operations and maintenance, materials (e.g., chemical offgassing, microbial contamination, deterioration), and emissions drawn into the building from the exterior.

Investigators can identify and evaluate these potential pollutant sources by one or more of the following:

- Conduct a thorough inspection to locate pollutant sources, both inside and near the building, that could impact the study area.
- Review water or steam treatments that impact IAQ (e.g., cooling tower near intake, boiler steam used for humidification).
- Note potential indicators of microbial, chemical, or physical contaminants such as odor, accumulated dust, staining, or dampness.
- Spot-check carbon monoxide concentrations (increases over outside air indicate the presence of combustion products). Where combustion sources are present (e.g., parking garage), near worst-case times and locations should be tested, where possible.
- Review maintenance procedures including those for HVAC upkeep, general repairs, construction, routine and special cleaning, and pest control.

TABLE 49.5 HVAC Evaluation Questions

Occupant complaints	• When and where do uncomfortable conditions exist? • When and where do unusual odors occur?
Documentation review	• How were HVAC systems designed in relation to IAQ concerns?
O&M interviews	• What is indicated by balance and controls reports? • How are systems typically operated? • What preventive maintenance and troubleshooting procedures are performed?
Inspections	• What is the cleanliness and operational status of key system components? • Are there contaminant sources by critical locations (e.g., outdoor air intakes)?
Measurements	• What do representative readings for CO₂, temperature, and relative humidity, and smoke tube observations indicate? • Are detailed airflow measurements needed?

- Review building policies related to IAQ (e.g., smoking).
- Identify other potential sources of airborne contaminants through observation of work activities, interviews with occupants and operators, and review of any historical documentation. Focus for this should be on areas subject to recent remodeling, moisture damage, unusual odors, special emissions, etc. and the spaces should be evaluated in more detail.
- Conduct an odor survey during off-hours (no mechanical ventilation) to more clearly identify odor sources.
- Track potential migration pathways with smoke tubes to locate areas that may be impacted by pollutant sources. Wind patterns influencing the impact of exterior sources should be noted.
- For intermittent sources, reinspect building when active emissions are occurring.

In addition to pollutant sources, IAQ complaints may also be caused by other environmental factors in the building. In this regard, investigators may want to make other observations such as:

- Note areas that are dimly lit or overly bright or VDT screens which have noticeable glare and whether these may correlate with reports of work-related headaches or eyestrain.
- Note workstation layouts that may correlate with reports of work-related fatigue or soreness (ergonomic problems).
- Note any unusual noise or vibration that may correlate with reports of work-related discomfort or headaches.

On the basis of initial observations, many sources may be considered routine and not related to the complaint (contaminant levels in the “normal background” range). Potentially significant sources, however, should be identified for further evaluation. For each entry in this latter category, the following should be estimated:

1. Under a worst-case emission scenario, what type of impact might be expected?
2. What building areas might be affected?
3. When would worst-case conditions be expected to occur?

Where the source appears to be critical to understanding the complaint but cannot be reasonably estimated from initial findings, the investigator should proceed to collect more detailed information.

Results should be compared to the type, timing, and location of complaints. See Table 49.6 for a summary of steps commonly used to inventory emission sources.

Pollutant Sampling

In the early stages of a building investigation, there is seldom sufficient information to base a meaningful pollutant sampling strategy or subsequently interpret test results. While many IAQ problems can be resolved by observing general conditions and noting obvious deficiencies in building operation, poorly conceived pollutant sampling may actually obscure an effective solution to the problem. Measurements should generally be limited to indicators of HVAC performance (CO_2 , temperature, relative humidity, airflow) unless initial findings suggest that pollutant data are needed to establish the cause of occupant complaints. Comparison of limited pollutant measurements from complaint and control sites may suggest causation (test data should be considered as just one factor in the evaluation—other observations should be consistent with a given hypothesis). Sampling may also be requested for site documentation (e.g., liability concerns).

TABLE 49.6 Emission Source Inventory

Occupant activities	• What equipment and products are used? • What are the sources of detectable odor?
Building O&M	• Are odors and dust from repair and construction work controlled? • Are there complaints about pest control or housekeeping activities?
Surfaces	• Where and why is there staining or dust accumulation? • Do materials or furnishings produce odors?
Exterior sources	• Are there pollutant sources under, adjacent to, or on top of the building? • Do measured carbon monoxide levels exceed background?

Whenever pollutants are sampled, the status of HVAC systems, emission sources, and occupant activities must be documented. Interpretation of air quality data should then consider the status of these factors relative to the range of conditions likely to occur in the building.

An objective basis for judging pollutant measurements should be determined before sampling. Monitoring results are often best evaluated by comparison with control sites. If available, generally accepted exposure guidelines or appropriate (low-level) toxicology can also be considered in the assessment.

In general, collection of microbial samples may be helpful where widespread moisture and/or symptoms suggest the possibility of a serious health problem related to microbial growth. Chemical sampling may be indicated where sources present a major health risk or persistent odor. Particulate sampling may be indicated where dust is present in unusual and potentially harmful amounts.

Preliminary pollutant screening generally involves tests at a limited number of key sites, such as locations with complaints or emission sources, along with comparable control sites. Sampling procedures and strategies must be sensitive enough to differentiate unusual conditions from normal background. Analyses may be for composite measurements (e.g., total VOCs) or specific parameters.

Several strategies are available for obtaining representative building samples. These may include locating test sites:

- In each HVAC zone
- In representative HVAC zone by type (e.g., interior versus perimeter)
- In complaint versus noncomplaint areas (or in a noncomplaint building as a control)
- By relationship to major sources (e.g., based on proximity to smoking area or printing shop)

It is best to measure pollutants arising from the building structure, furnishings, or ventilation (e.g., formaldehyde, VOCs, microbial contamination) in the morning if the ventilation system is turned off overnight or over the weekend. Pollutants generated by the occupants (e.g., carbon dioxide) or by the occupant's activities (e.g., use of photocopiers) are best checked toward the end of the working day in order to detect the highest concentration.

The time of year is also an important consideration. If the building is on an economizer cycle, outdoor air supply will be less during very cold or very hot weather, which generally makes pollutant concentrations higher. Also, some sources are seasonal (e.g., humidifiers and air-conditioning systems).

Sampling strategy should be designed to include periods of near worst-case conditions, such as instances of maximum equipment emissions, minimum ventilation, or disturbance of contaminated surfaces (in some cases a combination of ventilation and source factors

must be considered). Near worst-case sampling results may help estimate peak occupant exposure, in some cases suggesting that the range of exposure does not appear to be significant. Duration of sampling, another consideration, should be based on analytical method sensitivity, the emission pattern, and other variables.

Failure to detect IAQ problems through measurement of pollutants does not necessarily indicate that no problem exists. It may simply mean that an intermittent contaminant was not airborne during the test period (e.g., mold spore). Other explanations for false negative results include an inappropriate level of detection, an irrelevant parameter, or exposure guidelines inadequate to determine if air contaminants may affect sensitive individuals.

Formulating Conclusions

Complaint patterns can be compared to the potential impact, timing, and location of any HVAC deficiencies, emission sources, or other unusual conditions. Hypotheses involving non-IAQ factors should always be considered in examining apparent building-related symptoms. A general consistency or lack of consistency between IAQ factors and the complaints may form the basis for overall conclusions. Because of the many human and building variables involved, perfect correlation should not be expected. Cost-effective improvements to building environment conditions should be considered even where health complaint correlation is unclear (e.g., make building cleaner or more comfortable).

While one round of environmental investigation often provides a good explanation for complaints, this is not always the case. Where follow-up study is needed, focus may be narrowed to those factors that appear to be more significant. Methodology may shift from semiquantitative to quantitative at this point. The additional detail generated will hopefully lead to the development of more successful hypotheses.

Verification

Follow-up verification of findings from an IAQ survey is difficult, since neither building conditions nor occupant complaints remain static. Where the original IAQ study identified building problems that have since been addressed by corrective measures, key observations can be repeated to determine if the adverse condition has been eliminated (e.g., lack of odor over a period of time may be sufficient to assume effective control). Repeat measurements, if made under comparable conditions to those in the original IAQ survey, may also be used to demonstrate whether conditions have improved. Follow-up evaluation of seasonal IAQ problems (e.g., related to heating or cooling season) should be conducted during the relevant time of year.

Where health and/or comfort complaints are found to be IAQ-related and recommendations have been implemented, a before-and-after polling of occupants may be considered. Ideally, the same interview, questionnaire, or diary format should be repeated (at the same time of year, if possible). Where formal polling is not feasible, discussion with key complainants and/or supervisory personnel may give a qualitative indication as to whether conditions have improved.

In evaluating the validity of earlier investigation findings, it is important to recognize situations that would tend to mask the role of IAQ factors. Since IAQ complaints in some buildings have a variety of underlying causes, follow-up results may be misleading. For example, psychosocial issues (e.g., poor labor management relations) might cause perception of a problem to continue even after it is corrected. New problems can also develop in buildings after the original problems are resolved. Such confounding factors must be considered in any follow-up study and may make verification difficult.

Verification becomes even more challenging where corrective measures have not been implemented or the investigator has concluded that complaints are not related to building conditions.

49.5 QUANTITATIVE STUDIES

Where building conditions are highly complex, illnesses are severe, or substantial documentation is otherwise required, extremely detailed (quantitative) methods may be necessary. Such procedures should generally be implemented only by specialists from the appropriate field. Selection of specialists and determination of their test strategies should be based on findings from preliminary surveys.

Results of more detailed sampling, engineering, and medical evaluations can be analyzed statistically where there are sufficient data. Positive correlations may be found where the impact, timing, and location of adverse building conditions are generally consistent with at least some complaints.

More direct involvement of medical professionals in the building investigation team may be needed for a better understanding of complaint patterns and their possible relationship to the building. Steps may include completion of medical histories and conducting physical exams. Physicians normally use a differential diagnosis procedure to suggest or rule out causes of a patient's symptoms. In the context of a building investigation, the team's environmental investigator should provide the physician with a general exposure scenario. The physician can consider this along with the patient's history and other medical findings to suggest if there is a plausible relationship to building conditions. A clinical-based conclusion by the physician alone may be misleading. Ideally, consensus by a multidisciplinary building investigation team provides the strongest evidence for a positive or negative association between an illness and building conditions.

More detailed investigative steps for HVAC systems include an engineering analysis to identify critical conditions and determine if the system is balanced (can control heat loads and moisture and provide adequate ventilation). Where thorough ventilation measurements are needed, the most important variables to measure are the outdoor airflow rates to the occupant zone (normally the room) and the degree of recirculation of air (intentional or due to HVAC equipment leakage). Other parameters such as pressure drop created by filters may also be helpful.

Continuous measurements of temperature, relative humidity, and/or CO₂ over a several-day period coinciding with major changes in outdoor weather may help identify problems related to thermal and ventilation control. In-depth measurements of air and radiant temperature or operative temperature, and air velocity may be useful when it is not obvious what is causing thermal comfort complaints.

Where the HVAC system is a major contributing factor to IAQ complaints, a follow-up study may be needed to specify the most cost-effective solution (e.g., does it make more sense to change HVAC configuration, modify its operation, or rearrange space use?).

More detailed steps available to evaluate potential emission sources may include:

- Obtain detailed product and emission data from suspect activities.
- Access walls, floors, or ceilings where needed to observe water damage or potential microbial growth, take moisture measurements, or collect microbial samples.
- Conduct stack tests to document equipment emissions.
- Conduct chamber tests on material samples removed from the building to characterize emissions.

- Perform differential pressure readings using a (digital) manometer to document potential migration pathways.
- Conduct tracer gas tests to document contaminant pathways and the extent of pollutant migration.
- Identify microenvironmental conditions in areas occupied by specific complainants.
- Measure illumination.
- Conduct ergonomic evaluations.
- Measure sound levels and/or low-frequency vibrations.

Collecting sufficient air samples for statistical analysis is cost- and time-prohibitive for most practical investigations.

In addition to direct measurement of pollutants in the breathing zone, other diagnostic methods exist to quantify potential contributing pollutants (e.g., microbial growth in settled dust or bulk samples). For example, surface dust densities may suggest possible irritation by contact or resuspension and indicate more intensive cleaning is needed. Dust samples collected from floors, seats, and partitions may be analyzed for parameters such as allergens, endotoxins, fibers, pesticides, or metals when relevant to the problem under investigation. Such samples can be used to integrate contaminants over time and area. Lacking standards, investigators must compare results to other studies in order to determine if concentrations are unusual and could be a plausible contributor to the symptoms reported.

49.6 COMMUNICATIONS

Procedures should be defined for handling complaints and for communicating information before, during, and after an investigation. Lines of communication should identify key people, such as occupants, building staff, workplace health and safety committees, management and union representatives, and health and regulatory agencies. Ultimately, however, the building owner will have to resolve the problem. Cooperation and early action can lead to a successful solution. Without open communication, any IAQ problem can be amplified by frustration and distrust, delaying resolution.

It is in the building manager's best interest to respond promptly and seriously to all complaints about the indoor environment and to establish credibility through open communication with the building occupants. Building managers should not underestimate the anxiety and frustration that can result if occupants believe that no action is being taken or that important information is being withheld.

Building occupants can be valuable allies in solving IAQ problems, particularly in observing odors or patterns with respect to IAQ complaints. To encourage this cooperation, it is advisable to consider occupants' theories during the investigation. Building occupants should be informed of the scope and purpose of investigations, with opportunities provided for input and feedback. Final results and proposed implementation plan should also be available.

Communicating with building occupants in the context of an IAQ investigation can be enhanced by the following steps:

1. Establish trust.
2. Identify and attempt to resolve anger.
3. Involve occupants in the investigation, providing appropriate tasks and attention to concerned individuals.

4. Set up an open communication process (e.g., present all parties with results when available in context).
5. Explain technical information in understandable terms, avoiding over- or underreaction.
6. Educate occupants regarding relevant details of building operations, health aspects of IAQ, and other potential causes of symptoms.

BIBLIOGRAPHY

The U.S. EPA has developed useful documents to assist building operators and managers. These documents provide guidance on how to prevent IAQ problems and how to establish an organizational structure to manage IAQ events. The reader is referred to the EPA Indoor Air web site to order “Tools for Schools” and “Building Air Quality: A Guide for Building Owners and Facility Managers” at www.epa.gov/iaq. CHAPTER 50

TRACKING ULTRAFINE PARTICLES IN BUILDING INVESTIGATIONS

Richard Fogarty

*New Trend Environmental Services
Dartmouth, Nova Scotia*

Peter A. Nelson,¹ MBA

*TSI Incorporated
St. Paul, Minnesota*

50.1 INTRODUCTION

Particulate pollution is everywhere in our modern society, from natural sources such as volcanoes and dust storms to artificial sources, such as asbestos, construction dust, and industrial processes. In this complex arena, even something as simple as combustion produces a range of pollution products—from wood smoke to diesel exhaust to environmental tobacco smoke. Several preceding chapters have discussed many of these particles as they relate to health aspects of indoor air quality. This chapter discusses one method for addressing particulate hazards—especially the hazards associated with smaller particles, or “ultrafines.”

This chapter is divided into four major parts. The first part, Sec. 50.2, describes the latest instrumentation available to track ultrafines in real time. The second part, Sec. 50.3, is a discussion of the sources of ultrafine particles and their relative concentrations. The third part, Sec. 50.4, describes methodologies in which the instrument can be used to identify the ultrafine particle sources discussed in the second part. The chapter concludes with Sec. 50.5, a series of case studies where this methodology has been used to effectively eliminate indoor air quality complaints.

We start though with a brief expansion on the focus of this chapter—ultrafines. Ultrafines are generally described as those particles less than 0.1 μm in diameter. The current definition does not differentiate according to particle composition. That is, a 0.05- μm particle of diesel exhaust is just as much an ultrafine as a 0.05- μm particle of road dust.

¹Current affiliation: Larco, Brainerd, Minnesota.

The atmospheric research community has known for years that ultrafines represent the greatest *number* of particles in a given sample of air, although their total mass may be only a fraction of the total sample mass. Scientists also know that the body's defense mechanisms do not remove ultrafine particles as readily as larger particles, allowing the ultrafines to penetrate into the deepest parts of the lungs. These very small particles are one of the current concentrated research topics in linking health effects and particles.

Although a causal link to specific health effects may not be concretely confirmed, ultrafines have been implicated as a prime cause of poor indoor air quality in literally thousands of buildings. At this point in time, there is no "scale" of toxicity for the various ultrafines that would indicate which are worse than others or at what concentration a specific ultrafine will cause symptoms. However, there is a distinct correlation between reducing ultrafines and eliminating sick building syndrome (SBS) complaints. The focus of this chapter is on the methodology of tracking ultrafines in buildings in order to eliminate SBS complaints. The methodology is briefly described as follows:

The IAQ investigator begins by mapping the areas of concern and recording the relative level of ultrafine particles in each area. Ultrafine particles are defined as particles with a diameter less than $0.1\ \mu\text{m}$. It is important to include areas of acceptable IAQ, unacceptable IAQ, and outdoor reference levels. In the areas of highest ultrafine particle concentration, the source must be identified. When the source is identified, it must be remediated. After remediation, the process is repeated for the next highest level measured. This iterative process continues until the occupants' and investigator's IAQ concerns are eliminated.

This method is simple in concept but can quickly become complex in its application. The sources of indoor air pollutants include photocopy machines, printers, boilers, furnaces, vehicles, industrial processes, and many others, both intermittent and continuous. These sources can often emit ultrafine particles at a density in excess of 200,000 particles/cm³. The HVAC system will usually be the driving force, moving indoor pollutants from one area to another. The areas of interest will minimally include areas containing the pollutant sources and areas of occupancy.

50.2 INSTRUMENTS

Instruments similar in fundamental concept to the instrument described here are generically referred to as a condensation particle counter (CPC) or condensation nuclei counter (CNC) in the scientific literature. CNCs are not a recent development; Aitken first described them more than 100 years ago. The continuous-flow CPC concept used in the design described here was first reported by Agarwal and Sem (1980). Continuous-flow technology is critical for obtaining the fast response and high sensitivity needed for this application.

Other particle size classifying devices are available and operate over particle size ranges of 0.01 to $10.0\ \mu\text{m}$. The most widely recognized instrument is the scanning electron microscope. However, this method requires that a sample be taken and subsequently analyzed in the laboratory, thus the real-time aspect is not achievable with this technique. Some laser-based particle counters have a lower size sensitivity that can reach into the ultrafine regime, but they are not easily portable and are usually limited to laboratory applications. The other common method is to utilize particle charging techniques; however, because of their size and complexity, these methods are also usually limited to laboratory use. Each of these alternative methods has the benefit of gaining some size classification information within its operating range, but they are far more expensive in

both acquisition cost and operator training, making them much less attractive alternatives for the application described here.

At this time, there is only one cost-effective portable instrument capable of measuring ultrafine particles in real time—the P-TRAK™ Ultrafine Particle Counter, Model 8525, from TSI Incorporated (see Fig. 50.1). The instrument is based on the concept shown in Fig. 50.2.

Particles are drawn through the instrument by using a built-in pump. Upon entering the instrument, particles pass through a heated saturator tube where they mix with isopropyl alcohol vapor. The particle-alcohol mixture then passes into a condenser tube where alcohol condenses onto the particles, causing them to grow into a larger droplet. The droplets then pass through a focused laser beam, producing flashes of light, which are sensed by a photodetector. The particle concentration is determined by counting the light flashes. If the particles were not grown into larger droplets, they would not produce (scatter) enough light to be detected.

The lower size sensitivity and counting efficiency of the instrument are shown in Fig. 50.3. The counting efficiency is 100 percent for the particle size range of 0.03 to 1.0 μm . The response to particles greater than 1.0 μm has not been well characterized because of the insignificance of these large particles in a typical number concentration distribution.

This unique single-particle counting capability for very small particles differentiates a CPC from all other IAQ monitoring methodologies. The measurements are made in units of particles per cubic centimeter ($\text{particles}/\text{cm}^3$) without size differentiation or chemical composition speciation. This unit of measurement contrasts with traditional aerosol measurements of mass in terms of milligrams per cubic meter (mg/m^3) made by real-time photometers and filter samples.

A CPC has a unique property inherent in its principle of operation. While the CPC counts each particle separately, it also treats each particle the same way. That is, it does not differentiate between particle size or chemical composition. This brings the CPC's measurement results into conflict with current regulatory guidelines that rely upon a knowledge

FIGURE 50.1 P-TRAK™ Ultrafine Particle Counter (TSI Incorporated, Model 8525).

FIGURE 50.2 Schematic diagram of a condensation particle counter (P-Trak™ Ultrafine Particle Counter, Model 8525, TSI Incorporated).

of chemical identity and mass concentration. As a result, the readings from a CPC cannot be related to a permissible exposure limit (PEL) or threshold limit value (TLV).

50.3 SOURCES

Airborne particles are found everywhere in the world from a variety of sources, natural and artificial. Major sources such as volcanoes and forest fires are natural occurrences produc-

FIGURE 50.3 Counting efficiency of the CPC as a function of particle size.

ing huge quantities of ultrafines. However, many more sources of particles are artificial and often related to combustion. These airborne particles cover a very wide range of sizes, from the smallest fume to quick-settling road dust. Figure 50.4 provides size ranges for various particles.

Figure 50.4 also indicates the area where conventional particle counters are best used—for larger particle sizes. There is logic behind this fact. Given that conventional thinking regarding health effects is dependent on the mass-dose relationships, it logically follows that measurement of these larger sizes would be more important.

Alternatively, when one deals with smaller particle sizes or ultrafines, which typically represent a very small fraction of the total sampled mass, one can no longer use mass-based instruments and one must use instruments that can count individual particles. This then is the basis for a CPC's application in IAQ investigations.

A major issue now arises as one ventures into the ultrafine particle counting arena. That is a lack of a reference point. Given that most IAQ professionals have been trained in the world of mass-based measurements, how do they interpret CPC readings? To illustrate the ranges for such readings, Table 50.1 shows typical ultrafine concentrations for a variety of sources. It should be noted that the upper concentration limit of 500,000 particles/cm³ shown in Table 50.1 is a function of the instrument limitations. The actual concentrations may be much higher.

As Table 50.1 and Fig. 50.4 show, ultrafines exist in a range of sizes and types originating from many sources. In some cases, such as the peeling of citrus fruits, it is not intuitive that any detectable particle could be traced to this source. All, however, share the common property of being able to act as a seed for the formation of an alcohol droplet—the operating basis of a CPC.

Many of these sources are very common. In IAQ situations, this fact leads to the situation where a given building may be impacted by a variety of very different sources all having one aspect in common—they all produce ultrafines.

A typical collection of ultrafine particle sources may be viewed as layers. As one particle source is removed, a second particle source that was initially hidden is revealed. As this iterative process continues, one gets to smaller sources and, eventually, one gets to the final prize—good indoor air quality.

FIGURE 50.4 Typical particle size ranges.

50.4 METHODS

It is not known whether ultrafine particles are the actual source of irritations or if they simply are a surrogate tracer to the actual irritant. Either way, observations of improved comfort and perhaps health have coincided with the reduction, source remediation, and/or control of ultrafines. This fact leads one to a new way of looking at indoor air quality measurements. The traditional approach has been to compare air-testing results against some fixed standard—whether that be a PEL, TLV, or an ASHRAE standard. However, given that there are no standards for ultrafines, all measurements become relative to the specific situation.

The methodology of detecting ultrafines as a tracer has an interesting history. As an example, CPCs were used onboard aircraft in World War II to identify the locations of submarines. The submarines were diesel powered and as such were high emitters of ultrafine particles. A CPC could be used to locate high concentration plumes above the water surface as a way of locating the submarines. The technique has also been used as a very early warning fire detector in highly critical operations. The ultrafine particles resulting from combustion are perhaps the earliest signal, occurring far before noticeable flame or heat.

A variety of different approaches are used for ultrafine particle surveys in IAQ applications. We will discuss three here:

- Rapid surveys
- Evaluating air filter effects
- Trend analyses

They are described below.

TABLE 50.1 Typical Ultrafine Concentrations Observed in Near Vicinity or at Discharge Point

Ultrafine source	Typical range, particles/cm ³
Laser printers	0–100,000
Fax machine	0–10,000
Cleaners	0–100,000
Photocopier	0–100,000
Laminator	0–20,000
Peeling citrus fruits	0–30,000
Auto emissions (readings inside buildings from such sources as parking garages, doors, fresh air intakes)	5000–20,000
Stack emissions (readings inside buildings due to recirculation into fresh air intakes)	5000–40,000
Boiler/furnace leaks	10,000–500,000
Humidification	10,000–35,000
Kitchen/cooking	10,000–75,000
Vacuum cleaners	0–100,000
Tobacco smoke	20,000–200,000
Laundry operations	30,000–75,000
Laboratory acids	50,000–80,000
Wood, welding/auto shops	50,000–200,000
Battery charging operation	5000–50,000
Chimney cracks	200,000–500,000
Outdoor air	2500–50,000

Rapid Surveys

The most straightforward method of tracking is the *rapid survey*. In this method, one uses the real-time abilities of a CPC for tracking and identifying contaminant sources. This is often complaint-driven and is most simply thought of in terms of a traditional indoor air quality “walkthrough” investigation, encompassing the following steps:

1. Gather detailed information relating to locations and times where indoor air quality complaints are more frequent than others. The problem locations will naturally serve as an area of focus for the investigation. Other areas, including the outside, will serve as control or reference areas.

2. Complaint timing patterns can be used in two ways. First, to time the tests (e.g., if the worst time is at 4:00 P.M., time your tests for then). Secondly, it can be used as a clue to potential problem areas. Examples of particle sources that have unique time patterns include:

- Exhaust from idling vehicles at common or usual delivery times.
- Kitchen/cooking emissions near break or lunch times.
- Leaking furnaces in winter with continuous or intermittent on/off cycles.
- Timing controls on HVAC systems on weekends or late at night that may shut the systems down during off-peak hours.
- Rush hour traffic or emissions from underground garages in early mornings and late afternoons, when they are in more frequent use.
- Second-hand environmental tobacco smoke at break times.
- High volumes of photocopying and/or printing activities (see Fig. 50.5).

FIGURE 50.5 Measuring photocopier emissions.

3. Normally, the first reading to take is the outside air, away from the building itself and any other known particle sources one can avoid. In cases where sources cannot be avoided, a series of readings from different locations should be taken and averaged. For this outside or background test, the CNC is observed for a few minutes or long enough to establish a range. The high and low peak levels, as well as the average, are noted.

The outside reading will serve as a background level to compare with air entering the building through the HVAC system, windows, and doorways.

4. The next test locations will be the air entering the building via pathways such as doorways, windows, and the outside air found in the HVAC system before the air intake filters. These readings should be similar to the average background readings taken earlier. If any readings exceed the high background peak then that location should be investigated to determine if there is an unusual source entering the building at that location. Common sources include chimney exhaust recirculation, automobile exhaust, and tobacco smoking.

For buildings with an HVAC system, the next reading to take is in the supply air plenum after the filters. If humidification is present, it should be turned off during the survey because it is sometimes detectable by the CPC and could mask other sources. A filter check can be conducted at this time to ensure that the filter is properly sealed and intact (see fol-

lowing section). This reading will provide the baseline for the building survey. Any areas with a reading higher than this baseline should be investigated to determine the source. Buildings without HVAC systems should use the reading from the nearest open window or outside doorway as the baseline reading. The idea here is not to survey every intake (every building, no matter how airtight will have too many openings to make such an exercise useful). Instead, one is collecting readings from the major intakes.

A reading of the return air plenums can also be taken as a check to see if the reading is significantly higher than the baseline. If it is, it indicates that a source is generating ultrafine particles in the area serviced by that air handling unit. This source should be found during the rapid survey of that area.

These readings of the air drawn into the building should be compared with the outside air sample taken in step 2. If the particle concentration entering the air handling system, or windows and doors, from outside is significantly higher than the outside air readings taken at ground level in 2, you should start looking for local outside contaminant sources that are being drawn in.

5. After completing the survey of possible outside sources, move inside. Usually, you start in the problem area to locate sources quickly. Ideally, you should also take the opportunity to talk to people in the affected areas. This serves four functions:

- In many jurisdictions, staff involvement is a legal right that must be respected.
- It allows you to fill in any missing or vague data on the occupants' actual complaints.
- It serves as an opportunity to show the occupants that their complaints are being taken seriously by management.
- It allows you an opportunity to take advantage of one of the major features of real-time CPC devices—*instant, easy to read and understand results*. By showing the staff how the instrument is reacting at the various locations, and why the numbers they are seeing on the CPC lead you to identify certain contaminant sources, occupants usually become very supportive of and confident in the solutions you propose. This makes the work much easier.

6. This completes the “walking around” part of the survey. As you have taken measurements and explored areas, your activity can be likened to that of a bloodhound following a scent. You should now look at the readings closely to identify areas of high particulate concentration relative to the baseline reading taken in the above steps.

A final part of the investigation is one of the most crucial for success: the follow-up survey. This is especially important because the ubiquitous nature of particle emissions makes it very easy for one large source to mask hidden layers of smaller, yet equally irritating, sources. Unless all sources are addressed, occupant dissatisfaction is likely to continue. Thus, as one particle source is removed, a second particle source that was initially hidden is revealed.

Although follow-up surveys may seem like an endless make-work task of repetitious surveys, experience shows this is not true. While large ultrafine sources masking smaller ones are common, most significant sources can be identified by the third iteration. Follow-up surveys at a later date are also crucial to demonstrating the permanence of the implemented solutions.

Evaluating Air Filter Effects

The evaluation procedure described here is simply a rough test to check for gross problems with the air filters. It is not a substitute for an actual technical test using generally accepted

test methods published by ASHRAE or other professional groups. Where such tests are called for, an appropriate specialist should be contacted.

Many, perhaps most, large office buildings use mechanical ventilation systems that include air filters as an integral part. Despite the filter's importance and despite the range of problems they can encounter, there are very few methods that allow in situ testing. A CPC device is one of the few instruments that can be used to address indoor air quality issues by evaluating the efficiency of air filtering units. Specifically, these devices can determine if the filters being used are the correct ones and whether there are any leaks around the gaskets.

To do this test, you must take two readings—one directly outside the intake (i.e., before the filters) and one after the filters. In large, walk-in size filter units, the “after” reading can be taken inside the plenum. In smaller units, readings can be taken at duct outlets or by drilling holes in ducts. It is important to note that the after reading should be taken immediately following the filters and ahead of any air being added to the system, such as recirculated air. The readings will be incorrect if they are influenced by the mixing of other air ahead of the measurement point.

The efficiency of the filter as determined with a CPC is then calculated by using the equation:

$$\text{Filter efficiency} = \frac{\text{before-filter reading} - \text{after-filter reading}}{\text{before-filter reading}} \times 100\%$$

The calculated efficiency should reasonably agree with the stated or claimed efficiency for the filters you are using. Table 50.2 illustrates the expected measurements for commonly found urban air.

Measured removal efficiency should be within 10 percent of the expected values. Otherwise, a further investigation into the cause is warranted. Some common causes of lowered filter efficiencies are:

- Loose filters
- Missing gaskets
- Missing or damaged filters
- Incorrect filters installed
- High air velocity
- Overloaded filters

TABLE 50.2 Expected Filter Effectiveness as Measured with CPC

ASHRAE filter rating, estimated minimum efficiency reporting value (MERV)	ASHRAE filter rating (estimated dust spot) % efficiency	Expected reduction of ultrafine particles, %	Measured concentration of ultrafine particles, particles/cm ³
N/A	No Filter (Ambient)	0	10,000
N/A	HEPA	100	<1
15	95	90–93	700–1000
14	90–95	85	1500
11	60	35–40	6000–6500
9	40	20–30	7000–8000
8	<30	10–20	8000–9000

It is important to reemphasize that the evaluation procedure described here is simply a rough test to check for gross problems with the air filters. It is also important to assure that the measurements taken are immediately before and after the filters so that the measurements are not influenced by any air mixing, such as recirculated air.

Trend Analysis

The previous two procedures make an assumption that remedial action will follow immediately from the initial survey. While the user-friendly displays and commonsense approach of CPC devices often makes this assumption valid, it is also possible that the remedial action could involve large expenditures of money and time. Thus, it is common for managers to request more evidence of a cause-effect relationship than the one-time survey can provide. In such cases, trend analyses can often be used.

In these cases, make an initial hypothesis about where the contamination originates. Then consider what evidence would be needed to support that hypothesis and set up sampling locations to allow the CPC to gather the needed information. The CPC is placed in a relevant area and data recorded for a period of time. The results, in the form of a graph like Fig. 50.6, can be evaluated later.

It may be desirable to have an IAQ complainant carry the instrument around and log data during the daily routine. This type of exposure is shown in Fig. 50.6 for an evening commute. One can easily see a sharp change in ultrafine particle concentrations. The spikes were attributed to different types of vehicles and/or driving through local sources. The last portion of the commute was the cleanest.

FIGURE 50.6 Changes in ultrafine particle concentrations.

Company X Air Quality Tests

Winter, 1998

FIGURE 50.7 Correlation of inside and outside ultrafine particle concentrations.

The CPC results can also be used in a more formal, mathematically precise way. As an example, let's review a real-life case solved by a CPC device. In this scenario, initial tests suggested that occupant complaints were related to vehicle exhaust being brought in from outside. To test this hypothesis, we established two locations outside the building and five locations distributed throughout the inside area. Nine tests were then taken at these locations over the course of a month, averaged, and displayed on a graph reproduced in Fig. 50.7. Analyzing the data by simple linear regression showed that 88 percent of the variation in the inside concentration could be attributed to variations in the outside concentration.

Trend analysis is also useful when investigating:

- The effect one contaminant source has on another building (in this case, trends comparing favorable and unfavorable wind directions are useful)
- The effect of a process on building air quality (in this case, comparing particulate levels when the process is running to when it is shut off)

Naturally, the degree of scientific precision and care will be dictated by the degree to which the eventual decisionmakers need statistical certainty.

50.5 CASE STUDIES

The previous sections have discussed ultrafine particles in general and how they can be measured and tracked. In this section we will discuss four case histories in detail that use the described instrument and the methodology. All the measurements are in terms of particles/cm³. Filter efficiencies are stated as dust spot efficiencies.

Hospital Indoor Air Quality Investigation

Workers in the complaint area of a hospital emergency department were experiencing symptoms possibly related to poor indoor air quality and shared their concerns with building management. These symptoms included headaches, eye irritation, sore throats, chest pains, and fatigue. Of the entire emergency department, only one area experienced these symptoms even though a single air-handling unit supplied the entire department. The complaints could not be correlated to time of day or specific events. However, all of the complaints had occurred within the previous three months and were growing in severity and frequency.

Building management made many attempts to address these complaints. These actions included several investigations using conventional IAQ measurements and additional testing for volatile organic compounds. None of the results revealed any problems.

After established procedures failed to identify the source of the complaints, building management authorized an investigation of ultrafine particle levels to evaluate building conditions. The investigator used a CPC device to measure ultrafine particle levels in outside air and at various locations within the emergency department.

Before the investigator left, the building manager had a clear understanding of the conditions in the department. See Table 50.3. The background ultrafine particle level outside was 11,800 particles/cm³ (somewhat typical of a built-up area with moderately heavy traffic). As expected with the 95 percent efficient bag filters and 60 percent efficient pre-filters, ultrafine levels in the supply air and other emergency department locations were 800 to 900. The complaint area, however, exhibited a much higher level of 13,200. Since the ultrafines were not entering the complaint area through the air supply system or from the occupied areas of the emergency department, the investigation centered on the complaint area itself.

By checking wall and ceiling penetrations, the investigator quickly identified the source pathway. Elevated ultrafine levels were entering the complaint area through the ceiling tiles. Further investigation showed ultrafine readings above the ceiling tiles as high as 29,700. The investigator tracked increasingly higher particle levels to joints in the concrete block walls, where measurements exceeded 162,000. On the other side of the wall, the investigator found an ambulance bay and learned that an ambulance had just left the area.

The high ultrafine particle levels at the wall, in combination with those in the adjoining ambulance bay, prompted building management to check the ambulance bay exhaust system. Management determined that the starter motor for an exhaust fan was malfunctioning. After maintenance repaired the exhaust fan starter and sealed the block joints in the wall, a follow-up survey showed ultrafine levels in the complaint area equal to those in the supply air and the adjacent offices. Complaints from the area ended.

TABLE 50.3 Measurements of Ultrafine Sources in a Hospital*

*In particles/cm³.

Tracking Environmental Tobacco Smoke

With complaints of headaches, eye irritation, and sore throats, employees at a 50-person organization were missing work and attributing their illnesses to the building's poor indoor air quality. The company's leased office space was part of a building complex that included a swimming pool, cafeteria, and smoking area, all likely sources of indoor air pollutants. Exhaustive IAQ investigations produced inconclusive results. Believing that there were no other alternatives to reducing absenteeism, the office manager relocated the staff to a new, 10-floor, environmentally friendly building. The new location was well-maintained, with no evidence of mold or water damage. Air quality appeared to be good, and the building's smoke-free policy appealed to the office manager. Soon after the relocation, however, employees began voicing their complaints again. Concern arose that they had brought their problem with them.

Frustrated by the high costs and inconclusive results of previous IAQ investigations, the office manager authorized an investigation of ultrafine particle levels at the new building. Using a CPC device, the investigator measured ultrafine concentrations (particles/cm³) at a background location outside the building and at various locations throughout the building. Within 3 hours, the office manager had a clear picture of building conditions. See Table 50.4.

The average outside ultrafine reading was 4110 particles/cm³. With 60 percent efficient filters, the investigator anticipated an office area reading less than 2500. Instead, the ultrafine level exceeded 15,600. Further investigation revealed an ultrafine level of 16,200 coming from the supply air diffusers in the employees' first-floor office area. The investigation of the air handling unit provided similar results. Ultrafine levels at the supply air plenum were 16,200, while the reading for outside air was the same as the previously recorded background of 4110. The return air plenum provided the highest reading of all. This reading of 29,700 indicated that the ultrafines might be coming from within the building.

With this knowledge, the investigator methodically surveyed the building, starting with single readings near the elevator on each floor. He then returned to the third floor, where readings were the highest. Again starting at the elevator area, the CPC tracked the high ultrafines to a closed office door, where the reading was 50,300 from the openings around the door. Behind the door, three workers were smoking cigarettes. The CPC showed an ultrafine level of 85,600 within the room. This third-floor activity appeared to be the likely cause of the first-floor complaints.

Agreements signed by all building tenants and employees clearly prohibited smoking within this building. To prove this clandestine smoking was a problem, building management reminded employees of the no-smoking policy. They then aired out the building using higher than normal ventilation rates. Once that was done, they again checked ultrafine levels throughout the building. A follow-up survey with the CPC confirmed that ultrafine levels had been reduced to the expected level of 2550. The relocated employees were finally able to work in their new offices without complaints and absenteeism related to building conditions.

Reentraining Building Exhaust

Occupants throughout an eight-floor office building were routinely complaining to building management about poor indoor air quality. Their symptoms included headaches, eye irritation, sore throat, and fatigue. These widespread and persistent complaints were primarily general in nature and could not be correlated to particular locations, time of day, or specific events. Management was also aware of anecdotal claims of more serious illnesses. Although never specifically related to air quality, these claims heightened occupant concern. Building management made many attempts to address the complaints. The most comprehensive efforts related to air quality evaluations based on the ASHRAE Standard 62. These evaluations failed to reveal any deficiencies based on the standard. The resulting reports were interpreted by some occupants as a message from management saying, "You're not sick. It's your imagination."

When all conventional approaches were exhausted, building management authorized a new investigation that used ultrafine particle levels to evaluate building conditions. This 6-hour survey employed a CPC device to measure ultrafine concentrations in outside air and at various locations throughout the building. See Table 50.5.

The ultrafine concentration in outside air, measured at ground level and upwind (south) of the building, averaged 5230 particles/cm³. With 60 percent efficient filters in the rooftop air-handling unit, a reading of 2000 to 3000 was expected. Average readings in the office, however, were 16,200. The highest indoor reading—22,600—was tracked to an air supply diffuser. Additional testing demonstrated that ultrafine readings within the building were consistently higher than those outside the building. Most significantly, the highest outdoor reading—40,000—occurred where the wind was blowing in the direction that would send the building's own exhaust toward its fresh air intake. See Fig. 50.8.

These findings focused the investigation on the roof, specifically just above the outside air intakes. Readings of 40,000 between the exhaust stack and the air intake demonstrated that the exhaust from the building's own boiler was being drawn down to roof level by downdrafts caused by a 12-story building located directly south. This exhaust air was then drawn back into the building's HVAC system. Building management and employee representatives were able to easily see and understand the ultrafine measurement results because of the real time nature of the device.

With the suspicion that boiler exhaust was the source of the IAQ complaints, building management developed a strategy to ensure that exhaust was discharged away from outside air intakes. The first recommendation—raise the original exhaust stack beyond its original 6-foot height—was straightforward. A section was added to the stack to make it 13 feet tall.

The question now was "Did the remediation work?" Again, the CPC gave an answer. By measuring the UFP concentrations around the roof and the outside air intake, investigators showed that, while these concentrations had decreased by 75 percent, an unacceptable amount of ultrafines still entered the building. The stack was then run horizontally 25 feet and the height was increased to 25 feet. An exit cone was inserted at the top to increase the upward velocity of the exhaust. The CPC showed that the particle concentrations at the

TABLE 50.5 Measurements of Ultrafine Sources of Building Exhaust

Air from air supply diffuser	22,600
Near exhaust stack and air intake	40,000
Average inside after retrofit	2,500

FIGURE 50.8 Influence of prevailing wind and building envelope.

air intakes were the same as those upwind of the stack. Tests inside the building showed a substantial reduction in ultrafine concentrations. The reduction was accompanied by a dramatic decrease in complaints and a “thank you” from the occupants for the successful effort by management to improve air quality.

Total cost for the investigation and remediation, including follow-up tests of the stack, was less than \$10,000.

Chemical Storage

A junior high school chemistry student could not participate in laboratory sessions because the laboratory environment aggravated his asthma. He experienced difficulty breathing shortly after entering the laboratory, even when chemicals were not in use. The student did not have these symptoms at any other location in the school. The student’s parents wanted their child to attend this laboratory class and asked the school board to determine the cause of his complaints.

The school board, familiar with ultrafine particles and their application in tracking pollutant sources, authorized an investigation employing a CPC device. Within 2 hours after arrival, the investigator measured ultrafine concentrations at various locations outside and within the school and characterized air quality within the laboratory. See Table 50.6. The investigator first surveyed outside air and found an ultrafine level of 4300 particles/cm³. Knowing that the school’s HVAC system had 30 percent efficient filters, the anticipated reading within the building was 2870. These levels were found throughout the building—except in the chemistry laboratory. Here the ultrafine level was 22,600 or nearly 5 times greater than outside air concentrations. The investigator systematically surveyed the entire laboratory and found a count of 85,600 at a chemical storage closet. This unventilated storage area held several containers of corrosive acid, many with damaged caps. Acid fumes were leaking from these containers, condensing into ultrafine particles, and escaping from the closet.

School maintenance provided a ready solution to this problem when they discarded outdated chemicals and transferred the remaining containers to a properly ventilated storage cabinet. Once maintenance completed this work, ultrafine readings in the laboratory decreased to the same levels as elsewhere in the school. The student could enter the laboratory and participate in the laboratory class without experiencing any breathing difficulty.

TABLE 50.6 Measurements of Ultrafine Sources in a Chemical Laboratory

Background (outdoors)	4,300
Chemistry laboratory	22,600
Other school locations	2,900
Chemical storage closet	85,600
Laboratory after chemicals were moved	2,900

50.6 CONCLUSION

This chapter has described a new method of targeting the source of indoor air pollutants and eliminating indoor air complaints.

It is well proved that ultrafine particles are virtually always present in a particle-generating process, especially combustion processes. The scientific community has also shown that these particles can be reliably measured by proven technology. The adverse health effects of ultrafine particles are not well known. However, research has suggested that a causal link does exist. Aerosol researchers and epidemiologists are teaming to confirm that a causal link exists and to define the physiology of the process.

Some IAQ investigators are not waiting for science to confirm this causal link. Instead, they have found that applying this new methodology to building investigations leads to the identification of pollutant sources not identified through traditional methods. Remediating the sources of ultrafine particles has reduced or eliminated IAQ complaints.

The simplicity of this technique causes one to conclude with a question as to whether this method could be the basis of a “purer” broadly applied IAQ standard. Specifically, *no sources of ultrafine particles should be allowed to exist, regardless of whether they can be proved harmful (i.e., have a PEL or TLV) or not*. Using this standard, one would address all sources of contamination until the levels of ultrafines in buildings are reduced to levels typical of the outside atmosphere.

CHAPTER 51

INSTRUMENTS AND METHODS FOR MEASURING INDOOR AIR QUALITY

Niren L. Nagda, Ph.D.
Harry E. Rector, B.S.
ENERGEN Consulting, Inc.
Germantown, Maryland

51.1 INTRODUCTION

Finding measurement technologies that are suited to the monitoring task is an ongoing struggle for indoor air quality (IAQ) investigators. While monitoring technologies have greatly improved since the 1970s, relatively few systems have been explicitly designed for use in residential, educational, and commercial settings. This situation is due in large part to the lack of regulatory pressures for indoor air quality. Regulations have spurred development of technologies and practices related to outdoor ambient air quality (Clean Air Act), workplace monitoring (Occupational Safety and Health Act), hazardous waste (the Comprehensive Environmental Response, Compensation, and Liability Act), and affiliated problems like chemical and biological weapons inspections.

Defensible results (i.e., conclusions from data that adequately and truthfully represent the situation and can withstand adversarial scrutiny) are of principal importance because IAQ monitoring very often amounts to collection of evidence to support or counter courtroom arguments. Some technologies developed for monitoring ambient air quality and workplace exposure are well suited to IAQ. Others, because they may represent the only affordable means to measure certain contaminants at all, have entered routine use but fail to deliver defensible results.

This chapter briefly reviews monitoring technologies for indoor air quality investigations and presents a practical framework for selecting equipment from commercial sources. Section 51.2 describes the framework for selecting measurement systems on the basis of characteristics of the problem and the data. Section 51.3 summarizes measurement technologies along with contact information for leading vendors, and Sec. 51.4 discusses quality assurance issues.

51.2 INSTRUMENT SELECTION PROCESS

Instrument selection requires a firm understanding of the goals of the planned monitoring exercise (see, for example, Nagda, et al. 1987). In most circumstances, IAQ data are collected for the purpose of ultimately comparing observations with values judged to represent a demarcation between acceptable and unacceptable conditions. We call this demarcation the “level of concern.” The level of concern often relates to adverse effects on human health. Sometimes the level of concern corresponds to a threshold for human response to sensory irritants and objectionable odors. Liability issues may force the investigator to determine whether or not specific air pollutants exceed accepted guidance levels or, in more limited circumstances, regulatory limits.

Regardless of the underlying motivation for the measurements, the level of concern is the singularly most important concept in selecting measurement systems because it represents the basis for recognizing the problem and/or its resolution. We have defined an iterative process for instrument selection (Fig. 51.1) that begins with defining the level of concern. The level of concern is then used to define ideal levels of precision, accuracy, and other data quality objectives that relate to data interpretation. Operational requirements, defined by elements of the monitoring scene and resources available for the investigation, are then used to define the basis for evaluating available systems. The instrument selection process needs to be separately applied for each pollutant to be monitored. Finally, it is important to document results of the instrument selection process.

Step 1. Identify Levels of Concern

The level of concern for each pollutant is defined by reviewing applicable regulations, standards and guidelines. Table 51.1 illustrates the potential range of choices for the level of concern for carbon dioxide (CO_2), carbon monoxide (CO), and acetaldehyde. These three chemicals represent different types of gas phase contaminants: CO_2 , a ubiquitous constituent of the atmosphere, is produced by biological respiration and combustion but is not considered an air pollutant; CO is a product of incomplete combustion, and its atmospheric concentration is regulated by ambient air quality standards; acetaldehyde, which is produced by human metabolism as well as combustion processes, is not regulated by ambient air quality standards.

Carbon dioxide receives probably the most routine attention among indoor pollutants. The 1000 ppm level commonly used to judge IAQ, however, does not represent undue exposure to CO_2 . Rather, it indicates acceptability in terms of human body odor, and does not represent indoor pollutants arising from other sources (see, for example, Persily 1993). Occupational exposure limits for CO_2 include the 5000 ppm time-weighted average (TWA) developed under the Occupational Safety and Health Act (29 CFR 1910). The OSHA TWA for CO_2 corresponds to the TWA recommended by the American Council of Governmental Industrial Hygienists (ACGIH). ACGIH also offers the 30,000 ppm short-term exposure limit (STEL). While these levels relate to adverse health consequences of exposure to CO_2 , they are nonetheless below the Immediately Dangerous to Life and Health (IDLH) value of 40,000 ppm. The potential range of choices for the level of concern for CO , in contrast, is well defined by the National Ambient Air Quality Standards (NAAQS) developed explicitly for public health. While the NAAQS exposure limits for CO are similar to the TWA and STEL that would apply to workplace exposures, these values are many orders of magnitude below the IDLH value. Acetaldehyde is a strong irritant that also is listed as a carcinogen. Workplace standards for acetaldehyde are many orders of magnitude above the odor detection threshold, but the sub-ppm range is more likely to correspond to problems in nonindustrial settings.

FIGURE 51.1 Instrument selection process.

Thus, the most important aspect of the review to select levels of concern is to seek a close match with conditions and characteristics of the problem under investigation. Furthermore, it is necessary to conduct separate reviews for each pollutant. Returning to the example of acetaldehyde, selecting a monitoring system geared to measuring concentrations that correspond to an odor problem in an office or school would require measuring concentrations that are 2 or 3 orders of magnitude less than concentrations that would be of concern in an industrial workplace. Such a problem is less likely to prevail for CO because concentrations of concern for public exposures and workplace exposures are not so far apart.

Several information resources are needed to initiate the review to identify levels of concern. The following publications form a good “starter set” to begin the review:

- *Ventilation for Acceptable Indoor Air Quality* (ASHRAE 62-1999), published by the American Society of Heating, Refrigeration and Air-Conditioning Engineers, contains listings of consensus standards that apply to indoor air quality (*Note:* This standard is constantly reviewed and updated by ASHRAE).

TABLE 51.1 Example Levels of Concern

Criteria	CO ₂ , ppmv	CO, ppmv	Acetaldehyde, ppmv
IDLH ^a	40,000	1200	2000
ACGIH STEL ^b	30,000	—	25
ACGIH TWA ^b	5000	25	—
OSHA STEL ^c	—	—	—
OSHA TWA ^c	5000	50	200
NAAQS-8h ^d	—	9	—
NAAQS-1h ^d	—	35	—
Odor ^f	1000	—	0.067

^cCode of Federal Regulations, Title 29 CFR 1910. Occupational Safety and Health Act.

^dCode of Federal Regulations, Title 40 CFR Part 50. National Ambient Air Quality Standards.

^eD6245-98, Guide for Using Carbon Dioxide Concentrations to Evaluate Indoor Air Quality and Ventilation, *Annual Book of Standards*, vol. 11.03, ASTM, West Conshohocken, PA, 1998.

^fACGIH Odor Thresholds for Chemicals with Established Occupational Health Standards, AIHA Press, Fairfax, VA, 1993.

- *National Ambient Air Quality Standards* (40 CFR 50) establishes primary standards to set limits related to protection of public health (including the health of “sensitive” populations such as asthmatics, children, and the elderly) for the primary air pollutants (CO, Pb, NO₂, O₃, SO₂, plus PM₁₀ and PM_{2.5}). Secondary standards set limits related to protection of public welfare (including visibility, damage to animals, crops, vegetation, and buildings) for emissions of nearly 200 VOCs.
- *Occupational Safety and Health Act* (29 CFR 1910) establishes workplace permissible exposure limits for approximately 200 hazardous substances.
- *Threshold Limit Values for Chemical Substances and Physical Agents and Biological Exposure Values*, published by ACGIH, gives threshold limit values and short-term exposure limits to define acceptable limits for workplace exposure.
- *Odor Thresholds for Chemicals with Established Occupational Health Standards*, published by AIHA Press, is a peer-reviewed document that contains odor thresholds for a wide variety of chemicals.

For pollutants not covered by guides or regulations, specialized databases may be consulted to develop levels of concern. Such resources include the Agency for Toxic Substances and Disease Registry (ATSDR), the Health Effects Assessment Summary Tables (HEAST), the Integrated Risk Information System (IRIS), and the Registry of Toxic Effects of Chemical Substances (RTECS). The U.S. Environmental Protection Agency recently published an analysis of test data availability for nearly 3000 organic chemicals of concern to various regulatory initiatives (USEPA 1998a). Interpretation of these information resources, however, requires input from a qualified toxicologist or health-effects specialist.

The listing of levels of concern developed from these sources needs to be prioritized in order to select a level of concern that is most appropriate for the pollutant and situation in question. Highest priority should be given to information developed explicitly for indoor air quality applications such as ASHRAE Standard 62 (ASHRAE 1999), and many of the

guidelines and regulations cited therein. The next level of priority would be for environmental standards developed for protecting the general public, such as the National Ambient Air Quality Standards. The lowest level of priority is for standards or guidelines developed for occupational exposures.

If a workplace standard is used for defining a level of concern associated with exposure concerns for the general public, then a safety factor should be considered to account for uncertainties. Sources of uncertainty include (1) extrapolating toxicological data from controlled animal testing to estimated health effects in humans, (2) extrapolating lowest observed adverse effect levels (LOAEL) to a no observed adverse effect level (NOAEL), and (3) variations in individual responses. Regulatory agencies usually require safety factor values of 10, 100, or 1000 in different situations. If the NOAEL has been derived from high-quality data in humans, then a factor less than 10 may be appropriate, provided test conditions are similar to conditions under investigation. If the NOAEL is derived from less similar or less reliable studies, then a factor such as 100 or 1000 may be required (NRC 1994). The selection and use of a safety factor should be done by a qualified toxicologist or health-effects specialist and the scientific rationale for the selected safety factors must be documented.

Step 2. Define Data Quality Objectives

Data quality objectives (DQOs) specify minimum acceptable levels of uncertainty associated with results or decisions derived from measurement data. Generally accepted practice (see, for example, Taylor 1987, USEPA 1998b) defines minimum DQOs as a series of quantitative statements that include the following concepts:

- *Precision.* A measure of the repeatability of a measured value under a given set of conditions
- *Accuracy.* A measure of the correctness of data, as given by the difference between the measured value and the true or standard value
- *Method Detection Limit (MDL).* The minimum concentration that has a stated probability of being identified and reported to be greater than zero
- *Representativeness.* The degree to which measurements are characteristic of the whole medium, exposure, or dose for which the data will be used to make inferences.

In the absence of regulatory requirements, the investigator has the latitude (and responsibility) to determine DQOs. One way to discover the limits of acceptability is to examine the effects of precision and accuracy on data interpretation. This second stage of the selection process is focused on examining these effects and on developing DQOs suited to the purpose.

Measurements can be viewed in terms of random and systematic departures from the “true” value. Precision (the random departure) is calculated from the standard deviation, and accuracy (the systematic departure, sometimes called bias) is the difference from the “true” value. Figure 51.2 illustrates how measurement systems can provide data ranging from precise and accurate to imprecise and inaccurate.

Repeated measurements of an unchanging quantity tend to be dispersed along a normal distribution (Fig. 51.3), with the standard deviation (denoted by σ) giving a measure of the scatter about the mean. The separation between the mean, $\bar{X}$, and the “true” value is the accuracy. About two-thirds of the observations will fall within 1σ on either side of $\bar{X}$, a little over 95 percent of the observations will fall within 2σ , and just over 99 percent of the observations will fall within 3σ . Precision often receives more attention than accuracy. As noted by Mandel (1991), if the equipment has been calibrated, the bias will be zero (or at

FIGURE 51.2 Precision and accuracy.

least quite small). Thus, it is simply better to calibrate equipment on a regular basis than to rely on specifications. The advent of simplified equipment, in turn, makes for easier calibrations than in earlier times. Some manufacturers offer specifications of precision without mentioning accuracy at all (under the assumption that accuracy or bias is minimized by calibration). Precision and accuracy statements also may be combined into a total uncertainty term that can be treated as precision. Discussions below concentrate on precision, but can address total uncertainty if accuracy is known to be large enough to cause concerns.

As shown in Fig. 51.4, a normal distribution can be viewed as overlapping regimes representing the probability of occurring within an interval and the probability of being less than a particular value. The mirror image of the “less than” case gives the probability of exceeding a particular value. The probability of a measurement falling within the $(\bar{X} \pm 1\sigma)$ interval is 68 percent. Given underlying symmetry, the probability of exceeding the $(\bar{X} + 1\sigma)$ level is just under 16 percent. This gives a statistical confidence of 84 percent that the “true” value is less than the $(\bar{X} + 1\sigma)$ level. Thus, for example, if the level of concern corresponds to the $(\bar{X} + 1\sigma)$ level, the basis exists for declaring with 84 percent statistical confidence that the level of concern has not been exceeded. The probabilities associated with the 2σ and 3σ cases follow the case pattern, giving nearly 98 and 99.9 percent confidence at those levels, respectively.

Conclusions are often stated with 90, or 95, or 99 percent confidence. Table 51.2 summarizes the number of standard deviations that apply to these intervals and levels. Any other degree of statistical confidence can be used as long as it satisfies the needs of decision making. Relevant values can be determined from standard tables found in any statistics textbook.

The highest reading that would be judged to be below the level of concern is a useful index for making preliminary judgments. This index concentration X_L represents a special limit for data interpretation and, because it must be explained to nonscientific audiences, it

FIGURE 51.3 Precision and accuracy in terms of the normal distribution.

**FIGURE 51.4** Probability and data interpretation.

TABLE 51.2 Probability Regimes of the Normal Distribution

A (number of standard deviations)	$\bar{X} - A < X_i < \bar{X} + A$, %	$X_i < \bar{X} + A$, $X_i > \bar{X} - A$, %
1.00	68.2	84.1
1.28	80.0	90.0
1.65	90.0	95.0
1.96	95.0	97.5
2.00	95.5	97.7
2.33	98.0	99.0
2.58	99.0	99.5
3.00	99.7	99.9

represents a potential barrier to communications between the technologist and the public. The index concentration is calculated for a particular confidence level (using the appropriate value of N_s , the number of standard deviations, selected from Table 51.2) as follows:

$$X_L + N_s \sigma < \text{LOC} \quad (51.1)$$

In many circumstances, precision is stated as a percentage. In the case at hand, the percent precision ($\sigma_{\%}$) would be expressed as the ratio of the standard deviation and X_L :

$$\sigma_{\%} = 100 \frac{\sigma}{X_L} \quad (51.2)$$

and Eq. (51.1) becomes:

$$X_L + N_s \left(\frac{\sigma_{\%}}{100 X_L} \right) < \text{LOC} \quad (51.3)$$

Thus, for example, if $\sigma_{\%}$ were $\pm 10\%$, and the level of concern were 100 ppm, then any measured value less than 81.1 ppm would be interpreted with at least 99 percent statistical confidence ($N_s = 2.33$) as being smaller than the level of concern. At the 90 percent statistical confidence level ($N_s = 1.28$), on the other hand, the index concentration would be 88.7 ppm. The reduced confidence for higher values of X_L is caused by the interval shrinking against a fixed level of concern.

Precision exerts a fairly strong influence on interpretation of measured values. If the precision is ± 25 percent, the index concentration for 100 ppm would be 63 ppm at the 99 percent confidence level, and 76 ppm at the 90 percent confidence level. The burden of explaining this is eased by attaching the confidence intervals to the data report.

If we define the analytical range to set the maximum expected concentration and include the detection limit, then a few general rules for an ideal measurement system can be stated:

- Precision and accuracy should be small enough to provide acceptable statistical confidence when comparing a measured value with the level of concern.
- The detection limit should be well below the level of concern—usually by a factor of 10.
- The analytical range should extend far enough—usually to at least twice the level of concern—to provide acceptable statistical confidence to judge whether or not a measured value is above the level of concern.

These relationships are illustrated in Fig. 51.5. This kind of quantitative exercise is a useful prelude to reviewing available technologies because it provides specific criteria for identifying those technologies that would meet measurement objectives.

The key point in Step 2 of the instrument selection process is recognizing the importance of the level of concern to the data interpretation process. Delivering data that features ± 25 percent precision may not be so bad if measurement objectives relate to determining whether or not the level of concern is exceeded and there is adequate room between the detection limit and the level of concern. Delivering data that features ± 10 percent precision may not be useful if measurement objectives relate to determining whether or not concentrations are below the level of concern and if the detection limit is too close to the level of concern.

Step 3. Evaluate Operational Requirements

DQOs also address the concepts of representativeness (the degree to which samples are characteristic of the exposure or dose) and completeness (the amount of valid data collected). These concepts relate to the problem scenario as well as the capabilities of the investigator and the equipment. Representativeness embraces the details of time and place, while completeness addresses things that can go wrong. Key concepts related to representativeness and completeness include the following:

- *Temporal representativeness.* The frequency and duration of measurements should relate to the problem being investigated. A 24-hour integrated sample may not be capable of representing a 1-hour exposure episode. A point-in-time measurement may miss an abbreviated or even an extended episode altogether.

FIGURE 51.5 Ideal measurement characteristics.

- *Spatial representativeness.* Measurements must be taken in the physical location identified with the problems. A cramped office cubicle may not present enough space for normal activities and larger-sized monitoring equipment.

Other factors that have an impact on representativeness and completeness include the following:

- *Electric power.* Many equipment items require alternating current to operate. Any floor-space already in use for another purpose is likely to have appliances plugged into available sockets. Access to unused electrical sockets is likely to be blocked by furniture.
- *Loss control.* The equipment may be at risk to vandalism or accidental damage, especially if unattended monitoring is necessary.

These and similar concepts lead to an appreciation of desirable operating characteristics based on practical details of the monitoring objectives. Equipment characteristics, along with the level of experience and facilities available for the investigation, require decisions in the following areas:

Mode. Active (requiring a pump or aspirator to convey sample) or passive (relying on diffusion)

Output. Continuous, point in time, or time-weighted average

Recording. Electronic signal, field observation, or laboratory report

Mobility. Hand-held (<1 kg), portable (<5 kg), or stationary (>5 kg)

Power requirements. Battery, standard alternating current, or mechanical

Calibration. Standard atmospheres, colocated references, laboratory procedures, and/or factory procedures

Equipment costs. Purchase/lease of equipment

Facilities costs. Current/new/outsourcing laboratory and other support

Personnel. Training requirements for current staff, new hires, and outsourcing

Step 4. Evaluate Available Technologies

This step in the selection process begins with a review of publications and other resources to collect relevant information on available systems. Specifications and characteristics are then examined in the light of DQOs (Step 2) and operational requirements (Step 3) to guide final decisions.

Tracking down equipment manufacturers is fairly straightforward. In addition to the publications that arrive as a matter of membership in professional societies and trade organizations, a range of published and electronic resources is available to identify equipment and vendors. Textbook-quality publications are led by the major reference, *Air Sampling Instruments*, published by ACHIH (Cohen and Hering 1995). This work, originally published in 1960 and updated every few years since, provides well-written reviews of basic technologies in addition to extensive instrument-specific summaries. The primary value of this book, though, comes from the technology reviews. It is useful for identifying measurement systems and vendors, but publishing schedules of 1 year or more coupled to update cycles of 4 to 5 years allow new product lines and other rearrangements of the marketplace to outpace reader needs.

A number of other resources exist to deliver information in a more timely fashion. Leading examples that provide at least some focus for IAQ measurement systems are sum-

marized in Table 51.3. *IEQ Strategies* and the *Indoor Environment Review* are fee-based subscription monthlies that deal exclusively with the indoor environment. In addition to basic review articles on theory and practice, *IEQ Strategies* publishes an annual directory of IAQ-oriented products and services. The *Indoor Environment Review*, on the other hand, features extensive advertising from a variety of companies active in the field in addition to articles covering theory and practice. The *Review* also dedicates a separate area of its Website to connect users with these advertisers.

Nearly every professional society that deals with measurement systems publishes a product guide tailored to the membership. *EM*, the monthly news publication of the Air & Waste Management Association, and *Environmental Science & Technology*, the monthly journal published by the American Chemical Society, both offer product guides. The American Chemical Society also provides an excellent online listing through its Website.

Rimbach Publishing produces two trade magazines, *Pollution Equipment News* and *Industrial Hygiene News*, that are designed to disseminate product information in the environmental fields. Both of these publications are subscription-based, but at no cost to the subscriber (in return for market profile information).

The exponential growth of the Internet has provided manufacturers with the means to exhibit their wares to a wider audience. The Air Infiltration and Ventilation Centre, headquartered in the United Kingdom, is supplementing its Website with an online listing of products and services related to the indoor environment. The ISA Directory and SEARCH-SPEC are both excellent online gathering points for identifying manufacturers of all types of instrumentation.

The American Society for Testing and Materials (ASTM) is a primary focus for developing consensus standards that relate to monitoring technologies and procedures. The consensus framework of ASTM brings together manufacturers, researchers, and practitioners to concentrate all aspects of experience in developing standard test methods, specifications, practices, guides, classifications, and terminology. Two areas of special interest to IAQ include Committee D-22 on Sampling and Analysis of Atmospheres and Committee E-6 on Building Constructions.

While ASTM standards do not serve to highlight particular equipment items, they nonetheless provide valuable information relating to basic performance characteristics (e.g., precision and accuracy, calibration, and maintenance), and practical limits of application. Existing ASTM standards are formally reviewed every 5 years and must be either approved for renewal or withdrawn. The *Annual Book of ASTM Standards* consists of 73 volumes divided among 16 sections to collect test methods, specifications, practices, guides, classifications, and terminology along relevant themes. Volume 11.03 (ASTM 1999a) brings together standards related to measuring air pollutants, and Vol. 04.11 (ASTM 1999b) brings together ASTM standards related to measuring air exchange and airflows. ASTM also publishes the standards as separate reprints.

Evaluating the information gathered in the reconnaissance is a matter of identifying systems that meet performance and operational criteria developed under Steps 2 and 3, and selecting those products that meet budgetary constraints. The situation can reach a fair degree of complexity, however, when alternatives that have long-term consequences are considered. Decisions in this regard often involve recognizing the benefits of purchasing versus leasing. Costs associated with buying and maintaining expensive equipment subject to infrequent use can be moderated by lease arrangements. Establishing a laboratory, however, needs to satisfy various regulatory requirements (e.g., licensing/certification, hazardous waste disposal), and should be evaluated from level-of-need and resource-commitment perspectives.

The reconnaissance process may fail to discover systems that meet expectations. When this occurs, it may be desirable to reconsider operational criteria or revise measurement objectives and DQOs (Step 2). Basic considerations are summarized below.

TABLE 51.3 Information Resources for IAQ Measurement Systems

Resource	Contact
<i>IEQ Strategies</i> —Monthly fee-based publication covering regulatory and technical issues in the indoor environment field; publishes annual directory of companies specializing in indoor air quality services and equipment.	Cutter Information Corp. 37 Broadway, Suite 1 Arlington, MA 02474 Phone: 800-964-5125 www.cutter.com
<i>Indoor Environment Review</i> —Monthly fee-based publication covering regulatory and technical issues in the indoor environment field. Provides technology reviews and reader service links to advertisers. Also provides <i>READERINK</i> , a searchable online listing of IAQ products and services.	IAQ Publications, Inc. 7920 Norfolk Ave. Bethesda, MD 20814 Phone: 800-394-0115 www.iaqpubs.com
<i>Industrial Hygiene News</i> —Bimonthly no-cost subscription trade publication covering equipment and technology for industrial hygiene and safety; publishes annual product guide.	Rimbach Publishing Co. 8650 Babcock Blvd. Pittsburgh, PA 15237 800-245-3182 www.rimbach.com

<i>ASTM</i> is responsible for over 10,000 consensus standards that relate to measurements. Maintains committees on indoor air quality and building performance.	ASTM 100 Barr Harbor Drive West Conshohocken, PA Phone: 610-832-9500 www.astm.org

- Operational characteristics can be reconsidered, provided adjustments do not disable the validity of data interpretation. If the ideal approach seeks continuous monitoring, for example, and the only viable alternatives involve laboratory analysis of field samples, then a judgment could be made to accept the latter, provided representativeness is not greatly compromised, and that laboratory facilities are available.
- If the methodology involves collecting time-weighted-average samples, then replicate sampling allied to averaging of results can reduce statistical uncertainty. As a last resort, less-than-ideal precision and accuracy can be accommodated by accepting reduced statistical confidence (e.g., using a 90 percent confidence level instead of 99 percent).

It is very difficult to justify modifying the level of concern to accommodate less-than-satisfactory measurement systems because such actions can cripple data interpretation. Thus, if a satisfactory system cannot be identified (or if the means cannot be discovered to deal with insufficiencies), it is usually better to forego the measurement than to collect data that fails to represent the problem.

Step 5. Document Decisions and Rationale

Once decisions are finalized, it is good practice to record the details of the selection process. The measurement system selection report could be as brief as a memorandum to file, or lengthy enough to be a formal report. At a minimum, the report should address the following topics:

- *Monitoring objectives.* Describe the purpose of the measurements.
- *Levels of concern.* Summarize the information sources consulted to define and select each level of concern for each pollutant and describe the basis for selecting them.
- *Data quality objectives.* Summarize the logic and derivations for specifying precision and accuracy, method detection limit, and analytical range.
- *Selections.* Summarize characteristics of each measurement system selected for use.

51.3 MEASUREMENT TECHNOLOGIES

Rather than attempt to identify all possible mission-specific factors that would lead to detailed choices, this review focuses on highlighting equipment that is generally suited to conducting IAQ monitoring in buildings and other enclosed spaces and delivering data that is compatible with data quality objectives discussed earlier.

Performance characteristics for various IAQ measurement systems are summarized in Tables 51.5 through 51.12. This summary covers three broad areas of consideration: (1) basic operating characteristics and logistics, (2) technical performance, and (3) advantages and disadvantages. Operating characteristics include the following:

- *Mobility.* Hand-held (<1 kg), portable (<5 kg), or stationary (>5 kg).
- *Sampling mode.* Active (pump) or passive (diffusion).
- *Sampling approach.* Continuous, integrated, intermittent.
- *Power.* Battery, standard alternating current, mechanical.
- *Size, weight, and cost.*

Technical performance characteristics include the following:

- Range, method detection limit, precision, and accuracy.
- Calibration—standard atmospheres, collocated references, laboratory procedures, factory procedures.
- Output—electronic signal, field observation, laboratory report.

These summaries also note specific advantages and disadvantages that relate to using the technology for IAQ monitoring. Contact information for example vendors named in Tables 51.5 through 51.12 is listed in the appendix to this chapter. Cost factors, summarized in Table 51.4, are considered in five broad categories: A: <\$500; B: \$500 to \$1000; C: \$1000 to \$5000; D: \$5000 to \$10,000; and E: >\$10,000. These costs are for general guidance, and do not include taxes or shipping.

Bioaerosols

Monitoring for bioaerosols (Table 51.5) involves collecting field samples for analysis in the laboratory. Basic technologies are reviewed by Burge (1995) and by Macher and colleagues (1995). Viable particles, captured in suitable nutrient media, are incubated under controlled conditions, and analyzed in terms of the abundance of colony-forming units that grow during the incubation period. The analysis requires extensive training to classify key species (especially for fungi and molds). Size-selective sample collection is necessary in order for measurements to represent inhalation exposure. Inertial impactors like the Andersen sampler, therefore, are generally preferred. Gravitational samplers, involving open Petri dishes to catch particles settling out of the atmosphere, are sometimes proposed as a cost savings, but such samples represent size ranges well above the inhalable range, and still require the same degree of laboratory effort. In terms of heft, sampling equipment for bioaerosols can be hand-carried into the monitoring scene. In operation, however, samples are collected from fixed locations because collection times for viable particles is usually 30 minutes or less to avoid dessicating the sample and thereby compromising viable colonies. Equipment costs for sampling bioaerosols are fairly low (Table 51.4), as are analytical costs through service laboratories. A number of commercial laboratories lease sampling equipment as part of an overall service.

Carbon Dioxide and Carbon Monoxide

Basic technologies for monitoring CO₂ and CO are reviewed by Woebkenberg and McCammon (1995). Nondispersive infrared (NDIR) spectrometry is the preferred technology for CO₂ monitoring (Table 51.6). The technology has been in routine use for more than 30 years. Engelhard recently introduced miniaturized NDIR transducers packaged for hand-held monitoring. These units give performance that is comparable to the more expensive benchtop models. While inexpensive (less than \$500), the miniaturized monitors rely on diffusion to deliver sample air to the transducer. Thus, for any type of application where the monitor is separated from the sampling point to be represented, an external air pump is required to draw air to the instrument. Such conditions could arise if security precautions require placing the instrument within a protective housing, or if the monitor needs to be in another room. Calibration for NDIR instruments is accomplished from gas mixtures of known concentration. Pressurized containers of calibration gases can be purchased from a variety of suppliers.

TABLE 51.4 Summary of Unit Costs for Equipment

Technology	Field operations			Support operations	
	Hand-held Equipment	Portable Equipment	Benchtop Equipment	Calibration Equipment	Analytical Services

*Technology requires air pump; minimum cost is category A.

Cost categories: A: <\$500; B: \$500 to \$1000; C: \$1000 to \$5000; D: \$5000 to \$10,000; E: >\$10,000.

TABLE 51.5 Laboratory-Based Methods for Bioaerosols

Technology	Guidance	Example vendors	Comments
<i>Inertial impaction</i> —sample air is drawn through aerodynamic inlet, and particles of biological interest are collected on a suitable medium that is returned to the laboratory for analysis via culture growth (viable particles), immunoassay (allergens), or microscopy (spore count).	Burge (1995) Macher et al. (1995) Range: Accuracy: Precision: MDL:	Andersen	No standard methods exist. Requires external air pump. Aseptic conditions must be maintained to avoid contaminating sample. Requires sophisticated laboratory for preparation and analysis.
<i>Liquid impingement</i> — sample air is drawn through an aerodynamic inlet, and particles of biological interest are collected on a liquid medium that is returned to the laboratory for recovery analysis via culture on prepared media.	Burge (1995) Macher et al. (1995) Range: Accuracy: Precision: MDL:	Burkard, SKC	No standard methods exist. Requires external air pump and requires handling liquid reagents in the field. Aseptic conditions must be maintained to avoid contaminating sample. Requires sophisticated laboratory for preparation and analysis.
<i>Rotating impactor</i> —particles of biological interest are collected on rotating rigid rods or slides coated with silicone grease or other adhesive material and returned to the laboratory for microscopic identification.	Burge (1995) Macher et al. (1995) Range: Accuracy: Precision: MDL:	Burkard	No standard methods exist. Clean conditions must be maintained to avoid contaminating sample substrate. Requires sophisticated laboratory for preparation and analysis. Representativeness is limited primarily to larger particles (spores and pollens).
<i>Gravitational settling</i> —particles of biological interest are collected on horizontal surfaces.	Burge (1995) Macher et al. (1995) Range: Accuracy: Precision: MDL:	SKC	No standard methods exist. Samples are biased toward larger particles and fail to adequately represent inhalation exposure.

TABLE 51.6 Instrumentation for Carbon Dioxide

Technology	Guidance	Example vendors	Comments
<i>Electrochemical</i> —sample air is passed through a cell wherein reduction of CO ₂ produces a signal that is proportional to concentration.	Woebkenberg and McCammon (1995) Range: 0–5000 ppmv Accuracy: ± 50 ppmv Precision: MDL:	Solomat	Very specific for CO ₂ ; portable units are available.
<i>Nondispersive infrared (NDIR) spectrometry</i> —absorption of infrared radiation by CO ₂ in a sample cell is compared to that of a reference (CO ₂ -free) absorption cell.	Woebkenberg and McCammon (1995) Range: 20–20,000 ppmv Accuracy: $\pm 5\%$ Precision: $\pm 5\%$ MDL: 200 ppmv	Engelhard, LiCor, Monitor Labs, Solomat, Thermo Environmental	Very specific for CO ₂ ; portable units are available (Engelhard, LiCor, Solomat). Some units may require an external pump for certain applications.
<i>Colorimetric tube</i> —sample gases are drawn through a chemical treated sorbent bed that changes color in the presence of CO ₂ ; length of color stain is correlated with concentration.	ASTM D 4599 Range: 100–200,000 ppmv Accuracy: $\pm 25\%$ Precision: MDL:	Draeger Safety, Sensidyne	Requires external air pump (may be hand-powered). Disposable system (single use) that relies on factory calibration. May be of lower resolution than other technologies. Not generally recommended for monitoring public exposure to CO ₂ .

As summarized in Table 51.7, NDIR spectrometry is also the preferred technology for monitoring CO. Detailed guidance is available in ASTM D 3162 [Test Method for Carbon Monoxide in the Atmosphere (Continuous Measurement by Nondispersive Infrared Spectrometry); see ASTM 1999a]. One manufacturer (Engelhard) has miniaturized the NDIR technology for portable or hand-held operation. Electrochemical detectors may operate on principles of conductivity, potentiometry, coulometry, or ionization. Electrochemical detectors based on aqueous solutions have seen the most use for IAQ applications. Solid-state electrochemical sensors that exploit ionic properties of ceramics and polymers are receiving renewed attention (McGheehin et al. 1994). As with CO₂, calibrations are accomplished from gas mixtures of known concentration.

Specificity for most electrochemical sensors is achieved by using selective scrubbers on the inlet airstream to remove interfering compounds. Some investigators have noted strong interference effects approaching 100 ppm while monitoring CO in areas containing vapors from common household products like hairspray, perfumes, and other solvent-bearing materials (Wilson et al. 1992). This problem is readily addressed by increasing the capacity of the scrubber. Certification for workplace monitoring routinely addresses the interference effects of acetylene, ammonia, hydrogen sulfide, and other gases commonly encountered in indus-

TABLE 51.7 Instrumentation for Carbon Monoxide

Technology	Guidance	Example vendors	Comments
<i>Electrochemical</i> —sample air is passed through a cell wherein oxidation of CO produces a signal that is proportional to concentration.	Woebkenberg and McCammon (1995) Range: 1–100 ppmv Accuracy: $\pm 5\%$ Precision: $\pm 5\%$ MDL: <1 ppmv	Capteur, Draeger Safety, Figaro, Gas Tech, KD, Interscan, Metrosonics MSA, Neotronics, Sensidyne	Can be very specific for CO; portable units available. Specificity is achieved by inlet scrubber of uncertain efficiency for some chemicals.
<i>Nondispersive infrared (NDIR) spectrometry</i> —absorption of infrared radiation by CO in a sample cell is compared to that of a reference (CO-free) absorption cell.	ASTM D 3162 Woebkenberg and McCammon (1995) Range: ≤ 1 –100 ppmv Accuracy: $\pm 5\%$ Precision: $\pm 5\%$ MDL: <1 ppmv	Engelhard, Monitor Labs, Thermo Environmental	Very specific for CO; based on EPA reference method; portable units are available (Engelhard).
<i>Colorimetric tube</i> —sample gases are drawn through a chemically treated sorbent bed that changes color in the presence of CO; length of color stain is correlated with concentration.	ASTM D 4599 Range: 5–100,000 ppmv Accuracy: $\pm 25\%$ Precision: MDL:	Draeger Safety, Sensidyne	Requires external air pump (may be hand-powered). Disposable system (single use) that relies on factory calibration. May be of lower resolution than other technologies. Not generally recommended for monitoring public exposure to CO.

trial settings. Such evaluations do not always evaluate the role of alcohols and other chemicals that could occur in residential, educational, and commercial environments.

Colorimetric tubes, described in ASTM D 4599 (Standard Practice for Measuring the Concentration of Toxic Gases or Vapors Using Length-of-Stain Dosimeters; see ASTM 1999a), are sometimes proposed as a cost-saving alternative. This technology usually falls short of giving quantitative results, and its use should be limited to providing qualitative indications only.

Ozone

General technologies for monitoring O_3 have been summarized by Woebkenberg and McCammon (1995). Ultraviolet absorption photometry is the reference-grade technology for measuring O_3 . A full description of the technology and its use is provided in ASTM D 5156 [Standard Test Methods for Continuous Measurement of Ozone in Ambient, Workplace, and Indoor Atmospheres (Ultraviolet Absorption); see ASTM 1999a]. Relatively few options are available for monitoring O_3 in the indoor environment. Choices for reference-grade ultraviolet absorption O_3 instruments are predominantly limited to

TABLE 51.8 Instrumentation for Ozone

Technology	Guidance	Example vendors	Comments
<i>UV absorption photometry</i> —absorption of ultra-violet radiation by O ₃ is compared to absorption in an ozone-free (reference) cell.	ASTM D 5156 Woebkenberg and McCammon (1995) Range: 1–1000 ppbv Accuracy: ±10% Precision: ±10% MDL: 1 ppbv	Monitor Labs, Thermo Environmental	Very specific for O ₃ . Commercially available units are generally too expensive and bulky for portable operation.
<i>Electrochemical cell</i> —sample air is passed through a cell wherein ozone-specific reactions produce a signal proportional to concentration.	Woebkenberg and McCammon (1995) Range: 30–1000 ppbv Accuracy: ±10% Precision: ±10% MDL: 30 ppbv	Capteur, EIT	Portable units available. Electrochemical cells may exhibit sensitivity to changes in pressure and humidity. May be inadequate at lower concentrations.
<i>Dry colorimetry</i> —sample air passes through a paper tape impregnated with ozone-specific dry reagent system; photometrically measured color change is proportional to concentration.	Woebkenberg and McCammon (1995) Range: 31–300 ppbv Accuracy: Precision: ±5% MDL: 31 ppbv	Zellweger	Portable units available. System can be reconfigured for up to 50 different gases by changing to other reagent-impregnated tapes. May be inadequate at lower concentrations.

benchtop instruments that may be too expensive for most budgets (Table 51.8). Electrochemical and dry colorimetric ozone sensors are generally affordable, and feature portable operation. Detection limits for aqueous electrochemical cells and dry colorimetry may approach a significant fraction of the National Ambient Air Quality Standards, however, and their use for most IAQ applications should be approached with caution. Solid-state ozone sensors are just entering the marketplace, and show more promising performance (McGhee et al. 1994). Calibrations for ozone equipment can become expensive. Equipment costs for ozone calibrators are high. Standard calibrations require an ozone source (a UV lamp that generates reproducible levels of ozone) and a standard reference instrument to either establish the ozone level in the calibration feedstream through gas phase titration or through an absolute photometric reference.

Particulate Matter

For particulate matter, choices include gravimetric samplers that require laboratory analysis, as well as continuous sensing based on optical properties and other effects (Hering, 1995, Pui and Swift 1995). As shown in Table 51.9, a variety of size-selective inlets are available to collect sample mass onto a filter. The basic requirements for filter weighing and flow calibrations can be set up in a laboratory space, but special attention is required to

TABLE 51.9 Instrumentation and Methods for Particulate Matter

Technology	Guidance	Example vendors	Comments
<i>Optical backscatter</i> —aerosol mass is measured on backscatter from a calibrated light source probing a characteristic sample volume.	Pui and Swift (1995) Range: to mg/m^3 Accuracy: $\pm 10\%$ Precision: $\pm 10\%$ MDL: $10 \mu\text{g}/\text{m}^3$	MIE, TSI	Requires aerosol-specific calibration; size-selective monitoring requires external air pump and aerodynamic inlet.
<i>Gravimetric</i> —sample air is accelerated through one or more stages of an inertial impactor to separately deposit size fractions. Aerosol mass is determined by weighing tared substrate in the laboratory.	Hering (1995) Range: to mg/m^3 Accuracy: $\pm 10\%$ Precision: $\pm 10\%$ MDL: $10 \mu\text{g}/\text{m}^3$	Andersen, SKC	Can be configured for inhalable ($10 \mu\text{m}$) and respirable ($2.5 \mu\text{m}$) size ranges. Requires external air pump. Requires laboratory support for mass determination.

control for humidity and electrostatic effects. High-volume sampling methods developed for outdoor ambient air quality monitoring (see Lodge 1989, USEPA 1998c) should be avoided for indoor air quality applications, however. The equipment, designed for unattended outdoor monitoring, is usually too large and noisy for occupied airspaces, and sample collection rates are high enough that particle removal could affect representativeness (that is, the high-volume sampler could act more as an air cleaner than a sample collector). Miniaturized equipment designed to operate at a few liters per minute from battery-powered pumps has seen widespread use (see Hering 1995). The resolving power of most analytical balances is limited to a few micrograms. Consequently, the use of miniaturized equipment for gravimetric samples in a low-concentration environment usually requires lengthy sampling periods to accumulate sufficient sample mass.

Continuous monitors utilizing optical principles deliver time series data that allow the investigator to better observe the immediate impacts of indoor sources. Working principles, reviewed by Pui and Swift (1995), use optical extinction or backscatter/sidescatter profiles as a proxy for aerosol mass, and calibration is achieved by comparisons with gravimetric samples. A caution should be noted: Direct-reading analyzers for particulate matter that rely on optical properties are calibrated in the laboratory by using a size distribution that is characteristic to the calibration material. Unless the size distribution relates to that which prevails in the monitoring scene, misleading or even erroneous results are likely (Nagda et al. 2000).

Organics

The hundreds of gas-phase and particle-bound organic chemicals represent probably the greatest sampling/analytical challenge for IAQ investigations. The following broad classes have been defined on the basis of physical properties (Lewis and Gordon 1996):

- Very volatile organic compounds (VVOCs) occur predominantly in the gas phase at room temperatures (vapor pressures >15 kPa at 25°C) and, because boiling points are typically below 30°C , VVOCs evaporate very rapidly from the liquid phase.
- Volatile organic compounds (VOCs) also occur predominantly in the gas phase at room temperatures (vapor pressures $>10^{-2}$ kPa), and slightly higher boiling points (typically 30 to 180°C) allow for fairly rapid evaporation from the liquid phase.
- Semivolatile organic compounds (SVOCs) typically have vapor pressures between 10^{-2} and 10^{-8} kPa at room temperature, and typical boiling points of 180 to 350°C allow SVOCs to occur in both the gas phase and the condensed phase.
- Nonvolatile organic compounds (NVOCs) have vapor pressures below 10^{-8} kPa at room temperature and typically occur in the condensed phase.

Demarcations separating VVOCs, VOCs, SVOCs, and NVOCs are somewhat blurred, and older terminology employing only VOCs and SVOCs remains in use. VOCs (and VVOCs) comprise the large number of alcohols, aromatics, chlorinated hydrocarbons, aldehydes, and other compounds emitted from consumer products, materials, and processes that commonly occur in buildings. SVOCs (and NVOCs) include polynuclear aromatic hydrocarbons (PAH) produced by combustion sources as well as their halogenated derivatives such as the polychlorinated biphenyls (PCBs) and a number of pesticides and dioxins. A number of comprehensive reviews of the basic technologies for monitoring VVOCs, VOCs, SVOCs, and NVOCs exist in the professional literature (Lodge 1989; USEPA 1990a, 1990b, 1998c; Wolkoff 1995; Lewis and Gordon 1996).

The primary choices for monitoring VVOCs and VOCs are between collecting field samples for subsequent analysis in the laboratory (Table 51.10), and real-time monitoring onsite using portable analyzers (Table 51.11). Sample collection techniques in current use include whole-air sampling (drawing air into a suitable container that is returned to the laboratory for subsequent analysis), and sorbent collection (drawing air through a sorbent bed to concentrate chemicals of interest for subsequent analysis in the laboratory).

Whole-air samples collected into an evacuated stainless steel canister have come into increased use because a wide variety of compounds can be collected in a single sample. Full descriptions of the canister collection methodology are found in ASTM D 5466 [Standard Test Method for Determination of Volatile Organic Chemicals in Atmospheres (Canister Sampling Methodology); see ASTM 1999a] and in USEPA publications (USEPA 1990a, 1990b). Collecting air samples into polymeric bags is sometimes proposed as a low-cost alternative. Controlled testing has shown, however, that sample losses can be significant (USEPA 1990a, Wang et al. 1996, Groves and Zellers 1996). Because cost savings are driven primarily by the collection apparatus (analytical requirements would be similar to achieve the same detection limits and precision/accuracy), such savings could come at the cost of unsatisfactory results.

Sorbent collection techniques are described in ASTM D 6196 (Standard Practice for the Sampling and Analysis of Volatile Organic Compounds in Air by Pumped Sorbent Tube and Thermal Desorption; see ASTM 1999a), and in USEPA publications (USEPA 1990a, 1990b). Significant attention is required in selecting sorbent tubes and flow rates in order to optimize capturing chemicals of interest while avoiding breakthrough and undue formation of artifacts. Commercial sorbent tubes can be packed with up to three sorbents to collect a broader range of VVOCs and VOCs.

Whole-air and sorbent collection techniques share the common requirement of an analytical laboratory that is equipped for analysis via gas chromatography (GC). In many cases, gas chromatography will require more sensitive mass spectrometry detection (GC/MS) to measure at ppb levels commonly required by IAQ investigations. Other detection systems include flame ionization (GC/FID), electron capture (GC/ECD), and

TABLE 51.10 Laboratory-Based Methods for Organic Compounds

Technology	Guidance	Example vendors	Comments
<i>Canister collection</i> —sample gases are collected into a passivated stainless steel evacuated container and then returned to laboratory for analysis by GC/MS.	ASTM D 5466; USEPA (1990a, 1990b) Range: to high ppmv, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: < 1 ppbv	Andersen, Meriter, Restek	Evacuated canister may be filled passively or by using a pump. Extremely low humidity may affect recovery of some VOCs. Capable of monitoring for other gases like CO, CO ₂ . Canister volume affects field logistics. Method requires a sophisticated laboratory.
<i>Bag collection</i> —VOCs are collected into a polymeric bag and then returned to laboratory for analysis of individual compounds by GC/MS.	USEPA (1990a, 1988) Range: to high ppmv, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: < 1 ppbv	SKC, Alltech, Andersen	Capable of monitoring for other gases like CO, CO ₂ . Bag volume affects field logistics. Sample losses are commonly observed. Bags should not be reused for sampling low-concentration environments. Method requires a sophisticated laboratory.
<i>Sorbent tube</i> —VOCs are collected onto a granular sorbent and then returned to laboratory for thermal desorption and analysis by GC/MS.	ASTM D 6196; USEPA (1990a, 1990b) Range: to high ppmv, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: < 1 ppbv	SKC, Supelco	Different types of sorbents are required for polar, nonpolar compounds. Sorbent tubes may be packed with up to 3 different sorbents. External pump is required. Sorbent tubes typically can be reused up to 100 times. Method does not require a sophisticated laboratory.
<i>DNPH tube</i> —aldehydes are collected onto a granular sorbent coated with DNPH and returned to laboratory for analysis by HPLC	ASTM D 5197; USEPA (1990a, 1990b) Range: 10–5000 ppbv, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: 0.5 ppbv	SKC, Waters	Field apparatus is compact. Requires external pump. O ₃ at high concentrations interferes negatively. Method requires a sophisticated laboratory.
<i>Passive dosimeter</i> —VOCs are collected onto a sorbent via molecular diffusion and returned to laboratory for desorption and analysis by GC.	ASTM D 4597; USEPA (1990a, 1990b) Range: varies, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: varies	3M, Draeger Safety, K & M Environmental, SKC, Supelco, Varian	Field apparatus is compact, and does not require an external pump. In most cases, desorption is via solvent elution, which limits response at low concentrations. Method requires a sophisticated laboratory.
<i>PUF tube</i> —SVOCs collected on polyurethane foam (PUF) cartridge that is returned to laboratory for analysis by GC/FID, GC/MS, or HPLC.	ASTM D 4861; USEPA (1990a, 1990b) Range: to high ppmv, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: < 1 ppbv	SKC	Collects particle-bound and gas-phase SVOCs; field apparatus is compact. Requires external pump. Method requires a sophisticated laboratory.
<i>Solid-phase microextraction (SPME)</i> —analytes are absorbed on coated fused silica fiber and desorbed to GC/MS for analysis.	Zhang et al. 1994; Pawliszyn 1997 Range: to high ppmv, Accuracy: $\leq 25\%$, Precision: $\leq 25\%$, MDL: < 1 ppbv	Supfelco, Varian	Sample collection apparatus is compact. Technology has been successfully applied to aromas and flavors, VOCs, and pesticides. Method requires a sophisticated laboratory.

TABLE 51.11 Portable Analyzers for Organic Compounds

Technology	Guidance	Example vendors	Comments
<i>Real-time GC</i> —sample gases are delivered to a chromatographic column for separation and detection of individual VOCs.	Woebkenberg and McCammon (1995) Range: to high ppmv Accuracy: $\pm 25\%$ Precision: $\pm 25\%$ MDL: <1 ppbv	FemtoScan, HNU, Inficon, Perkin-Elmer, Sentex, Varian	Field-portable units are available; carrier gas required. Portable technology may not be easily optimized for some compounds of interest. Operator training required.
<i>Infrared spectroscopy</i> —sample gases are introduced into a chamber wherein absorption in specific IR wavelengths is measured.	Woebkenberg and McCammon (1995) Range: to high ppmv Accuracy: $\pm 5\%$ Precision: $\pm 10\%$ MDL: <1 ppbv	Foxboro, INNOVA	May be configured for any IR-absorbing gas (including CO, CO ₂ , H ₂ O). Sensitivity and selectivity for some gases is limited. Operator training required.
<i>TVOC</i> —sample gases are delivered to a photoionization detector and concentrations are read as total VOC.	Woebkenberg and McCammon (1995) Wolkoff (1995) Mølhave et al. (1997) Range: to high ppmv Accuracy: $\pm 25\%$ Precision: $\pm 25\%$ MDL: <1 ppbv	Perkin-Elmer, RAE Systems, HNU, Thermo Environmental	Technology not yet consistently applied or accepted by the scientific community.

photoionization (GC/PID). Canisters, bags and sorbent tubes can be reused provided sufficient attention is given to cleaning prior to subsequent use. A number of commercial vendors exist to provide equipment, supplies, and services.

The logistics of whole-air sampling can be encumbered by the air volume collected. Standard laboratory methods to analyze samples collected in canisters require the transfer of about 450 mL of air sample (USEPA 1990a, 1990b). Stainless steel canisters are available in volumes ranging from about 0.5 L on up to about 6 L, and polymeric bags in volumes as large as 100 L. Canisters and bags are lightweight, but handling a few dozen samples at a time in the field requires serious attention to logistics. Sorbent tubes represent much more compact field apparatus. Their use, however, requires a sample pump to draw air through each tube, and the pumps require calibration to certify flow rates.

Aldehydes (particularly ubiquitous irritants like formaldehyde and acrolein) could be counted as VOCs based on boiling point and vapor pressure, but sampling/analytical techniques usually require derivitization (conversion of the aldehyde to a stable adduct that will survive transfer to the laboratory). Consequently, these compounds are monitored separately. The preferred method involves collecting aldehydes using a tube or cartridge containing silica gel coated with 2,4-dinitrophenyl hydrazene (DNPH). Detailed guidance is available from USEPA (1990b, 1988) and ASTM D 5197 (Standard Test Method for Determination of Formaldehyde and Other Carbonyl Compounds in Air; see ASTM 1999a). The aldehydes form specific stable adducts with the DNPH that, in the laboratory, are readily analyzed by high-performance liquid chromatography (HPLC).

The polyurethane foam (PUF) tube is the principal means for collecting SVOCs (and many NVOCs) for analysis in the laboratory. The technique requires a pump for sample collection, and sophisticated laboratory support is required for preparation and analysis. Detailed guidance is available from the USEPA (1990b, 1988), and ASTM D 4861 (Standard Practice for Sampling and Selection of Analytical Techniques for Pesticides and Polychlorinated Biphenyls in Air; see ASTM 1999a).

Passive dosimeters have been available since the 1970s (see, for example, Lautenberger et al. 1980). VOCs are collected via diffusion onto a sorbent, and, in the laboratory, analytes are extracted by a suitable solvent and a microliter-sized aliquot is injected into the gas chromatograph for analysis. Basic principles for passive dosimeters have been reviewed by Rose and Perkins (1982), and more recently by Brown and Monteith (1995). Reliance on diffusion restricts the device to relatively low collection rates, and solvent extraction is generally less efficient than thermal desorption. Nonetheless, the dosimeters work quite well in the 10- to 100-ppm levels commensurate with workplace concerns. It is possible to overcome the effects of relatively low collection rates by sampling for longer time periods, but such an approach risks collection of water vapor and other interferences, and the representativeness of the sample could be brought into question if occupancy patterns change radically during the collection period. Researchers at the University of Texas have improved performance by strengthening laboratory procedures, especially in the area of solvent purity and sonication-aided extraction (Morandi et al. 1996a, 1996b).

Solid-phase microextraction (SPME) is a relatively new method of sample collection that presents an attractive alternative for monitoring IAQ. SPME was developed in the late 1980s, and involves exposing a short length of fused silica fiber (about 100 μm in diameter) coated with a thin polymeric layer to the sample environment (Zhang, et al. 1994). Chemicals of interest are absorbed by the polymer coating, and the exposed fiber is returned to the laboratory for thermal desorption and analysis via GC/MS. The technique has been successfully applied to problems of measuring ppb-level concentrations of VOCs and SVOCs in the general atmosphere as well as in headspace and aqueous samples. Commercially available holders for SPME fibers are about the size of a ballpoint pen. Simply exposing the bare fiber allows collection of an equilibrium sample in a few minutes; diffusion-controlled sample collection can be utilized to integrate the sample over a number of hours (see Martos and Pawliszyn 1997). Although consensus standard methods are not yet developed, reliable procedures are evident in peer-reviewed publications (Pawliszyn 1997).

Real-time monitors for organics are available. Portable gas chromatographs have been in use for industrial hygiene and hazardous waste applications for some time (see, for example, Spittler et al. 1983). Emerging interest in detecting chemicals associated with antiterrorist and military activities has spurred development of hand-held and portable instruments capable of monitoring at sub-ppm levels (CBIAC 1995). Significant advances have been made in the area of ion mobility scanning (IMS) to monitor semivolatiles near the ppb level (McLoughlin et al. 1999). Considerable progress has been made in recent years to address a lengthening list of chemicals, and a growing interest in lower concentrations. The USEPA's Environmental Technology Verification (ETV) Program specifically addresses technologies of interest to indoor air quality (USEPA 1998c). All portable GCs are relatively expensive, and field personnel require significant training. Infrared spectroscopy offers somewhat simplified operation (compared to a portable GC), but utility is limited to chemicals with distinctive IR absorption bands, and equipment costs are fairly high. Also, detection limits for some chemicals are high relative to whole-air and sorbent techniques.

The notion of total volatile organic compounds is routinely invoked for IAQ investigations. No singular approach has emerged to stabilize the situation, and implementation continues to be limited by problems associated with monitoring technology and data

interpretation. In the 1980s and early 1990s, initial efforts focused on defining a simple parameter based on summing all measured VOCs, and subsequent approaches have evolved to address specific individual compounds by summing compounds on the basis of an understanding of the role of functional groups (see Mølhave et al. 1997). The applications community is currently split between using the easy-to-measure but difficult-to-interpret approach of blind summation versus the difficult-to-measure but easier-to-interpret approach of selective speciation and functional summation. Blind summations can be implemented by using direct-reading analyzers while functional summation requires the use of sorbent tubes or whole-air collection. Summing compounds from laboratory analysis presents a means to report simplified results without losing the identity of individual compounds (Wolkoff 1995, Mølhave et al. 1997).

Direct-reading TVOC instruments do not detect and speciate individual compounds. Rather, using the same types of detectors used for laboratory analysis (e.g., FID or PID), such devices respond to the joint influences of the mixture of VOCs because there is no chromatographic column to separate individual compounds. Simplified TVOC monitors can give misleading readings in the presence of complex mixtures because the relative abundance of individual compounds cannot be known from the measurement. A number of hand-held units are available that draw sample air past a general photoionization detector to give a real-time TVOC signal. Direct-reading TVOC analyzers are fairly inexpensive compared to techniques that speciate chemicals of interest, but because of potentially misleading assumptions, their diagnostic value is quite limited for quantitative studies. The direct-reading TVOC analyzer does have practical value in isolating indoor sources.

Air Exchange

A knowledge of airflows is sometimes needed to relate pollutant concentrations to sources and to discover whether a mitigation strategy actually works. Basic concepts have been summarized by Nagda et al. (1987) and in ASTM D 5157 (Standard Guide for Statistical Evaluation of Indoor Air Quality Models; see ASTM 1999a). Major transport pathways affecting IAQ at a specific location include the following:

- *Air exchange.* Air leakage through adventitious openings (e.g., cracks and seams) is usually termed *air infiltration*. Air also enters and leaves a building via *natural ventilation* (e.g., purposely opened windows and doors) as well as *mechanical ventilation* (i.e., fans for controlled intake and exhaust).
- *Interzonal airflows.* Transport through doorways, ductwork, and service chaseways that interconnect rooms or zones within a building.
- *Local circulation.* Convective and advective air circulation and mixing within a room or within a zone.

Two basic measurement strategies are available: (1) pressurization testing to measure the effective leakage area of the building envelope and (2) tracer-gas techniques to measure air exchange (Table 51.12).

Fan pressurization techniques artificially increase the indoor-outdoor pressure difference (to as much as 50 Pa) while monitoring the airflow needed to support observed levels of pressurization (or depressurization). This technique evaluates the effective leakage area of the building shell, a more or less constant property of the building. Mathematical tools exist to relate effective leakage area to air exchange (see, for example, Sherman 1992). Doing so, however, relies on empirical assumptions (e.g., physical distribution of leakage area on the building surface) and requires a knowledge of meteorological conditions for the time period being modeled. Fan pressurization techniques are supported by consensus stan-

TABLE 51.12 Equipment for Measuring Air Exchange and Interzonal Airflows

Technology	Guidance	Example vendors	Comments
<i>Fan pressurization</i> —effective leakage area is calculated from airflow necessary to achieve particular levels of pressurization.	ASTM E 779 Nagda et al. (1987) Sherman 1995	Energy Conservatory, Infiltec, Retrotec	Airflow requirements generally limit application to smaller buildings; technology does not directly measure air exchange.
<i>Tracer gas dilution</i> —a small amount of tracer gas is released and measured after mixing; air exchange is related to time rate of change for indoor concentration.	ASTM E 741 Nagda et al. (1987) Samfield (1995)	Innova, Lagus Technologies (also see Tables 51.10 and 51.11)	Measurements represent conditions at time of test only.
<i>Constant concentration</i> —tracer gas release rate is controlled to maintain a constant indoor concentration; air exchange is calculated from necessary release rate.	Nagda et al. (1987) Samfield (1995)	Innova, Lagus Technologies (also see Tables 51.10 and 51.11)	Requires real-time tracer gas monitoring and feedback logic for concentration-controlled tracer gas release.
<i>Pulse injection</i> —a known amount of tracer gas is released and airflows are calculated from integrated concentration profiles and known injection.	Persily and Axley (1990)	Innova, Lagus Technologies (also see Tables 51.10 and 51.11)	Can be implemented to measure interzonal airflows; analysis can be real-time or integrated.
<i>Constant injection</i> —tracer gas is released at a constant rate and indoor levels measured; air exchange is calculated from indoor concentration and known release rate.	Dietz and Cote (1982) Dietz et al. (1986) Samfield (1995) Sherman (1989)	Brookhaven National Laboratory	Field apparatus is compact; sampling period of 3–7 days usually required.

dards in the form of ASTM E 779 (Standard Test Method for Determining Air Leakage Rate by Fan Pressurization; see ASTM 1999b), and equipment needs are supported by a variety of vendors (see Table 51.12). Portable equipment is available for pressurization testing of low-rise residential and smaller light commercial buildings. For larger buildings, it is possible to use the air-handling system to pressurize the building (CGSB 1996), but such approaches could force the air-handling system to operate beyond acceptable limits.

Tracer-gas techniques, on the other hand, set up a controlled source-receptor relationship within a defined indoor zone (or within a collection of zones), and thus provide a more direct measure of air exchange and airflows under the assumption that outdoor concentrations are zero (or at least invariant) and that the indoor airspace is well mixed. Basic technologies were recently reviewed by Samfield (1995). The ideal tracer gas has the following properties: (1) measurable at very low concentrations by interference-free techniques; (2) inert, nonpolar, and not subject to absorption; (3) nontoxic, nonallergenic, nonflammable, and nonexplosive; and (4) not a normal constituent of air (Lagus and Persily 1985). While no single gas exhibits all of these properties, sulfur hexafluoride (SF_6) and various fluorocarbon gases have entered widespread use.

The basis for tracer-gas measurements has a long history, dating from the early work of Lidwell and Lovelock (1946). Three basic tracer-gas strategies have evolved to measure air exchange: (1) concentration decay, (2) constant concentration, and (3) constant injection. Tracer-gas techniques are supported by consensus methods in the form of ASTM E 741 (Standard Test Method for Determining Air Change in a Single Zone by Means of a Tracer Gas Dilution; see ASTM 1999b). The basic method involves releasing a small amount of tracer gas, mixing it into the full air space and monitoring the change in concentration with time. The constant-concentration technique (Harrje et al. 1990) and the constant-injection technique (Condon et al. 1980) operate under similar considerations, but require measurement of the tracer-gas release rate and indoor concentrations.

A greatly simplified constant-injection tracer-gas technique has been developed by researchers at the Brookhaven National Laboratory. The BNL technique (Dietz and Cote 1982, Dietz et al. 1986) involves releasing perfluorocarbon tracers (PFTs) at a constant rate using permeation-limited sources in conjunction with diffusion-limited (integrated) sampling by capillary adsorption tube samplers (CATs). The air samples are returned to the laboratory for thermal desorption and analysis by GC/MS. Measurement periods can be as brief as a few hours (provided adequate time is allowed to thoroughly mix the PFTs prior to beginning the sample collection) to a week or longer. Although the PFT measurement system is relatively simple to apply in the field, it requires a highly sophisticated laboratory to quantitate the small sample mass (about 10^{-12} g) captured by the CATs.

Tracer-gas techniques are not limited to measuring only air exchange. Interzonal airflows can be examined with tracer gases by assigning a separate tracer to each zone (Lagus and Persily 1985). Multiple-tracer techniques are most readily invoked in the context of constant injection. Multiple-tracer measurements can reach a fair degree of complexity in terms of equipment, setup, and laboratory (or real-time) analysis. The BNL technique (Dietz et al. 1986) is a viable approach that has seen widespread use, but the approach gives time-averaged results that may not meet all study objectives.

Persily and Axley (1990) examined multiple-chamber capabilities of pulse-injection techniques, a variation on the tracer-gas decay approach, using a short-duration (pulse) tracer release allied to integrated sampling. Tracer injections separately label the air in each zone, and concentration profiles are measured in all zones. Measurements can be accomplished with a single tracer by injecting each zone in sequence (after tracer levels from earlier trials have decayed away) or with multiple tracers injecting two or more zones at a time.

Interzonal and indoor-outdoor airflows estimated by tracer-gas techniques are very often encumbered by the underlying assumptions that conditions are unchanged during the

test and that the indoor airspaces are well mixed. This is especially true for the BNL technique because of the relatively long integration time.

51.4 QUALITY ASSURANCE ISSUES

The quality assurance system represents a formal commitment to delivering defensible results. The overall approach to quality is traditionally split into quality assurance (QA) and quality control (QC). Quality assurance is composed of procedures and policies employed to ensure that defined standards of quality are met, while quality control is composed of technical activities undertaken to measure quality control and, if results warrant, make adjustments to achieve quality goals. Whether data are collected to support litigation or as part of a purely scientific inquiry, a written QA plan resolves adversarial issues prior to conducting the measurements, and thus focuses attention on results. Major aspects of quality assurance are discussed below.

QA Plans

A written QA plan is an opportunity to think through all phases of the operation ahead of time and to document a plan of action. Having a written plan leads to increased operational efficiency by focusing attention on core activities, and increases everyone's confidence in results. At a minimum, a QA plan should address the following issues:

- *Data quality objectives.* Quantitative statements of precision, accuracy, method detection limit, representativeness, completeness, and comparability for each measurement parameter.
- *Assessment of data quality.* Define how the achievement of data quality objectives is measured.
- *Standard operating procedures.* Describe all operations to be carried out in the field, in the lab, and in the office.
- *Internal quality control checks.* Describe routine calibrations and performance evaluations necessary to proving reliability.
- *System, performance, and data audits.* Describe how the measurement systems are evaluated against independent standards and reference materials.
- *Document control.* Identify what goes into the formal record and where the records are kept.
- *Corrective measures.* Describe how problems are recognized and resolved.

Writing a QA plan is never meant to be difficult. Rather than develop an entirely new QA plan for every monitoring mission, it is sometimes valuable to write a central plan (usually termed a QA program plan) that lays out the largely constant features of the QA system while giving rules for developing investigation- or project-specific plans. Developing the QA project plan can then concentrate on special attributes while carrying salient features of the QA program plan forward. Basic guidance for developing QA plans is available in the following publications:

- ANSI/ASQC Q94-1987: Quality Management and Quality System Elements—Guidelines, American Society for Quality, Milwaukee, WI, 1994
- EPA QA/G-5: EPA Guidance for Quality Assurance Project Plans, Quality Assurance Division, USEPA, Washington, DC, 1998

Standard Operating Procedures

Developing standard operating procedures (SOPs) is probably the most difficult step in building a QA system. Separate SOPs should be developed for each technical activity. The very first SOP to be written should address the form, content, and review of SOP documents. Depending on operational details, it may be advantageous to segment activities into separate SOPs. It is reasonable to separately address field operations, laboratory operations, and data processing, for example. This is especially valuable if different people are involved at each step. Wherever feasible, however, SOPs should be developed from existing standard procedures whose acceptability has been documented. This not only saves time and effort, it also strengthens credibility because the procedures will have been tested. Basing SOPs on existing procedures also helps to establish QA objectives and provides confidence that such objectives can be met. A few examples of information sources related to SOPs for IAQ are listed below.

- Survey of Protocols for Conducting Indoor Air Quality Investigations in Large Buildings. Report No. EPA 600/A-92-226, USEPA Office of Radiation and Indoor Air, Washington, DC, 1992
- Compendium of Methods for the Determination of Air Pollutants in Indoor Air. Report No. EPA/600/4-90/010, USEPA Office of Research and Development, Research Triangle Park, NC, 1990
- General Principles for the Investigation of IAQ Complaints. Report No. TFII-1996, International Society for Indoor Air Quality and Climate, Milan, Italy, 1996.

Additionally, ASTM has published a few dozen standard methods, practices, and guides that bear directly on indoor air quality measurements. These standard documents are updated every 5 years, and new standards are published each year. Leading examples published in the *Annual Book of ASTM Standards* (ASTM 1999a, 1999b), and available as separate reprints, are listed below.

- D 1356 Standard Terminology Relating to Sampling and Analysis of Atmospheres
- D 3162 Test Method for Carbon Monoxide in the Atmosphere (Continuous Measurement by Nondispersive Infrared Spectrometry)
- D 4597 Standard Practice for Sampling Workplace Atmospheres to Collect Gases or Vapors with Solid Sorbent Diffusive Samplers
- D 4599 Standard Practice for Measuring the Concentration of Toxic Gases or Vapors Using Length-of-Stain Dosimeters
- D 4861 Standard Practice for Sampling and Selection of Analytical Techniques for Pesticides and Polychlorinated Biphenyls in Air
- D 5075 Standard Test Method for Nicotine and 3-Ethenylpyridine in Indoor Air
- D 5156 Standard Test Methods for Continuous Measurement of Ozone in Ambient, Workplace, and Indoor Atmospheres (Ultraviolet Absorption)
- D 5157 Standard Guide for Statistical Evaluation of Indoor Air Quality Models
- D 5197 Standard Test Method for Determination of Formaldehyde and Other Carbonyl Compounds in Air (Active Sampler Methodology)
- D 5280 Standard Practice for Evaluation of Performance Characteristics of Air Quality Measurement Methods with Linear Calibration Functions
- D 5466 Standard Test Method for Determination of Volatile Organic Chemicals in Atmospheres (Canister Sampling Methodology)

- D 5791 Standard Guide for Using Probability Sampling Methods in Studies of Indoor Air Quality in Buildings
- D 6196 Standard Practice for the Sampling and Analysis of Volatile Organic Compounds in Air by Pumped Sorbent Tube and Thermal Desorption
- D 6245 Guide for Using Carbon Dioxide Concentrations to Evaluate Indoor Air Quality and Ventilation
- D 6306 Standard Guide for Placement and Use of Diffusion Controlled Passive Monitors for Gaseous Pollutants in Indoor Air
- D 6345 Standard Guide for Selection of Methods for Active, Integrative Sampling of Volatile Organic Compounds in Air
- E 741 Standard Test Method for Determining Air Change in a Single Zone by Means of a Tracer Gas Dilution
- E 779 Standard Test Method for Determining Air Leakage by Fan Pressurization

In cases where standard methods do not exist, accounts of work published in peer-reviewed journals are preferred. Formal reports and other publications may be used if the publication cycle includes a formal review process. Newly developed procedures should undergo formal testing to define precision, accuracy, and detection limits before being released to routine use. In use, SOPs should be reviewed periodically to respond to improvements. Such improvements may come through primary experience as well as through published experience of others.

Quality Control Samples

Low-level contamination of environmental samples and laboratory measurement systems is an insidious problem that can jeopardize data integrity. A sorbent tube sample for VOCs, for example, may contain only a few *picograms* of the one VOC that is of interest. A stray fingerprint also could contain as much material. A monitoring mission seeking even only one measurement, then, should include a reasonable number of QC blanks to verify that the measurement represents the contents of the air that was sampled. Contamination occurs when interfering materials enter the system from unrecognized sources. Examples include cleaning residues and inadequate purge cycles in the laboratory as well as collection of material from unwanted sources in the field. Effects may be additive (as when additional pollutant mass is unknowingly captured, or a contaminant interferes with detection), subtractive (as when a contaminant degrades or removes the pollutant from the sample matrix), or factorial (as when a contaminant alters collection recovery efficiency). Judicious insertion of QC blanks into the sample handling queue provides the means to recognize the occurrence of contamination, and to identify the source of contamination (see, for example, Simes and Harrington 1993).

Routine review of the analytical results of QC blanks is the primary tool for recognizing sampling/analytical contamination. A QC blank undergoes preparation, handling, and analysis in the same fashion as “live” sample media, but without actually collecting a sample. Systematic review of analytical results for sample blanks provides the means to relate abnormally high (or abnormally low) readings to specific phases of the handling cycle (see Fig. 51.6). Calibration blanks provide the baseline for judging all blanks; under ideal conditions, analytical results for laboratory and field blanks are indistinguishable from calibration blanks. Differences exhibited among blanks inserted at critical steps associated with preparation, storage, shipping, collection, and analysis allow for identification of likely sources of contamination. Subsequent steps then concentrate on verifying such identifications, developing and verifying practical remedies, and revising affected procedures.

FIGURE 51.6 Relating sample blanks to sources of contamination.

CHAPTER 52

MEASURING VENTILATION PERFORMANCE

Andrew Persily, Ph.D.

*National Institute of Standards and Technology
Gaithersburg, Maryland*

This chapter describes the fundamentals of ventilation performance measurement, including reasons for making these measurements, performance parameters of interest, and procedures for measuring these parameters. It is written for practitioners, including IAQ investigators, industrial hygienists, and proactive building owners, managers, and operators. The information in this chapter will be useful to someone who wants to perform such tests, to understand test results reported by someone else, or to procure testing services. This chapter does not cover research-grade measurement techniques in much detail, though many are mentioned. However, many of the techniques described may be useful in research efforts, particularly building surveys where ventilation is one of many parameters being assessed. The focus is on commercial and institutional buildings, though some of the procedures may also be useful in residential buildings. While the descriptions may not contain all the details needed to perform the measurements, references are provided to obtain other important information. Much of the material in this chapter is based on two previous publications by the author (Persily 1994, 1995).

52.1 INTRODUCTION

Buildings are ventilated for three major reasons: the provision of outdoor air for the health and comfort of the occupants, removal of internally generated contaminants, and the maintenance of specific pressure relationships between certain indoor spaces and between these spaces and outdoors. These objectives are achieved through one or more of the following approaches: infiltration, natural ventilation, and mechanical ventilation.

The evaluation of how a building is actually being ventilated, or ventilation performance evaluation, is useful in building operation and maintenance, in building performance investigations, and in building research. However, activities in these fields do not always

employ consistent or reliable approaches to ventilation evaluation. One reason for the variable consideration of building ventilation is the complexity of ventilation and air movement, particularly in large, multizone buildings, and the wide variety of mechanical ventilation systems in buildings. Other more specific reasons include the lack of, or in some cases the lack of use of, standardized approaches to assessing building ventilation, the cost and performance limitations of available instrumentation, and a lack of understanding of this instrumentation and its use.

Reasons to Evaluate Ventilation

There are several situations in which building ventilation performance is evaluated, including the following:

- Construction and renovation
- Building commissioning
- Diagnosis of IAQ complaints
- Proactive building management
- Identification of energy conservation opportunities
- Research

Ventilation evaluation is appropriate during building construction and renovation to verify the implementation of special ventilation strategies being used for contaminant control. When buildings are under construction, in particular during renovation projects, special ventilation strategies are often employed to prevent contaminant buildup and migration to occupied portions of the building. These strategies include continuous ventilation system operation, maximum levels of outdoor air intake, high rates of building exhaust ventilation, and operation of temporary exhaust ventilation systems. During construction, these strategies are used to remove pollutants emitted by new building materials before they can be adsorbed onto other building surfaces for potential reemission at a later time. During building renovation activities, ventilation strategies include isolation of the space being renovated with a temporary physical barrier, exhaust ventilation from the construction area, and the maintenance of specific pressure relationships between the renovation zone and other building zones. Of course care must be taken to ensure ventilation system components do not become contaminated during this process as well.

Ventilation evaluation is also an important component of building commissioning. Commissioning is the process by which the installation and performance of an HVAC system is evaluated to ensure that the system is performing as designed. While commissioning is sometimes thought of as occurring only when a building is first constructed, it should continue throughout the life of a building as system components deteriorate and as space use and occupancy change. The ASHRAE Guideline for Commissioning of HVAC Systems describes procedures and methods for commissioning during the various phases of a building's life, i.e., predesign, design, construction, acceptance, and postacceptance (ASHRAE 1989). In terms of ventilation evaluation, commissioning includes testing, adjusting, and balancing (TAB) of the HVAC system, where TAB is a procedure in which the building HVAC systems are checked and adjusted to meet the design performance requirements. TAB involves all HVAC-related systems including air and water distribution, electrical and mechanical equipment, controls, and sound and vibration. TAB procedures and instrumentation requirements are well documented (AABC 1989, ASHRAE 1988, Bevirt 1984, NEBB 1991, SMACNA 1983), and there are industry certification and training programs for TAB personnel. While TAB procedures are commonly applied in

new buildings, systems in existing buildings also need to be recommissioned and rebalanced periodically to ensure that they are performing as intended and are meeting the current ventilation requirements of the building.

Another application of ventilation evaluation is the diagnosis of indoor air quality complaints. Ventilation evaluation is important in determining the role, if any, of ventilation in causing these complaints, determining the potential for ventilation to reduce these complaints, and enabling the interpretation of contaminant measurements made in the diagnostic effort. The ventilation evaluation procedures employed in indoor air quality diagnosis cover a broad range in terms of detail and level of effort. Proactive building management is another application of ventilation evaluation. This approach to building management reduces the potential for indoor air quality complaints and excessive energy consumption. It involves devoting staff and resources to ensure that building systems are operated as designed, performing routine maintenance on system components, and modifying the system as required when there are changes in building use. The ventilation-evaluation aspects of proactive management include system inspections, performance evaluations involving the measurement of system airflow rates and other parameters, reassessment of ventilation system design in response to changes in building use, and testing and balancing of the system during recommissioning. Proactive building management could also involve continuous monitoring of ventilation system performance parameters, such as airflow rates and supply air temperatures, for the verification of proper operation and the early identification of performance deficiencies. Another use of ventilation evaluation, related to proactive management, is the identification of energy conservation opportunities in a building. Such efforts would include identifying situations of overventilation, systems operating more often than intended or needed, and control system sensors needing calibration.

Research that involves the evaluation of building ventilation falls into two categories, building ventilation research, and indoor air quality research. Building ventilation research is concerned with building air change with outdoors and air movement within buildings. These studies employ a variety of techniques to measure building component airtightness, building air change rates, interzone airflow rates, and ventilation system airflow rates. Indoor air quality research studies are designed to understand the factors affecting indoor contaminant levels and the response of occupants to indoor environmental conditions. Ventilation evaluations are employed in indoor air quality studies to enable the interpretation of other environmental measurements.

Background Information on Ventilation

Ventilation system performance, indoor air quality, and energy consumption are all affected by outdoor airflow into buildings and airflow within buildings. These airflows and their effects need to be understood in evaluating ventilation system performance. This section provides some background information on building ventilation; some additional discussion is contained in the ASHRAE *Fundamentals Handbook* (1997a). It discusses some of the terms relevant to ventilation, which are sometimes the subject of some confusion, and then summarizes some of the causes and impacts of airflow into buildings from outdoors and within buildings.

ASHRAE Standard 62-1999 (1999) defines *ventilation* as the “process of supplying and removing air by natural or mechanical means to and from any space.” The term is sometimes used to describe only the outdoor air provided to a space. It is also used to describe the total of the outdoor air and recirculated air. Confusion between outdoor air and supply air can be avoided by using the terms outdoor air ventilation and supply air or total ventilation instead of just ventilation. Ventilation rates are given in units of liters per second (L/s) or, alternatively, cubic feet per minute (cfm) or as air change rates in units of air

changes per hour (or h^{-1}). An air change rate is a ventilation rate in units of L/s (or cfm) divided by the volume of the space. It can be calculated as:

$$Qk/V \quad (52.1)$$

where Q = ventilation rate, L/s (or cfm)

k = normalizing constant for time (3600 for L/s, 60 for cfm)

V = volume of space in liters (or cubic feet)

Mechanical ventilation is ventilation provided by fans. Mechanical ventilation provides outdoor and supply air to a space and removes air from a space for recirculation by the ventilation system or exhaust to the outdoors. *Natural ventilation* is ventilation through intentionally provided openings, such as open windows and vents.

Infiltration is the flow of outdoor air into a space through unintentional openings such as cracks around window frames and wall-floor joints. Infiltration is driven by pressure differences across these openings caused by wind, inside-outside temperature differences, and the operation of ventilation equipment. *Exfiltration* is airflow from a space to the outdoors through unintentional openings. Infiltration is often used to describe both infiltration and exfiltration. Infiltration rates are usually given in air changes per hour. *Air leakage* is sometimes used to describe infiltration across the building envelope. It is also sometimes used to describe the airtightness of a building envelope and is independent of weather conditions and ventilation system operation. It is measured with a fan pressurization test according to ASTM Standard E779. Air leakage is usually expressed as the building air change rate at a reference pressure difference across the building envelope or as an effective leakage area that accounts for all the leaks in the building.

The *air change rate* of a building or space can be any one of the above quantities in units of air changes per hour. It is used to describe the total or supply ventilation airflow rate, the mechanically induced rate of outdoor air intake, the infiltration rate, or the sum of all outdoor airflows into the building. Confusion is avoided if the air change rate is specified as infiltration, total outdoor air, or supply air.

Outdoor airflow into buildings includes both outdoor air intake via the air-handling system and infiltration through leaks in the building envelope. Ideally the outdoor air intake rate is controlled, but the infiltration rate and the distribution of infiltration air in a building is always uncontrolled. Commercial building infiltration rates are usually assumed to be small compared to outdoor air intake rates. However, field measurements have shown that infiltration and outdoor intake rates can be similar in magnitude under certain operating conditions (Grot and Persily 1986, Persily and Norford 1987).

Outdoor air intake rates depend on the ventilation system design and operation, and can vary with time, depending on the system controls. While the system design may call for a specific rate of outdoor air intake under certain circumstances, the actual damper positions and air handler operation may cause the outdoor air intake rate to be very different from the design value. If the system is properly balanced and maintained, such differences will be minimized.

Uncontrolled infiltration rates through the building envelope are usually assumed to range from zero to 0.2 air changes per hour in commercial buildings. However, because of leaky envelopes and poor ventilation system control, infiltration rates can be as high as 0.5 air changes per hour (Grot and Persily 1986). Pressurization tests of commercial buildings have shown that they are as leaky as typical U.S. residential buildings (Persily 1999). The infiltration rate of a mechanically ventilated building depends on the amount of envelope leakage, the location of these leaks, and the pressure differences across the leaks. Envelope leakage occurs at many locations over the building envelope, with most of the leaks at interfaces between envelope components such as window-wall and floor-wall intersections. The

distribution of these leaks over the envelope depends on the envelope design, construction quality and deterioration over time. There is a relationship between the pressure difference across each opening and the airflow rate through it, and this pressure-flow relationship depends on the shape and size of the opening.

Pressure differences across building envelope leaks are caused by indoor-outdoor temperature differences (sometimes called the stack effect), wind, and ventilation system operation. If there is a temperature difference between the inside of a building and the outdoors, there will be a pressure difference across the envelope that varies with height. Under heating conditions, air will flow into the building at lower levels and out of the building at higher levels. During the cooling season, the directions of the pressure differences and airflows are reversed. The size of the stack pressures depends on the building height, the indoor-outdoor temperature difference, and the resistance to vertical airflow within the building caused by the interior walls and floors. Pressure differences across the envelope are also caused by wind, with higher pressures on the windward side and lower pressures on the other sides of the building. Wind-induced pressures vary over the building and depend on the wind speed, direction, and obstructions surrounding the building.

Pressure differences are also caused by the operation of ventilation systems. If there is more supply airflow into a space than return airflow out (or vice versa), this will contribute to the pressure difference across the exterior walls. These pressure differences can be larger than stack and wind pressures. Most commercial buildings are designed to have more supply air than return air to reduce envelope infiltration and to ensure the proper operation of exhaust air systems. Good system maintenance is required to achieve this design goal.

Airflow within buildings is an important means of pollutant movement and can transport contaminants to spaces within buildings that are far from the pollutant sources. Airflow rates within buildings depend on the number and location of internal leaks, the pressure differences across these leaks, and the relationships between airflow rate and pressure difference for these leaks. The pressure differences that produce these airflows are caused mainly by the stack effect and ventilation system operation. The stack effect that pulls air into the building on lower floors during heating also causes air to flow from lower floors to upper floors. When the building is being cooled, the direction of the pressure differences and airflows is reversed.

Ventilation system operation causes air movement between different spaces when the supply airflow into a space is different from return airflow out. If the supply airflow rate is higher, the space will be at a higher pressure than adjoining spaces, unless they have an even larger supply air excess. Air will flow from such a pressurized space through any available opening. Similarly, a space with excess return or exhaust airflow will be at a negative pressure, and air will flow into the space. System-induced pressure differences and airflows can be complex, with many spaces involved in the pressure and airflow interactions.

52.2 INSTRUMENTATION

This section describes some of the instrumentation used in the ventilation measurement techniques. Approximate information on cost is included, but it is approximate since the cost depends on features such as accuracy, range, and response time. Some of the instrumentation has been traditionally used in testing, adjusting, and balancing and is described in the references (ASHRAE 1988, Bevirt 1984, NEBB 1986 and 1991, SMACNA 1983). Hand-held digital instruments have more recently become available and are much easier to use. Some of these instruments combine the measurement of several factors such as temperature, relative humidity, airspeed, and pressure difference and are capable of data logging and averaging. These multichannel systems range in cost from about \$1000 to \$3000,

depending on the specific features of the system. Two important issues in considering the purchase of instrumentation and judging the appropriateness of its use by others include the accuracy of the device and the measurement range relative to the range of interest.

Air Temperature

The temperature of indoor and outdoor air and ventilation system airstreams can be measured with digital electronic thermometers. These hand-held, battery-powered devices employ either a thermocouple, thermistor, or resistance temperature detector (RTD). A variety of probes are available that differ in response time and measurement range. Digital electronic thermometers cost from about \$100 to \$250. Devices that can also measure relative humidity cost \$200 to \$400.

When measuring outdoor air temperatures, one must use a probe with an appropriate range, that is, not a probe intended for indoor temperatures. Also, air temperature measurements can be affected when surrounding surfaces are at significantly different temperatures from the air. For example, outdoor temperature measurements are affected by solar radiation, and indoor measurements can be influenced by nearby windows. Temperature probes with radiation shields are available to reduce these errors.

Relative Humidity

The relative humidity of indoor, outdoor, and ventilation air can be measured with digital thermohygrometers, sling psychrometers, and digital psychrometers. Digital thermohygrometers are hand-held, battery-powered devices with sensors that respond to a change in relative humidity with a change in resistance or capacitance. The device converts the sensor response into a digital output in percent relative humidity (% RH). Sling and digital psychrometers consist of two thermometers, one with a moistened wick around the bulb. When air flows across the bulb with the wet wick, this thermometer provides the wet-bulb temperature. For sling psychrometers, the airflow across the wet bulb is achieved by whirling the device through the air.

A psychrometric chart is used to convert the dry and wet-bulb readings to relative humidity. Digital psychrometers have a battery-powered fan to provide the airflow and a digital readout of relative humidity. Digital thermohygrometers cost from \$200 to \$500, sling psychrometers from \$50 to \$100, and digital psychrometers from \$100 to \$200. The accuracy of relative humidity measurements can be compromised in several ways unless factors such as response time, usable range, and hysteresis are appropriately accounted for.

Differential Pressure

Differential pressure is measured across ventilation system components and building partitions, and in performing pitot tube traverses. These measurements can be made with digital electronic pressure manometers, inclined manometers, and diaphragm-type gauges. Digital electronic pressure manometers come in a variety of measurement ranges. Devices with very low ranges can be used to measure velocity pressures at airspeeds well below the 3 m/s (600 ft/min) limit for inclined manometers. Some electronic manometers can average a series of pressure readings. Since pressures in ventilation ductwork usually fluctuate, automated averaging is very helpful. Pressure differences across interior and exterior partitions can be very small, on the order of 1 to 5 Pa (0.004 to 0.02 in H₂O gauge), and a gauge with an appropriate range and resolution must be used in these applications. Digital

manometers range in price from \$750 to \$1500, depending on the accuracy and features of the device.

Inclined manometers are standard equipment in testing and balancing. They come in different scales, and are sometimes combined with vertical manometers to read higher pressures. Inclined manometers are applicable only to pressure differences greater than 5 Pa (0.02 in H₂O gauge), i.e., for velocity pressures corresponding to airspeeds above 3 m/s (600 ft/min). Inclined manometers must be leveled prior to use and can take a long time to equilibrate when used with a pitot tube. Their cost ranges from \$100 to \$200, depending on the pressure scale.

Diaphragm-type magnetic linkage pressure gauges or Magnehelic® gauges have a magnetic spring that rotates when a pressure difference displaces a diaphragm. These devices are available in a variety of ranges, the lowest being 0 to 60 Pa (0.24 in H₂O gauge). These devices have an accuracy of 2 percent of full scale, limiting their ability to measure low pressure differences [less than 15 Pa (0.06 in H₂O gauge)].

Pitot-Static Tubes

Pitot tubes are used to measure velocity pressures in ventilation airstreams. A pitot tube has one opening in its tip that is pointed directly into the airstream and is connected to a total pressure port at the base of the tube. Additional openings are located around the length of the tip that is parallel to the airstream; these are connected to a static pressure port. The total and static pressure ports are connected to a differential pressure gauge to measure the velocity pressure. The ports can also be used to measure the total and static pressure in the airstream. Drawings of pitot tubes, showing critical dimensions, are provided in a variety of references (AMCA 1990, ASHRAE 1997a, Bevirt 1984, NEBB 1986).

Hot-Wire Anemometers

Hot-wire or thermal anemometers are used to measure airspeeds in ducts. These devices use a probe with a heated wire that is either supplied with a constant current or kept at a constant temperature with a variable current. In constant-current devices, the wire's electric resistance depends on airspeed. In constant-temperature devices, the current required to keep the probe at a constant temperature is related to airspeed. The probes are very sensitive and can measure airspeeds as low as 0.05 m/s (10 ft/min). Hot-wire anemometers come in a variety of measurement ranges, and cost from \$500 to \$1000, depending on their accuracy and additional features.

Rotating-Vane Anemometers

Rotating-vane anemometers consist of lightweight propellers and are used to measure airflow rates at air outlets and inlets, dampers, and filter and coil banks (ASHRAE 1988, NEBB 1986). Digital meters display the average airspeed over a set time period; analog devices display the instantaneous airspeed. Mechanical devices are also available that display the linear meters (feet) of air passing through the propeller. Mechanical vane anemometers are used with a timer to convert the length into the average airspeed over the measurement period, and usually require a correction factor to compensate for friction. Mechanical devices are applicable to airspeeds between 1 and 10 m/s (200 and 2000 ft/min), while electronic devices can be used below 1 m/s (200 ft/min).

To determine the airflow rate at coils and at air outlets and inlets, the average measured airspeeds must be multiplied by an application factor, called *K* factor or free-area factor.

These factors have been studied for different configurations of coils, outlets, and inlets, and are sometimes available from the manufacturers of these components.

Flow Hoods

Flow hoods measure airflow rates at supply outlets and return or exhaust inlets. They consist of a hood that fits over the outlet or inlet and a measuring device at the base of the hood. The airflow rate is measured with a pressure or velocity sensor connected to an analog or digital meter that reads out directly in L/s (cfm). Flow hoods usually have several hood attachments to fit over outlets and inlets of different sizes. They cost from \$1500 to \$2500, depending on the number of hoods and the type of display. Smaller hoods are also available for small outlets and inlets in hard-to-reach locations, and these devices cost about \$1000.

Flow hoods have ranges from about 25 to 1000 L/s (50 to 2000 cfm) and accuracies from 5 to 10 percent of reading. When flow hoods are used in the field, the measurement errors can be significantly larger than these values, and they should not be used for airspeeds above 10 m/s (2000 ft/min). ASHRAE (1988) recommends their use to proportion flows between air distribution devices and not to certify system performance.

Tracer-Gas Monitors

Tracer-gas monitors measure tracer concentrations when tracer-gas techniques are used to study ventilation. Several different tracer gases are used in these techniques, such as sulfur hexafluoride (SF_6), some refrigerants, and carbon dioxide (CO_2). The type of monitor will depend on the tracer gas and the range of concentration expected during the test. Tracer-gas concentrations should be measured with an accuracy of 5 percent, and the monitor should be calibrated with each use.

ASTM Standard E741 (1995) is a test method describing how to make tracer-gas measurements of building air change rates. It presents equipment requirements and measurement procedures, and discusses desirable properties of tracer gases. A tracer gas should be inert, not absorbable on building materials and furnishings, easily and inexpensively measurable at very low concentrations, nontoxic, nonallergenic, nonflammable, and nonexplosive.

Smoke Tubes

Smoke tubes are used to study airflow patterns within buildings and in rooms. They are also used for finding leaks in ducts and from spaces intended to be airtight. Smoke tubes come in several forms, including sticks and guns that contain titanium tetrachloride, a chemical that reacts with water vapor to produce smoke. Smoke candles are also available in a variety of sizes and burning times. The smoke produced by these devices can be irritating, and they must be used with care. They are generally not appropriate for use in occupied spaces.

52.3 MEASUREMENT TECHNIQUES

This section describes a number of ventilation measurement methods and related techniques. The first two, differential pressure and tracer-gas concentrations, are used in a number of other approaches. Pressure differences are also sometimes measured on their own to characterize specific performance issues. The remaining techniques provide information on

building airflows and ventilation system performance. In all cases, the presentation is brief and references are included for more detailed information.

Pressure Differences

Pressure differences can be measured across components in air-handling systems and across exterior and interior walls. In the first case, pressure differences are measured across components, such as filter banks or cooling and heating coils, in order to compare these pressure differences to those expected on the basis of system design or experience. High pressure differences can indicate dirty filters or coils, an obstruction, or some other problem. These measurements are made by connecting the two ports of a differential pressure gauge to static pressure taps located on either side of the component. The high-pressure side of the gauge should be connected to the upstream pressure tap. These pressure differences usually range from 25 to 250 Pa (0.1 to 1 in H₂O gauge), and the gauge must have an appropriate scale. Pressure differences in ventilation systems are likely to fluctuate because of turbulence. Therefore, the pressure difference across a system component should be read a number of times, and the results averaged. Some devices store readings and perform the averaging automatically.

Static pressure differences across walls and partitions are of interest in understanding airflow patterns in buildings and the impacts of ventilation system operation. Some spaces, bathrooms, for example, are designed to be at lower pressures than adjoining spaces. Pressure differences across exterior walls can have a critical impact on moisture transport in some situations. Measurements of pressure difference can be useful in assessing such situations. It is important to note that the values of these pressure differences vary with weather and ventilation system operation, and therefore the values at a particular moment in time may not necessarily apply to other situations.

To measure the pressure differences across interior or exterior walls, the two sides of a pressure gauge are connected to pressure taps on either side of the wall. These pressure taps can be the ends of tubes run underneath doorways or through other openings. The tubes must not be compressed, and this is avoided by positioning them carefully and using small-diameter tubes. In measuring pressure differences across exterior walls, the pressure gauge should be located indoors to avoid temperature effects. Pressure differences across exterior walls should be measured under low wind speeds, unless one is interested in the effects of wind. In some situations, the pressures will fluctuate, and in these cases an average value will generally be of more value.

Tracer-Gas Concentration

Tracer-gas concentrations are measured in the occupied space, outdoors, and in ventilation ducts. The measurement techniques apply to all tracer gases, including carbon dioxide, and depend primarily on whether the concentration monitor is portable or stationary. Portable monitors measure the tracer-gas concentration at the sampling location. With a portable monitor, the air must be sampled for a length of time that is based on the monitor's response time. Stationary monitors are used by collecting air samples in containers and bringing them to the concentration monitor for analysis. In collecting air samples for analysis with a stationary monitor, the volume of the air sample should be large enough to allow at least three concentration readings with the monitor. After the air samples are collected, they should be analyzed as soon as possible with the stationary monitor. After the three readings from the sample are determined with the monitor, their average should be calculated. Wide discrepancies in the reading may indicate an instrument stability problem or collector

contamination. Stationary monitors can also be used with an air sampling network of tubing and pumps that bring the air to the monitor. When measuring tracer-gas concentrations in ventilation ducts, one must consider the possibility that the tracer-gas concentration is not uniform across the duct. This is particularly important in measuring downstream of a point where two airstreams mix, such as a recirculation stream and an outdoor airstream. If the concentration in the duct is stratified, then the average concentration must be determined from multiple readings across the duct cross section. When using a portable monitor with carbon dioxide as the tracer gas, the person making the measurements must avoid exhaling near the monitor or air sampling equipment.

Percent Outdoor Air Intake

The percentage of outdoor air in the supply airstream can be determined from an energy balance based on the temperatures of the outdoor, recirculation and supply airstreams or from a mass balance based on tracer-gas concentrations in these three airstreams. Figure 52.1 shows the outdoor air intake, recirculation, and supply airstreams in an air-handling system. The percent outdoor air intake, %OA, is given by

FIGURE 52.1 Schematic of an air-handling system.

$$\% \text{ OA} = 100 \times \frac{Q_o}{Q_s} \quad (52.2)$$

where Q_o and Q_s are the outdoor air intake rate and supply airflow rate, respectively. As discussed below, both the temperature and tracer-gas techniques require a significant difference between the indoor and outdoor air temperatures (tracer-gas concentrations) relative to the uncertainty of the temperature (concentration) measurement to yield reliable results. The temperature approach is not useful under mild outdoor weather conditions.

Percent Outdoor Air—Temperature

Percent outdoor air intake can be determined from an energy balance of the recirculation, outdoor and supply airstreams. From this energy balance and a mass balance of the airflows, the percent outdoor air intake is given by

$$\% \text{ OA} = 100 \times \frac{T_R - T_S}{T_R - T_O} \quad (52.3)$$

where T_R , T_S , and T_O are the recirculation, supply, and outdoor air temperatures. T_R can be measured in the return air duct, which is often more accessible than the recirculation duct. The return air temperature should be measured in the main return duct of the air handler, not at a return vent in the occupied space or in a ceiling return air plenum. The supply air temperature should be measured at the air handler, as far downstream as possible from the point where the outdoor and return airstreams mix, but it generally should not be measured at a supply air outlet in the space.

The temperature approach requires that there be no energy input or removal between the three temperature measurement points. Therefore, the supply air temperature must be measured upstream of any active heating and cooling coils and the supply fan, and the return temperature should be measured downstream of the return fan.

The uncertainty in %OA calculated by a temperature balance depends on the uncertainties in the measured temperatures and on the differences between T_R and T_O and between T_R and T_S . The uncertainty in %OA, referred to as $\Delta\%$, is estimated with the following equation:

$$\Delta\% = \% \text{ OA} \left[\frac{\Delta T_R^2 + \Delta T_O^2}{(T_R - T_O)^2} + \frac{\Delta T_R^2 + \Delta T_S^2}{(T_R - T_S)^2} \right]^{1/2} \quad (52.4)$$

where ΔT_R , ΔT_S , and ΔT_O are the uncertainties in the recirculation, outdoor, and supply air temperatures. The uncertainty in %OA calculated with this equation accounts for only the precision of the measured temperatures and neglects bias due to faulty calibration and operator error.

The uncertainty in %OA is larger when the outdoor air temperature T_O is closer to the return air temperature T_R . For example, when T_O is relatively close to the indoor air temperature, the uncertainty in %OA will be very large, and the temperature balance technique should not be used.

Percent Outdoor Air—Tracer Gas

Percent outdoor air intake can be determined from a tracer-gas mass balance in the recirculation, outdoor, and supply airstreams. From this mass balance and a mass balance of the airflows, the percent outdoor air intake is given by

$$\% \text{ OA} = 100 \times \frac{C_R - C_S}{C_R - C_O} \quad (52.5)$$

where C_R , C_S , and C_O are the tracer-gas concentrations in the recirculation, supply, and outdoor airstreams. C_R can be measured in the return air duct, which is usually easier to access than the recirculation duct. The return concentration should be measured in the main return duct of the air handler, not at a return vent in the occupied space or in a ceiling return air plenum. The supply concentration should be measured at the air handler, downstream of the fan to enhance mixing of the outdoor and return airstreams. C_S should not be measured at a supply air outlet in the space.

This technique can be used with any tracer gas with a constant outdoor concentration. Sometimes occupant-generated carbon dioxide (CO_2) is used to measure percent outdoor air. In other cases a tracer gas, such as sulfur hexafluoride (SF_6), is injected into the building. When using CO_2 , the measurement should be made when the indoor concentration is well above the outdoor concentration. This will generally be in the late morning and mid- to late afternoon.

The tracer-gas approach is based on several requirements. First, there must be no tracer gas released into or removed from the system between the three concentration measurement points during the concentration measurements. Also, the tracer-gas concentration of each airstream must be an average value across the airstream. This is more of an issue for the supply airstream where there can be stratification from imperfect mixing of the recirculation and outdoor air.

When a tracer gas is injected into the building, it should be released into the return or supply airstream so that the return concentration is raised significantly above the outdoor concentration. The volume of tracer gas released depends on the building volume and the concentration measurement range of the tracer-gas monitor. If the building volume is V and the full-scale concentration of the tracer-gas monitor is C , then the tracer-gas volume released should be around 75 percent of V_T , where V_T is given by

$$V_T = VC \quad (52.6)$$

V_T and V are in the same volume units. If C is in units of parts per million by volume (ppmv), then the right side of the equation must be multiplied by 10^6 . The value of C should be significantly above the outdoor concentration to reduce the uncertainty in the value of the percent outdoor air intake.

The amount of tracer gas released into the building does not have to be measured precisely, but it should be controlled. The tracer can be released all at once from a syringe or other container of known volume, or it can be injected at a constant rate by a flow meter and a compressed gas supply. There must be no additional tracer gas released in the building after the injection and during the concentration measurements.

After the tracer-gas concentration in the building has stabilized, usually on the order of an hour after injection, the tracer-gas concentrations are measured in the recirculation, outdoor and supply airstreams. These concentrations can be measured directly with a portable monitor or air samples can be collected for analysis with a stationary monitor.

One measurement procedure, intended to address the variation in tracer-gas concentration over time, is as follows:

1. Measure the concentration, or collect an air sample, in the return duct.
2. Measure the concentration, or collect an air sample, in the supply duct.
3. Measure the concentration, or collect an air sample, in the outdoor air.
4. Repeat the concentration measurement in the supply duct, or collect another air sample.
5. Repeat the measurement of the concentration in the return duct, or collect another air sample.

This procedure should be completed over about one-half hour. If air samples are collected in containers, the tracer-gas concentrations should be measured as soon as possible.

The two return air concentrations are averaged and the average concentration used in the percent outdoor air calculation. Similarly, the two supply air concentrations are averaged for the calculations. The percent outdoor air intake %OA is calculated by using Eq. (52.5).

The uncertainty in %OA depends on the uncertainty of the measured concentrations and on the differences between C_R , C_O , and C_S . The following equation should be used to estimate the uncertainty in %OA:

$$\Delta\% = \%OA \left(\frac{\Delta C_R^2 + \Delta C_O^2}{(C_R - C_O)^2} + \frac{\Delta C_R^2 + \Delta C_S^2}{(C_R - C_S)^2} \right)^{1/2} \quad (52.7)$$

where ΔC_R , ΔC_S , and ΔC_O are the uncertainties in the recirculation, outdoor air, and supply air concentrations. As in the case of temperature, the uncertainty in %OA calculated with this equation accounts for only the precision of the measured concentrations.

The uncertainty in the measured tracer-gas (CO_2) concentration has a large impact on the uncertainty in the percent outdoor air intake. The uncertainty in %OA is also affected by the value of the percent outdoor air intake because the value of %OA determines the size of the differences between C_R and C_O and between C_R and C_S . Lower values of %OA lead to larger concentration differences and smaller uncertainties in %OA. The impact of these concentration differences is particularly important in using occupant-generated carbon dioxide as a tracer, because indoor CO_2 concentrations cannot be controlled. Making these measurements after the CO_2 concentration has built up well above the outdoor level will increase the concentration differences and decrease the uncertainties in %OA, but this delay limits the times of day at which CO_2 can be used to measure %OA. When injecting another tracer gas into the building, the uncertainties in %OA can be reduced by making the difference between C_R and C_O as large as possible.

Airflow Rate

This section describes techniques to measure airflow rates in ventilation system ducts and at air outlets and inlets using pitot tubes, hot-wire and vane anemometers, and flow hoods.

Pitot Traverses in Ducts. Pitot tube traverses are commonly used to measure airflow rates in ducts in the testing and balancing process, and the technique is described in several references (AMCA 1990, ASHRAE 1988, Bevirt 1984, NEBB 1986). In this technique, a pitot tube and a differential pressure gauge are used to measure the velocity pressure at several points in a duct cross section referred to as a traverse plane. The average airspeed in the duct is calculated from the velocity pressure readings and is then multiplied by the cross-sectional area of the duct to determine the airflow rate.

The accuracy of pitot traverse measurements depends on the uniformity of the airspeed in the duct and on the accuracy of the pressure gauge used to measure velocity pressure. Most discussions of pitot traverse measurements are based on the use of inclined manometers, and therefore limit pitot traverses to airspeeds above 3 m/s (600 ft/min). However, the use of digital electronic manometers allows the measurement of lower airspeeds. The accuracy of pitot tube traverse measurements is estimated to be from 5 to 10 percent under good field conditions (AMCA 1990, ASHRAE 1988). When the traverse plane is not in a good location, errors can exceed 10 percent.

Some references recommend that the traverse plane be in a straight section of ductwork, 6 to 10 duct diameters downstream and several diameters upstream of any elbows, branches, transitions, or other obstructions (NEBB 1986). A more specific requirement is that at least 75 percent of the measured velocity pressures are greater than 10 percent of the maximum velocity pressure in the traverse plane (AMCA 1990, ASHRAE 1988). The traverse plane should also be located so that the air flows at a right angle to the traverse plane

and the cross-sectional shape of the duct is not irregular. It is often difficult, if not impossible, to find traverse planes in the field that meet these requirements. In these situations, one should use the best location available, avoiding elbows, offsets, transitions, and obstructions. One can also increase the number of traverse points.

It is often difficult to find an acceptable traverse location at outdoor air intakes. In these situations, one can determine the outdoor air intake rate by measuring the supply airflow rate and multiplying it by the measured percent outdoor air intake rate. This so-called multiplicative method is described below.

A pitot traverse measurement of airflow rate begins with the measurement of the inside dimensions of the duct. In a round duct, one measures the diameter. In a rectangular or oval duct, one measures the height and width. If the duct has interior insulation, these dimensions are measured inside the insulation. From the shape and size of the duct, one determines the points at which the velocity pressure will be measured during the traverse. The traverse plane in rectangular ducts is divided into equal areas, with a traverse point in the center of each. There should be at least 20 traverse points, located no more than 0.15 m (6 in) apart. In round ducts, the traverse points are located on two duct diameters at right angles to each other, with the locations of the traverse points based on the duct diameter. In oval ducts, the traverse points are located on the major and minor axes of the duct, with locations of the traverse points based on lengths of the two axes. Several references provide more details on the selection of traverse points (AMCA 1990, ASHRAE 1988, NEBB 1986).

During the pitot traverse, the velocity pressure at each traverse point is measured with a pitot tube and differential pressure gauge. At each measurement point, the tip of the pitot tube must be pointed directly into the airstream and held in position for a period of time that is based on the response time of the gauge. The velocity pressure will usually fluctuate because of turbulence. Therefore, the velocity pressure should be read a number of times (six is a reasonable number), and the average of the velocity pressures calculated.

The results of the traverse are the average velocity pressure in Pa (in H₂O gauge) at each traverse point. To convert these pressures to airflow rates, the root mean square velocity pressure $P_{v,rms}$ is calculated from the individual velocity pressure readings $P_{v,i}$ according to:

$$P_{v,rms} = \left[\frac{\sum (P_{v,i})^{0.5}}{\text{number of readings}} \right]^2 \quad (52.8)$$

The root mean square velocity pressure $P_{v,rms}$ is converted to the average airspeed in the duct, $\bar{V}$, in SI units, according to:

$$\bar{V} = \sqrt{\frac{2P_{v,rms}}{\rho}} \quad (52.9)$$

where $\bar{V}$ is in m/s, $P_{v,rms}$ is in Pa, and the air density ρ is in kg/m³. In inch-pound units, the root mean square velocity pressure is converted to the average airspeed according to:

$$\bar{V} = 1096 \sqrt{\frac{2P_{v,rms}}{\rho}} \quad (52.10)$$

where $\bar{V}$ is in ft/min, $P_{v,rms}$ is in in H₂O gauge, and ρ is in lb/ft³. The air density is determined from air temperature and barometric pressure.

The average airspeed in the duct is then multiplied by the cross-sectional area of the duct to determine the volumetric airflow rate in m³/s (cfm).

Hot-Wire Traverses in Ducts. The use of hot-wire anemometers to measure airflow rates in ducts is similar to the use of pitot tubes, except the airspeed is measured directly at each traverse point. The location of traverse planes and measurement points in ductwork dis-

cussed for pitot tubes also applies to hot wires. The uncertainties of airflow rates measured by hot-wire traverses are not discussed in HVAC and TAB industry standards and guidance documents, as they are for pitot tubes. Hot-wire traverses are omitted, in part because reliable hot-wire anemometers have only recently been available at a reasonable cost and because these documents have not been updated for several years. However, if one assumes that airspeeds measured with hot-wire anemometers are as accurate as those obtained with pitot tubes, then the uncertainty of the airflow rate should be the same as that quoted for a pitot traverse, i.e., from 5 to 10 percent under good field conditions (AMCA 1990, ASHRAE 1988). When the traverse plane is not in a good location, the errors can exceed 10 percent.

During a hot-wire traverse, the airspeed at each point is measured with a hot-wire anemometer. The hot-wire probe must be positioned at each measurement point as directed in the instructions for the device and for a period of time that is based on the response time of the hot wire. The airspeed reading will usually fluctuate because of turbulence. Therefore, the airspeed should be read once every 10 seconds to obtain a number of readings, and the average of these readings calculated. The results of the traverse are the average airspeeds in m/s (ft/min) at each point in the traverse plane. The average airspeed in the duct is calculated from the measured airspeeds and multiplied by the cross-sectional area of the duct to determine the volumetric airflow rate in m³/s (cfm).

Tracer-Gas Measurement of Airflow Rates in Ducts. The airflow rate in ducts can be measured by tracer-gas techniques (ASTM 1999). The most common approach employs a constant tracer injection into the airstream and a concentration measurement downstream of the injection point. Assuming that the tracer injection is well mixed with the airstream prior to the measurement point, which should be verified, the airflow rate is given by:

$$Q = cq \quad (52.11)$$

where c is the tracer-gas concentration and q is volumetric rate of tracer-gas injection. Equation (52.11) can also be expressed in terms of mass concentration and mass flow rates instead of on a volumetric basis. In either case, care is required in handling the units, as the units used to measure tracer-gas injection rates are generally not the same as the units used to measure airflow rates. For example, if c is in ppmv and q is in cm³/min, their product must be divided by 6×10^7 to determine the airflow rate in m³/s.

Vane Anemometer Traverses at System Coils. While pitot tube and hot-wire traverses are the preferred techniques for measuring airflow rates in ducts, vane anemometer traverses are sometimes performed at system coils when no suitable traverse locations exist in a supply air duct. While industry guidance documents and standards discourage the use of vane anemometer traverses (NEBB 1986, ASHRAE 1988), they point out that coil traverses are sometimes the only option for measuring supply airflow rates.

Industry documents do not describe the use of vane anemometers to measure airflow rates at system coils, but some information exists based on reports of field experience and laboratory testing (Howell et al. 1984, 1986, 1989; Sauer and Howell 1990; Suppo 1984). In this technique, the airspeed is measured at multiple points across the face of a coil bank. There should be at least 20 measurement points, located in the centers of equal-area sections of the coil face. During the measurements, the anemometer should be held directly against the downstream coil face. The airflow rate is equal to the average of the measured airspeeds multiplied by both the cross-sectional area of the coil face and a so-called K factor. The K factor accounts for airflow obstructions caused by the coil tubes and fins. Research has shown that K depends on the airspeed, the number of rows of coils, the spacing of the fins and tubes, and the tube diameter (Sauer and Howell 1990). A value of 0.75

can often be used for K , resulting in a measurement uncertainty in the airflow rate of 20 percent for uniform airflows. When the airflow is very nonuniform, the uncertainty can be 30 percent or more.

Flow Hoods at Outlets and Inlets. Accurate airflow rate measurements at air outlets and inlets are difficult because of irregular airflow patterns and because the measurement device can affect the airflow rate. Among the instruments available for measuring these airflow rates, flow hoods require less training and experience than the alternatives. However, flow hood measurements can be subject to large errors in the field (ASHRAE 1988).

To measure the airflow rate, the hood is held against a supply outlet or return/exhaust inlet, and the airflow rate is read directly from the display. It is important that the vent be completely covered by the hood and that the hood be positioned securely against the surface containing the vent. If the hood has multiple measurement ranges, then the user should select a range so that the readings are near the middle of the range. After a large number of measurements with a flow hood, the user may experience fatigue, making it more difficult to position the device properly.

Vane Anemometers at Outlets and Inlets. Airflow rates at supply outlets and at return and exhaust inlets can also be measured with rotating-vane, swinging-vane, and hot-wire anemometers. The use of swinging-vane and hot-wire anemometers requires a great deal of care and experience, and measurement errors in the field have not been well characterized (ASHRAE 1988). However, rotating-vane anemometers have been shown to produce reliable results if used properly.

Vane anemometers can be used to measure airflows only at grilles and openings, and not at high-velocity induction diffusers. The opening is divided into equal area squares, approximately 10 cm (4 in) on a side. An airspeed reading is taken in the center of each square, and the measured airspeeds are averaged. The airflow rate is determined by multiplying the average airspeed by both the “designated” opening area and by an application factor provided by the manufacturer of the opening or grille. For exhausts, the designated opening area equals the area of the grille, uncorrected for the percent of open area. For supplies, the designated opening area equals the average of the uncorrected grille area and the free open area. If no application factor is available from the manufacturer, ASHRAE Standard 111 (1988) recommends an application factor of 1.03 for supplies and 0.85 for returns and exhausts for airspeeds between 2 to 7.5 m/s (400 to 1500 ft/min). These application factors are limited to rectangular exhaust openings more than 10 cm (4 in) wide, with an area up to 3700 cm² (600 in²), and with at least 60 percent free open area. The same restrictions apply to supply openings, except that the free open area must be at least 70 percent and there must be no directional vanes. Application factors for lower airspeeds and larger openings are discussed in an appendix to ASHRAE Standard 111 (1988).

The accuracy of airflow rate measurements at openings and grilles with rotating vane anemometers is 5 percent under good conditions, i.e., with a long, straight length of duct upstream or downstream of the opening. When there is no such duct, system effects can lead to measurement errors as large as 15 to 30 percent (ASHRAE 1988).

Multiplicative Method of Determining Outdoor Airflow Rates. Outdoor airflow rates can be measured in air distribution systems with the so-called multiplicative method. In this technique, the supply airflow rate Q_s is measured with a pitot tube, a flow hood, tracer gas, or a hot-wire or vane anemometer traverse, and the percent outdoor air intake %OA is measured as described previously. The supply airflow rate is then multiplied by the percent outdoor air intake to determine the outdoor air intake rate Q_o according to:

$$Q_o = \%OA \times Q_s \quad (52.12)$$

Q_s can be measured at an air handler, supply air duct, or supply air outlet to determine the outdoor airflow rate at that point in the air distribution system. In most cases, the percent outdoor air intake %OA can be measured at the air handler and used at any point in the air distribution system. In induction and in dual-duct systems, the technique is somewhat more complex, and its use in these systems is not discussed in this chapter.

The uncertainty in Q_o is estimated from the uncertainty in %OA (referred to earlier as $\Delta\%$) and the uncertainty in the measurement of Q_s , referred to as ΔQ_s . The uncertainty in Q_o , referred to as ΔQ_o , is given by:

$$\Delta Q_o = \sqrt{(Q_s \times \Delta\%)^2 + (\Delta Q_s \times \%OA)^2} \quad (52.13)$$

Whole-Building Air Change Rates

The outdoor air change rate of a building is the rate of outdoor air entering the building in L/s (cfm) divided by the building volume and is usually expressed in air changes per hour (h^{-1}). The air change rate includes both outdoor air intake via the air-handling system and infiltration through leaks in the building envelope. This section describes two techniques for determining building air change rates: tracer-gas decay and equilibrium carbon dioxide analysis.

Tracer-Gas Decay In the tracer-gas decay technique (ASTM 1995), a tracer gas is released to obtain a uniform tracer concentration throughout the building. The decay in tracer-gas concentration is monitored over time, and the air change rate is determined from the rate of concentration decay. If the air change rate is constant, then the tracer-gas concentration $C(t)$ decays according to

$$C(t) = C_0 e^{-It} \quad (52.14)$$

where t is time, C_0 is the tracer-gas concentration at $t = 0$, and I is the air change rate in units of inverse time. If t is in hours, then I is in units of h^{-1} , or air changes per hour. The air change rate I is equal to the outdoor airflow rate into the building Q (intake and infiltration) divided by the building volume V . Tracer-gas concentrations measured in decay tests are usually analyzed by taking the natural logarithm of each side of the equation above.

$$\ln C(t) = \ln C_0 - It \quad (52.15)$$

where $\ln C(t)$ is the natural logarithm of the tracer-gas concentration at time t . The value of I is determined with least squares linear regression to calculate the slope of this line for a series of concentration readings over time.

Equations (52.14) and (52.15) apply only over periods of time during which the air change rate is constant. The average air change rate can be determined over a time period from t_1 to t_2 , during which it might vary, by the following equation

$$I = \frac{\ln C(t_1) - \ln C(t_2)}{t_2 - t_1} \quad (52.16)$$

where $C(t_1)$ is the tracer-gas concentration at the beginning of the time period and $C(t_2)$ is the concentration at the end of the period.

The tracer-gas decay technique requires that the tracer-gas concentration in the building be represented by a single value, i.e., the tracer-gas concentration is uniform. This condition is sometimes referred to as the single-zone assumption, or less accurately as perfect mixing. This

assumption will be valid if the tracer is carefully released into the building and if the building airflow patterns keep the concentration uniform. In mechanically ventilated buildings, the tracer gas can be injected into the building air handlers so that the air distribution system distributes the tracer. Recirculation of building return air helps achieve a uniform concentration. These equations also require that the outdoor tracer-gas concentration be zero. If the outdoor concentration is not zero but constant, the technique can still be used with slightly modified equations. Additional detail on the tracer-gas decay technique related to equipment requirements, procedure, and data analysis is contained in ASTM Standard E741.

It is tempting to consider application of the tracer-gas decay technique to a single room to determine its air change rate, and this is sometimes done in practice. However, because the tracer-gas decay technique is a single-zone approach, its application in a single room of a multizone building is not appropriate and the decay rate will not in general yield the air change rate of the room of interest. The reason for this is that the single-zone mass balance equation on which Eqs. (52.14) through (52.16) are based does not account for tracer-gas entry from other zones in the building; it only accounts for the interaction between the building and the outdoors. If all the zones of the building are at the same tracer-gas concentration, as the single-zone assumption requires, then the equations apply. Otherwise, as is often the case, the tracer-gas concentration will vary among the rooms of a building and the single-zone approach will not work.

The ASTM standard also describes two other tracer-gas techniques for determining air change rates in single-zone buildings. One is the constant concentration approach, in which the tracer-gas injection rate is controlled to maintain the indoor tracer concentration at a constant value. The volume of tracer injected over a period of time is then analyzed to determine the air change rate. This technique requires more sophisticated instrumentation than the decay technique, and its use is generally restricted to research efforts. The other tracer-gas technique is the constant injection approach, in which tracer is injected into the building at a constant rate and the buildup in concentration is analyzed to determine the air change rate. A specific application of this approach, using occupant-generated carbon dioxide as the tracer gas, is discussed in the following section.

Equilibrium Carbon Dioxide Analysis. Air change rates can be estimated from peak carbon dioxide concentrations, but the applicability of this technique is limited (Persily and Dols 1990, Persily 1997, ASTM 1998). If the CO_2 generation rate inside a building and the outdoor airflow rate into the building are both constant, then the indoor concentration builds up to an equilibrium concentration C_{eq} . In practice, a constant CO_2 generation rate means a constant number of building occupants. If the outdoor CO_2 concentration C_{out} is constant and the average CO_2 generation rate per person, G_p , is known, then the outdoor airflow rate into the building is given by the following equation

$$Q = \frac{\text{number of building occupants} \times G_p}{C_{\text{eq}} - C_{\text{out}}} \quad (52.17)$$

The value of G_p depends on a person's age and activity level. A typical value of G_p for office buildings is $5.3 \times 10^{-6} \text{ m}^3/\text{s}$ (0.011 cfm) per person. The value of Q is divided by the building volume V to determine the air change rate.

The indoor CO_2 concentration must be at equilibrium to obtain reliable results with this technique, and the time required to achieve equilibrium depends on the building air change rate. At lower air change rates, it takes longer to reach equilibrium. To reach equilibrium, the CO_2 generation rate (building occupancy) must be constant for the amount of time required for the concentration to reach equilibrium, which depends on the air change rate. In most office buildings, the CO_2 generation rate is constant for only a few hours a day. Unless the building air change rate is very high, at least 1 h^{-1} , the indoor concentration may never reach equilibrium. If the CO_2 concentration prior to equilibrium is used in the equation given above, the building air change rate will be overestimated.

This technique also requires that the CO_2 concentration be uniform throughout the building interior. This requirement means it is inappropriate to use this technique to estimate air change rates of individual rooms when the rooms are at different concentrations. This technique can be used only to estimate whole building air change rates.

Field studies have demonstrated the potential for large errors when CO_2 concentrations measured before equilibrium are used to calculate air change rates (Dols and Persily 1995). This technique is not reliable for determining building air change rates unless the CO_2 concentration is at equilibrium and the other assumptions of the technique are valid.

Outdoor Air Distribution

The outdoor air change rate is obviously a critical ventilation performance parameter. However, the distribution of this outdoor air to the various occupied spaces within a building is also important. The net outdoor air change rate may be more than adequate, but certain spaces may not be receiving their share of this outdoor air because of a variety of air distribution problems. Poor air distribution can arise from design, construction, or installation errors, maintenance problems such as broken or improperly positioned dampers, and a number of other circumstances. There are two primary ways to evaluate outdoor air distribution in mechanically ventilated buildings: direct measurements of system airflow rates and tracer-gas measurements of local age of air.

Outdoor air distribution can be assessed by measuring relevant system airflow rates to determine the amount of outdoor air being brought into the building by the ventilation system and the supply airflow rates to the various zones being served. Assuming that the outdoor air intake is well mixed into the supply airstream, which is not necessarily a valid assumption, one can calculate the amount of outdoor air being distributed to each zone of the building. This approach does not account for excess ventilation capacity in the recirculation airstream when some of the spaces are receiving more supply air than required. Such cases can be analyzed, however, by using the multiple spaces approach in ASHRAE Standard 62-1999 (Stanke 1998).

Alternatively, outdoor air distribution can be assessed by tracer-gas measurements of the local age of air. The local age of air is the average amount of time that has passed since the air molecules at some location in a ventilated space entered the building from outside. The local ages throughout a space can be averaged to determine the average age of air for that space. Tracer-gas techniques exist to determine the age of air (Sandberg and Sjoberg 1983, Persily 1992), and a standard test method exists that allows one to determine the age of air in a space (ASHRAE 1997b). While this test method is applicable to laboratory conditions, it may also be useful in some field settings.

CHAPTER 53

ASSESSING OCCUPANT REACTION TO INDOOR AIR QUALITY

Gary J. Raw, D.Phil.
Building Research Establishment Ltd.
Garston, Watford, United Kingdom

Occupant surveys are widely used to assess the reactions and responses of occupants to the air quality in their indoor environments; such surveys are a powerful tool in both research and practice in the field of indoor air quality (IAQ). This chapter describes the role of occupant surveys and how to use them most effectively; the chapter is divided into the following four main sections:

1. *The role of occupant surveys.* Why would someone want to carry out an occupant survey at all? How do occupant surveys fit into the wider picture of IAQ? What can they achieve and what can they not achieve?
2. *Deciding to conduct an occupant survey.* Given that there is a general case for conducting occupant surveys, how should someone (e.g., a building manager or a researcher) decide specifically when, where, and for what purpose to conduct a survey?
3. *Instruments for the survey.* This is the first part of conducting a survey: choosing the right instrument (usually a questionnaire) for the job.
4. *Procedures for the survey.* Having chosen the instrument, how should the survey be conducted?

For each of these items, the issues are more complex than many suspect, but with a little understanding of the principles and available methods, an approach that is both manageable and effective can be created.

53.1 THE ROLE OF OCCUPANT SURVEYS

Introduction

This section provides the theoretical underpinning for the three more practical sections that follow. It addresses the basic issues of why would someone want to carry out an occupant

survey at all and how such surveys fit into the wider picture of IAQ. Anyone carrying out or commissioning an IAQ survey should seek to acquire an understanding of these fundamentals.

Much of the discussion in these chapters is focused on surveys of groups of 50 or more people sharing a common environment (e.g., the occupants of an office building). Although the general points will apply to other kinds of environment (e.g., individual homes), much of the specific guidance would need to be adapted.

The Primacy of Occupant Reactions

The starting point for this discussion is to question, from a theoretical perspective, what we mean by an IAQ problem and how we can know when one exists. This chapter is concerned with the impact of indoor pollution on people, as distinct from effects on building and furnishing materials, animals, and plants. In this context, there are three main ways of defining a “problem”: health (either identifiable illness or the occurrence of nonspecific symptoms), comfort, and productivity. Of course, criteria for IAQ will often find expression in terms of environmental variables such as pollutant levels or ventilation rates, but the bases for the criteria are human responses.

It follows that occupants have a key role in defining the quality of the air in their indoor environments. Objective measurements (e.g., contaminant concentrations) have the attraction that they are generally reproducible and that it is possible to define precisely what is being measured. However, it is not always so clear that they are directly relevant to human responses. It is possible for an investigator (whether a research scientist or IAQ practitioner) to be precisely and accurately measuring the wrong environmental parameters or measuring the right parameters at the wrong time or place. This is not to suggest that the investigator is incompetent: it is simply a fact that we have an inadequate understanding of how complex mixtures of air pollutants (together with other environmental, social, and personal factors) determine occupant responses.

In summary, it is not sufficient to assume that conforming to published IAQ criteria will always prevent complaints about IAQ. Environmental measurements are only as useful as their capacity to predict human responses; therefore, if human responses can be recorded, it makes sense to use them as direct indicators of IAQ. Whatever the environmental measurements suggest, if the occupants are dissatisfied, there is a problem. The investigator must determine exactly what is wrong.

Conversely, if the occupants were found to be satisfied with the indoor environment, it would seem strange to say they ought to be dissatisfied on the evidence of environmental measurements. There are exceptions to this because there are hazardous agents that the occupants would be unable to perceive, for example radon or carbon monoxide. Hence, to obtain a comprehensive assessment of IAQ, occupant reactions need to be used alongside environmental measurements and medical diagnosis of illness. Although specific illnesses such as lung cancer or Legionnaires’ disease would not be diagnosed by means of occupant surveys, there are many circumstances in which IAQ problems are best assessed with such surveys.

The Value of Occupant Data

In carrying out occupant surveys to investigate IAQ, the investigator is not limited to counting complaints. Indeed, unsolicited complaints are generally a poor guide to the nature and magnitude of IAQ problems. Instead, the investigator can make use of the remarkable capacity of people to act as measuring instruments and data loggers. The nose and mucous membranes of the eyes and airways are sensitive to airborne chemicals, some at extremely low concentrations. Consequently, people can detect, describe, and quantify a very wide range of environmental factors over a huge dynamic range. They can do this for specific

factors, locations, and times (e.g., the smell of tobacco smoke in the corridor on Monday afternoon) or for combinations of factors, averaged over time and space (e.g., the general air quality in the whole building during the past year). The information can be recorded at the time of exposure or it can be reported retrospectively, even without prior warning; this means that people are often the only source of data about how the air quality has been in the past. Some kinds of information can be acquired only by occupant surveys (e.g., symptoms of ill health related to being in a particular building).

In using this rich source of data, there are two key problems: poor calibration and inefficient downloading. Calibration refers to the need to use data from different individuals, who respond and think differently from each other, to make valid judgments about indoor air quality and how to improve it. Put simply, two people in the same environment will rarely have identical reactions to that environment. This difference may reflect inherent susceptibility, the modifying effects of various environmental factors, and differences in reporting. There are two main ways to reduce this variability: (1) to train people to give similar responses and (2) to average the responses from sufficient people to reduce variation to a level that is acceptable for the purpose of decision making. Of course, sometimes individual variation is the subject of a study rather than a nuisance to be controlled, as in the case of research into the distribution of susceptibility and its determinants.

Even if two people have identical reactions to a particular aspect of the environment, they may not give identical responses in a questionnaire; not only this, but slightly different questions on the same issue will elicit different answers. This is the problem of *downloading data* from people (obtaining information that is both valid and reliable). People's breadth of measuring and logging capacity can thus become a limitation of occupant surveys, particularly if the survey process is not carefully managed so that the investigator knows what the occupants are reporting and according to what criteria. Fortunately, there are procedures for addressing these problems, as discussed later in this chapter.

The Key Issues Addressed in Occupant Surveys

The three principal occupant reactions to be addressed using occupant IAQ surveys are acute nonspecific symptoms, environmental discomfort, and the adverse effects of poor IAQ on worker productivity. Surveys can also assess social and personal factors that can modify response to IAQ, such as underlying medical conditions, management issues, personality variables, and sensitivity to air pollutants; however such measurements are outside the scope of this chapter.

Acute Nonspecific Symptoms (Sick Building Syndrome). In comparison with specific illnesses, there is less established knowledge about the causes of a range of acute nonspecific symptoms, which some people report when they are in certain buildings. The majority of surveys of occupant reaction to IAQ have been conducted in the context of seeking to explain such symptoms, even when the questions themselves have been about environmental parameters or modifying factors rather than the symptoms themselves. Hence these symptoms are discussed at greater length under "Sick Building Syndrome," below.

Environmental Comfort. Along with nonspecific symptoms, there are commonly complaints about aspects of the indoor environment itself (e.g., the odor level might be too high or the humidity might be too high or too low). These are complaints about the environment rather than about the person's perceptions of his or her own health.

The importance of such perceptions is illustrated by their use in setting ventilation rates. In contrast to the procedures for setting pollutant limits, ventilation rates in nonindustrial workplaces have generally been set according to criteria of comfort or acceptability since the work done by Yaglou et al. (1936).

Productivity. Although productivity or staff efficiency would appear to be a potential basis for standards, a principal barrier has been defining and measuring productivity. To use work performance as a criterion is feasible in some settings, for example, where people are doing repetitive routine tasks, but in other cases it is much more difficult to assess whether performance has been improved or reduced by attaining a certain level of IAQ. For some types of work it may be some years after a piece of research was performed before its usefulness can be established. In practice there is little readily usable data linking IAQ with productivity. Nevertheless, productivity is a key element in the motivation to improve IAQ in the workplace because it is generally assumed that healthy, comfortable staff are also productive staff.

Sick Building Syndrome

The investigation and study of sick building syndrome (SBS) requires occupant surveys to obtain population-level data because it cannot be diagnosed through other means. SBS can be not only a difficult health issue but also a costly problem.

What Is SBS? The concept of SBS has caused confusion since it was introduced. This section seeks to break through the confusion by offering a usable definition of SBS and showing how the definition is necessarily linked to the means of diagnosis. It is inherently difficult to characterize SBS and its causes unless there is an agreed definition that can actually be used in practice. There has so far been substantial variability among the definitions offered; in many studies, no definition at all has been given. The definition adopted in this chapter is as follows:

Sick building syndrome is a phenomenon whereby people experience a range of symptoms when in specific buildings. The symptoms are irritation of the eyes (e.g., dry/watering eyes), nose (e.g., runny/blocked nose), throat (e.g., dry/sore throat), and skin (e.g., dryness/redness), together with headache, lethargy, irritability, and lack of concentration. Although present generally in the population, these symptoms are more prevalent among the occupants of some buildings than of others and are reduced in intensity or disappear over time when the afflicted persons leave the building concerned.

Because the symptoms are associated with particular buildings, they are often called *building related*. The time required for recovery can vary from hours to weeks, depending on the type and severity of the symptom. Thus, to say that SBS is a real phenomenon is merely to say that there is a variation in symptom prevalence among buildings, not a clear division into “sick” and “healthy” buildings but a continuous variation.

Some studies have used more extensive lists of symptoms, including for example, airway infections and coughs, wheezing, nausea, and dizziness (WHO 1982); high blood pressure (Whorton and Larson 1987); and miscarriages (Ferahrian 1984). However, although these conditions are mentioned as occurring among staff in certain sick buildings, they probably should not be included in SBS. Taste and odor anomalies are not necessarily symptoms: they are better considered as environmental perceptions and are therefore best excluded from the list of defining symptoms.

SBS is thus defined, as many health problems have been in the past, in terms of symptoms and conditions of occurrence rather than cause (except at the very general level that buildings are somehow responsible). The reason is that there is no single proven causal agent, and any attempt to introduce etiology into the definition is likely to be misleading at present. This would apply equally to specific causes (e.g., “tight” buildings) and to common generalizations such as SBS being diagnosed only when there is no known cause or

where there are multiple causes. It is nevertheless possible to talk of preventive and remedial measures, much as many diseases were to some extent prevented (e.g., by hygiene practices) and treated by reducing specific symptoms (e.g., fever) long before the cause of them was identified.

Although SBS can be defined, the definition of a case of SBS (a sick building or SBS-affected person) is to some extent arbitrary. A theoretical definition of a case could follow from the definition of SBS, but in practice the identification of specific cases would depend on what is regarded as an acceptable level of symptoms among the occupants.

Diagnosis. The definition of SBS suggested in this chapter implies that the definition is inseparable from the means of diagnosis. This is because the range of symptoms reported in a given building population, and their prevalence rates, will depend on the number and nature of the questions used to elicit the information. The choice of survey instrument is thus critical for the diagnosis of SBS.

Because definition is tied closely with diagnosis, if the diagnostic approach is not standardized, the definition is effectively variable across investigations. For example, if two different questionnaires are used in studying two different buildings, it may be that two different instruments are being used to measure the same phenomenon. In fact, because the questionnaire determines what is measured, two nonidentical phenomena are being measured. Diagnosis can also become inconsistent if different clusters of symptoms are statistically derived because these clusters will vary among buildings or groups of buildings (see Raw et al. 1996a, 1996b).

Although this discussion may appear somewhat academic, it highlights a key issue in the current approach to diagnosing SBS. We have imperfect instruments, but we need to use them rather than to wait for agreement on the perfect diagnostic procedure. Greater standardization is critical to advancing understanding of SBS. It is important to keep in mind for this purpose that SBS is a complaint of people, not buildings, and can be diagnosed only by assessing the building occupants, not by examining the building itself.

An attempt to define a working criterion for SBS diagnosis (Raw et al. 1990) specifies a level of more than two symptoms per person, recorded using the same questionnaire as in the U.K. cross-sectional survey reported by Wilson and Hedge (1987). This was the level at which respondents, on average, reported a negative effect of the indoor environment on their productivity.

SBS Matters. It is generally recognized that SBS is not an isolated or occasional phenomenon. A WHO working group (Akimenko et al. 1986) estimated that, although frequency of occurrence varies from country to country, “up to 30% of new or re-modelled buildings may have an unusually high rate of complaints” (these complaints may extend beyond SBS). This estimate is again to some extent arbitrary and could be set considerably higher or lower by taking a different criterion for what would be considered a “high rate of complaints.”

Apart from effects on productivity when staff are at work, SBS has been shown to affect absenteeism and quite obviously makes demands on the management and trade unions that spend time trying to resolve the problem. Other likely effects are on unofficial time off, reduced overtime, and increased staff turnover. In extreme cases buildings may be closed for a period. If building users were to associate SBS with energy-saving measures such as controlling ventilation rates, this could inhibit moves toward greater energy efficiency.

Although neither life threatening nor necessarily disabling, SBS is clearly perceived to be important to those affected by it, particularly if they are affected at home (e.g., the elderly or sick in residential care) and cannot leave the affected building. The economic significance of IAQ problems is addressed further in Chapters 4 and 56.

The Causes of SBS. The list of suggested causes for SBS is very long indeed, as addressed in other chapters of this book. Although this chapter does not review the evidence on the possible causes, it should be noted that, although many studies have focused on IAQ and ventilation rates, there seem to be some contributions from a wide range of other factors in the environment (particularly temperature, humidity, cleanliness of offices, and personal control over the environment). Current evidence suggests that no single factor can account for SBS: there are probably different combinations of causes in different buildings.

The statement is sometimes made that we do not know the cause of SBS; this is unhelpful because we know many causes of SBS. The problem is one of identifying the cause or causes in particular buildings because this entails consideration of interactions occurring at the following four levels among etiological factors:

- *The building.* The design, construction, and location of a building and its services and furnishings may contribute to IAQ problems in a variety of ways, from the site microclimate through shell design (i.e., depth of space) to the building services and build out.
- *The indoor environment.* The effects of the building and site will generally be mediated by characteristics of the indoor environment (e.g., temperature or allergen levels).
- *The occupants.* Households or organizations that occupy and operate buildings may contribute to IAQ complaints, for example, via the quality of building maintenance and workforce management.
- *The individual.* Reported experience of IAQ problems varies from one person to another within buildings for a number of reasons, which would include personal control over the environment, constitutional factors, behavior, and current mental and physical health.

In addition, causes of SBS may stem from the earliest origins of a building, from the original concepts, specification, and design for a building through the construction, installation, and commissioning to the maintenance and operation of the building. Hence it is too simplistic to talk about the causes of SBS only at the level of IAQ parameters causing certain symptoms. The investigator must remember that the determinants of SBS cannot be addressed adequately using only an occupant survey.

53.2 DECIDING TO CONDUCT AN OCCUPANT SURVEY

Introduction

The process of deciding to carry out an occupant survey is important because it should identify the reason for the survey or hypotheses to be tested, which in turn will be a key factor in deciding the method to be used. The decision-making process should also bring all the interested parties together in consensus over the approach. The most common reasons for initiating a survey would be as follows:

- There is a suspected problem with the indoor environment, based on spontaneous complaints, illness reports, sickness absence, or environmental monitoring.
- There is a desire to be proactive in monitoring the quality of the indoor environment.
- It fits the needs of a research project.

Each of these is addressed in turn.

Response to Suspected Problems

If an IAQ problem is suspected, there is rarely a good reason for not conducting an occupant survey. Neither the act of conducting a survey nor the results found define liability for the IAQ problem. Rather, the survey is a first step toward finding a solution. In many cases, the occupants may consider that they have already made a diagnosis, that remedial action should be taken, and that any further survey is likely to be uninformative. Although such feelings are understandable, an unsystematic and anecdotal collection of complaints is a poor guide to what action should be taken. On the other hand, some managers would prefer to believe that there is no problem and that surveys will only cause further complaints. Unless spontaneous complaints are investigated in a more rigorous manner, such conflicts in views cannot be resolved. Either the occupants will continue to be affected by SBS, with implications for their health and the success of the company occupying the building, or effort may be wasted addressing a problem that never existed.

A good occupant survey should not just confirm (or otherwise) the level of complaints in the building but should also provide information about where and when there are problems and what types of complaints are being made. It may also give an indication of the cause of the problems, but this must always be backed up with further investigations involving other measurements and/or interventions. A survey will also provide a basis for evaluating the effectiveness of any remedial measures that might subsequently be undertaken. This application could include piloting remedial measures in one part of a building and assessing the outcome before extending the measures to other parts of the building. This type of application has many of the characteristics of a research project, with all the methodological rigour entailed.

Proactive Monitoring

It is sometimes claimed that faulty management is responsible for IAQ problems. At one stereotyped extreme, problems in the workplace can always be attributed to bad management. At the other extreme, blame is placed purely on the environment. A proper balance between these views can be struck by establishing in specific terms what management could have done to have avoided the problems. Broadly speaking, management can be seen as contributing to IAQ problems if it does not act effectively to create a good indoor environment or if it does not establish a good organizational environment for reducing stressors that foster complaints about IAQ and for dealing with complaints should they arise.

Carrying out an occupant survey only in response to complaints might be called bad management, although it is more conciliatory to call it good management, albeit too late. By analogy, consider a company that did not routinely check the safety of its vehicle fleet but chose instead to wait until a truck reached the point of swerving off the road before checking the whole fleet. If we can be proactive with machines, why not with people?

Occupant surveys indicate whether the final clients (i.e., the people who occupy the building) are satisfied with the architect and building services engineer's final product (i.e., the indoor environment and the control of that environment). The data provided by such surveys have two essential purposes:

- To tell the facilities manager and other parties whether a building is performing to an acceptable standard

- To tell those who contribute to future buildings about how to create better environments (whether their contribution is in design, building, installation, commissioning, operation, maintenance, or management)

In other words, the purpose of carrying out surveys is to improve the “product,” whether that product is the environment in a current building or in a future building.

In a busy facilities management situation, it can be tempting to believe that occupant surveys are not necessary (because occupants will complain if there is a problem) or actually counterproductive (because they create or exaggerate problems or create an awareness of problems). A forward-looking company will set aside these concerns in favor of the goal of achieving greater client satisfaction.

Occupants do complain, but their complaints are often an unreliable indication of the scale and nature of any problems because complaints are also motivated (positively or negatively) by a range of factors unrelated to the subject of the complaint. Besides, what kind of service provider can really afford to wait until the situation becomes bad enough to provoke complaints? It is good practice in any industry to identify and deal with complaints before they “break out” and are labeled as “a problem.” Thus, the second objection (i.e., that occupant surveys create problems) is unsound. Surveys will identify whether a problem exists and thereby offer an opportunity to solve the problem.

By using a standard questionnaire, the results of the survey can be compared with a wider database to show how the building is performing in relation to comparable stock (see Section 53.3). Alternatively, repetition of the survey will show whether there are changes over time in the performance of a building, which would give an even clearer indication of impending problems. An interval of 2 years between surveys is a reasonable norm, but the interval could be shorter or longer depending on the pace of change in the building or workforce.

Research, Including Following Up Mitigation Attempts

Survey research on SBS can be seen to have passed through three phases, representing a transition from exploratory to confirmatory studies. The approaches represented by each of the three phases have validity for specific purposes, but each needs to be done well if meaningful results are to be achieved.

The first phase of research was concerned with the existence of the problem. It effectively commenced in the late 1970s, although there were earlier warnings of the emerging problem of SBS (Black & Milroy 1966). By the early 1980s, it had demonstrated to the satisfaction of most researchers that there was a phenomenon that we now call SBS.

Second, notably in the 1980s, there were many investigations that relied on comparisons of occupants’ symptom prevalences between buildings. These studies provided evidence on what can be termed *risk factors* (e.g., open plan offices and low perceived control over the indoor environment). These factors cannot necessarily be regarded as direct causes because of the many confounding factors and confusion over causal pathways. For example, air-conditioning was identified as a risk factor, but the causal factors could include various building characteristics that are commonly associated with air-conditioned buildings, such as deep building plans, reliance on artificial lighting, and lack of personal control of the indoor environment.

Now, in the third phase of SBS research, the risk factors constitute important clues as to the causes, clues that are being followed up by making experimental changes to buildings. The basic plan of such intervention studies is first to apply theoretical knowledge and an examination of a building to generate hypotheses about causes of SBS in the particular building being studied. Modifications are then made to the building and/or the indoor

environment, and measurements are made to determine whether the modifications have been successful in reducing the symptoms experienced. This approach allows for control of potential confounders and thus provides stronger evidence on the causes of SBS.

Identifying the type of research that is to be carried out is the key to choosing the right research design and the right survey instruments. Research that seeks only to identify sick buildings requires a relatively simple *screening* questionnaire. A search for risk factors requires the collection of additional data on potential determinants and modifying factors. Intervention studies require yet another layer of sophistication: Their design has recently been discussed at length (Berglund et al. 1996) and is summarized later in this chapter.

53.3 INSTRUMENTS FOR THE SURVEY

Choosing an Approach

Occupant data can be collected by a number of means, including structured or unstructured interviews (medical examinations generally include an interview with the patient, and this interview may be more or less structured), discussion groups, diaries, and self-completion questionnaires. Medical examinations are outside the scope of this chapter, but they do have a role to play, especially where complaints have become sufficiently serious for rapid action to be required or where the nature of the symptoms is unusual.

Although the presence of symptoms of SBS is normally assessed by self-completion questionnaire, this is for convenience, and most of the symptoms can be assessed by other means and shown to be correlated with questionnaire responses (see the later discussion of reliability and validity). Demonstrations that symptoms can be reduced markedly in blind trials of remedial measures (Raw et al. 1993) also support the validity of the questionnaires used. The remainder of this section assumes the use of self-completion questionnaires. Most of the information provided would apply equally to structured interviews or diaries.

Selecting or Designing a Questionnaire

Introduction. For most surveys, the use of an existing questionnaire is preferred, whether the purpose is proactive monitoring, response to complaints, or a screening survey carried out in a research project. Designing a new questionnaire is time consuming and difficult, if done properly. By using a standard questionnaire, the results of the survey can be compared with a wider database. In some cases, there will be a need to modify an existing questionnaire. In such cases, or where questions are borrowed from existing questionnaires to create a new one, pretesting is important because the meaning of questions can be affected by even small wording changes and by the context provided by neighboring questions in the questionnaire (Rathouse and Raw 2000).

Various general guidelines on questionnaire design have been produced (e.g., Sudman and Bradburn 1982, Converse and Presser 1986). The following sections can be used to gain an understanding of questionnaires for the purpose of selecting, adapting, or designing. Readers should be aware that no single SBS questionnaire has been selected as a “gold standard.” For example, the phrasing of questions can be used to bring about large variations in measured symptom prevalence; such data therefore have little value unless norms are available for a particular standard questionnaire. In every study, some key common questions should be used that have proven validity relative to other similar surveys.

Reliability and Validity. One problem in IAQ research is that questionnaires have been accepted without sufficient evidence of validity or reliability. It is important to characterize these properties of any instrument, including questionnaires.

The *reliability* of a measurement refers to how precisely it measures. The reliability is usually expressed as a reliability coefficient, which is the proportion of obtained variance that is due to true variance in the variable being measured. Repeatability is one indicator of reliability because if an instrument is imprecise, there will be a low correlation between repeated measurements; this is how reliability was established for the U.K. Office Environment Survey (OES).

The *validity* of a measurement refers to how well it measures what it intends to measure. One type of validity is *empirical validity*, the degree of association between the measurement and some other observable measurement. For example, the OES was validated in comparison with medical interviews (Burge et al. 1990), whereas others have used objective measures such as tear film breakup (Franck & Skov 1991). An alternative type of validity is *construct validity*, which means that the measurement should correlate with all other tests with which theory suggests it should correlate and should not correlate appreciably with other tests with which theory suggests it should not correlate. The OES symptom prevalences correlate with environmental discomfort and productivity but much less with control over the job.

Symptoms are, by their nature, subjectively reported. Hence, symptom reports have an implicit validity because what the respondent says is important in its own right. This is helpful only up to a point because if the report has no relation to physiological states, the investigator could be misled about the nature of the problem. The important point is that good practice should be used in recording symptom reports.

Recall of the Past. Valid descriptive data are obtained from questionnaires that focus on the current, the specific, and the real (Turner and Martin 1984). Questions on the past in general appear to be more difficult than questions on the present, especially if (1) a decision was made almost without thought in the first place, (2) an event was so trivial that people have hardly given it a second thought, (3) questions refer to events that happened long ago, and (4) recall is required of many separate events. Even important events can fade with time or require specific cues to bring them into focus.

The following five techniques have been recommended to improve the validity of reporting on past events (Converse and Presser 1986):

- Bounded recall addresses overreporting due to “forward telescoping” outside the requested time range (it may be controlled by establishing the baseline in an initial survey).
- Narrowing the reference period for survey reporting is a good corrective means.
- Averaging refers to questions about typical conditions, which provide more representative data than “single day” focused questions.
- Landmark *events* may be referred to instead of specific dates to anchor the timing of other events. The question could ask about a symptom experienced “since Christmas,” instead of “during the last month.”
- Cueing means that cues are provided to help memorizing. The purpose of cues is to stimulate recall by presenting a variety of associations.

Simplicity Is the Rule, Complexity the Exception. There is a need for simplicity, intelligibility, and clarity. It is imperative that common language should be used, questions should be short, and confusions should be avoided (Sheatsley 1983). If the respondents are faced with a task they cannot manage or they believe they cannot manage, the responses

have low information value. It is generally easier to answer questions bearing on one's own experience and behavior (facts) than questions on opinions and attitudes (evaluations). The latter are assumed to be more open to the respondent's own definition than the former.

Ranking scales have a long history in survey research. Alwin and Krosnick (1985) showed that rankings (rank order is given) do not show the same relationship to predictor variables as ratings (category scale value is given) even though the same factors were investigated. Magnitude estimation scales are a third, more complex, technique of responding. Magnitude scaling of attitudes has been "calibrated" against numerical estimation and physical line-length estimation of physical stimuli such as light, sound, and odors (Berglund et al. 1975, Berglund and Lindvall 1979, Lodge 1981). Although these more complex techniques have considerable interest and potential usefulness, they have been little used in survey research into IAQ (Garriga-Trillo and Bluyssen 1999).

Questionnaires with closed questions are easiest to standardize. A widespread criticism of closed questions is that they force people to choose among offered alternatives instead of answering in their own words. Nevertheless, because closed questions give the same response options, they are more specific than open questions and therefore more apt to communicate the same frame of reference to all respondents. The typical survey question incorporates assumptions not only about the nature of what is to be measured but also about its very existence.

Questionnaire Construction. A number of basic issues have to be decided in constructing a new questionnaire, including the following:

- Type of response format (e.g., ranks, ratings, magnitude estimation scales).
- Open or closed questions (closed questions are easiest to standardize but they are sometimes criticized for limiting the respondent's options).
- The effect of the context of other questions, especially neighboring questions, in the questionnaire.
- The overall length and difficulty of the questionnaire (consider the amount of information collected per respondent, how useful the information is, and how many sampled people will respond at all).

In some cases, other issues will need to be considered; for example, the questionnaire might need to be completed by children or by adults who have restricted literacy. If the questionnaire is to be translated into other languages, it should be checked to ensure that adequate translation is possible and that the questions are likely to be culturally acceptable wherever they are asked.

Investigators should characterize the instruments to be used by the following:

- Piloting or otherwise validating the instrument
- Knowing the meaning of each measure, score or index
- Assessing and correcting for any predictable source of error such as habituation, practice, response sets, and false responses

This would require reading the literature on an instrument (including questionnaires) and being trained in its use. Sometime researchers may rely on developing an understanding of the instrument in the course of the study, but this carries obvious risks.

The following should be considered in the pilot: variation in responses, meaning, task difficulty, respondent interest and attention, flow and naturalness of the sections, the order of questions, "skip" patterns, timing, respondent interest and attention overall, and respondent well being (Converse and Presser 1986).

The Example of the ROES Questionnaire

Introduction. In the United Kingdom, an expert group set up by the Royal Society of Health has agreed on a standard questionnaire, the Revised Office Environment Survey questionnaire (ROES) together with instructions for its use and normative data (Raw 1995). ROES is intended to be used for screening surveys to determine the prevalence of SBS in a particular building. An account follows of the issues that need to be covered when designing or selecting a questionnaire for indoor environment surveys, with examples taken from the development of ROES (see Appendix A for sample of the ROES). More detail on ROES itself can be found in Raw (1995).

Two other major questionnaires, used extensively in the United States by the Environmental Protection Agency (EPA) and National Institute of Safety and Health (NIOSH) are discussed at greater length in Chapter 3. Another questionnaire that has been widely used is the Swedish MM Questionnaire (Andersson et al. 1988).

The Symptoms to Be Included. The starting point for the selection of symptoms to be included was the list of symptoms in the largest U.K. study of SBS, the Office Environment Survey, or OES (Burge et al. 1987, Wilson and Hedge 1987). The same list has been used in many subsequent and previous U.K. studies. Using the same list of symptoms provided immediate reference to an established database. These symptoms were as follows:

- Dry eyes
- Itching or watering eyes
- Blocked or stuffy nose
- Runny nose
- Dry throat
- Headache
- Tiredness or lethargy
- Flulike symptoms
- Difficulty breathing
- Chest tightness

The last three of these are probably not correctly regarded as typical SBS symptoms. Runny nose is also problematic as a defining symptom because it appears to indicate primarily respiratory infections. Itching or watering eyes may also be nonessential because itching partly duplicates dry eyes, and watering may reflect specific allergic reactions. An analysis carried out in the course of the development of the questionnaire (Burge et al. 1993) showed that a building symptom index (BSI—the mean number of symptoms reported per person in a building) based on the remaining five symptoms is almost perfectly correlated with an index based on all 10 symptoms.

The following five symptoms—dry eyes, blocked/stuffy nose, dry throat, headache, and tiredness/lethargy—would therefore be enough to provide an index of SBS. Consideration was given to including only these five symptoms on the questionnaire, but this approach was rejected for two reasons. First, the above analysis was based on removing the symptoms at the analysis stage; removing them from the questionnaire might have a very different effect; some evidence for this is provided by Raw et al. (1996a). Second, a shorter list of specified symptoms would place a greater load on the final item concerning “other” symptoms.

The first point represents a lesser problem regarding flulike symptoms, difficulty breathing, and chest tightness because these appeared at the end of the list in previous

surveys and are unlikely to be misreported as earlier symptoms on the list. It was therefore agreed to delete these symptoms.

A number of questionnaires, particularly in Scandinavia (Andersson et al. 1988, Skov et al. 1989), have included skin symptoms on the list (e.g., dry skin, skin rash, redness of the skin). For the sake of greater international compatibility it was thought advisable to introduce a question about skin symptoms at the end of the list.

If particular investigators or researchers added symptoms to the end of the list, it could still be possible to compare with a database unless the symptoms added were similar to those on the main list. However, it would be advisable to test this assumption. If questions were subtracted, or if the symptom descriptions were changed, comparison with the database would be invalidated.

The layout of the symptom questions was changed from that used in the OES (Burge et al. 1987, Wilson and Hedge 1987) because the opening question ("in the past 12 months have you had more than two episodes of any of the following symptoms") was considered ambiguous and, with the questions now covering more than one page, likely to be forgotten by the respondent. The question is therefore now asked separately for each symptom. This creates some monotony but at least the question is clear.

Recall Period. The response of any one individual to IAQ will vary over time. This variation might occur over minutes (e.g., because of adaptation to odor or changes in the interpretation of perceptions), hours (e.g., delayed reactions of sensory irritation), or years (e.g., as awareness and understanding of IAQ issues develops). Some psychological variables will be continuously varying over time, whereas other variables will be present or absent or will be discrete events. The selected time period of a study will "censor" the data by design: If the study period is made longer, for example, there is a greater possibility of symptom occurrence.

The reference period for reporting symptoms in the ROES questionnaire is 12 months, as in most U.K. questionnaires, based on two or more occurrences over the period. Seasonal variation of the symptoms can be addressed separately if it is suspected that this was likely to occur in a particular building.

Recall over a 12-month period is unlikely to be reliable in absolute terms: it is likely to represent mainly the previous few weeks, possibly moderated by recall of particularly severe symptoms prior to this or any marked seasonal variation. It is necessary to emphasize here that the questionnaire's main function is to make comparisons among buildings or over time for a particular building. Thus it is not appropriate to attempt to assign absolute meanings to the questionnaire responses. The use of relative ratings largely circumvents the problem of recall because it is the same for each building and each occasion.

The test-retest reliability of the symptom questions is good (Wilson and Hedge 1987), but they should not be repeated within too short a period because this tends to create a decline in the number of symptoms reported (Raw et al. 1993). The critical interval for this is not known, but an interval of a year is probably adequate to prevent it (there would normally be no reason to conduct screening surveys at shorter intervals).

If the requirement is to assess a building in relation to the whole year, not just the time of the survey, the only alternative to using 12-month recall would be to repeat the questionnaire during the course of a year, perhaps four times with 3-month recall on each occasion. A requirement to carry out a survey more frequently would increase costs and would discourage use of the questionnaire. Frequent repetition would also affect interpretation of the symptom scores, as noted above. It would therefore be necessary to collect data from repeat surveys in a sample of buildings to generate a new database for comparison.

Questionnaires are available to cover shorter recall periods, where this is required. The Swedish MM questionnaire (Andersson et al. 1988) has been translated into English and a number of other languages. It uses a 3-month recall period. The U.S. EPA (BASE)

questionnaire uses a 4-week period, as does the related NIOSH questionnaire. The ROES was adapted for 1-month recall and for reporting current conditions, as part of the European IAQ audit project (Groes et al. 1995). These questionnaires would generally be suitable for intervention studies in which changes over a period of much less than a year normally need to be detected.

Building Relatedness. The ROES questionnaire seeks to establish whether symptoms are related to being in the target building by asking the question Was this better on days away from the office? From the point of view of comparison with the OES data, it is preferable to maintain this approach. However, the question is not specific about the comparison to be made and demands interpretation on the part of the respondent. For example, does it mean on whole days away from the office, away from the office at home or away from the office in other buildings or outdoors or on holiday. For building-level comparison, it should be valid, assuming that people will, on average, adopt the same kind of interpretation. It also appears, in fact, that the phrasing of the building-relatedness question has little effect on symptom reports (Raw et al. 1996a).

Frequency of Occurrence. For screening purposes, it is not necessary to include ratings of the frequency of the symptoms, although such scales can be useful. A frequency scale has been included, placed after the assessment of building relatedness to maintain compatibility with the U.K. database. The scale meets the dual requirements of (1) covering the complete scale of frequency without (2) having overlap between categories. Including such a scale gives the potential for greater sensitivity in comparing symptom prevalence between buildings or over time.

Layout. The layout of the questions (i.e., whether it is question by question or with the responses given in a grid) may be significant. Where responses are given in a grid, Raw et al. (1996a) report that respondents have a greater tendency simply to pick the symptoms that particularly apply but not give a response to the others at all (i.e., there are more “missing” responses). They also found that there is less variance in response within respondents, as though there is a tendency to stay within or close to a particular column (frequency category) of the grid. Therefore, although a grid would require less space (probably one page rather than two), separate questions are preferred.

Questions about the Environment. Ratings of the environment can assist in the identification of causes but cannot be always taken at face value; their primary purpose should be to indicate what aspects of the environment give rise to most concern and therefore which aspects offer the best chance for improvement. A very large number of ratings could be included in a questionnaire, depending on the level of detail with which environmental factors need to be specified. For a screening survey, only the main likely problem areas should be evaluated, normally with separate ratings for summer and winter. The key ratings would generally be temperature, humidity, air movement, and air quality. Lighting, noise, and vibration are probably less important in most cases of SBS, and therefore ROES has only a single question on each of them for each season. More detailed questions, or a follow-up questionnaire, could be added in specific surveys if the investigator wished to do so. As with symptoms, the impact of doing this should be assessed before comparing with the database.

A rating of office cleanliness has also been added. Some studies have used a rating of office cleaning, but it was felt that this could be ambiguous, including for example the extent to which cleaners interrupt work or feelings about the use of chemicals that may damage the indoor or global environment. The previous OES question on personal control over heating, ventilation, and lighting has been rephrased to remove any ambiguity concerning which part of the office the “control” refers to. The question about exposure to tobacco smoke has also been made less ambiguous.

If the environment questions are not required in a particular survey, they can be omitted by taking out the central pages of the questionnaire. This has subtle effects on symptom reporting, depending on the gender of the respondent and the overall quality of the indoor environment, but it does not affect the overall symptom prevalence (Rathouse and Raw 2000).

Questions on Confounding Factors. Two kinds of confounding factors can be included in an SBS questionnaire: variables that permit adjustment of the building symptom score and variables that may provide insight into the causes of problems in the building (and modifying factors and confounders). The building symptom index (BSI) can be corrected for gender, job type, and visual display unit use (the latter is a relatively minor modifying factor). If some staff are part time or spend time in different parts of the building, this also may need to be taken into account.

In a screening questionnaire, there is only a limited role for seeking to identify the cause of SBS: The existence of the problem should be determined before its causes. However, a limited number of questions were included about the office environment as discussed above, plus questions on speed and effectiveness of the management in dealing with indoor environment problems, privacy, office layout, and decor. Ratings of overall working conditions, productivity, personal medical history, alcohol consumption, and work breaks are not included because they are not likely to add significantly to data at the building level. Questions about the job and quality of management are also not included because these are not primary issues in screening (they may be relevant in certain research studies) and may inhibit some managers from agreeing to the survey and some staff from returning the questionnaire.

Consideration was given to including some kind of check for honest and consistent reporting, to improve the validity of responses. This could significantly increase the length of the questionnaire, and the usefulness of a lie scale is likely to reduce over time as people become aware of its existence. The required comparisons are in any case probably valid without this kind of check because the database used for comparison would have any tendency to misreport built into it. The presence of unusual patterns of response to the questionnaire could in principle be used as a form of lie scale, but this idea has not been developed.

Adding Questions. It is always tempting to collect too much information, much of which will never be subjected to any useful analysis. The ROES questionnaire is designed with this in mind: It is a basic screening questionnaire to determine whether there are problems with occupant health and comfort, not a method of showing what is causing the problems. If there is any intention, in a particular survey, to add to this questionnaire, it can be useful to ask the following questions:

- Is it possible or necessary to carry out a statistical analysis of the information to be gathered?
- How much, approximately, should the study cost, how long should it take to complete, and what uncertainty can be tolerated in the results?
- What are the motives and purposes of the study and for gathering particular items of information, and would they be credible to the respondents?

53.4 PROCEDURES FOR THE SURVEY

Introduction

A questionnaire is not in itself a method; it is an instrument, which will produce valid results if used in accordance with the “manufacturer’s instructions.” There is very little

value in using a standard questionnaire without following the data collection method recommended for that questionnaire. A questionnaire study is an important part of monitoring the health of people in the workplace, and it is worth a little effort to organize it well. Much effort can be wasted through simple oversights, but a few basic principles will make the task more manageable. The following guidance is based on that given with the ROES questionnaire. If available, the guidance provided with whichever questionnaire is used should be followed.

Planning the Survey

The survey should be carried out by an organization that can guarantee (to the satisfaction of the staff) that the survey is confidential and that information on individuals will not reach management or other staff in the building without the consent of the individuals concerned. Eligible organizations could be, for example, a body that is independent of the building management or, if one exists, the occupational health department of the organization occupying the building.

It is of value to plan with all parties concerned with the study and to do the following:

- Hold preliminary discussion between the organization that will carry out the survey, management, unions, and other representatives of the building occupants, safety officer, maintenance staff, and so forth (the survey should nonetheless be seen by staff to be independent of management and unions).
- Ensure that staff know the survey is approved by management and other parties as appropriate and can therefore be regarded as part of their work.
- Establish agreements about confidentiality and lines of communication between all parties.
- Agree to inform building management immediately about any health risks that are discovered.

Confidentiality is particularly important, not only from the point of view of motivating the respondents but also for evaluation of the results.

If the survey is being conducted as part of a research project, an early stage of the work will often be to select a building. This selection will depend on the purpose of the project and cannot be covered in detail here. However, in the case of an intervention study, the following should be considered when selecting a building:

- A single large building (with many rooms and people) allows better specification of experimental/control conditions than several small buildings, unless the small buildings are all very similar in design, operation, occupancy, and management—in either case the objective is to reduce confounders by making the experimental and control groups as similar as possible.
- The initial level of SBS symptoms should be high in the building, to be able to demonstrate an improvement—one way of identifying such a building is by examining the level of spontaneous complaints from building users, but the actual level of symptoms should be confirmed by a structured survey.
- There needs to be a high level of cooperation from all parties concerned with the building, especially in relation to carrying out the intervention.
- The management of the study will probably be simplified if the organization that occupies the building is also responsible for its maintenance.

There is of course the additional question of when the researcher should embark on a major study: Should obvious problems with the building be put right first and should the first questionnaire survey be carried out before any such remedial measures? The answer will depend largely on the researcher's resources and research objectives. It may be of interest to assess whether any obvious problems in a building are actually responsible for occupant complaints. In such cases it will be necessary to carry out a first stage of monitoring before carrying out any remedial measures. If, however the requirement is to identify the causes of problems once the building appears to be operating within normally accepted conditions, the first stage of the monitoring could be delayed. If it is delayed, it should be well after the first remedial measures have been completed—at least as long as the recall period of the questionnaire.

Survey Sampling

The survey sample design should be developed as an integral part of the overall study design. Survey sampling is a highly specialized and developed component of the survey process. Therefore the wisest decision for a researcher with limited sampling knowledge is to consult an experienced survey statistician, particularly in relation to the size of the sample to be used. Some general guidance is given here.

The total number of people who could, in principle, complete the questionnaire may be referred to as the *target population*. This might be, for example, all the staff in a particular building or in certain parts of the building. The advantage of defining the target population is that the exclusion of any subgroups is explicit and the restrictions of the survey will be known.

When practical constraints are considered (for example, the target population may be very large), the target population is often replaced by a *survey population*, or *sample*. About 100 workers need to be included in a sample to produce reasonably reliable results (Raw et al. 1996b). If the target population is larger than this, a sample can be used of approximately 100 workers. The sample size should be increased if different areas of the same building are to be compared (e.g., 100 from an area where complaints have been made and 100 from a comparison area). If fewer than 100 workers are available, a survey can still be conducted, but as the number of workers is reduced there is a progressive decrease in the reliability of the results and an increase in risk of bias due to variation in individual sensitivity among occupants. Unless the target population is very large, it is often easier (logistically and politically) to include every person present during the survey than to go through the process of selecting a sample and then finding the selected persons.

The most basic sampling procedure is simple random sampling, which requires that each person or workstation has an equal probability of being included in the sample. Strictly, this means that a list of people or a plan of workstations should be available. For example, people might be chosen randomly from a staff list. In this way, selection biases are avoided. A reasonable approximation to random sampling can generally be achieved by selecting from a plan of workstations. However, if sampling is based on workstations rather than persons, rigorous care is needed to follow a plan and not to select only the workers who are present at the time of the first visit to the workstation. With any sampling strategy, a complete sample will only be obtained if those who are unavailable through absence or for other reasons are contacted at a later date.

Several common practical sampling designs are modifications of simple random sampling (Kalton 1983, Lee et al. 1989), as follows:

1. With systematic sampling, each n th element is selected after a random start in a list or a chosen route around the building.

2. Stratified random sampling classifies population elements (e.g., people) into strata (e.g., departments, job grades), and random sampling is then carried out separately from each stratum. This can be complex but may be useful to ensure an adequate statistical sample of any small population subgroups. Any mean values calculated for the building as a whole would then have to be corrected to take account of the overrepresentation of particular groups.
3. Multistage cluster sampling can be used when the population is very large, for example, an estate of many buildings. Clusters of elements are selected randomly in one or more stages (e.g., 5 out of 20 buildings, then half the floors on each selected building), and then at the final stage individuals are randomly sampled.
4. "Probability proportional to size sampling" would select, for example, a sample of rooms weighted by number of individuals in each room (i.e., the more people in the room, the more likely it is to be selected).

In general, samples should be balanced for workers near windows and near the center and on different faces and floors of the building.

The above approaches are all examples of *probability sampling*. Nonprobability sampling covers a variety of procedures, including the use of volunteers and other bases for choice of elements for the sample with the purpose that they are "representative" of the population (Kalton 1983). Of course, the weakness of all nonprobability sampling is its subjectivity. A sample of volunteers or a representative sample chosen by an expert can be assessed only by subjective evaluation, not by assumption free statistical methods.

Motivating the Respondents

Questionnaire studies can be perceived by busy respondents as wasting time, and they do not always understand the purpose of the survey. The loss of respondents from the sample is therefore a risk if proper care has not been taken, and this can have two consequences. First, there may be insufficient responses for satisfactory statistical analysis (particularly if there is a small sample to start with). Second, there may be biased sampling. In particular, people with more complaints may become overrepresented in the sample.

To achieve a reasonably representative sample, response rates of over 80 percent are needed from either whole building populations or from occupants randomly selected from a population. In practice it should be possible to achieve over 90 percent for a single survey (this can be difficult to maintain if repeated surveys are conducted of the same population at short intervals). The following paragraphs provide recommendations for recruiting and retaining a sample.

First, consider the demands to be made on the respondent, for example the length and complexity of the questionnaire, and the number of occasions on which it is to be completed. If the number of respondents is sufficiently small, a meeting could be held in advance of the survey; otherwise hold a meeting with representatives (possibly trade unions) and/or send a letter to the respondents in advance of the survey and/or in a letter accompanying the questionnaire when it is distributed. This exercise should seek to do the following:

- Convey the value of the study (this ought to be straightforward if the study may lead to remedial measures to improve the indoor environment).
- Explain the need to have the participation of everyone who has been selected.
- Make clear who is carrying out the study (e.g., independent researcher who is neutral to any conflicts within the building is likely to have an advantage).
- Make the information collected completely confidential and inform the respondent of this.

- Give a contact point for queries.
- Fix dates for feedback to respondents, especially the end of the study.

Direct social interaction can also be valuable by showing appreciation, understanding that they are tired and busy, and showing a presence. A few minutes dealing with a simple misunderstanding or objection can prevent nonresponse. Of course it is critical that the investigators do not actively influence the answers that respondents give in questionnaires: Social interaction should be kept at a moderate and professional level. This interaction should be achieved by delivering the questionnaire personally to each selected person and collecting the questionnaire a short time later. The questionnaire should be collected the same day if possible in case the respondent is absent the following day. On collection, the questionnaire should be briefly checked for any obvious errors and for completeness. Errors can then be corrected at this time, or the respondent can be encouraged to complete the whole questionnaire. It can be helpful to monitor nonresponses and, where possible, to understand the reasons for them. This may make it possible to reinstate a respondent or to avoid the nonresponse of others. Analysis of nonresponse is not necessary if the target of 80 percent is achieved.

Analysis

Definition of Outcome. Usually, ratings of environmental conditions are considered as independent scales. Symptoms of SBS are also sometimes treated as independent but often as all relating to a common phenomenon, which can be represented by an index or score based on all the symptoms. An intermediate approach is to use several indexes, based on hypothesized mechanisms or anatomic location of the symptoms. For example, Jaakkola (1986) calculated a score consisting of six components: skin, eye, nasal, pharyngeal symptoms, headache, and lethargy. A presence of one or more symptoms of each component during the past 7 days added 1 to that score (range 0–6).

The intensity or severity of the symptoms has rarely been considered in detail; however, see Jaakkola et al. (1991), Reinikainen et al. (1991), Berglund et al. (1990a, 1990b), and Lundin (1991) for studies of the frequency of symptoms over a longer time period.

Index or Score to Describe the Total Phenomenon. The principal measure to be obtained from the ROES questionnaire will normally be the sum of the building-related symptoms reported by each person, giving the person symptom index (PSI). The mean PSI of a random sample of building occupants is the BSI. The BSI can be used in one of two ways: for comparison with the OES database or for comparing over time using repeated surveys of the same building.

Eight symptoms are listed on the questionnaire; seven are listed in Table 53.1, and a final symptom (dry, itching, or irritated skin) has been added to the questionnaire since the OES, and comparison data are therefore not available. As the use of the questionnaire progresses, comparison data will be published. Of the remaining symptoms, two (itchy or watery eyes and runny nose) have been included to maintain comparability with the OES data and to avoid too many symptoms being entered under “other.” They are probably less relevant to SBS than the remaining five symptoms.

If the results from different buildings are being compared with each other or with the OES figures, it is recommended to use a BSI based on five core symptoms: dry eyes, blocked or stuffy nose, dry throat, headache, and lethargy or tiredness (Burge et al. 1993). Each symptom that a respondent experienced on at least two occasions in 12 months, and that was better on days away from the office, scores 1. Where a respondent has not marked either yes or no to the question about whether a symptom has been experienced, but has

TABLE 53.1 Percentage of Respondents Reporting the Occurrence of Each Symptom

Symptom	% Reporting
Lethargy	57
Blocked or stuffy nose	47
Dry throat	46
Headache	43
Itchy or watery eyes	28
Dry eyes	27
Runny nose	23

indicated that the symptom is better when away from the office, this can be counted as a building-related symptom and scored 1. All other responses score 0. The PSI_5 and BSI_5 will therefore range from a minimum of 0 to a maximum of 5.

Of the 46 buildings in the OES, the best 8 (all naturally ventilated) had a BSI_5 of less than 1.5 symptoms. This level can be regarded as indicative of minimal problems with SBS. The worst 13 buildings had a BSI_5 of over 2.5 (maximum 3.4), and of these, 11 were air-conditioned. This can be regarded as an action level, above which steps should be taken to reduce the BSI. Between 1.5 and 2.5 there is a case for taking action, but the levels are more open to interpretation, depending on the frequency of the symptoms, other health and safety problems in the workplace, and the degree of commitment to health in the workplace. The percentage of respondents reporting each symptom is shown in Table 53.1.

A case can be made for correcting the BSI_5 for gender and job category; this produces a basis for comparing buildings while reducing any bias that might be due to the particular people who happen to be occupying the building at the time of the survey. This is most easily done by applying weightings to the individual scores. Dividing a PSI_5 by the appropriate weighting will standardize the score to that which would be expected of a male manager. Care should be taken in interpreting corrected scores because part of the variance attributed to gender and job type may in fact be a result of nonrandom allocation of staff to working locations. For example, people in lower-paid, more routine jobs might have lower-quality accommodation and less power to get conditions changed. Uncorrected scores represent the building as it is, with its current occupants. Its meaning is therefore transparent, and it will normally be sufficient for most purposes. However, the same building could give a different score if occupied by a different population.

The BSI can be based on all eight symptoms on the questionnaire if comparisons within a particular building are being made. This may arise for example if the questionnaire is repeated at intervals as a monitoring procedure to determine whether good environmental conditions are being maintained. A different sample of respondents can, in such cases, be used on different occasions so long as the sampling procedure is the same. In such cases there is little advantage to be gained from adjusting scores for gender and job type. The results should be stable over time unless the environment has changed, given an interval of a year or more. Short intervals between surveys will reduce the BSI if the same respondents are used in each survey.

Interpretation of Environmental Ratings. There is no absolute interpretation of the ratings of environmental comfort. Each individual rating should be taken as what it is claimed to be: a subjective rating. This means that there are three major limitations on the interpretation of the ratings. A poor rating means that something is wrong with the environment, but

- The obvious interpretation is not necessarily the correct one (e.g., ratings of dry air can mean that the air is dusty or polluted with organic vapors, ratings of stuffiness can mean that it is too warm, and reports of offices that are too warm can be due to low air movement rather than air temperatures in excess of recommended levels).
- The suggested failing in the environment may well be present, but it is not necessarily related to SBS in the building.
- Symptoms could cause adverse perceptions of the indoor environment, rather than vice versa.

As a guide, some figures from the OES are given in Table 53.2. The mean is not necessarily the optimum, but it does give an indication of what can reasonably be expected.

Most of the scales are unipolar: One extreme is “good” and the other “bad.” In these cases, any score higher than the mean should be investigated further, and any figure more than one standard deviation above the mean should be a cause for concern. Three scales (temperature, air movement, humidity) are bipolar: Neither end of the scale is ideal, and a deviation above or below the mean of more than one standard deviation represents a cause for concern. In all cases, interpretation of the environmental ratings should be complemented by local knowledge of the conditions in the building and/or by objective monitoring of the indoor environment.

Ethical Considerations

Environmental change intended as treatment of subjects who have SBS may cause ethical problems for the researcher. In the laboratory experiment, the researcher may avoid the

TABLE 53.2 Means and Ranges of Environmental Ratings from the OES

Rating	Mean	S.D.

Control of		
Temperature	2.05	1.77
Ventilation	2.35	2.01
Lighting	3.31	2.39

ethical problems by exposing only voluntary subjects to known concentrations of specific pollutants for controlled periods. In field settings, the building occupants have to be fully informed about their participation in an experiment and about the possible consequences of the environmental change. Because the occupant's best interests have to be met by the scientific manipulation, what the researcher may accomplish will be restricted in field research. For ethical reasons the researcher should be able to reasonably well assure that the occupants are provided the best treatment by the planned environmental change.

Rothman (1986) lists a number of constraints that have to be considered for ethical reasons. One obvious constraint is that exposures assigned to occupants should be limited to potential preventives of disease or disease consequences, thus including SBS. Another constraint is that the exposure alternatives should be equally acceptable under present knowledge. A third constraint is that by being admitted to the study, occupants should not be deprived of some preferable form of treatment or preventive measure that is not included in the study. For example, it is unethical to include a placebo therapy measure (e.g., an unconnected ventilation inlet) in circumstances for which there is an accepted remedy or preventive measure.

Intervention Studies

The power of intervention studies has recently become more widely realized, but many attempts at this kind of research have been subject to methodological problems. The design of intervention studies has been discussed at length in a recent report (Berglund et al. 1996), which makes recommendations on minimum requirements for the study design, measurement procedures, assessment of outcomes and determinants, and data analysis.

53.5 CONCLUSION

Making sense of IAQ problems depends not on any single research finding but on putting together the right conceptual framework and using it in research that has been well designed and implemented. The following are necessary interrelationships among three important issues regarding SBS:

- The definition of SBS
- Diagnosis of SBS in specific buildings
- Establishing and comparing the prevalence of SBS in different buildings and contexts

This chapter has set out a definition that makes diagnosis possible and a diagnostic method that produces consistent and useful results. The method comprises both a questionnaire and a procedure for using the questionnaire; both are essential. The method is not unique, and an indeterminate number of other approaches might be taken. It is better to choose a single approach even if it is for no other reasons than that this particular approach has been tried and has produced a database of comparison figures. Against this conceptual framework, the benefits and methods of intervention studies have been described.

Future research and problem solving will need to be directed in an integrated and multidisciplinary manner to all stages in the life of the building and will need to cover the building itself (and its location), the indoor environment, the organizations that occupy buildings, and the needs of individual workers. There are many possible causes of complaints about IAQ, and they are interrelated and interactive, creating multifactorial problems that demand a multidisciplinary approach: a comprehensive view and systematic checking of possible problems, not a standard solution applied to all buildings.

APPENDIX: REVISED OFFICE ENVIRONMENT SURVEY¹

Office Environment Survey

This questionnaire concerns the environment in your office. It is being used as part of an evaluation of your working environment.

NEITHER THIS QUESTIONNAIRE NOR ANY INFORMATION FROM IT WILL BE PASSED TO YOUR EMPLOYER, EXCEPT AS AVERAGED AND ANONYMOUS DATA.

PLEASE ATTEMPT ALL THE QUESTIONS. DO NOT TAKE TOO MUCH TIME OVER YOUR ANSWERS. JUST GIVE YOUR INITIAL RESPONSE.

IT IS IMPORTANT THAT YOU RECORD YOUR OWN VIEWS, WITHOUT TALKING TO COLLEAGUES.

PLEASE READ THE FOLLOWING INSTRUCTIONS

- 1) Most questions ask you to select from a number of choices. For each of this type of question, please use **crosses** rather than ticks. E.g. ☐ ☒ ☐ ☐ ☐
- 2) When asked to write information into the blank spaces provided, please try to use **black ink, write clearly** and always use **block capitals**. E.g.
- 3) When box style spaces are provided, please write in **only one letter or number per box**. E.g.

A	N	E	X	A	M	P	L	E

¹This questionnaire remains the copyright of Building Research Establishment Ltd of Garston, Watford, Hertfordshire, WD2 7JR, United Kingdom, and is reproduced by permission. The right to use the questionnaire can be acquired by purchasing the questionnaire and guidance for its use, as provided in the following publication: 'Raw GJ ed. 1995. A questionnaire for studies of sick building syndrome. BRE Report Construction Research Communications, London.' Data collected using this questionnaire can be compared with the benchmark values provided in the publication only if the prescribed method of use is followed.

Personal Well-being

The following questions ask about your general well-being over the last 12 months.

Please mark a **cross** in the box representing your answer to each question. If you are undecided about your answer to any question, then please mark 'No' for that question.

You do not need to report the frequency of a symptom unless it was better on days away from the office.

In the past 12 months have you had more than **two** episodes of:

Dryness of the eyes

Please mark a cross in one box

Yes ☐

No ☐

If 'Yes', was this better on days away from the office?

Please mark a cross in one box

In the past 12 months have you had any other symptoms which you think are related to working in this building?						
Yes ☐		No ☐				
If 'Yes', please describe						

Environmental Comfort

This section of the questionnaire asks you to judge how comfortable you find your typical working conditions in the office in both winter and summer.

How would you describe typical working conditions in the office in **WINTER**?

If you have not worked in the office in the winter, then please leave these questions blank and go on to the questions about working conditions in the summer (on this page).

Please mark a cross in one box on each scale.

Temperature in Winter

Comfortable	1	2	3	4	5	6	7	Uncomfortable
	☐	☐	☐	☐	☐	☐	☐	
Too hot	1	2	3	4	5	6	7	Too cold
	☐	☐	☐	☐	☐	☐	☐	
Stable	1	2	3	4	5	6	7	Varies during the day
	☐	☐	☐	☐	☐	☐	☐	

Air Movement in Winter

Other Aspects of Your Office Environment

How much control do you personally have over the following aspects of your working environment?
Please mark a cross in one box on each of the following scales

Temperature	None at all	1 2 3 4 5 6 7	Full control
Ventilation	None at all	1 2 3 4 5 6 7	Full control
Lighting	None at all	1 2 3 4 5 6 7	Full control

Is the amount of privacy which you have at work satisfactory or unsatisfactory?
Please mark a cross in one box

Satisfactory	1 2 3 4 5 6 7	Unsatisfactory

How much do you like the following in your office?
Please mark a cross in one box on each of the following scales

Layout (e.g. furniture, space, storage, privacy)	Like very much	1 2 3 4 5 6 7	Do not like at all
Decor (including any plants, posters etc you might have added)	Like very much	1 2 3 4 5 6 7	Do not like at all

How would you describe the cleanliness of your office?
Please mark a cross in one box

Satisfactory overall	1 2 3 4 5 6 7	Unsatisfactory overall

Have you or your colleagues ever made requests for improvements to the heating, ventilation or air-conditioning in your office?
Please mark a cross in one box and give details

☐ Yes ☐ No

Brief details

If 'Yes', how satisfied were you with the following?
Please mark a cross in one box on each scale

Speed of response	Satisfactory	1 2 3 4 5 6 7	Unsatisfactory
Effectiveness of response	Satisfactory	1 2 3 4 5 6 7	Unsatisfactory

Have you or your colleagues ever made requests for improvements to other aspects of your office environment?
Please mark a cross in one box and give details

☐ Yes ☐ No

Brief details

If 'Yes', how satisfied were you with the following?
Please mark a cross in one box on each scale

Speed of response	Satisfactory	1 2 3 4 5 6 7	Unsatisfactory
Effectiveness of response	Satisfactory	1 2 3 4 5 6 7	Unsatisfactory

Background Information

How long have you been working in this building? <i>Please write in</i>	Years	Months	
How long have you been working in this particular office? <i>Please write in</i>	Years	Months	
How would you describe the type of work you do? <i>Please mark a cross in one box</i>	☐ Managerial	☐ Clerical/secretarial	
	☐ Professional	☐ Other _____	
	<i>Please describe</i>		
How old are you? <i>Please write in</i>	Years		
What is your sex? <i>Please mark a cross in one box</i>	☐ Male	☐ Female	
On average, how many hours per week do you spend in this building? <i>Please write in, to nearest whole number of hours</i>	Hours	On average, how many hours per week do you operate a VDU at work? <i>Please write in, to nearest whole number of hours</i>	
		Hours	
Are the windows in your room openable? <i>Please mark a cross in one box</i>	☐ Yes	☐ No	
How many people, including yourself, normally share the room or open-plan space where you work? <i>Please write in</i>			
Do you smoke while in the office? <i>Please mark a cross in one box</i>	☐ Yes	☐ No	
		Do others in your immediate environment smoke in the office? <i>Please mark a cross in one box</i>	
		☐ Yes	☐ No

Comments

Is there anything else you would like to say about your office environment? *Please write in*

CHAPTER 54

BUILDING-RELATED DISEASES

Michael Hodgson, M.D., M.P.H.

*U.S. Department of Veterans Affairs
Occupational Health Program
Veterans Health Administration
Washington, DC*

Building-related diseases (BRD) may be classified, among other ways, by mechanisms of disease, as is traditional in medical texts; by presenting symptoms, as is useful in the diagnosis and treatment of patients; or by source and etiologic agent, which are useful approaches in engineering and regulatory strategies. Some redundancy will occur in all three classification systems. This chapter will present diseases according to the first categorization (see Table 54.1).

Users of this text should remember the distinction between the sick-building syndrome (SBS) and what is often called building-related illness (BRI). The latter represent clearly recognized clinical conditions with operational criteria (i.e., medical conditions for which wide agreement exists on how to make a diagnosis). Even for these, though, there may be disagreement on individual diagnoses, on best treatment strategies (as even national consensus guidelines may fail to address adequately specific occupational or environmental health aspects of treatment strategies such as removal from work or the importance of exposure control), and on the true cause. On the other hand, the SBS remains a term without operational criteria. Although the epidemiology of building-related complaints has been described since the mid-1980s (Finnegan 1984, Kreiss and Hodgson 1984, Mendell 1993) and dose-response relationships have been recognized for over 10 years (Hodgson et al. 1991), few studies have examined the mechanism of symptoms in an epidemiologic context. Such attempts for eye and nasal symptoms will be described later. Nevertheless, Jaakola (1998) suggests that the term *SBS* currently represents a construct for discussion purposes only. As the mechanisms for the various symptoms, from odor and irritation through headaches and allergies, are clarified, researchers will characterize the nature and severity of the underlying conditions and support the use of diagnostic tests in the clinical diagnosis of individuals. Individual components of what is now labeled SBS may become building-related illnesses.

TABLE 54.1 Disease Categories

Disease	Symptoms	Mechanisms	Diagnostic Criteria
Rhinitis, sinusitis	Stuffy or runny nose; postnasal drip; sinus congestion; nosebleeds	Allergy (IgE)	Eosinophilic granulocytes in nasal secretions Specific changes on nasal provocation symptoms
		Irritation	None described
Allergic fungal sinusitis	Stuffy nose, postnasal drip, headache	Allergy (IgE), other?	CT-scan evidence of inflammation, eosinophilic mucous, fungal hyphae visible on staining
Asthma (airways disease)	Coughing, wheezing, shortness of breath, chest tightness	Allergy (IgE, IgG)	Airways hyper-reactivity (more than 15 percent change in FEV1) Reversibility of obstruction with bronchodilators
Hypersensitivity pneumonitis	Cough, shortness of breath, muscle aches, feverishness	Pharmacologic irritant	See above, history of exposure during onset of asthma
		Type IV allergy (cell-mediated immunity)	Granulomas on biopsy, reversible restrictive changes, (DL _{CO} , TLC, CXR), CT scan, thin-section CT scan
Organic dust toxic syndrome (inhalation fevers)	Cough, shortness of breath, muscle aches, feverishness	Endotoxin response (macrophage receptor based effect)	DL _{CO} , TLC, spirometry, white blood cell count elevations
Contact dermatitis (allergic)	Dry, itching, scaling, red skin	Type IV skin allergy	Inspection, skin biopsy, patch testing
Irritant contact dermatitis	Dry itching or weeping skin	Irritation	Inspection, skin biopsy
Contact urticaria testing	Red, irritated skin, hives	Type I allergy	Inspection, RAST or skin price
Conjunctivitis (allergic)	Eye irritation, dryness, tearing	Type I allergy	Inspection, RAST or skin prick testing, tear-film break-up time, conjunctival staining
Conjunctivitis (irritant)	Eye irritation, dryness, tearing	Irritation	Inspection, tear film break-up time
CNS toxicity	Headaches, cognitive impairment	Carbon monoxide VOCs	Elevated carboxyhemoglobin (COHgb) Abnormal neuropsychological tests
		Heat, noise	Calculated heat indices outside range; noise levels above comfort range

Diagnostic tests	Linkage strategies	Causes
Nasal secretions; eosinophiles CT scan for chronic inflammatory changes Acoustic rhinometry Rhinomanometry (anterior and posterior)	IgE-based: RAST or skin prick tests; nasal challenge symptom patterns	Sensitizers in the workplace (allergens) including molds, carbonless copy paper, photoactive processes (toners), and secondary exposures, e.g., cat dander brought to work on clothing; pesticides (OPs, pyrethrin)
None described	Symptom patterns	Irritant exposures, including cleaning agents, volatile organic compounds, dust, molds and bacteria, low relative humidity
Surgical tissue for eosinophilic staining in mucous, fungal bodies	Recurrences at work, same organisms in workplace	Bioaerosols at work
Physical examination Spirometry with bronchodilators Methacholine challenge Substance specific challenge See above As above	Temporal relationship of lung function decrements at work (PEFR, spirometry) Immunologic tests (skin prick tests, RAST tests) As above Clinical history	As allergic rhinitis irritant exposures, including cleaning agents, volatile organic compounds, dust, molds and bacteria, low relative humidity
Granulomas, restrictive changes in lung function in a convincing clinical setting	Physiologic linkage (acute disease: reversible patterns) Immunologic linkage: IgG exposure only; lymphocyte transformation to specific antigens	Molds and thermotolerant bacteria related to moisture
Bronchial lavage, DLCO, TLC, spirometry, white blood cell count elevations related to work	Temporal pattern and exposure documentation	Gram negative bacteria, molds, polymers in thermal degradation
Inspection, skin biopsy, patch testing	Patch testing, temporal pattern	Formaldehyde, molds, laser toners, Behenic acid (photoactive process)
Clinical history, "lactic acid application" ("stinger test")	Temporal pattern	Office products, VOC based
Clinical history, RAST test	Temporal pattern; RAST or skin prick test	Office products
Punctate conjunctivitis, shortened tear film break-up time, RAST or skin prick testing, cobblestoning on physical examination	Clinical impression	Molds, sensitizers
Inspection, tear film break-up time	Clinical impression	Irritants (VOCs, dust, low relative humidity), failure to blink at VDUs
Neuropsychological tests, COHgb levels	COHgb > 3% in nonsmokers, > 8% in smokers	Fossil fuel sources: Home—attached garages, backdrafting appliances, barbecues; commercial/public buildings—entrained exhaust, indoor CO sources
Abnormal neuropsychological tests	Abnormal neuropsychological tests	Imbalance between local VOC source and exhaust ventilation
None	Clinical impression	Inadequate control strategies

TABLE 54.1 Disease Categories (*Continued*)

Disease	Symptoms	Mechanisms	Diagnostic criteria
Legionnaire's disease	Coughing, phlegm production, fevers	Legionella exposure, susceptible host	Four-fold rise in antibody titers, culture of same Legionella strain from source as from tissue, epidemiologic clustering
Tuberculosis	Coughing, phlegm production, fevers, weight loss	Infection with Mycobacterium tuberculosis	Isolation of organisms, positive skin test with typical chest x-ray pattern

FEV1 = forced expiratory volume in the first second, PCR = polymerase chain reaction-based lab test, RAST = radioallergosorbent test, DL_{CO} = single breath carbon monoxide diffusing capacity, TLC = total lung capacity, CXR = chest x ray, and PERF = peak expiratory flow rate..

54.1 GENERAL APPROACHES

Diseases related to indoor environments are treated no differently than are conditions potentially related to other environmental and occupational exposures (see Table 54.2). The basic approach includes the following steps:

- Document disease
- Document exposure
- Define linkage (or exclusion) criteria
- Develop a management plan

For reasons described below, this approach has not been as successful in indoor environments as elsewhere, and the scientific basis for this approach is often still missing.

Document Disease

Physicians and other health care providers make a diagnosis of a condition based primarily on symptoms. Over 75 percent of conditions encountered in primary care need no further documentation (Peterson 1992). In fact, for many there is little objective evidence on an individual basis. In the setting of lawsuits and workers compensation proceedings, physicians are often asked to provide "evidence." It is therefore important to seek objective signs on physical examination and measurements of abnormal organ function in laboratory testing, which can often be found. Even then, a few patients with symptoms will have evidence of some physiologic or immunologic process without meeting a set of diagnostic criteria for any specific condition.

At times, even in symptomatic patients, tests are negative. That all tests may have false negative results is a fundamental truth, defined in the relationships of sensitivity, specificity, and predictive value. As a test identifies a greater proportion of individuals correctly as having a specific outcome, it also identifies more individuals without those characteristics. As tests are more precise, and identify fewer "false positive" results, more individuals with the condition are missed. In the absence of economic conflicts, physicians feel very comfortable ignoring unexpected and unlikely results. In the setting of workers compensation proceedings and litigation, where economic outcomes are implicit, physicians are often at a loss to explain their reasonable approaches. Elsewhere, evidence-based medicine seeks

Diagnostic tests	Linkage strategies	Causes
Fourfold rise in antibody titers, culture from human samples, epidemiology	Same organisms from putative source and from patient, clinical pattern	Aerosol dispersion, aspiration
PCR similarity between organism from patient and from source	PCR similarity between organism from patient and from source	

consensus from a broad range of published literature to establish diagnostic and treatment guidelines. Such literature is often still missing for diseases related to indoor environments, as it is for much of occupational and environmental disease. This chapter will focus primarily on the management of building-related diseases and provide evidence where we recognize it.

Document Exposure

The discipline of industrial hygiene grew out of physician's needs to understand the exposures that made their patients sick and of engineers' need to evaluate the control strategies underlying engineering processes. Since the early part of this century, a major goal in the field has been the definition of *limits*, criteria levels below which no adverse health effects were likely to occur. Setting such limits had as a consequence the development of evaluation methods, later also used for enforcement. Table 54.2 represents a compilation of exposure levels commonly used for the traditional occupational environment, for ambient environmental conditions, and for indoor environments. For building-related diseases, the exposures remain poorly defined for three reasons.

First, the specific pertinent component remains unknown for many agents. Therefore, in hypersensitivity pneumonitis, it is unclear whether to measure for fungi with viable samplers (using culturable agents as the outcome), spore traps (using visible spores), immunological testing (in the absence of knowing which antigen), or biological assays such as endotoxin (which may trigger existing diseases without being the true cause). Second, even for diseases as clearly linked to environments with physiologic testing as hypersensitivity pneumonitis and asthma, the correct analytical methods are unclear. Because it is unclear whether only culturable (viable) particles are important for sensitization to fungal agents, and which components of other antigens, such as dust mites, are important, the appropriate analytical methods are unclear. Third, the best sampling approaches remain undefined. The exposures required for sensitization (duration, intensity, specific agent, and cofactors) or triggering of attacks are generally unknown, despite universal beliefs about the importance of dose-response relationships.

Similar considerations arise for the spectrum of volatile organic compounds, for noise and vibration, and for other exposures in the indoor environment. For this reason, traditional industrial hygiene approaches (identification of the primary pollutant of concern, quantitative assessment, and comparison with a criterion level) have uniformly been unsuccessful in solving problems in the indoor environment. The evolution of building sciences

This table was prepared with Hal Levin for an appendix of Standard 62 ("Ventilation for Acceptable Air Quality") and Guideline Project Committee 10 within the standards development process at the American Society of Heating, Refrigerating and Air-Conditioning Engineers.

[] Numbers in brackets refer to either a ceiling or to averaging times of less than or greater to 8 hours (m = minutes, h = hours, y = year, C = ceiling, L = long-term). Where no time is specified, the averaging time is 8 hours.

^aThe values summarized in this table include the following:

- *Canadian*. Recommended maximum exposures for residences developed in 1987 by a committee of Provincial members convened by the federal government to establish consensus, "guideline"-type levels. A revised version is being considered. These were not designed to be enforceable. They were designed explicitly for the residential environment.
- *WHO/Europe*. Environmental (nonindustrial) guidelines developed in 1987 by the WHO Office for Europe (Denmark).
- *NAAQMS*. Criteria for outdoor air developed under the Clean Air Act by the U.S. EPA. The guidelines must, by law, be reviewed every 5 years, although this does not always occur. These levels are ostensibly selected to protect most sensitive individuals. Exposure level may vary by duration of exposure. Sensory irritation was not a consideration in establishing levels.
- *NIOSH*. Recommended maximum exposures for industrial environments developed by NIOSH (Centers for Disease Control). NIOSH criteria documents contain both a review of the literature and a recommended exposure guideline. Sensory irritation was not a consideration in establishing levels. These are not enforceable and not reviewed regularly. These levels are not selected to protect most sensitive individuals.
- *OSHA*. Enforceable maximum exposures for industrial environments developed by OSHA (U.S. Department of Labor) through a standard setting process. Once a standard has been set, levels can be changed only through reopening the rule-making process. These levels are not selected to protect most sensitive individuals. Sensory irritation was not a consideration in establishing levels.
- *ACGIH*. Recommended maximum exposures for industrial environments developed by ACGIH's Threshold Limit Values Committee. The committee reviews the scientific literature and recommends exposure guidelines. The assumptions are for usual working conditions, 40-hour weeks, and single exposures. These levels are not selected to protect most sensitive individuals. Sensory irritation was not a primary consideration in establishing levels.
- *MAK*. Recommended maximum exposures for industrial environments developed by the Deutsche Forschungsgemeinschaft, a German institution akin to the National Academy of Sciences and Institutes of Health, without regulatory powers. Levels are set on a regular basis, with annual reviews and periodic republication of criteria levels. These levels are enforceable in Germany. These levels are not selected to protect most sensitive individuals. Sensory irritation was not a consideration in establishing levels.
- *SMA-C*. Spacecraft Maximal Allowable Concentrations were developed by a Committee of Toxicology convened by the National Academy of Sciences. They were developed for prolonged exposure periods with consideration of continuous (24 hours per day) exposure. The Committee Report was funded by NASA.

The four major questions to be considered in relying on the data from this table are as follows:

- Does the standard aim to prevent the effect of concern in the setting in which it is being used?
- Does the standard recognize the presence of susceptible groups or address the "normal" population?
- Are interactions between various contaminants of concern considered?
- Are the assumptions and conditions set forth by the standard met (such as 8-hour day, 40-hour workweek)?

At times, the selection of a specific target level is best made by a team with wide experience in toxicology, industrial hygiene, and exposure assessment.

^bTarget level of .05 ppm because of its carcinogenic effects. Total aldehydes limited to 1 ppm.

^cAs one example, readers should consider the applicability of carbon monoxide concentrations. The concentrations considered acceptable for nonindustrial, as opposed to industrial occupational, exposure are substantially lower. This is due to the recognition that individuals with preexisting heart disease may develop exacerbation of heart disease at levels below 15 ppm.

^dMMAD = mass median aerodynamic diameter in microns (micrometers). Less than 2.5 μm are considered respirable; less than 10 μm are considered inhalable.

^eNuisance particles not otherwise classified, not known to contain significant amounts of asbestos, lead, crystalline silica, known carcinogens, or other particles known to cause significant adverse health effects.

^fThe U.S. EPA has promulgated a guideline value of 4-pC/VL indoor concentration. This is not a regulatory value but an action level where mitigation is recommended if the value is exceeded in long-term tests.

^gNot to be exceeded more than once per year.

has led to the need to review building plans, initial design and construction logs, commissioning strategies, operations and maintenance logs, and renovation work in an attempt to identify likely sources associated with the outcome of concern.

Linkage

Linkage between diseases and exposures may occur on the basis of three theoretical considerations (Brennan 1987). The presence of all three is most convincing, but lesser evidence suffices for most purposes.

Epidemiology. Epidemiologic linkage criteria are widely recognized (Bradford Hill 1965). Nevertheless, they presuppose that adequate numbers of epidemiologic investigations have been completed, using the outcome of interest as an endpoint, and that these measured the pertinent exposures. Such epidemiologic evidence exists to support the association of nonspecific symptoms such as headaches or mucosal irritation with large office buildings or with formaldehyde offgassing from ureaformaldehyde foam insulation. It generally does not support more serious conditions such as asthma or hypersensitivity pneumonitis.

Toxicology. Linkage based on toxicologic considerations assumes the presence of research generally conducted on animals, usually with markers of exposure and effect. Most toxicologic documentation relies on some marker of exposure or effect, validated on an individual level, which exists only for infectious disease, carbon monoxide, and some pesticides. These allow treating physicians to document the same effects and markers in humans. For some rare phenomena, such as headaches associated with carbon monoxide poisoning, pesticide poisoning after misapplication, or hemorrhagic pneumonitis after exposure to *Stachybotrys chartarum* and *Aspergillus versicolor*, at least some mechanistic evidence exists, either in animal or in human studies. Other effects, such as formaldehyde causing irritation, are easily recognized. Still, in individual cases, linkage is difficult.

Clinical Models. Finally, in the absence of generalizable evidence, clinical findings may be quite persuasive. The use of lung function tests to document worsening of disease in a specific environment, such as is possible in asthma, may be quite persuasive to physicians even though professionals from other disciplines may fail to understand the significance of such results. Such approaches have been used for unusual conditions for which no other linkage strategies are available.

Clinical Practice: The Sentinel Events Model. A fundamental belief of practitioners of occupational and environmental medicine is that single cases of disease related to an exposure represent *sentinels*, markers for an exposure, an exposed group that requires follow-up, and a cause that may be remediated. The *sentinel health events* mode of practice is fundamental to the good practice occupational and environmental medicine. Failure to seek further cases of disease in this setting is considered inappropriate practice.

As discussed under exposure assessment, once dose-response relationships and sampling strategies have been defined clearly for specific exposures, practitioners may use measured levels to develop knowledge of causal relationships. In the built environment, practitioners must rely on checklists, understanding of complex systems and their design and operations problems, and maintenance failures to interpret symptoms and diseases. Often, this leads to outbreak investigation approaches of screening for similar disease in a population, comparison of symptom or disease rates in a control population, and attempts to approximate exposure differences or surrogates for likely mechanisms of disease.

Management Plans

Standard medical treatment exists for many of the diseases attributed to indoor environments. Infections such as tuberculosis or Legionnaire's disease must be treated with antibiotics. Asthma usually requires medical treatment with anti-inflammatory agents. Mucosal irritation may benefit from local treatment. In parallel to medical treatment (i.e., of the affected individual), treatment involves some considerations of exposure control, either through removal from work or through workplace intervention (Bracker 1999). Decisions to remove individuals from further exposure are appropriate to support symptomatic improvement, to prevent acute attacks of a disease, and to prevent long-term progression of disease.

The medical and scientific literature suggests that the psychological components of disease are as important in clinical improvement, rehabilitation, and return to work as objective measures of organ function. A first major step for all health care providers is then the "negotiation" with patients about disease for clinical improvement. The usual steps in a sometimes complicated dance are as follows:

- Showing respect
- Educating the patients
- Negotiating around differing sets of beliefs
- Defining obstacles
- Agreement on a plan

In the absence of these steps it is unlikely that, at least in subjectively severe cases, patients will improve dramatically, even if their objective evidence of disease resolves. The first step is often simply the expression of sympathy and the willingness to listen to the patient's story. Cutting off the story line, interrupting the patient early on, and downplaying the severity of the problem are likely to impede a strong relationship.

After completing the more traditional medical activities (history taking, physical examination, lab testing, obtaining a diagnosis), physicians must educate patients. During such discussions, the knowledge of exposures, systems, dose-response relationships, causal relationships, and the limits of knowledge and uncertainty must be addressed. Often patients will have read widely and sometimes have belief systems that differ from the traditional scientific approaches of physicians. When conflicts in belief systems cannot be resolved, providers and patients must negotiate a strategy to move forward despite these beliefs. This may identify obstacles that may be resolved in the course of discussions with other involved parties.

The implementation of environmental solutions to indoor environmental problems may require participation of additional parties: landlords, building owners or managers, maintenance contractors, cleaning personnel, school boards, and other groups with little familiarity with health considerations. Each of these may have a personal and differing set of beliefs that requires a process similar to the one outlined above. Developing a management plan requires disseminating information appropriately, developing consensus (or defining the level by which a solution may be forced), and documenting the benefits of solutions.

In general, communication strategies that avoid laying blame, that offer solutions, and that suggest mutual ownership of the problem are most helpful. Obtaining as much certainty about the actual cause of disease as possible, for example through dynamic physiologic testing, allows health professionals far greater certainty in their initial contacts with employers, building owners, and other nonmedical personnel. Such greater certainty appears to be associated with the greater likelihood of persuading those parties of the severity of the problem, of the credibility of the professionals involved, and of the likelihood of successful intervention.

54.2 LUNG DISEASE TESTING

Several tests may be used for lung disease. These include spirometry, which measures the amount of air exhaled in timed volumes. Forced vital capacity (FVC) is the total amount of air breathed out, and forced expiratory volume in the first second (FEV₁) is the timed volume after 1 second. Their ratio (FEV₁/FVC ratio) represents a better indicator of airways obstruction (asthma, chronic obstructive pulmonary disease), that is, blockage in breathing out, than the FEV₁ alone. A flow-volume loop measures forced in- and expiratory maneuvers and can distinguish an obstruction in the chest (e.g., asthma) from upper airways obstruction (e.g., laryngeal spasm associated with hoarseness and laryngitis).

Lung diffusing capacity (DL_{CO}), measured in several different ways, can document the decreased ability of the circulation to transport oxygen efficiently and is most commonly used as an indicator of oxygen diffusion across the lungs. Static lung volumes, total lung capacity (TLC), and functional residual capacity (FRC) are taken as evidence of reduction in the amount of air in the lung, as occurs in diffuse inflammation and stiffening of the lung tissues.

Measured values are compared with a set of normal values, obtained from large groups of individuals (of which there are approximately 20 different sets), taking into account gender, age, height, and, sometimes, ethnic derivation because of anthropomorphometric differences. For all of these, common clinical usage holds that results of less than 80 percent of that predicted represent likely clinical abnormalities. As results approach 70 percent of that predicted, that certainty grows. Decreases in FVC, DL_{CO}, TLC, and FRC are used as indicators of the restrictive lung disorders; decreases in FEV₁ with a preserved FVC or FEV₁/FVC ratios are taken as evidence of obstructive disease.

Dynamic comparison of such tests may be undertaken in the laboratory or in the field. Provocation with nonspecific irritants, such as methacholine, may document airways hyperreactivity (twitchiness), usually considered evidence of asthma. Specific provocation with immunologically active agents, such as bioaerosols, may be used to document asthma or hypersensitivity pneumonitis, although such undertakings are often quite expensive. This assumes one has identified the correct antigens. Similarly, evaluation of lung function before and after exposures at work, whether on a single day, single week, or several weeks, is useful to document associations when no specific agent has been identified, purified, and characterized.

54.3 INTERSTITIAL LUNG DISORDERS

The interstitial lung diseases (ILDs) occur at a prevalence rate of about 70 per 1,000,000 persons and an incidence of 30/1,000,000 person years (Coultais 1994). Less than 3 percent of these represent hypersensitivity pneumonitis (HP), the disease most clearly associated with moisture and mold and widely acknowledged as the most likely disease to be building related when it occurs. Approximately 5 percent of these represent other work-related ILDs, such as asbestosis and silicosis, 5 percent represent sarcoidosis, and the remaining 80 percent represent diseases with recognized clinical characteristics but unknown causes.

Hypersensitivity Pneumonitis

Since the report of Fink (1971), hypersensitivity pneumonitis has been recognized as a consequence of contaminated ventilation systems. Outbreaks are associated with moisture in

large buildings (Anonymous 1984) and with moisture in the home (Kreiss and Hodgson 1984). Population-based data suggest that between 1 and 4 percent of randomly selected office workers describe symptoms consistent with hypersensitivity pneumonitis, also consistent with organic dust toxic syndrome (ODTS, discussed later).

The disease occurs on the basis of cell-mediated immunity, although several other components such as cytotoxicity may play a role. The disease may present in two different temporal patterns and varying degrees of severity. It may present acutely, with feverishness, chills, muscle aches, and chest symptoms of coughing and shortness of breath, often resembling an infectious pneumonia. This pattern generally leads to the recognition of a specific exposure. On the other hand, patients may present with insidious onset of fatigue and some shortness of breath without coughing.

As the disease grows more severe, patients generally feel more ill. Cases have been documented with lung biopsy after patients simply felt very tired and nauseous, with chest symptoms arising only on strenuous exercise (Rose et al. 1998). Such disease is almost always completely reversible. On the other hand, patients may present with an acute pneumonia requiring hospitalization in intensive care units and may undergo biopsy, documenting characteristic lesions. Repeated episodes, and persisting exposure, are associated with worse prognosis, including with long-term persisting decreases in lung function. Once fibrosis is evident on chest x ray, full recovery is unlikely.

Differing clinical traditions held that all patients with interstitial lung disease require a biopsy, if only for the determination of prognosis, whereas others have felt comfortable with clinical tests alone. With the spread of managed care, biopsies appear to be undertaken less frequently. This controversy has increased as more recent outbreaks have identified disease earlier on biopsy without any objective evidence of disease on usual clinical tests.

The usual clinical tests include spirometry, lung volumes, and lung diffusing capacity for documentation of physiologic abnormalities; chest x rays (CXR), gallium scanning, and thin section (high resolution) computerized tomography for imaging (HRCT); and bronchioalveolar lavage (BAL) and lung biopsies for documentation of anatomic characteristics and inflammatory markers. The characteristic physiologic abnormalities include decreased FVC, DL_{CO} , TLV, and FRC. Early on, patients may have evidence of abnormalities only on exercise testing (treadmill). When disease is clinically severe, almost all patients will show abnormalities. When disease is identified early, before irreversible scarring has occurred, such tests are often still normal. Characteristic abnormal results on imaging include diffuse uptake on gallium scanning, ground glass appearance on HRCT, and alveolar and interstitial changes on CXR. HP is increasingly recognized without abnormal CXRs (Hodgson 1989, Lynch et al. 1992, Rose et al. 1998), HRCTs (Lynch et al. 1992, Rose 1998), or gallium scans (Lynch et al. 1992). Transbronchial biopsy remains the gold standard of diagnosis, but up to 10 forceps bites may be needed for an identification rate of over 90 percent. Antibody testing (IgG) is often undertaken but has been shown to have very little utility (Burrell and Rylander 1981) in the diagnosis of disease although it is often considered a reasonable marker of exposure.

Diagnostic Strategies/Linkage. After an initial history and physical examination, appropriate tests may suggest the presence of disease. Physicians are then left with the question of how to link disease to exposure. This often occurs through temporal linkage. A first step may be to evaluate individuals' ability to return to work with a trial of removal and reexposure because this may show work-related decrements. Individuals may demonstrate major improvement in lung function even when tests are within the normal range when exposure ceases, so following tests dynamically over time appears useful. The presence of potential sources at work or at home makes this more likely (Table 54.3). Some authors find antibody testing useful despite old scientific literature documenting its frequent futility.

TABLE 54.3 Causes of Hypersensitivity Pneumonitis

Roof leaks (membranes, flashing)
Below-grade moisture incursion
Wall penetration

Prognosis and Surveillance. Often, patients have been unable to return to work (or their home) even after intervention that appeared successful based on disappearance of visible bioaerosols. It remains unclear whether more rigorous cleaning would solve such problems or whether buildings have some ecological characteristics that lead to the persistence of antigens. Few data have attempted to follow actual exposures, symptoms, and recurrence in buildings.

At times patients have been able to return to the offending location. No long-term studies document that this may occur without deleterious consequences. It is therefore worth implementing a formal surveillance program in an attempt to document recurrence persistence of recovery. In general, symptoms are likely to recur if patients' disease recurs. Greater reliance should be placed on symptoms than on objective testing, particularly as diffusing capacities and lung volumes tend to be far more variable than spirometric indexes.

Long-term disability evaluation follows standard clinical practice. In general, exercise testing is the most suitable objective test for the documentation of residual abnormalities.

Other Forms of ILD

Increasing evidence suggests that other forms of interstitial lung disease may be associated with work in buildings. For each there is anecdotal evidence, either in case reports or in outbreaks of disease. Only for asbestosis is there planned, generalizable research.

Asbestosis. Cases of asbestos-related interstitial lung disease (i.e., asbestosis) are associated with work indoors for electricians, plumbers, carpenters, and other building trades. These exposures are no different than for similar occupations working outside of public access buildings. Teachers and other building occupants, such as children, who have no sustained contact with disturbed asbestos are usually not considered at risk. Two recent reports suggest that there may be very rare exceptions to this rule (Anderson et al. 1991, Lilienfeld 1991).

The diagnosis of asbestosis is made on the basis of long-standing (i.e., usually years of daily exposure) exposure to asbestos and evidence of interstitial lung disease on radiographic studies. Although lung biopsy will show characteristic asbestos bodies or provide fiber counts indicating substantial exposure, these are usually considered unnecessary.

Sarcoidosis. In general, sarcoidosis is thought likely to have some identifiable etiology (Newman et al. 1996). Evidence of moisture in basements (musty odor or floods) or mold

growing on bathroom walls is associated with sarcoidosis (Ortiz 2000). Recent reports of HP, initially diagnosed as pulmonary sarcoidosis (Thorn 1997, Forst 1994) have suggested, as have prior studies, some difficulties distinguishing these sarcoidosis from hypersensitivity pneumonitis in clinical practice.

Usual Interstitial Pneumonitis. Usual interstitial pneumonitis (Mullen et al. 1998) may be associated with moisture in basements. Additional case-control studies have suggested that ILDs are associated with exposure to a range of bioaerosols, including wood, grains and hay, and farm animals (Iwai 1992, Scott 1991, Baumgartner 2000). At least one case report of nonspecific interstitial pneumonitis, distinct from HP, associated with a myopathy and antibody responses similar to HP, has been attributed to *Aspergillus* exposure (Lonneux et al. 1995).

Organic Dust Toxic Syndrome. Some evidence exists that office workers may develop yet another form of interstitial pulmonary response, possibly more frequently than commonly assumed, called an *organic dust toxic syndrome*, the same disease as humidifier fever. Beginning with C. A. C. Pickering's search for humidifiers as a cause of symptoms among office workers (Finnegan 1984), excess rates of chest tightness and flulike illness have been seen in buildings with humidification (Finnegan et al. 1984), HVAC systems with water (Burge et al. 1987), and buildings with moisture problems (Sieber 1997). Data from a Dutch study of office workers suggested a tripling of symptom rates associated with a tenfold increase in airborne endotoxin concentrations (Teuw and Vandenbroucke 1994). A reanalysis of several older data sets (Apter et al. 1997) suggested that a symptom cluster of chest tightness, difficulty breathing, and flulike illness was distinct from those of mucosal irritation, central nervous system symptoms, and skin irritation. Although this syndrome is considered benign and self-limited, there is some evidence for impairment of lung function after long-term exposure or more severe illness (Milton 1966, 1996, 1997).

54.4 ALLERGIC AIRWAYS AND UPPER AIRWAYS DISEASE

Asthma

Between 5 and 8 percent of the U.S. population have asthma. In adults, about 20 per 100,000 persons will develop new onset asthma from their workplace (Milton 1998) and at present approximately 15 percent of these (between 0.5 and 1 percent of the U.S. population) are thought to have occupational asthma (Venables and Chan-Yeung 1997). According to reports to the Health Departments in Michigan and Massachusetts (Kreiss 1999), where occupational asthma is a reportable disease, about 20 percent of work-related asthma reported in the last years appear related to buildings relying on SENSOR criteria (Matte et al. 1990). Only one outbreak of building-related asthma has been described (Hofman et al. 1993). Jajoski et al. (1999) suggest that approximately 10 percent of work-related asthma reported to state departments of health in 1992–1993 was attributed to office buildings. More recently, substantially greater proportions appear to be building related (Gassert et al. 1998). Nevertheless, in support, in a recent series of NIOSH building investigations, chest symptoms appeared related to specific aspects of buildings operations including moisture and dirt and debris in the ventilation system (Sieber et al. 1996). This suggests that building-related asthma may in fact be much more common than recognized.

Because linkage strategies for asthma are well developed, such reports can be rigorously evaluated. In addition to a careful history, the primary linkage rests on documentation of temporal relationships. Initial onset or recurrence of asthma after beginning work in a building, or exacerbation of previously stable asthma, may lead to suspicion of work relatedness. Linkage relies on examination of lung function at and away from work. Although peak expiratory flow rates are relatively easy to collect, they are often thought to produce insensitive (high rates of false-negative tests) results. Spirometry is the preferred technique but is often difficult to collect because of accessibility primarily through physicians' offices. Commercially available portable diarying spirometers have recently become available and facilitate the collection of longitudinal data before, during, and after work to identify patterns of exacerbation at work and improvement over weekends. Although changes of 15 percent are considered diagnostic of asthma in laboratory settings, many physicians pursue further diagnostic testing with decrements of greater than 5 percent in the course of a day.

The standard calculations for population attributable risk (or etiologic fraction) suggest that the population-attributable risk of asthma ranges from 13 to 26 percent for moisture in buildings, including homes and work places. Lost work time does not enter into such calculations. In fact, very few cases of occupational asthma related to buildings are recognized as such. Nevertheless, a Swedish study of office workers (Toren et al. 1991) suggested that those cases die more frequently of asthma than does the general population. Premature mortality costs are also not covered in direct medical benefits. Nevertheless, a follow-up study did not confirm this elevation. That means that of the \$4 billion to \$6 billion in annual medical costs, about \$.52 billion to \$1.56 billion of direct medical costs may be related to buildings. See Chapter 4 for a more complete discussion of indoor air quality health cost.

Allergic Rhinitis

Twenty to 30 percent of the U.S. population has complaints of a stuffy or runny nose, approximately half thought to be allergic rhinitis and some proportion of these are chronic irritation. Although the disease is clearly recognizable, no good linkage strategies have been developed for clinical use. Such symptoms among office workers are meanwhile thought to reflect both allergy and simple mucosal irritation. Few data allow estimation of a specific fraction due to either. Menzies et al. (1998) suggested that only 1 percent of nasal symptoms represented an allergic response to the work environment, although in general 20 to 30 percent of office workers describe regular nasal symptoms, and of these half appear at least temporally work related (Malkin et al. 1998).

Studies of the upper respiratory tract suggest that at least some measures of effect, including cells in nasal lavage fluid, physiologic changes in the nose, and biopsy evidence (Koren et al. 1992, Ohm et al. 1993, Ohm and Juto 1993, Willes et al. 1992, Mølhave et al. 1993), are present when sought with sophisticated techniques. Similarly, challenges with specific substances are well known and widely accepted as accurate, although they are rarely performed and not widely available clinically.

Individuals with atopic rhinitis often describe mucosal irritation in the office environment. It is clear that they experience irritation at lower levels of exposure than do nonatopics in controlled clinical trials (Kjaergard et al. 1985). In addition, their irritation thresholds may be substantially lower (Shusterman et al. 1998) even when they are not acutely ill. Whether this results from residual inflammation or represents some intrinsic characteristic of atopy remains unclear.

The direct medical costs for allergic rhinitis are estimated at \$1.8 billion (Malone et al. 1997). People with allergic rhinitis may lose several days of work per year or, for the period

when they are symptomatic, have decreased productivity. Recent data suggest that at least some of this lost productivity may result from the choice of medications (Cockburn et al. 1999). Under the assumption that half of these cases are associated with work, based on questionnaire surveys, and under the assumption that these are associated with moisture indicators, population-attributable risks suggest an etiologic fraction of less than 6 percent for the workplace.

At present, no specific diagnostic techniques have been described to link such disease to the workplace. It is possible to use the techniques outlined above to document changes at work, although the implementation of such studies is likely to be difficult for some techniques. One recent attempt to use acoustic rhinometry raised the question of allergies to cockroaches and molds being risk factors for work-related decrements in nasal function (Apter et al. 1997). Striking in that study was the rarity with which subjects who described work-related nasal symptoms actually described changes in nasal symptoms on a Monday at work.

Allergic Fungal Sinusitis

Allergic fungal sinusitis is a third form of nasal disease that is at least potentially related to indoor environmental exposures. The frequency is at present unclear. Diagnosis is made through documentation of mucosal thickening on CT scan or other primary diagnostic procedures, the documentation of eosinophilic mucin in sinus drainage or biopsy material, and the presence of fungal organisms in those same materials (deShazo et al. 1997). Although the syndrome has been defined, no cases have been documented in the scientific literature as occurring because of exposures in the built environment. It is unclear whether fungal species present in the indoor environment are more likely to cause such disease or whether exposure in the workplace is any more likely to cause such disease than exposures elsewhere. The organisms associated with such disease, primarily *Aspergillus* species, are thought to occur more frequently where moisture problems occur indoors.

54.5 MUCOSAL IRRITATION

The presence of symptoms alone is often unpersuasive as the basis for economic decisions, both in the clinical and the regulatory setting. The term *nonspecific symptoms* has been used to refer to such symptoms, implying the lack of specific mechanisms. This fails to acknowledge the distinction between irritant and allergically induced symptoms. In clinical settings, markers used in the diagnosis of mucosal irritation include decreased tear film break-up time, as an indicators of dry eyes, and punctate conjunctivitis, documented with lissamine green or fluorescein staining. In addition, in epidemiologic studies, fat foam thickness or canthal foam represent markers of susceptibility, markers of chronic effects, or mechanisms of disease that remain unclear. If these markers do not represent acute effects, they cannot be used in clinical linkage strategies. Punctate conjunctivitis, documented with lissamine green or fluorescein staining, represents an acute effect. Irritation is discussed in Chaps. 17, 25, and 26.

Eye irritation is a common complaint among office workers and is thought to be by some the primary driver for interest in office worker complaints. The studies on mucosal irritation over the last 15 years by two groups of investigators are meanwhile well known.

The work by Cain and colleagues (Cain 1996) has documented the predictable effects of volatile organic compounds on the irritant receptor in the eyes and nose. Complex mixtures of such agents are likely to cause more symptoms than are individual agents at low levels. Quantitative structure activity relationships suggest a predictable, dose-dependent

effect (Abraham 1996), at least for nonreactive, or relatively inert, compounds. This suggests that mucosal symptoms among office workers may represent simple irritation by commonly encountered volatile organic compounds.

Work by Franck, Kjaergard, Skov, and Mølhave (Kjaergard 1992) suggests that complaints of eye irritation are measured reliably by different questionnaires, that there are physiologic indicators of eye irritation, and that at the very least subjects with those markers are at greater risk of eye irritation than subjects without. A primary hypothesis of this group of investigators is that volatile organic compounds indoors may change the physical characteristics of tear fluid and allow irritants to reach the mucosal surface in greater concentrations. See Chaps. 17 and 25.

The work by Cain and colleagues (Cain 1996) has shed more light on the consideration that mucosal symptoms may represent simple irritation by commonly encountered volatile organic compounds. Individual agents are therefore clearly shown to have an irritant threshold, usually two to four orders of magnitude below established criteria such as Permissible Exposure Levels (PELs) set by the Occupational Safety and Health Administration, the American Conference of Governmental Industrial Hygienists, or other standard setting bodies. (See Chap. 20.)

Diagnostic steps may include examination of the eyes using a slit lamp and the instillation of staining materials to determine dry eyes and punctate conjunctivitis. Limited clinical interventions are possible. A first important step is the explanation of the mechanism by which such symptoms arise. Second, the use of artificial tears often provides symptomatic relief. Finally, some limited evidence suggests that better cleaning, with lowering of particle levels, and humidification, especially where humidity levels are below 30 percent, may be helpful. Where bioaerosol contamination has been identified, remediation is appropriate.

54.6 HEADACHE

Headaches are a common complaint among office workers, often associated with subjective loss of productivity (Schwartz et al. 1997, 1998). Although attribution to buildings is a common approach, it is generally not a successful intervention for individuals, and a substantial proportion of headaches are attributed to the indoor environment without adequate characterization. Formal diagnostic approaches exist to identify the causes of headaches (ISSH 1993). Possible indoor environmental triggers and subsequent attribution to specific sources may lead to specific recommendations. On the other hand, identification of nonwork-related factors and appropriate interventions are equally important. Because headaches represent such a frequent cause of decreased work productivity, some employers have implemented workplace headache programs with some success (Schneider et al. 1999).

54.7 INFECTIONS

Much interest in infections indoors has developed because of concerns that these might be transmitted through ventilation systems. These include human-source infections, such as tuberculosis, pneumococcal pneumonias, and viruses; infections emanating from building systems, such as Legionnaire's disease from cooling towers or potable water systems; and infections from other sources such as animal research facilities.

Outbreaks of tuberculosis in hospital settings are well known. Such ventilation-system-associated clusters have also been reported for office workers (Nardell et al. 1991) and attributed to dysfunctional ventilation systems in jails (Steenland 1997, Cooper-Arnold et

al. 1999). Outbreaks of animal-source diseases, such as Q-fever or histoplasmosis from pigeon droppings, have been attributed to entrainment into ventilation systems (Kreiss and Hodgson 1984). At least one outbreak of pneumococcal pneumonia has been attributed to crowding in jails (Hoge et al. 1994), although this was thought due to person-to-person transmission. Similarly, viral epidemics of highly contagious agents such as chicken pox and measles have occurred through dissemination through ventilation systems.

More interest has arisen recently about whether common respiratory tract viruses, primarily rhinoviruses, are likely to cause excess preventable respiratory tract disease among office workers that may be reduced by changes in ventilation rates (Fisk and Rosenfeld 1997), although they do not distinguish between the viruses that may and those that may not be transmitted through droplet aerosols. Older literature supported hand-to-hand transmission through secretions and suggested both experimentally and in-field studies that this was a more effective form of transmission than the airborne route (Gwaltney 1988, 1989). At the same time, experimental evidence suggested that droplet transmission might in fact contribute to the burden of disease (Dick et al. 1987). Because of the known associations with emotional states and fomite transmission, the importance of this mode A field study in barracks appeared to support this hypothesis although no data on ventilation or air exchange rates was available (Brundage et al. 1988). Even if disease is transmitted through droplets, reduction in frequency through general dilution ventilation may not come cheaply because of the inefficiency of general dilution ventilation in reducing local exposures (Nardell et al. 1991), nor may it intervene on the disease burden associated with emotional states.

54.8 DERMATITIS

Contact is recognized as a common problem among office workers. This ranges from allergic contact urticaria, sometimes with asthma (Marx 1981, 1984), to skin irritation from dryness. A recent review suggests, nevertheless, that most of these symptoms actually represent simple mucosal irritation rather than allergy. Rare cases of vasculitis (palpable purpura) have been associated with photoactive copy paper (Tencati 1983).

Recent interest has focused on whether low relative humidity is associated either with irritation alone or in combination with irritant exposures, such as volatile organic compounds. Close scrutiny of chamber studies shows that they clearly document mucosal irritation at levels below 20 percent (Andersen 1974). More recently, field studies have suggested that mucosal irritation increases as relative humidity drops below 35 percent (Nordstrom 1994).

54.9 MISCELLANEOUS DISORDERS

The built environment is put to many uses, so it is impossible to predict all of the potential exposures and diseases that may occur. Mixed-use buildings are those with work processes that are not just restricted to traditional office work. Printing shops, auto body shops, and dry-cleaning establishments may contribute to the levels of volatile organic compounds in offices. Garages, loading docks, and fossil-fuel-powered floor buffers may contribute to carbon monoxide levels.

Other processes indoors may lead to problems. Organophosphate poisoning has been attributed to entrained organophosphates (Hodgson 1987); such events may be more frequent than commonly assumed (Muldoon 1993). Emissions from architectural blueprint

machines have been associated with palpable purpura, a form of blood vessel allergy (Tencati 1981). Carbonless copy paper has been associated with contact urticaria and asthma (Marx 1986), although the majority of complaints attributed to this exposure are considered to represent simple mucosal irritation (NIOSH 1999).

Equally important, physical conditions indoors may lead to comfort problems. The combination of high indoor temperatures and low water consumption among teachers has been associated with mild heat illness presenting as headaches and fatigue. Transmitted vibration from mechanical building systems has been associated with headaches, dizziness, and irritability (Hodgson 1987).

When strong suspicion arises about potential building relatedness of complaints, very thoughtful approaches may be required to identify true causal connections.

Work Stress

Consistently, in cross-sectional studies, measures of work stress are associated with indoor environmental symptoms (Mendell 1993). This is true whether questionnaires simply asked ratings of work stressfulness or used formal validated work stress questionnaires. The scientific community generally agrees that work stress must be viewed as an effect modifier. That is, it may make the perception of irritation worse, but it will not lead to the perception of irritation without the presence of irritants. This does stand in contrast to some work in experimental psychology that suggests symptoms may arise without underlying causes but simply from expectation. In a case-control study, Eriksson (1996) suggested that control over work was the single most important factor. In any case, work stress is amenable to intervention.

Two component models of work stress argue that only job demands and the control over work are important in workers' perception of stress. Three component models include personality style and characteristics as components. The first implies an organizational analysis and identification of possible intervention strategies focused solely on the workplace factor. This would imply the need for management training in better supervisory practices. The second argues for the importance of scrutiny of the individual person, the environment, and the fit of the two. Solutions would then include focusing on the individual, including reeducation, personal stress management techniques, and coping skills. A more sophisticated view of work stress that argues that educating both workers and management about building needs and appropriate behaviors is appropriate risk communication, stress management, and good worker education practice. Such education could then focus on management and worker styles, address the recognized limitations of the current complex systems in the office, and lead to changed expectations. See Chap. 55 for more detail.

A lesson may also be learned from the world of hazardous waste sites, community outrage, and public health. The needs of communities, their perception of pollutedness, and their intellectual dependency on regulatory agencies, outside experts, the media, and other "forces beyond their control" lead to major distress on their part. Over the last several years, a set of guidelines has evolved to help such communities recover. These include listening to the concerns of the affected individuals, respecting their sense of priorities and importance, and developing agendas that respect both the public's and professionals' perceptions of needed action.

54.10 THE RESIDENTIAL ENVIRONMENT

The residential environment poses a broad set of hazards to adults and children, ranging from safety hazards with resulting injuries through planned emissions of pollutants, such

as oxides of nitrogen and carbon monoxide from cooking and heating appliances through problems generated in construction, operations, and maintenance of homes. Over the last 10 years, the residential environment has been recognized as a contributor to two primary health effects that are directly attributable to the home, distinct from the injuries and acute pesticide poisoning associated with homes. These conditions include respiratory tract disease associated with moisture and bioaerosols and carbon monoxide poisoning.

This chapter will not deal with the more recent literature on combustion products and children's asthma, including oxides of nitrogen. Nevertheless, the use of unvented space heaters appears to pose a similar risk for asthma. The literature on environmental tobacco smoke and asthma will not be recapitulated.

Beginning in 1988, Strachan suggested that home dampness is associated with respiratory tract symptoms. After an initial review of published studies in 1991 (Spengler 1992) suggesting a consistent though small increase, subsequent reviews (Cooper-Arnold 1997) have suggested that this effect is consistent. Dales et al. (1998) have recently identified not only respiratory tract symptoms but also white cell activation. Measures of association are stronger in studies with better measures of exposure. It remains unclear whether this effect is mediated solely through known antigens, such as dust mites, fungal allergens such as *Aspergillus* and *Penicillium*, or also from nonspecific bioaerosol mass. The prevalence of moisture problems is controversial, although some groups have identified a substantial number of houses as potential contributors to disease (Nevalainen et al. 1998). Lawton et al. (1998) have suggested that moisture flow through houses is the single best predictor of the total bioaerosol load. A recent Institute of Medicine publication emphasizes the importance of moisture and the building envelope for at least children's asthma.

Residential carbon monoxide poisoning has become common. Series of investigations suggest that problems arise from improper venting of fossil fuel appliances or from entrainment of carbon monoxide. Retrofitting homes with increased insulation, such as through the use of plastic sheathing over windows, construction of basement enclosures around furnaces and boilers, and simply increased envelope tightness (Pandian et al. 1993, Conibear et al. 1996) may contribute to the problem. Entrainment has been attributed primarily to garages and migration through doors and from the use of charcoal grills (Liu et al. 1992). A final important cause is the use of small appliances in enclosed space. Even the use of "adequate ventilation" according to manufacturers' recommendations may be inadequate to prevent CO poisoning. A recent study (Earnest et al. 1997) documented that air exchange rates are simply inadequate indoors even with dedicated ventilation.

54.11 CONCLUSIONS

Buildings provide shelter from the elements. Nevertheless, inadequate attention to building systems, in their design, operation, and maintenance, may induce a broad range of diseases. Many of these are widely recognized as diseases but often not clearly attributed to the true source, so disease progresses. Only cooperation between engineers, industrial hygienists, and health care providers allows the identification and remediation of problems and the maintenance of a healthy environment.

CHAPTER 55

METHODS TO ASSESS WORKPLACE STRESS AND PSYCHOSOCIAL FACTORS

Barbara Curbow, Ph.D.^{*,†}
David J. Laflamme,^{*} M.P.H., C.H.E.S.
Jacqueline Agnew, Ph.D.[†]

*School of Hygiene and Public Health, Johns Hopkins University
Baltimore, Maryland*

There is increasing evidence that a high percentage of workers are exposed to occupational stressors on the job and that these stressors can contribute to a wide range of negative health outcomes including cardiovascular disease, musculoskeletal disorders, psychological disorders, injury, suicide, cancer, ulcers, and impaired immune function.¹ In the environmental literature, stress has been associated with the perception and the reporting of symptoms related to indoor air quality (IAQ). Most frequently, this association is discussed within the context of sick building syndrome (SBS). In general, *sick building syndrome* “can be thought of as one of a spectrum of workplace disorders that are characterized by a variety of non-specific somatic and psychological symptoms” (p. 220).² Other commonly cited aspects of SBS are the worsening of symptoms during hours spent in the building and improvement on leaving the building and, often, an inability to find specific physical environmental causes. The problem of workplace stress often arises in building investigations, and in fact, the occurrence of SBS may heighten awareness of stressors and stress.

This chapter is designed to provide information for two audiences: IAQ researchers and IAQ problem solvers. Researchers may focus more on the application and development of the theories and methodological issues that we discuss. Problem solvers may be more interested in the relevance of these theoretical and research issues for implementation of solutions. In the first section of this chapter, we will define the concept of stress and present the major occupational stress conceptual approaches. This will be followed by a discussion of some possible models of the IAQ–stress link. In the next section, we will present an overview of the literature on the IAQ–stress link, and we will discuss the variables that have been most frequently investigated. In the third section, we will discuss measures of occupational stress as they represent the major conceptual approaches. In the final section, we offer suggestions concerning implementation of these theories in the workplace.

[†]Department of Environmental Health Sciences, Division of Occupational Health.

55.1 STRESS AT WORK

What Is Stress?

Although the terms *job stress* and *occupational stress* are frequently used common parlance, in the research literature they must be distinguished from two related concepts: stressors and strain. Job stressors are the work-related environmental conditions or exposures that can potentially affect the psychological, social, and physiological health of an individual.³ Stressors can be measured subjectively (i.e., a worker's perceptions of the environment) or objectively (i.e., actual characteristics of the environment). Strain refers to the negative outcomes (psychological, social, physical, and behavioral) associated with exposure to stressors.³ Stress is an intervening variable between stressors and strain. Using a definition by Lazarus,⁴ stress is the sense that environmental events tax or exceed the person's resources. The relationships among stressors, stress, and strain are depicted in Figure 55.1. Also included in the figure is another class of variables—modifiers. As will be discussed below, several of the dominant occupational stress models assume that the stressor → stress and the stress → strain relationships can be altered by the presence or absence of modifying variables, which are generally classified as external to the person (e.g., social support) or internal to the person (e.g., coping strategies, self-esteem). For example, a common hypothesis in the literature is that people who are exposed to stressors but who have high social support will not experience effects as negative as will people who have low social support.

Conceptual Approaches in Occupational Stress

We begin a discussion of measurement issues with an overview of the dominant conceptual approaches in the occupational stress literature because the selection of an approach should guide the variables that are examined in a study of the stress–indoor air quality link. Vagg and Spielberger⁵ recently described the four major conceptual approaches that have informed the general occupational stress literature: person–environment fit (P–E fit),⁶ the demand–control model,⁷ the effort–reward imbalance model,⁸ and the transactional model of stress.⁴ Although these models represent different views on the roles of the environment and the individual in the etiology of strain, shared aspects can be found among them.

Person–Environment Fit. According to Hurrell et al.,³ the modern era of research on job stress began in the early 1960s at the University of Michigan. French and Kahn⁹ (cited in³) began a program of research on particular aspects of the work environment that might be detrimental to the individual. These aspects included role ambiguity, workload, role conflict, having responsibility for other persons, and relationships among members of the group. This early research led to the formulation of the P–E fit model of job stress, which emphasizes the goodness of fit between the “characteristics of the person and the properties of the environment.”¹⁰ Although Vagg and Spielberger⁵ characterized P–E fit as the “most influential” and “most widely accepted” of the job stress models, they also noted that it has been heavily criticized on both theoretical and methodological grounds. However, there is empirical support for it in the literature. For example, Conway et al.¹⁰ demonstrated that a misfit between perceived and desired levels of control was associated with poorer psychological adjustment.

Demand–Control Model. The demand–control model of stress is concerned with the interactive effects of levels of job pressures (demands) and decision latitude (control).¹¹ Different outcomes are associated with varying levels of demands and control.¹¹ High demands and

FIGURE 55.1 Perceived stress as an intervening variable.

low control are associated with high levels of psychological strain; high demands and high control are associated with “good stress,” which can lead to high job motivation; and low demands and low control are associated with low job motivation. The demand-control model does not rule out a role for individual difference variables.^{7,11} Karasek et al.¹¹ write: “A dynamic version of the model integrates the job strain and active behavior hypothesis with personality characteristics measuring accumulated strain and self-esteem development⁷ with the goal of predicting strain development and learning over time” (p. 323). Although support has been found for the model by many researchers, others have found that there is incomplete support for it. For example, Fletcher and Jones¹² found small but independent effects (i.e., no interaction) for demands and control in predicting psychological strain and job and life satisfaction, but relationships with blood pressure were in the opposite direction. Bosma, Peter, Siegrist, and Marmot¹³ found support for the predictive ability of control but not demands for explaining new cases of coronary heart disease.

Effort–Reward Imbalance Model. This newer model states that “stress occurs when there is a lack of reciprocity between the effort that a worker puts into a job and the potential rewards she or he receives for completing it” (p. 295).⁵ Under conditions of high effort in response to external work pressures but low potential for reward (e.g., promotion), there is high work stress, which leads to health-related problems. Bosma et al.¹³ recently tested the effort–reward imbalance model against the demand–control model in predicting the risk of coronary heart disease and found that the full effort–reward imbalance model was associated with increased risk, but only the control component of the demand–control model was associated with increased risk. The concept of work rewards (or resources) has been investigated by other researchers in job stress—notably by Barnett and colleagues.¹⁴

Transactional Model. Lazarus¹⁴ conceptualization of the stress process differs from the previous three. In his model, potential stressors from the environment are subjected to a two-stage appraisal process: The person first appraises whether the event is a challenge or a threat and if it is the latter, he or she then appraises the level of coping resources available to deal with the event. Key to this model is the notion of resources or what a person “draws on in order to cope” (p. 158).¹⁵ Stress can occur when the person does not have the necessary resources—whether they are internal to the person (e.g., an optimistic disposition) or external to the person (e.g., social support)¹⁶—to adequately respond to the external threat.

Shared Features. All four of these models point to the importance of environmental stressors in the chain of events leading to a strain response. Two of the models (P–E fit and transactional) focus on the role of individual characteristics in modifying the stress response (e.g., coping resources) and two (demand–control and effort–reward imbalance) focus on additional aspects of work (e.g., job control or job rewards) as modifiers of the stress response. The concept of job

control is compatible with all of the models. As noted earlier, Conway et al.,¹⁰ using the P-E fit model, found that a misfit between perceived and desired control was associated with poorer psychological adjustment. Control is a central aspect of the demand-control model and, in fact, some researchers have found the main effect for control to be the most highly predictive component of the model.¹³ Having control at work can be conceptualized as a rewarding aspect of work (effort-reward imbalance), and perceived control has often been conceptualized as a personal resource that assists in adapting to stressors, for example, reference 17. Finally, two of the models explicitly acknowledge the importance of positive aspects of work (effort-reward imbalance and transactional) and the notion is compatible with the P-E fit model (e.g., misfit between perceived and desired rewards).

The NIOSH Model. The NIOSH Job Stress Model¹⁸ (Figure 55.2) integrates features of several of the dominant job stress models: It incorporates the measurement of stressors and job control and investigates their relationships with strain indicators and, ultimately, health outcomes. Additionally, it holds that the relationship between stressors → strain can be modified by internal resources and external factors. The only component not found in the NIOSH model is the concept of perceived stress—as used as an intervening variable. In fact, all of the approaches mentioned, except for the transactional model, do not explicitly measure the individual's overall sense of being taxed or overburdened by stressors. However, the NIOSH model represents an integrated model that can be used to conceptualize the aspects of the work environment and the person that may be critical to measure.

Models of the Indoor Air Quality–Stress Relationship

After selecting a conceptual approach to guide measurement of stressors, stress, and strain, it is necessary to focus on how the concept of indoor air quality fits within it. Three illustrative models of the stress–indoor air quality link are presented in Fig. 55.3; all of these mod-

FIGURE 55.2 NIOSH model of job stress and health. (From Hurrell.¹⁸)

els could be elaborated to include other factors. These models are all conceptually plausible, but they have very different implications for measurement, study design, problem solving, and worker–employer relationships.

Model A. In model A, exposure to workplace stressors leads to an increased perception of IAQ symptoms, irrespective of the actual exposure to contaminants. This model is compatible with explanations for the stress–IAQ link such as “mass psychogenic illness,”¹⁹ “mass hysteria,”²⁰ and “epidemic psychogenic illness.”²¹ Typical of the explanation of the stress–IAQ link is the following reasoning: High levels of occupational stress, especially when they are coupled with poor worker–management relationships, lead to an increase in stress-related symptoms (e.g., fatigue). When the stress-related symptoms are linked with some physical environmental cue (e.g., odor) or some social environmental cue from coworkers (e.g., fainting), the stress-related symptoms may be misattributed to IAQ by workers. This, in turn, leads to an increase in the perception and reporting of symptoms.

This explanation is often used post hoc by researchers when no detectable physical environmental cause can be found for the symptom reporting. It assumes that the problem originates in the psychosocial climate of the workplace, for example, in a poor organizational climate. If this model were to be tested, it would need, at a minimum, measures of the environmental stressors and perceptions/reporting of symptoms. It could, for example, be investigated within the demand–control or effort–reward imbalance conceptual frameworks such that these two aspects of the environment could be assessed for their associations with symptoms.

Model B. In model B, exposure to IAQ problems is considered a stressor within the workplace. Much as exposures to cold or noise at work are thought of as physical stressors that may increase perceived stress and lead to both physiological and psychosocial effects, IAQ problems could follow this same pattern. It is important to note that such a model would assume that the problem lies in the physical environment of the workplace and that IAQ problems would be perceived as stressors by most, if not all, of the exposed workforce. Investigators taking this stance would need, at a minimum, careful measures of the physical environment and a measure of perceived stress.

Model C. In model C, the perception of IAQ symptoms is caused by some combination of actual exposure to IAQ problems, other workplace stressors, and individual factors. This model might lead to hypotheses such as the following: People who are exposed to poor IAQ and who

FIGURE 55.3 Possible models of the IAQ-stressor link.

have high levels of workplace stressors and/or who have either a biological (e.g., allergies) or psychological (e.g., high trait anxiety) vulnerability would perceive and report a higher level of symptoms. This model would assume that the problem might lie in a combination of the physical environment, the psychosocial environment, and the individual. Using this model, researchers would need measures of the physical work environment, the psychosocial work environment, relevant internal (e.g., anxiety, depression, allergies) and external (e.g., relationships with coworkers) modifiers, and symptom perceptions and reporting. This model would be compatible with the P-E fit, NIOSH, and transactional conceptual frameworks.

55.2 THE IAQ-STRESS LINK: REVIEW OF THE LITERATURE

Overview

The literature reviewed here was compiled principally through online searches of the National Library of Medicine's PubMed database and the American Psychological Association's PsycINFO database. Some of the key words used in the search were *stress*, *psychological stress*, *workplace*, *sick building syndrome*, *psychosocial*, *mass psychogenic illness*, *indoor air pollution*, and *indoor air quality*. These were used in various combinations. Several more articles came from the *Indoor Air 99 Conference Proceedings* CD-ROM.²² The bibliographies for several of the major articles were cross-examined for commonly cited articles, and these were obtained. Although the search was not exhaustive, it was comprehensive and representative in scope. A total of 29 articles containing original empirical data on psychosocial variables relating to sick building syndrome or indoor air quality were retrieved and examined. Nearly 100 additional review and discussion articles were also retrieved and examined. Table 55.1 contains the 17 empirical articles containing psychosocial variables that are cited in this section. Several review/discussion articles and empirical articles containing no psychosocial variables are also cited; however they are not included in Table 55.1.

As noted earlier, the term *SBS* is used to describe a variety of symptoms reported by workers in a common building, usually an office building. The World Health Organization defines it as "specific symptoms with unspecified aetiology which are experienced by a proportion of people working or living in a particular building and disappear after leaving it."²³ Sick building syndrome symptoms are most evident during the work shift and diminish or disappear upon leaving the building. No specific cause or illness can be identified, although IAQ is often suspected. Although the name implies that building factors are the cause of the symptoms, research into this area has shown that nonbuilding-related factors contribute to SBS.

SBS symptoms reported by workers include eye, nose, or throat irritations, headache, nausea, dry cough, dry or itchy skin, dizziness, difficulty in concentrating, fatigue, and sensitivity to odors.²⁴ These symptoms are often vague and difficult to measure, and affected workers commonly show no clinical signs of illness.²⁵

Many studies have focused on IAQ as a cause for SBS and frequently have shown that complaints are not fully explained by contaminant levels.²⁶ For this reason, in this chapter we will present a review of SBS studies that have included measures of occupational stressors and psychosocial factors. For an in-depth discussion of SBS refer to Chapter 66 in this handbook.

More than one study examining SBS complaints found that they were not associated with IAQ.^{27,28} The prevalence of workers with at least one SBS symptom has been reported to be as high as 70 percent.²⁹ Although a few studies have used case-control designs, the majority

TABLE 55.1 IAQ-Stress Studies

Study	N/number of buildings*	Country	Instrument	Design	Measurements	Findings
Influences on sick building syndrome symptoms in three buildings ⁵⁴	62/3	South Africa	Profile of Mood States	Cross-sectional	Questionnaire: psychological state, job stress, interpersonal relationships at work, SBS symptoms, musculoskeletal pains, environmental exposures.	Psychological symptoms predictive of SBS symptoms. Also odors, humidity and temp. Job stress not statistically significantly associated w/SBS.
The role of psychosocial factors in the report of building-related symptoms in sick building syndrome ³³	111/3	United States	MMPI, Symptom Checklist-90-Revised, in-house neurobehavioral symptom checklist, and Perceived Stress Scale	Cross-sectional	Questionnaire: MMPI, Symptom Checklist-90-Revised, Neurobehavioral Symptom Checklist, Perceived Stress Scale.	Can't attribute SBS to psychological factors alone. Smoking associated w/symptoms. Control, SBS+ and SBS- groups did not differ significantly in PSS, MMPI, SC-90-R, or NSC.
Effects of personal and occupational factors on sick building syndrome reports in air-conditioned offices ²⁶	3155/18	United States	Job satisfaction scale adapted from Job Satisfaction Scale ⁵	Cross-sectional	Questionnaire developed from first author's previous work. Job stress, job satisfaction, physical environmental variables, smoking history, attitude toward tobacco smoke exposure, job category, VDT use, reports of SBS. Smoking policy used to separate into experimental groups.	Gender, job stress, job satisfaction, and VDT use significantly associated with total number of SBS symptoms, in the absence of significant levels of IAQ pollutants. These personal and occupational factors account for 10% of variation in the number of SBS symptoms reported.
Investigation of factors affecting mass psychogenic illness in employees in a fish-packing plant ⁵⁷	269/1	Canada	A component of Karasek Job Content Questionnaire and a component of the NIOSH General Job Stress questionnaire	Case-control	Perception of sociocultural stressors (work and outside work), skills discretion, skills creation, decision authority, decision latitude, physical exertion, psychological job demands, job insecurity, coworker support, supervisor support, family support, job satisfaction and social support from the family.	Mass psychogenic illness symptoms associated strongly w/skills creation. Also skill discretion, decision latitude, and decision authority when substituted in logistic model for skills creation.

TABLE 55.1 IAQ-Stress Studies (Continued)

Study	N/number of buildings*	Country	Instrument	Design	Measurements	Findings
Performance, mood, and health during exposure to intermittent odors ³⁸	90/—	United States	Semantic Differential Measures of Emotional State questionnaire	Experimental	Odor, task performance, health symptoms, mood, believed odor effects. (Not specifically an SBS study)	<i>Believed</i> health, task performance and mood effects associated with malodor.
Covariations among attitude to the indoor air quality, perception of the physical environment, study situation and sensitivity ⁴⁵	528/2	Sweden		Case-control	Psychosocial stress, workload, work content, demands control and social support. These variables were controlled while studying symptom reporting differences by study situation and physical environment.	A combination of stress from psychosocial factors and physical factors is associated with symptoms and satisfaction w/IAQ.
Health symptoms and the work environment in four nonproblem United States office buildings ²⁸	646/4	United States	Adapted from a variety of instruments including EPA Indoor Environmental Quality Survey, NIOSH-NCHS building and Library of Congress building study questionnaires, and the NIOSH Job Stress Instrument	Cross-sectional	Questionnaire: SBS symptoms, stress at work, outside of work, perceptions of environment, job satisfaction, decision latitude, hard or fast work, conflicting supervisory instructions.	No strong relationships between symptoms and air contaminants. Strongest symptom association with perceived physical workspace condition. Psychosocial factors (job satisfaction, influence over job tasks, working hard or fast, conflict in supervisory instructions, job stress) less strongly associated w/symptoms.
Indoor air quality and personal factors related to the sick building syndrome ³⁶	11 buildings	Sweden	Psychosocial rating scales included in article	Retrospective	Work stress, work satisfaction, climate of cooperation during the last 6 months, psychosocial index.	Degree of psychosocial dissatisfaction and SBS associated, as well as other nonpsychosocial variables. Multifactorial origin.
Volatile organic compounds, respirable dust, and personal factors related to prevalence and incidence of sick building syndrome in primary schools ³⁷	129/6	Sweden	Psychosocial rating scales included in article	Longitudinal	Work stress, work satisfaction, climate of cooperation at work, psychosocial index	Degree of psychosocial dissatisfaction and SBS associated, as well as other nonpsychosocial variables. Multifactorial origin.

Influence of indoor air quality and personal factors on the sick building syndrome (SBS) in Swedish geriatric hospitals ⁵⁹	287/8	Sweden	MM040B (Department of Occupational Health in Örebro, Sweden)	Cross-sectional	Questionnaire: SBS symptoms, personal factors (including work satisfaction, work stress, and degree of personal influence), noise, temperature, airflow.	Psychosocial work climate has influence on SBS symptom prevalence. Facial skin symptoms, eye irritation associated with psychosocial work climate.
Sick building syndrome: An emerging Stress-Related Disorder ²⁷	2160/6	Singapore		Cross-sectional	Questionnaire: stress, SBS symptoms.	In buildings w/no recognized environmental problems, health complaints typical of SBS were stress related. Dose-response. Complaints not predictive of IAQ.
Epidemiology of sick building syndrome and its associated risk factors in Singapore ⁶⁰	2856/56	Singapore		Cross-sectional	Questionnaire: stress, noise, lighting, health history, sex, age, temperature.	IAQ did not predict SBS symptoms. High levels of work-related stress, too much noise, history of allergy or other medical conditions, poor lighting, youth, female, predicted SBS symptoms.
Influence of personal characteristics, job-related factors, and psychosocial factors on the sick building syndrome ⁶⁰	2829/19	Denmark		Cross-sectional	Questionnaire: building factors, job category, sex, work functions, psychosocial factors (influence on organization of the daily work, varied work, satisfaction w/superior, work speed, quantity of work inhibits job satisfaction, little influence and high work pace.	Building factors strongly associated. All psychosocial factors strongly associated w/symptoms when added separately. Only dissatisfaction with superior or with quantity of work had significant effect on symptoms if all included.
The sick building syndrome (SBS) in office workers. A case-referent study of personal, psychosocial, and building-related risk indicators ³⁸	339/—	Sweden	Questionnaire described and validated in previous article by same author and referenced in this one	Case-referent (matched case-control)	Questionnaire: psychosocial work index, work load index, work place position.	Psychosocial conditions related to an increased prevalence of reported SBS symptoms. Workload index strongest.
Facial skin symptoms in visual display terminal (VDT) workers. A case-referent study of personal, psychosocial, building- and VDT-related risk indicators ³⁵	163/—	Sweden	Questionnaire described and validated in previous article by same author and referenced in this one	Case-referent (matched case-control)	Psychosocial work index, work load/support index.	Psychosocial conditions a risk factor for facial skin symptoms in VDT users.

TABLE 55.1 IAQ-Stress Studies (Continued)

Study	N/number of buildings*	Country	Instrument	Design	Measurements	Findings
Why do women report 'sick building symptoms' more often than men? ⁶⁰	4943/—	Sweden	Psychosocial workload index described in previous article by same author and referenced in this one	Cross-sectional	Gender, SBS symptoms, working hours, personal factors, exposure factors at home and work, perceptions of physical conditions, and perceptions of psychosocial work conditions (psychosocial work index—same as above).	Gender differences in SBS symptoms found to be real, rather than a reporting behavior difference.
No relation between indoor climate and other aspects of quality of working life ⁶¹	80/4	Netherlands		Cross-sectional	Electronic questionnaire: satisfaction with welfare (tasks, relationships, and conditions at work) and safety and health (indoor climate, light, furniture, equipment, physical health problems, noise, cleaning, fire hazards, toilets, etc.)	People in this setting (university chemistry department) did not misattribute their dissatisfaction to the wrong source.

*N = number of subjects/workers.

have used cross-sectional questionnaires and causal relationships are consequently difficult to assess (see Table 55.1). It is important to keep in mind that many of the variables discussed in this section are surrogates for actual measures of the causes of SBS, many of which are poorly understood or simply unknown. Sick building syndrome is perhaps best explained using a multifactorial approach such as that depicted by the model in Figure 55.1. The variables described below are categorized by the headings in this model.

Stimulus (Stressors)

Numerous stressors have been investigated in relation to sick building syndrome. These fall into two basic categories based on measurement characteristics: physical and psychosocial stressors. Often the physical stressors are measured objectively, and the psychosocial stressors are measured subjectively, although this is not always the case.

Physical Stressors

Physical stressors that have been measured in SBS studies include environmental tobacco smoke, vibration, lighting, noise, temperature, and a variety of other measures. Results from a study of 2856 office workers in 56 buildings³⁰ included noise, temperature, and poor lighting among the stressors that predicted SBS symptoms. Higher temperatures have been found by others to be connected with higher levels of symptoms.³¹ Noise complaints have originated from ceiling-mounted unit ventilators.³² When noise stems from ventilation units, there is the danger that levels of contaminants will increase because of occupants shutting down the noisy unit and interrupting the flow of proper ventilation. Tobacco smoke is an environmental factor that has been found to be associated with SBS symptoms,³³ in addition to being responsible for increased rates of lung cancer. Odors, humidity, and temperature in three buildings studied by Bachmann and Myers³⁴ were related to an increase in SBS symptoms. The Office Illness Project in northern Sweden³⁵ linked work responsibilities, such as video display terminal (VDT) use, with facial skin symptoms. Perceived physical workspace condition has also been shown to have a strong association with symptom reporting.²⁸

Psychosocial Stressors

Organizational factors such as work climate have not been as well examined in relation to SBS but nonetheless may have an effect on symptoms. Two Swedish studies^{36,37} found that a negative climate of cooperation at work was positively associated with SBS symptoms. Ooi and Goh²⁷ found similar results.

In a matched case-control study of SBS in office workers,³⁸ the psychosocial workload index was related to an increased prevalence of symptoms. The authors of this study created an index for psychosocial work from three questions asking about “interesting and stimulating work,” “too much work to do,” and “opportunity to influence the working conditions.” These concepts coincide nicely with the demand–control model described earlier.

Bachmann and Myers³⁴ based their measurement of job stress on questions asking the “extent subjects had enough time for their work, had spare time, chose their work, chose how and when to work, used their skills at work, and found their work interesting, rewarding or satisfying.” The authors cite Karasek’s work⁶ as the basis for these questions. Job stress was not statistically significantly associated with SBS symptom reporting. Interestingly, interpersonal work relationships were also investigated in this study. However, details were not provided on how this factor was measured. Interpersonal work relationships were not found to be associated with SBS symptoms.

In a study of four nonproblem U.S. office buildings,²⁸ a scale for job stress was based on the demand–control model, incorporating scores for perception of influence over work and having to work hard. Job satisfaction and conflicting supervisory instructions were also investigated. All of these factors were found to be statistically significantly associated with SBS symptoms, although the relationships were not very strong. “The questionnaire was adapted from a variety of instruments used by other researchers, including...the NIOSH Job Stress Instrument.”

Modifying Variables

Modifying variables act to moderate or mediate the effects of stressors on the person. They may be protective or they may increase susceptibility and are generally classified as internal or external to the person.

Internal. Regarding the effects of age, Ooi and colleagues³⁰ found that younger employees reported more SBS symptoms than did older employees. The researchers hypothesize that this effect could be a result of environmental adaptation and a self-selection process among older employees who had worked in the building longer. A history of allergy, not surprisingly, has been shown to be predictive of SBS symptoms.³⁰ This is an example of why it is so difficult to determine the causes of SBS—symptoms of SBS often match symptoms of other conditions such as allergic reactions.

Because it is known that females generally report health symptoms more than men do,³⁹ it is not unexpected to learn that this finding carries over into SBS symptom reporting.³⁴ It is not clear why females report symptoms at higher rates. Some researchers posit that women are simply more attuned than men to physical symptoms.²⁷ Stenberg and Wall⁴⁰ reported “females and males work under unequal physical and psychosocial conditions.” Their findings suggest that the gender differences in SBS symptoms are not the result of reporting behaviors. Mood states have also been shown to account for differences in symptom reporting between men and women.⁴¹ One study of SBS in three buildings³⁴ used questions derived from the Profile of Moods States Questionnaire to measure psychological symptoms such as anxiety, irritability, anger, depression, claustrophobia, tiredness, forgetfulness, and difficulty sleeping or concentrating, finding that these predicted several SBS symptoms. The authors noted, however, “it is arguable whether psychological symptoms are a cause or an effect of SBS.”

Personality has been postulated as potentially playing a role in SBS.⁴² Personality may act as a modifier between stressful workplace characteristics and SBS outcomes, mediating the effects on each individual. Crawford and Bolas,⁴³ in their review of SBS studies investigating personality, concluded, “the handful of studies in the area are inconclusive.” It has been measured using instruments such as the Minnesota Multiphasic Personality Inventory, the Eysenck Personality Inventory, or Raven’s Standard Progressive Matrices,⁴⁴ but these are general multifactorial inventories of personality, and they may not be specific enough to be of much use. Measures that are more specific should be included in future research to better define the possible relationship between personality and SBS symptoms.

Intervening Variable (Perceived Stress)

Job stress has consistently been shown by several studies^{27,30,34,45} to be predictive of SBS symptoms. Ooi and Goh²⁷ had subjects rate the climate of cooperation at work on a 10-point scale ranging from 0 (not stressful) to 10 (extremely stressful). Work-related physical and mental stress were similarly evaluated. A definition of stress was not provided to the respondents. Odds ratios calculated for these three measures showed consistent incremental changes that the authors concluded were suggestive of a positive dose–response relationship

between stress and SBS symptoms. The possibility of interaction between the perception of stress and several covariates (thermal discomfort, medical condition, noise, lighting, age) was investigated; however, no significant effect modification was found.

In another study investigating the effects of personal and occupational factors on SBS reports,²⁶ job stress and job satisfaction were measured using several questions answered on a 5-point rating scale (strongly agree, mostly agree, uncertain, mostly disagree, strongly disagree). Six questions making up the job satisfaction scale were adapted from a previously constructed job satisfaction scale.⁴ The five items making up the job stress scale were adapted from several sources. Factor analyses were performed on both scales, yielding Cronbach's values of .90 for job satisfaction and .70 for job stress. Both job stress and job satisfaction were significantly related to the total number of SBS symptoms, in the absence of significant levels of IAQ pollutants. Still, the occupational and personal factors investigated in this study only accounted for 10 percent of the variation in the number of SBS symptoms reported.

Summary of Literature Review

Overall, the literature supports the theory that SBS symptoms are not always related to IAQ problems. Job stress, job satisfaction, job demands, and job control play significant roles in SBS. Gender has clearly been identified as a confounding variable in SBS studies, and researchers and other SBS investigators must remember to stratify by gender when performing analyses.

The instruments used in the studies to date have been quite varied. Many investigators refine their instruments from study to study or adapt the instruments used by others, making it difficult to compare between studies. An attempt to develop summary statistics for the variables in the studies listed in Table 55.1 proved nearly impossible due to the inconsistencies in the measurement methodologies used in each study. There is an explicit need to increase the use of validated measurement instruments such as the ones described in the next section. Doing so will not only improve the validity and reliability of the measures in SBS studies but also will allow for cross-comparisons and pave the road for future meta-analyses.

55.3 INSTRUMENTS AND MEASUREMENT ISSUES

Problems Found in Existing Studies

Although, as seen in the previous section, several studies of indoor air effects have included psychosocial measures, few have explicitly related the selection of variables to a conceptual theory. Most studies designed with a psychosocial component have not addressed a comprehensive set of relevant domains. Additionally, Table 55.1 shows that the targeted domains, as well as their respective measures, have varied greatly.

Use of Theory. A theory-based approach to the investigation of indoor air quality questions provides a framework that guides both the selection of appropriate variables and the examination of their statistical relationships. A model such as that presented in Figure 55.2 allows for the comprehensive inclusion of relevant domains that may have main, modifying, or confounding effects on the health outcomes of interest. This enables characterization of the modifying effects of psychosocial variables in relation to environmental measures of chemical, physical, or biological exposures. It also allows for inclusion of variables previously reported to be associated with health outcomes. Additionally, studies

designed according to a theoretical model avoid redundancy among variables unless it is an aim of the study to develop or validate new measurement instruments.

Some investigations have collected data on several psychosocial variables but have subsequently included only one composite index, combining responses for separate measures, in the analyses.^{36,38} This approach neglects the richness of the data set and masks the influence of specific components of the index on any observed associations. Thus, the relative importance of single domains within the index will not be apparent. For example, social support has been shown to be an important modifier of workplace stressors,⁴⁶ but this relationship is obscured when the values for level of social support are embedded within a summed composite index. Thus, the use of composite indexes does not inform decisions regarding preventive interventions.

Psychometric Properties. To support sound inferences, psychosocial domains should be represented by measures that meet acceptable levels of validity and reliability. In addition to content validity, which indicates the ability of a measure to address its respective domain of the conceptual theory, measures should have established face validity, or conceptual clarity, and construct validity, indicating comparability of responses with other measures of the same constructs. Predictive validity, another desirable property, represents the degree to which the measure is known to correlate with expected criteria such as anticipated health outcomes. Finally, it is desirable to limit random measurement error by ensuring that the instrument is characterized by two forms of reliability, internal consistency and stability over time. Item intercorrelations and test-retest analyses provide the means for assessing these characteristics.

Several standardized instruments are available for which validity and reliability have been established. However, a number of investigators have employed measurement techniques for psychosocial concepts without reporting their respective psychometric properties. Better ascertainment and documentation of measurement characteristics would strengthen studies of the indoor environment–stress link. This process, which can take considerable effort, would constitute a contribution not only to the study at hand but also to future investigations.

Generic Instruments. Most studies that have considered the relationship between job-related stressors and health outcomes have depended on the use of generic measures to describe levels of job stressors. Examples are the scales typically used to measure work-related control, demands, and social support (i.e., Job Content Questionnaire¹¹). Although these tools can be used to demonstrate general effects of work factors on stress, a limitation is their inability to identify specific work-related stressors. This has been addressed by Baker,⁴⁷ who pointed to the need to identify specific stressors in developing realistic prevention strategies for reducing stress. For example, occupation-specific stress measures, based on job stress models, have been developed by our team and used with worker populations such as childcare, telecommunications, and military workers. The development of occupation-specific measures is a complex and iterative process, but it can better help explain the variance observed in stress-related health outcomes and thus better guide the design of effective preventive interventions.

Major Comprehensive Instruments

There has been a proliferation of broad-based comprehensive job stress measures over the past two decades. A recent issue of the *Journal of Occupational Health Psychology* was devoted to overviews of these instruments^{3,5} and to in-depth reviews of specific instruments.

TABLE 55.2 Measures of Occupational Stress and Examples of the Domains They Represent

Instrument/reference	Approach ⁵	Work-related stressors	Domains		
			Internal modifiers	External modifiers	Effects
1 Job Diagnostic Survey ²	P-E fit D-C E-R	Skill variety, task significance, task identity, autonomy, feedback	Internal motivation		Job satisfaction
2 Job Characteristics Index ⁶²		Skill variety, autonomy, feedback, coworker interaction, task identity, friendships			
3 Work Environment Scale ⁶³	P-E fit	Interpersonal relationships, orientation toward personal growth, organizational structure			
4 Occupational Stress Inventory ⁶⁴	P-E fit	Occupational role stress; vocational, psychosocial, and physical strain	Coping and social support		
5 Occupational Stress Indicator ⁶⁵	P-E fit D-C Transactional	Sources of pressure in work environment	Type A behavior, locus of control, coping strategies		Job satisfaction, physical and mental health
6 Stress Diagnostic Survey ⁶⁶		Role demands, workload, time pressure, task demands			Pressure-strain, job satisfaction, quality of work
7 Job Content Questionnaire ⁶⁷	D-C	Decision latitude, psychological and physical demands, exposure to physical hazards		Social support	Job satisfaction and security
8 Generic Job Stress Questionnaire ⁶⁸	P-E fit	Examples: role conflict and ambiguity, workload, control, cognitive demands	Self-esteem	Social support	Depression, somatic complaints, job satisfaction, illnesses
9 Work Stress Inventory ⁶⁹		Organizational stress, job risk			
10 Job Stress Survey ⁷⁰		Job pressure, organizational support			

TABLE 55.2 Measures of Occupational Stress and Examples of the Domains They Represent (*Continued*)

Instrument/reference	Domains				Effects
	Approach ⁵	Work-related stressors	Internal modifiers	External modifiers	
11 Pressure Management Indicator ¹¹	Transactional	Workload; relationships at work; recognition; organization climate; personal responsibility; managerial role; daily hassles; homework balance	Drive; patience-impatience; problem focus; life-work balance; use of social support; control; personal influence		Satisfaction with job, organization; perceived job security; commitment to organization; state of mind; energy level; confidence level; resilience; physical symptoms
12 Interpersonal Conflict at Work ⁷²		Conflict with others at work			
Organizational Constraints		Constraints on work			
Quantitative Workload Inventory		Amount of work and work pace			
Physical Symptoms Inventory					Somatic symptoms

Depicted in Table 55.2 are descriptions of 12 multicomponent instruments that are used most frequently in the literature. Further descriptions are found in the special issue of *JOHP*, in the literature, and on the instrument Websites. As can be seen in Table 55.2, all of the instruments cover multiple types of work-related stressors. Coverage of other domains is less consistent. Many researchers fill in the gaps in the coverage of domains by using additional, targeted instruments (e.g., for depression, anxiety).

Selection of an Instrument. When selecting an instrument, there are conceptual, methodological, and practical issues to consider. As noted in Table 55.2, most of the instruments have identifiable conceptual approaches that they represent. The primary conceptual issues are to select an instrument that represents the framework to be employed and that covers the constructs that are of interest. Methodological issues include consideration of the psychometric properties of the instruments (validity, reliability), whether normative data are available that pertain to worker characteristics of interest (e.g., by gender, race, type of job), the method of administration (survey, interview, observation), the reading level of the instrument (is it too high or low for the audience?), and the ease of scoring, analyzing, and interpreting the findings. Practical issues include cost of the instrument, amount of time to administer it, and whether additional expertise is needed in the team to be able to use the results.

Perceived Stress. Notably missing in Table 55.2 is a dimension representing perceived stress. This lack is because most instrument packages measure perceived stressors but not perceived stress (i.e., the feeling of being overwhelmed or unable to garner sufficient resources). A detailed discussion of the measurement of perceived stress has been provided by Monroe and Kelley.⁴⁸ They conclude that only one instrument is “an empirically established index...that falls into the category of general appraisal instruments” (p. 138)—the Perceived Stress Scale.⁴⁹ The original version of this instrument included 14 items such as, “In the last month, how often have you felt that you were unable to control important things in your life?” and “In the last month, how often have you felt that you were on top of things?” Shorter versions of the instrument have also been developed.⁵⁰

55.4 IMPLEMENTATION ISSUES

Ideally, the IAQ–stress link would be prevented through management of the physical environment and/or the psychosocial environment. Realistically, most IAQ specialists, unless they are conducting longitudinal research, will be brought into an ongoing situation. It is likely, if the problems have gone on for some time or if there is a poor organizational climate, that emotions and opinions of workers and management may be polarized. Within such a setting, it becomes more difficult to find a resolution that will satisfy all groups, and interpersonal communication becomes as important as scientific findings. Below, we outline some implementation issues that we believe are critical to consider; several of these issues have been presented in more detail elsewhere.⁵¹

Address Concerns in a Timely Manner

Although it may be tempting to take a “wait and see” attitude when responding to IAQ problems, this is problematic for at least three reasons. First, and foremost, workers’ health may be at risk and time may exacerbate health problems. Second, the most important characteristic of an IAQ team is credibility. In the persuasive communications field, source credibility is viewed as essential to most communications settings.⁵² Credibility is intertwined with

two related characteristics: knowledgeability and trustworthiness. Even the best of scientists (i.e., those high in knowledgeability) can be compromised by poor trustworthiness. A prompt response is essential to maintaining the trust of workers, as are other actions that will be described below. Third, it is difficult, if not impossible, to dismiss accounts of mass psychogenic illness (MPI) in the literature on IAQ. A prompt response is more likely to interrupt any potential sequencing of MPI events such as using cues from coworkers to attribute vague symptoms to IAQ problems.

Involve Workers from the Beginning

Worker representatives should be involved in the process to the greatest extent possible. There are several reasons for this. First, and most importantly, the imposition of a “solution” on a worker group is likely to be viewed negatively and as another violation of trust in the employee–employer relationship. When workers are barred from the process, it can lead to the circulation of rumors and half-truths, which can further undermine confidence in the IAQ team. Second, exclusion of workers sets up an “insider versus outsider” dynamic that prohibits positive interpersonal communications. Third, by not including workers, IAQ specialists are losing a vital source of information. Workers are “specialists” in providing information about how they see the IAQ problem (e.g., is it a matter of high or low concern?), the perceived causes for the problem (e.g., ventilation system versus carpeting), the influence of the problem on the social environment (e.g., is it causing rifts among groups of workers?), and communications needs of workers (what do they want to know, and who do they want to tell them?).

Some IAQ specialists may believe that if they conduct a session with workers to tell them what is happening and why, they have fulfilled their inclusion obligations. We disagree with this approach, which has been faulted in the risk communication literature.⁵³ There are multiple roles for workers in the inspection of the IAQ–stress link. First, a small but representative set of workers who have the trust and respect of their colleagues should be part of the core decision-making team. They can provide valuable insights into the dynamics of the workplace and how different approaches may be perceived by their coworkers. Second, larger groups of workers may be used in key informant interviews, focus groups, or surveys—all valuable tools to gather information on the issues listed above.

Use an Interdisciplinary Team

Although not all IAQ cases will warrant an in-depth response, there are times when the use of an interdisciplinary team may be critical. Cases that involve large groups of workers, highly publicized or politically sensitive issues, or vulnerable populations are candidates for an extensive examination of the IAQ–stress link. At a minimum, an interdisciplinary team should involve specialists in the areas of IAQ, occupational health, occupational stress measurement, and risk communication. Each of these disciplines can contribute to multifaceted examination and reporting of the issues.

Carefully Think Through the Conceptual Approach That Is Used

We have outlined four distinct and one hybrid conceptualizations of occupational stress in this chapter. The conceptual approach that is used will determine the variables to be measured, the study design, the assumed IAQ–stress model, and the conclusions that can be drawn. The IAQ team members should think about the entire scope of the work—from how

the problem is framed to the possible solutions—before selecting a model. For example, if the demand–control model is selected, it would imply the following: (1) Workers’ perceptions of the physical and psychological demands put on them and the amount of control that they have over their work would be in the primary areas of inspection (although, newer versions of this approach also include social support; (compare with reference 46). (2) The model implies that workers with high demands and low control would exhibit the strongest reactions to IAQ problems. (3) Appropriate interventions would include altering the levels of demands or control or the balance between the two. Each conceptual approach has distinct implications.

Use a Comprehensive Conceptual Approach from the Beginning. We advise IAQ teams to use a comprehensive approach from the beginning rather than to collect information in a fragmented and piecemeal fashion. For example, the NIOSH approach would allow for the collection of variables that could test an overall model.

Use Psychometrically Sound and Relevant Instruments

Psychometrically sound instruments are those that have high levels of validity and reliability and that have been developed using standard, accepted methods (compare with reference 54). Relevant instruments are those that (1) measure components of the conceptual approach used and (2) are appropriate for the population. Much has been written concerning the selection of psychometrically sound instruments in the occupational stress field, but the issue of relevance may be subtler. For example, when exploring the effects of personality as a moderator of stressors on SBS symptoms, some researchers have used extensive personality batteries such as the MMPI.³³ The problem with this approach is threefold. First, researchers have not justified the use of such a broad-scale instrument with sound, theory-based assessments of how and why certain components are important. Second, the length of such instruments makes it difficult to adequately cover other important aspects of the conceptual approach due to respondent fatigue. Third, the items in such batteries may seem overly intrusive and lacking in face validity to respondents. This, in turn, could threaten the overall acceptance of the entire data collection instrument. A second example of relevance is based on gender. There is speculation in the field that some instruments or approaches may not be suitable to adequately describe the work that women do.⁵⁵

Use a Strong Study Design

Most of the studies that we have reviewed involve cross-sectional data. A common limitation has been the inability to determine the temporal relationships between exposure to stressors and symptom outcomes. This is especially important in the study of stress-related conditions because of the possibility that health problems may change the way workers perceive their environment, therefore introducing a bias toward positive findings. Even some case-control studies have faced the difficulty of ascertaining the timing of symptoms relative to the stressor experiences. Although longitudinal studies may be challenging, they may be useful in circumstances where organizational changes are introduced and symptom development, or resolution, can be tracked. Longitudinal designs will be particularly helpful in the evaluation of intervention strategies.

Another feature of previous studies has been the use of internal control groups, often in studies of single buildings that have already been declared “problem buildings.” Although this design makes it possible to control for many factors that are unique to an organization, it can limit the external validity of the investigation. The ability to generalize findings will

be enhanced by studying populations most representative of those who experience the stressors of interest. These and other issues that lend strength to investigations, such as adequate power, blinding to exposure or outcome status, control for major confounding variables, and avoidance of measurement error have been discussed by Mendell.⁵⁶

Use Appropriate Data Collection Techniques

Three primary categories of data collection may be used in stress studies—self-administered surveys, interviews, and observations. By far, the most widely used method is the self-administered survey because it is less labor intensive and generally cheaper to conduct. No matter which method is used, several aspects of data collection need to be considered. First and foremost, worker confidentiality must be maintained. This is true for ethical reasons and to establish and maintain trust within the organization. Second, it is important to get as representative of a sample as is possible. If all of the worker group cannot be surveyed or observed, a random sample should be used. Once workers are selected to be in the targeted group, reasonable efforts to increase the response rate should be employed (multiple and varied contacts) to reduce the effects of selection bias.

Use Sensitivity in Communicating Results

As noted above, workers should be consulted on the communications issue. If they are kept apprised of the results as the study progresses, a crisis at the end of the study can be avoided. Workers should be assessed for their levels of knowledge on topics that are essential to fully understanding the results (e.g., probability). Efforts should be made to give workers the information tools that they need to understand and interpret the findings—this is essential to allay concerns. In addition, input from workers on what topics they want information about and who they want to tell them should be gathered. It may be that members of the IAQ team have sufficient credibility that workers will accept hearing the findings from them—or, they may prefer to have a neutral, outside person present the findings.

Special Issues around Null Findings. Logically, we might expect that the dominant emotion following negative results would be relief. However, this is not always the case. If negative findings are presented in a situation where there is mistrust and suspicion, they may raise feelings of hostility and anger in workers. Even within a situation of positive relationships, negative findings may lead to feelings of frustration because workers have to search for another cause for their symptoms. The IAQ team needs to recognize that negative emotions can surface even when things seem positive and that these negative emotions should not be belittled or minimized. Persons who have high levels of symptoms or concerns may need individualized attention.

55.5 CONCLUSION

The use of a conceptual framework and psychometrically sound instruments will aid the researcher and problem solver alike, providing a basis for understanding and measuring workplace stress and psychosocial factors that may be contributing to IAQ problems. There is no doubt that workplace stress and psychosocial factors often play a role in IAQ problems. By addressing these issues in an investigation, IAQ specialists will benefit from a greater understanding of the contributing factors in each unique situation. This will allow for tai-

lored solutions to be effectively designed and implemented, often leading to quicker and more complete resolution of the problems. Building residents may be more likely to welcome sensitive communication of findings based on scientifically sound investigations following the guidelines outlined in this chapter.

CHAPTER 56

COST OF RESPONDING TO COMPLAINTS

Clifford C. Federspiel,¹ Ph.D.

*Center for Environmental Design Research
University of California
Berkeley, California*

56.1 INTRODUCTION

When building occupants become sufficiently hot or cold and have exhausted all coping behaviors available to alleviate their discomfort, they often complain to the facility manager. These complaint events are called unsolicited complaints because they are not elicited by the facility management as are complaints obtained through surveys. Unsolicited complaints contribute to the operating cost of buildings. Because many complaints are affected by controlled environmental variables such as temperature, it should be possible to manage the frequency of complaints, and consequently the cost of complaints, through proper operation of the building control systems.

Before operational policies are formulated to manage complaints, a thorough understanding of the complaint generation and handling process is needed. The process of complaint generation and complaint handling in buildings has been studied much less than other processes that affect the operating cost such as energy usage, equipment reliability, and scheduled or predictive maintenance. Federspiel (1998) analyzed complaint logs from two large sets of buildings and concluded that complaints of “too hot” and “too cold” are collectively the most common kind of unsolicited complaint, that hot and cold complaints are rarely caused by interindividual differences in preferred temperature, and that there is a significant potential to reduce the labor cost associated with HVAC maintenance by reducing the frequency of hot and cold complaints. Federspiel (2000) proposed a mathematical model for predicting the frequency of hot and cold complaints.

Although there is comparatively little information in the literature about unsolicited complaint behavior, there is an extensive amount of knowledge about subjects such as thermal comfort and sick building syndrome that are related to unsolicited complaint behavior. Most of this knowledge has been derived from the use of surveys.

¹Formerly with Johnson Controls, Inc., Milwaukee, Wisconsin.

For thermal and olfactory sensations, relations between physical variables and perceptions have been studied in detail (Fang et al. 1996, Fanger et al. 1988, Fanger et al. 1985, Fanger 1982, McIntyre 1980, Olesen et al. 1978, Olesen 1977). These relations are often formulated as mathematical relations involving predicted percentage dissatisfied, where dissatisfied is normally defined as a rating with a magnitude above a certain level. Mathematical relations of this type are typically based on semiempirical correlations derived from laboratory tests in which surveys are used to acquire information about the sensation ratings. Although occupants may be assumed to be dissatisfied if they register an unsolicited complaint, the converse is not necessarily true. Therefore models of the percentage dissatisfied will not necessarily predict unsolicited complaint behavior.

The causes of ill-health symptoms and poor ratings of environmental conditions have been investigated with three different methods. All three involve the use of surveys. The first is the use of laboratory experiments described above. The second method is the epidemiological approach, which involves assessing the intensity and frequency of symptoms with a survey and then deducing cause based on correlations, often between survey data and physical measurements. For example Brill et al. (1984) used data from surveys to conclude that thermal comfort "complaints" were correlated with body size. Smaller occupants, who were more often women, were found to complain more about conditions being too cool and about temperature fluctuations. It was concluded that "purely environmental solutions to thermal comfort are probably unattainable, given that body type tends to alter responses so strongly." Hodgson et al. (1991) used a questionnaire and environmental measurements to demonstrate that mucous membrane irritation and central nervous system symptoms are related to concentrations of volatile organic compounds (VOCs), crowding, clothing insulation, and lighting intensity. A third method of investigating causation is with intervention studies. This method avoids some of the pitfalls of the epidemiological approach because there is a control group. Intervention has been used by Jaakkola et al. (1991) to show that reduced ventilation rates slightly increased the frequency of sick building syndrome (SBS) symptoms. Wyon (1992) used intervention to study the relation between SBS symptoms and nine technical intervention measures.

This chapter describes the current state of knowledge on complaint behavior in working buildings. Much of the information in this chapter is derived from Federspiel (1998). Additional but similar data and analyses have been included. Federspiel (2000) has proposed a mathematical model that predicts unsolicited thermal sensation complaint behavior as a function of three statistics of the temperature control process: the mean value of the temperature, the standard deviation of the temperature, and the standard deviation of the rate of change of the temperature. Because this complaint prediction theory is still evolving, it has not been included in this chapter.

56.2 STATISTICAL METHODS

Nonparametric statistical methods, which are described in detail in Siegel and Castellan (1988), were used to analyze the data. The use of these methods for this data is described in detail by Federspiel (1998).

For the location tests, the robust rank order statistic U was used. This statistic and the corresponding test is an alternative to the Wilcoxon-Mann-Whitney rank-sum statistic W and the test corresponding to W . The advantage of using U instead of W is that it is applicable to the Behrens-Fisher problem of testing location when the scale of the two populations differ, whereas the Wilcoxon-Mann-Whitney rank-sum test is not (Lehmann 1975). The sampling distribution of U is asymptotically standard normal, so U is interpreted in the same way as a standard normal deviate.

For scale tests, the Moses ranklike statistic was used. The sampling distribution of the Moses ranklike statistic is asymptotically normal, so the statistic is standardized, and the corresponding standard normal deviate associated with this statistic, denoted as Z_M , is reported.

For tests of association, the Spearman rank-order correlation coefficient R and the Kendall τ coefficient were used. The sampling distributions of these statistics are asymptotically normal, so the statistics are standardized, and the corresponding standard normal deviates associated with the statistics, denoted as Z_R and Z_τ , are reported.

The χ^2 test and the Kolmogorov-Smirnov test were used to test for goodness of fit.

Robust location (e.g., mean) and scale (e.g., standard deviation) estimators were used to analyze properties of the tails of some distributions because the data are known to be corrupted with manual entry errors. The estimates are determined by first eliminating outliers. Outliers are defined as those values that are more than 3 times a robust scale estimate from a robust location estimate. The final values of the robust location and scale estimates are computed as the sample mean and standard deviation of the population after the outliers have been removed. This method is called reweighted least squares (RWLS) and is described by Rousseeuw and Leroy (1987).

In addition to the test statistics, the probability associated with the test is reported. Single-sided tests are denoted by the subscript s on the p value, and double-sided tests are denoted by the subscript d .

56.3 COMPLAINT LOGS

It is common practice for facility managers to record complaint events in a computerized log. Complaint logs may contain a variety of different variables related to a complaint event and the corresponding service call including the time, location, and temperature at which the complaint occurs, the time required to respond to the complaint, and the response action taken.

The results in this chapter are based on the analysis of data in three computer-based complaint logs. They are referred to as Log A, Log B, and Log C. Log A is from a facility near the gulf coast of Texas consisting of 115 structures totaling approximately 3 million square feet. The structures include a wide range of building types from semipermanent trailers to large commercial office buildings. The structures are used for many different functions including weather monitoring and laboratory work in addition to typical office work. Approximately 7500 personnel work in the buildings corresponding to Log A. Complaints entered in Log A during the period beginning September 1, 1995, and ending August 31, 1996, were analyzed.

Log B is from a large set of facilities distributed throughout the midwestern United States. The total number of buildings corresponding to Log B is 575. Of these, 482 are central office buildings, and the remainder are administrative buildings or data centers. The total number of square feet is approximately 17.2 million, and the total number of personnel working in these buildings is approximately 16,000. Complaints entered in Log B during the period beginning January 1, 1997, and ending April 23, 1997, were analyzed.

Log C is from a 450,000-square-foot building located in an urban area of the northern midwestern United States. There are 386 personnel working in this building. Complaints recorded in Log C between November 29, 1995, and November 20, 1997, were analyzed.

56.4 RELATIVE FREQUENCY OF COMPLAINTS

There were 11,521 entries in Log B. Of these, 2123 could be classified as environmental complaints. The frequency of the environmental complaints is as follows: drafty (15), noisy

(69), too cold (1001), too hot (621), too humid (12), too dry (85), odor (60), smell (253), dusty air (3), air quality (1). If the too hot and too cold categories are combined into a single category called *thermal sensation*, the three most frequent categories in the log are repair (1823), examine (1663), and thermal sensation (1622). Because the repair and examine categories apply to many different kinds of complaints, the data indicate that thermal sensation complaints are the single most common kind of complaint, occurring even more often than any single kind of maintenance complaint such as burned out light bulbs, clogged toilets, or plumbing leaks. Figure 56.1 shows the absolute and relative frequencies of environmental complaints recorded in Log B. Smell, odor, dusty air, and air quality have been classified as indoor air quality (IAQ), and high and low humidity complaints have been classified simply as humidity. In comparison to other environmental complaints, thermal sensation complaints are the overwhelming majority (77 percent). This finding is consistent with BOMA (1988) and conflicts with Olesen and Madsen (1986), who state that “the most common complaint in air-conditioned spaces for sedentary work is draught.”

There were 3572 entries in Log C. Of these, 293 were triggered by environmental complaints. Figure 56.2 shows the relative frequencies of environmental complaints recorded in Log C. The result is similar to that of Log B. The only notable difference is that complaints of stuffy air were found in Log C but not in Log B. It is possible that these complaints were logged as “hot” in Log B.

FIGURE 56.1 Relative frequencies of environmental complaints in Log B.

FIGURE 56.2 Relative frequencies of environmental complaints in Log C.

56.5 TEMPORAL VARIATION IN COMPLAINT FREQUENCY

Figures 56.3 and 56.4 show the frequency distribution of hot and cold complaints recorded in Logs A and C, respectively, as a function of the time of day. The start-of-work times for the occupants associated with Log A were staggered from 7:30 to 9:00 A.M. to avoid traffic congestion. The start-of-work times for the occupants associated with Log C are unknown. In both figures, the frequency distribution of hot complaints is bimodal, whereas the frequency distribution of cold complaints is unimodal. As a result, the relative frequency of hot complaints first decreases from the early morning to midday and then increases in the afternoon. This effect is clearly shown in Figure 56.5. The variation in relative frequency of hot complaints to cold complaints may be due to human physiology and habit as well as to a variation in the thermal conditions of the buildings. For example, the reduction in the relative frequency of hot complaints in the morning may be due to a reduction in metabolism as the thermic effect of breakfast subsides. It is also possible that the normal routine of office work requires less energy expenditure later in the morning than earlier in the morning. The large increase in the relative frequency of hot complaints in the afternoon may be due to increased heat production caused by the thermic effect of food consumed during the lunch hour as well as to an increase in the building temperature.

FIGURE 56.3 Temporal frequency of hot and cold complaints from Log A.

FIGURE 56.4 Temporal frequency of hot and cold complaints in Log C.

FIGURE 56.5 Relative frequency of hot complaints to cold complaints during the day.

56.6 COMPLAINT TEMPERATURES

Log A contains temperatures at which each complaint event occurred. These temperatures were recorded manually. The occupants were asked to read the temperature indicated by the thermometer on the nearest thermostat, and these temperatures were recorded by the person taking the complaint call. Figure 56.6 shows the frequency distribution of the complaint temperatures. There are fewer complaints at extremely hot and cold temperatures because the frequency of exposure to extreme temperatures is low. Based on the complaint temperatures for humidity and air motion complaints as well as the temperatures recorded after complaints were resolved, Federspiel (1998) was able to deduce that the mean building temperature was 73.9°F. However, nothing could be said about the variance.

There are two important features in Figure 56.6. The first is that the mean values of the hot and cold populations are significantly higher and lower, respectively, than the temperature that is most commonly preferred for office work. The second is that the standard deviations of each population are sufficiently small relative to the difference between the means that there is little overlap between the hot and cold complaint temperature distributions. If the temperature had never dropped below 70°F or risen above 75°F, 96.5 percent of the complaints would not have occurred. These two features imply that few of the complaints should be attributed to interindividual differences in preferred temperature. Instead, they are likely the result of poor control performance and faults and therefore represent potential cost savings.

Gender Differences

Gender differences in complaint behavior were investigated. The name of the caller recorded in Log A was used to determine the caller's gender. Of the 2323 hot and cold com-

FIGURE 56.6 Space temperatures at the complaint locations at the time that the complaint was logged. (Reprinted by permission from *ASHRAE Transactions*, vol. 104, part 1.)

plaints, the gender of caller could be determined in 1901 cases. Of these 1901, 963 were female and 938 were male. The proportion of males and females in the workforce corresponding to Log A is unknown.

Table 56.1 summarizes the statistical findings regarding gender differences. Men and women complained that it was too hot at the same temperature, but there was more variability in the temperature at which men complained that it was too hot. Women complained that it was cold at a higher temperature than men, but the variability in the temperature at which they complained that it was cold was approximately the same.

These results are almost certainly confounded by women complaining for men and vice versa. However, the fact that two of the differences are statistically significant indicates that there are certainly gender differences, because removal of the confounding data could only make the apparent differences larger.

Gender differences in complaint behavior may be due to gender differences in clothing insulation or environmental exposure. They may also be due to fundamental differences between the sexes. Brill et al. (1984) have postulated that women are less satisfied with the temperature in buildings because they generally have a smaller body mass and are therefore more strongly affected by temperature changes. It has been shown that gender differences in preferred temperature are small (McNall et al. 1967, Fanger 1982, Nevins et al. 1975). However, it has also been shown that gender differences in the sensitivity to deviations from preferred temperature are large (McNall et al. 1968, Fanger 1982, Nevins et al. 1975), with women's thermal sensation being more sensitive than men's to such deviations. However, Nevins et al. (1975) found that the sensitivity of women's discomfort ratings (as opposed to thermal sensation ratings) was less than men's when they were cold and greater than men's when they were warm. Because gender differences in sensitivity to deviations from the preferred temperature have been demonstrated, gender differences in complaint temperature should be expected.

TABLE 56.1 Statistics Regarding Gender Differences

Complaint	Statistic	Female, °F (°C)	Male, °F (°C)	Test statistic	p_s
Hot	Mean	79.8 (26.6)	79.9 (26.6)	$U = 0.36$	0.39
Hot	Standard deviation	2.8 (1.6)	3.5 (1.9)	$Z_M = 2.72$	0.0033
Cold	Mean	66.3 (19.1)	65.5 (18.6)	$U = 3.0$	0.0013
Cold	Standard deviation	3.5 (1.9)	3.7 (2.1)	$Z_M = 1.15$	0.125

Differences between bold values are statistically significant.

Seasonal Differences

Statistical differences between thermal sensation complaints in summer and winter were investigated. Summer was considered to be June, July, and August, and winter was considered to be December, January, and February. Table 56.2 summarizes the statistical findings for seasonal differences. The robust estimation technique RWLS developed by Rousseeuw and Leroy (1987) was used to estimate the mean and standard deviation of the hot complaints because outliers in the data presented problems. The outlierfree data from the RWLS algorithm was then used in the nonparametric tests of location and scale. Occupants complained that it was too hot at approximately the same temperature in both summer and winter, but they complained that it was too cold at a higher temperature in the summer than in the winter. In the summer the variability in the hot-complaint temperature was less than in the winter, and the variability in the cold-complaint temperature was greater than in the winter.

Neutral Temperatures

Neutral temperatures were estimated for each gender in summer and winter. The neutral temperature is defined as the temperature at which the density function of the stated temperatures for hot complaints equals the density function of the stated temperatures for cold complaints. This definition is shown in Figure 56.7. The density functions were evaluated based on the RWLS estimates of the mean and standard deviation assuming that the density functions were normal. Using the model proposed by Federspiel (2000) for predicting unsolicited complaint frequency, this definition of neutral temperature corresponds to the temperature at which the probability of a space being in a “complaint condition” is minimized. This is not generally the same as the temperature that would minimize the rate of unsolicited complaints.

Table 56.3 shows the neutral temperatures for each of the four cases. The neutral temperatures are higher in summer than in winter. All of these values fall within the ASHRAE comfort zone (ASHRAE 1992). However, these results indicate that the difference between summer and winter neutral temperatures is smaller than what is indicated by the ASHRAE comfort zone when typical summer and winter clothing are used in the calculations. With typical summer and winter clothing, the midpoint of the ASHRAE comfort zone for summer is 5°F greater than the midpoint for winter. The difference according to the analysis of the stated temperatures is only 0.7°F for women and 2.0°F for men. These differences may

be small because the facility was located in an area where the winter weather is relatively mild and the summer weather is extremely hot and humid, so clothing insulation values may not be much higher in the winter than in the summer.

56.7 COMPLAINT-HANDLING PROCESS

Log A contains three time variables associated with the process of responding to complaints: the call-in time, the dispatch time, and the feedback time. From these three time variables, three time intervals can be calculated directly. The first is the time required to take, record, and dispatch the call. This time interval will be referred to as the central dispatch time, and it will be denoted as t_{cd} . The central dispatch time is calculated by subtracting the call-in time from the dispatch time. The second time interval that can be calculated directly is the time required by the field technician to respond to the dispatch message, travel to the complaint location, diagnose the problem, and (when possible) solve the problem. This time interval will be referred to as the transit and diagnosis time, and it will be denoted as t_{td} . The transit and diagnosis time is calculated by subtracting the dispatch time from the feedback time. The third time interval that can be calculated directly is the total time required to resolve a complaint. This time interval will be referred to as the total resolution time, and it will be denoted as t_r . The total resolution time is calculated by subtracting the call-in time from the feedback time. The definitions of these time intervals are depicted in Figure 56.8.

FIGURE 56.8 Timeline showing important events and intervals of a complaint and the resulting service call. (Reprinted by permission from ASHRAE Transactions, vol. 104, part I.)

Temporal Events and Intervals

Table 56.4 shows the sample mean and median of the three time intervals for the hot and cold complaint populations. Different samples were used to calculate these statistics because of missing data and data entry errors in the complaint log. One pattern that emerges from these statistics is that the mean values are consistently larger than the medians, indicating that the distributions are skewed to the left. Another consistent pattern that emerges is that the location parameters for cold complaints are larger than for hot complaints. These differences are statistically significant. The mean value of the central dispatch time for cold complaints was 0.1 hours (59 percent) greater than that for the hot complaints ($p_s < 0.001$). The mean value of the transit and diagnosis time for cold complaints was 0.4 hours (25 percent) greater than that for the hot complaints ($p_s < 0.001$). The differences were attributed to the fact that hot complaints sometimes have priority over cold complaints because hot conditions are more likely to cause damage to equipment such as computers.

Because the time at which the field technician arrives at the complaint location is not recorded, the transit time cannot be separated from the diagnosis time on a sample-by-sample basis. However, the mean and standard deviation of the transit time and the mean and standard deviation of the diagnosis time can be estimated based on a probabilistic model of the transit and diagnosis process. This was done with a simple model based on two assumptions. The first is that t_i is independent of t_d . The second is that t_i and t_d are exponentially distributed. The mean values (and standard deviations) of t_i and t_d were estimated by fitting the theoretical density function to the observed frequency distribution by minimizing the χ^2 norm. The observations were collected into 13 bins with 15-minute intervals for the first 2 hours, 30-minute intervals for the next 2 hours, and a single interval for the remaining time. This leads to a χ^2 test with 11 degrees of freedom. Table 56.5 shows the parameter estimates.

The χ^2 test was used to test the goodness of fit for each population. For the hot complaints, the residuals are statistically significant ($\chi^2 = 40.25$, $p < 0.001$), but for the cold complaints

TABLE 56.4 Mean and Median Values of Central Dispatch Time (t_{cd}), Transit and Diagnosis Time (t_{id}), and Total Response Time (t_{tr}) (Hours)

	Hot		Cold	
	Mean	Median	Mean	Median
t_{cd}	0.17	0.083	0.27	0.083
t_{id}	1.6	1.0	2.0	1.5
t_{tr}	1.6	1.0	2.1	1.5

they are not ($\chi = 15.24, p = 0.22$). Figures 56.9 and 56.10 show the observed and estimated frequency distributions for the hot and cold complaints, respectively. Although they appear qualitatively the same, the model is unable to satisfactorily estimate the magnitude of the peak of the hot distribution. The residual in that one bin is 30 percent of the χ^2 statistic.

The fact that the transit and diagnosis time may be modeled as a sequence of two exponential distributions (at least for the cold complaints) has at least two implications. The first involves the efficiency of the process. Exponential distributions arise when nonoverlapping intervals are independent. In this case, this means that each transit time is independent of the others, and each diagnosis time is independent of the others. Transit times may be inde-

FIGURE 56.9 Observed and estimated frequency distribution of transit and diagnosis times for hot complaints. (Reprinted by permission from ASHRAE Transactions, vol. 104, part I.)

FIGURE 56.10 Observed and estimated frequency distribution of transit and diagnosis times for cold complaints. (Reprinted by permission from ASHRAE Transactions, vol. 104, part I.)

pendent because the dispatcher does not know where the technician is located when she pages him. Diagnosis times may be independent because the technician has little information about the problem when he arrives at the complaint location. The fact that a double-exponential model passes the goodness of fit test for the cold complaints indicates that there is an opportunity to improve the efficiency and speed of the complaint handling process by providing the dispatcher and the technician with more information such as audio communications and remote, digital monitoring of process variables. It is possible that the double-exponential model of the transit and diagnosis time for hot complaints fails the goodness of fit test because there is more information available to the dispatcher and the technician when the hot complaint comes from a critical location. One would expect more remote, digital monitoring points for critical systems.

The double-exponential model also has implications for dispatching policies. Exponential distributions are memoryless. Mathematically this means that the conditional distribution is unaltered by the current value. Practically speaking, this means that no information about how much longer one must wait for a technician to arrive at the complaint location is gained by knowing how long one has already waited, and no information about how much longer a technician must be at the complaint location is gained by knowing how long the technician has already been there. These facts also imply a need for more information to improve the efficiency of the complaint handling process. Information about where the technician is and what the technician has learned is needed to improve the estimates of the remaining transit and diagnosis times.

Time-Temperature Correlation

Correlation between response times and stated temperatures was investigated. One might expect that more intensely hot complaints would be handled faster than less intensely hot complaints because of the priority given to hot complaints that affect temperature-sensitive equipment such as computers. Figure 56.11 shows a scatter plot of the total resolu-

FIGURE 56.11 Scatter plot of the total resolution time of each service call as a function of the complaint temperature. (Reprinted by permission from ASHRAE Transactions, vol. 104, part I.)

tion time versus stated temperature for hot and cold complaints. From the figure it is clear that within each population there is little correlation between the total resolution time and the stated temperature. Both the Spearman rank correlation coefficient and the Kendall τ coefficient were computed for every combination of the three time intervals and two complaint types. Of the 24 coefficients computed, 18 were negative. All of the coefficients for t_{cd} were negative, and all of the τ coefficients were negative. However, none of the tests based on these coefficients was statistically significant. The standard normal deviate with the largest magnitude was $Z_\tau = -1.07$ for cold stated temperatures and central dispatch times.

The implication of this finding is that the “intensity” of a thermal sensation complaint, as measured by the stated temperature, cannot be used to predict the time required for a response. From the point of view of the occupant, it means that one should not expect a faster response to a complaint when it is intensely hot than to a complaint when it is just moderately hot nor to a complaint when it is intensely cold than to a complaint when it is just moderately cold.

Actions in Response to a Complaint

In this section, an analysis of operator and field actions recorded in the complaint log is described. Figure 56.12 shows a frequency diagram of the operator actions performed, Figure 56.13 shows a frequency diagram of the field actions performed, and Table 56.6 lists action codes. Many of the operator actions involve adjusting setpoints, starting equipment, or stopping equipment. Many of these actions could be automated with a modern direct digital control (DDC) system if it were properly programmed. Many of the field actions also involve adjusting setpoints, starting equipment, or stopping equipment. These actions are performed in the field because of the absence of a networked DDC system. Most of the controls are pneumatic. With a modern DDC system these actions could be performed remotely, and like the operator actions of this type, they could also be automated.

56.8 COST AVOIDANCE POTENTIAL

To estimate the potential for reducing the complaint rate by upgrading the control system to a modern DDC system, assume that all setpoint adjustments could have been automated, that all start-stop operations could have been automated, and that the thermostat adjustments would not have been necessary. Furthermore, assume that the complaint would not have occurred if these tasks had been automated. In other words, assume that all complaints could have been eliminated except those that led to the generation of a work order (field action turned over to work crew), those that required minor work but not a work order, those that required airflow adjustment, and those that were turned over to engineering. Also, assume that none of the complaints with stated temperatures of 71, 72, 73, or 74°F could be avoided. Under these assumptions, the total number of hot and cold complaints could have been reduced from 2323 to 679, which is a 71 percent reduction. The total time spent fielding complaints would have been reduced by 2980 hours in the 12-month period studied. If the labor cost is \$35/hour, the cost reduction potential is \$104,300/year, or \$0.035/square foot/year. This is a labor cost reduction potential. In Dohrman and Alereza (1986), it was shown that the median and mean cost of labor for HVAC maintenance in 1983 for commercial buildings was \$0.15 per square foot and \$0.184 per square foot, respectively. Based on a 4 percent increase per year, the median estimated labor cost of HVAC maintenance for facility A in 1996 is \$750,000 per year, and the mean is \$920,000. These estimates imply that the potential for reducing thermal sensation complaints represents a potential reduction in the labor cost of HVAC maintenance of approximately 12 percent.

The cost reduction potential described above is probably not sufficient to justify the retrofit of all spaces. However, inspection of the data reveals that the complaint rate is not the same from space to space. Figure 56.14 shows the number of zones that had avoidable complaints numbering from 1 to 17. The figure shows that there were 1617 zones that reported just 1 complaint in the 12-month period covered by Log A and that there was one zone that reported 17 complaints during the same period. The figure also shows the payback period for retrofitting zones in the tail of this distribution, assuming that a retrofit would eliminate all of the avoidable complaints and that the retrofit cost would be \$750 per zone. For example, the payback period for retrofitting all zones with four or more com-

FIGURE 56.14 Frequency distribution of complaints and payback periods.

plaints in the 12-month period is 2.08 years. The payback for retrofitting just the one zone with 17 complaints is 8.4 months. By retrofitting only the worst-performing spaces, any payback period between 8.4 months and 8.5 years can be achieved solely from the reduction of complaint response cost.

56.9 CONCLUSIONS

The following conclusions can be drawn from the analysis in this chapter:

1. There is the potential to reduce the labor cost associated with HVAC maintenance by 12 percent (\$0.035/ft²/year) by reducing the frequency of hot and cold complaints.
2. Hot and cold complaints are rarely due to interindividual differences in preferred temperature. They are usually due to HVAC faults or poor control performance.
3. Statistically significant differences in the temperatures at which men and women complain that it is hot and cold exist. There is more variability in the temperature at which men complain that it is hot than there is for women. On average, women complain that it is cold at a higher temperature than men do.
4. The difference between summer and winter neutral temperatures may be significantly smaller than predicted by the ASHRAE comfort zones and typical summer and winter clothing. The neutral temperatures of both men and women are higher in the summer than in the winter.
5. There is no correlation between response time and thermal sensation complaint intensity.
6. Once on site, it takes 1.4 hours on average to diagnose a hot complaint and 1.7 hours on average to diagnose a cold complaint.
7. Most actions to thermal sensation complaints involve adjusting a control system setting.
8. Thermal sensation complaints are the single most common kind of unsolicited complaint in buildings and the overwhelming majority of unsolicited environmental complaints.

CHAPTER 57

MODELING IAQ AND BUILDING DYNAMICS

Philip Demokritou, Ph.D.

*Department of Environmental Health,
Environmental Science & Engineering Program
Harvard School of Public Health
Boston, Massachusetts*

51.1 THE INDOOR AIR ENVIRONMENT AS AN INTEGRATED DYNAMIC SYSTEM

The indoor air environment is a very complicated dynamic system. The main physical phenomena taking place in the indoor environment are the so-called transfer phenomena, which include heat transfer, mass transfer, and airflow (transfer of momentum). Additionally, there is a continuous interaction between the outside and indoor environment, as well as a human intervention through building technology in an attempt to control the comfort conditions.

As illustrated in Figure 57.1, the building indoor environment is mainly determined by various sources including the outdoor environment, the occupants and the heating, ventilation, and air conditioning (HVAC) system. These sources, through various heat and mass transfer paths and processes, determine the indoor climatic conditions. They are discussed in the following sections.

Outdoor Climate

The outdoor climatic environment can be characterized by parameters such as air temperature, humidity, solar radiation, wind speed, wind direction, radiant temperature and pollutants. Complex atmospheric dynamic phenomena determine the climatic conditions both regionally and over a period of time. Pollutants themselves represent a diverse group of particles, vapors, and gases. Because pollution sources vary in spatial densities and by their emission rates, characterization of pollutants at specific sites of interest may be required. The U.S. Environmental Protection Agency (EPA) publishes an air quality and toxic release inventory for various regions in the United States. A Website containing this information can be publicly accessed.

FIGURE 57.1 The indoor air environment as an integration of dynamic systems.

Occupants

The human body generates heat mainly by metabolism. The human dynamic thermoregulatory system tries to maintain an average organ temperature near to 36.7°C by exchanging heat with the environment. Heat transfer occurs mainly by radiation (40 percent), convection (20 percent), and evaporation of body fluids for example, by sweating, breathing (40 percent). The human body's temperature control system is considered one of nature's most complicated control systems and it has a highly nonlinear behavior. Metabolic rates are directly related to the body's activity level, age, and sex. Various metabolic emissions such as carbon dioxide, infectious material in shedding skin flakes, and bacteria can be a significant biological source of contamination. Thermal balance of the body is directly related to the thermal comfort conditions. Human activities such as cleaning and cooking also contribute to pollution generation.

HVAC System

The heating, ventilation, and air conditioning system controls the indoor climate by adding or extracting heat and adding or removing mass contents (i.e., humidifying or dehumidifying and filtering the air). The most important environmental parameters with respect to thermal comfort conditions are air temperature, relative humidity, mean radiant temperature, and the air velocity. These parameters directly affect the body's three basic mechanisms for heat rejection, convection, radiation, and evaporation. HVAC systems are trying to control the above thermal parameters to maintain acceptable comfort conditions. For example, an all-air HVAC system is heating or cooling the air to control the body's heat rejection by convection and maintain a proper body thermal balance. A radiant heating or cooling system is mainly trying to utilize heat exchange between the body and indoor environment by radiation to maintain the proper body thermal balance.

Unfortunately, maintaining acceptable thermal comfort conditions within the indoor environment does not necessary mean maintaining acceptable indoor air quality as well. On the contrary, misuse or bad maintenance of the HVAC system may cause severe indoor air quality problems. For example, a malfunction of the humidifier can spill water inside the

air duct system, which can trigger microbial growth if sufficient nutrients are present, causing a biological contamination problem. A poorly maintained cooling tower might be the amplification site for *Legionella pneumophila*, a deadly bacteria that can cause Legionnaire's disease. Several studies have been conducted to identify possible links between the HVAC systems, sick building syndrome, and the other building-related illnesses.

Indoor air quality has become a *design parameter* of the same or higher magnitude as any other thermal comfort parameter. Today's HVAC systems have a dual role to play, maintaining both thermal comfort and acceptable indoor air quality. Filtration and dilution ventilation are the two most common techniques being used in today's buildings to keep the various pollutants within the acceptable threshold limits.

Building Interiors

Building interiors include various appliances, cooking devices, lighting, furniture, and office equipment, which also add heat and mass content to the indoor environment. Off-gasing of the various furnishings, carpets, and other building materials is one of the major sources of volatile organic compound (VOC) gases in the building environment. Additionally, computers, printers, copy machines, and other high-tech equipment have been added in the last decade to the built environment, generating more air contaminants.

Furthermore, the increasing cost of energy and the advance of building technology led to high-tech fenestrations, with air tightness so low that air infiltration rates approach zero values. The energy crisis of 1974 also forced building owners and HVAC engineers to reduce the amount of outside air provided through the HVAC systems. The combination of new air contamination sources being added into the built environment and the decrease of dilution ventilation air led from the energy crisis of 1974 into today's indoor air quality crisis.

All the above sources of heat, mass, and momentum act via various transfer mechanisms. For example, the building envelope, which consists of the walls, windows, roof, doors, and floor, provides the major flow paths for heat and mass transfer from the outside environment. Air also flows directly through the building envelope into the building. Pressure- or temperature-driven airflows can also provide the pathways for air contamination migration within the various areas of the building itself. Numerous cases of cross-air contamination problems have been reported where unplanned air flows through dried out plumbing traps, elevator shafts, ceiling plenums, unsealed pipe chases, garages, and so forth, providing the pathways for pollutants to reach occupied zones within the building.

The various building heat and mass transfer mechanisms are regarded as very complicated dynamic phenomena. It is apparent that the indoor environment as a whole is a very complicated dynamic system consisting of several subsystems that may be regarded as complicated dynamic systems themselves. This reality is difficult to express in simple mathematical expressions, graphs, or correlations.

57.2 MATHEMATICAL REPRESENTATION OF THE INDOOR AIR ENVIRONMENT

The theory behind the transfer phenomena has been well established and mathematically documented over the years by the scientific community. The mathematical representation of the governing equations can be derived by applying fundamental conservation laws to the conservation of energy, mass, and momentum. The following set of nonlinear partial differential equations is the mathematical representation of the transfer phenomena taking place within the indoor environment:

- Equation of continuity
- Equation of momentum
- Energy equation
- Species concentration equation

All the above equations have two terms, a diffusive term and a convective term, as a result of the two major mechanisms of transfer, *diffusion*, and *convection*. Diffusion of energy, momentum, or mass occurs because of molecular interactions. Convection of heat, mass, or momentum occurs because of the massive mixing taking place because of the airflow.

The first two equations determine the airflow characteristics, and they are known as the Navier–Stokes equations. They were developed first by Navier in 1827 and extended later by Stokes in 1845 and govern the *laminar viscous* fluid flow phenomena. The Navier–Stokes equations do not have an analytic solution in their full form. Some analytic solutions can be obtained for simplified geometries and under other simplified assumptions (i.e., one-dimensional problems, simplified geometry, simplified boundary conditions). Most of the real-life engineering problems, including indoor airflows, are, however, not laminar but *turbulent flows* with complicated geometrical boundary conditions, which means an analytical solution cannot be derived from the Navier–Stokes equations.

Nearly all room flows contain turbulent and laminar flows. A laminar flow changes into a turbulent flow with the increase of Reynolds number. The main characteristics of a turbulent flow are the time dependency of the flow and the microscopic size of vortices. Navier–Stokes equations can be used to analyze a turbulent flow. When it is not critical to know the detailed time dependency of the turbulent flow, it is sufficient for most of the engineering applications to assume that the instantaneous value of a dependent variable is the sum of a time-averaged value and fluctuation. If all dependent variables of the original Navier–Stokes equations are substituted according to this assumption, a new set of equations is obtained where the new variables are the time-averaged quantities. This set of equations is called the *Reynolds equations*, and they have exactly the same mathematical form as the original equations but contain one additional term. This term represents the transport of energy, momentum, and mass due to the turbulent nature of the flow.

Boussinesq in 1877 made the assumption that this turbulent term can be expressed in a similar mathematical form as the diffusion term. Instead of the original diffusion coefficient, the *turbulent coefficient* was introduced. The turbulent diffusion coefficient, or Eddy viscosity, depends on the flow characteristics and it can be determined experimentally. Since then many turbulent models have been developed to predict the turbulent flows. The most well-known turbulent models for indoor airflows are the Prandtl mixing length model, the K- ϵ model, and the Reynolds stress model. The K- ϵ model is the most practical and most widely used turbulent model for room air convection problems. More research is needed to increase the accuracy and simplicity of the turbulent models.

57.3 MODELING THE INDOOR AIR ENVIRONMENT

An Introduction to Microscopic and Macroscopic Modeling

The same way computers and computer-aided design (CAD) tools can give the architect/planner the opportunity to create a “virtual building” and try a number of alternative design scenarios, looking for the optimum design, engineers and scientists can evaluate the building energy efficiency, thermal comfort, indoor air quality, daylight and light condi-

tions, and many other aspects of the building environment by using simulation tools. *Simulation is most likely the only opportunity the designer has to improve the design before its final implementation.* Design flaws can be avoided during the design process, not only saving time and money but also sometimes saving lives if we are dealing with life safety building services such as fire protection or ventilation systems for hospital isolation rooms.

Recent advances in computer power and the development of new computational methods led to a wide spread of this new technology in almost every scientific field. Despite the drawbacks of limited accuracy and sometimes the user unfriendliness of the methods, in the near future computer modeling will be advanced enough to be applied to everyday design and operation. Applications include the following:

- *Energy assessments.* Heating, cooling, ventilation and lighting of buildings
- *Comfort assessments.* Thermal and visual
- *IAQ assessments.* Pollutant behavior
- *HVAC system simulation.* Equipment sizing, control performance prediction
- *Airflow simulation.* Bulk/natural ventilation
- *Condensation prediction.* Surface, interstitial, humidity movement
- *Daylighting, lighting*

Predictive modeling is the art of developing a set of mathematical equations that faithfully represents the complex physical phenomena and then solving the equations to predict the behavior of real-life systems. The process of using the model to analyze the behavior of the real-life system is called *simulation*. Verification and experimental validation of the model to check the accuracy and establish the model's limitations are extremely important.

To date, modeling efforts for the indoor air environment have proceeded along two major paths, *macromodeling* and *micromodeling*. Macromodels are based on the basic mass balance equation and the perfect mixing assumption leading to lumped parameter formulations. Macromodels are characterized by ordinary differential equations. These models are usually used to predict the indoor air parameters from one zone to another within a building. No spatial distribution or surface phenomena such as particle surface deposition can be predicted using this type of modeling.

Micromodels are based on the full form of Navier–Stokes equations, as described above. These equations contain the spatial and time dependency of all indoor environment variables such as velocity vectors, temperature, and species concentration. Micromodels may have one, two, or three dimensions depending on the flow problem and application. Advanced numerical methods such as finite volume and finite element methods are needed to solve the Navier–Stokes equations. It is apparent that because of the complex mathematical form of the equations, more computational time and computer power than for macromodels are required to obtain a solution. On the other hand, because more complicated transfer mechanisms and their interaction are taken into consideration, the predictive capability of the model is enhanced.

Both modeling approaches are important, and which approach will be followed depends on the flow problem, the issues to be addressed, and the available computer power. For example, a macroscopic model is adequate to estimate the flow of a contaminant from one zone to another within a building, but it is inadequate to address the spatial distribution of the contaminant within a clean room. Table 57.1 summarizes the pros and cons of macroscopic and microscopic models.

In the last decade, with the impressive advance of computers, micromodels have been more widely used to predict the indoor air environment. Computational fluid dynamics (CFD) is the new, state-of-the-art micromodeling tool and has applications in numerous

TABLE 57.1 Pros and Cons of Macroscopic and Microscopic Models

Pros and cons	Micromodels	Macromodels
Ordinary differential equations	No	Yes
Partial differential equations (e.g., Navier–Stokes)	Yes	No
Prediction of spatial distribution of indoor parameters (one-, two-, and three-dimensional solutions)	Yes	No
Computational time—computer power	High	Low
Accuracy	Excellent	Good
Prediction of airflow conditions (velocity, etc.)	Yes	No

other fields of science and technology, including weather forecasting, structural analysis of buildings, and fluid flow applications. CFD methods are based on numerical approximation of the Navier–Stokes governing equations of mass conservation, conservation of energy, conservation of momentum, and conservation of species. Although those advanced numerical methods were considered quite impractical in the past, this type of numerical approach is becoming feasible and practical. The successful application of those techniques in other scientific fields, such as the aircraft industry, is a typical example of the power of this innovative technology. Commercial CFD computer software is also now available, including applications for the room air environment. Slowly but steadily the scientific community is increasing its use of CFD methods. The majority of the work in the CFD arena has been done in Europe and Japan.

Building Energy Modeling

The architect or engineer should estimate the hourly heating and cooling requirements of the building to properly size the HVAC equipment. Additionally, an important task of the design process is to estimate the annual building energy consumption for a given design, predict thermal comfort conditions, and compare various design scenarios, looking for the optimum design.

The first energy simulation methods for heating and cooling load calculations for building applications were developed in the 1950s and were based on simple analytical methods. The energy conservation equation is solved under many simplified assumptions, and many input parameters of the heat transfer problem must be given assumed values. Often such a method presents simple mathematical correlations or graphs from which the cooling load or energy consumption can be calculated for various values of certain independent variables (e.g., overall heat transfer coefficient, façade glazing ratio). Engineers with a simple calculator can make manual calculations without the use of a personal computer, of the hourly building cooling requirements or the other thermal comfort conditions. These methods are known as *manual methods*. The term *manual* may be misleading in the sense that nowadays these methods are often computerized in the sense that simple programs such as spreadsheets can be used to save the time needed for the manual calculations. Nevertheless, these are manual methods, and therefore the same accuracy limitations apply. To date, for design purposes, engineers still use the manual methods. A typical example of this generation of methods is the *transfer function method* (TFM) developed by Mitalas and Stephenson in 1967 for cooling load calculations and prediction of the thermal conditions within the building environment. This method has been adopted by the American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE) and is still being used widely by engineers as simple correlations or graphs.

Recent advances in analysis, computational methods, and computer power have led to more advanced methods for energy analysis of the building environment. The new generation of methods is based on microscopic modeling and numerical solution of the differential energy equation. The new generation of simulation systems aims to take into account as many building energy flow paths as possible, but computer power and user friendliness pose certain limitations. There are many energy analysis programs available that have varying sophistication and accuracy. The user should be aware of the limitations, assumptions, and the applications of those programs. For example, a program that can be used to predict the cooling and heating load requirements of a building might not be accurate enough to be used to predict the annual energy consumption of the building.

The most widely used energy analysis computer programs are DOE-2, ESP-r, BLAST, TRANE/TRACE. There are also many specialized building energy simulation computer programs that focus only on one particular aspect of the indoor environment (i.e., on airflow in a CFD software or on lighting in visualization models). The most sophisticated and integrated ones, covering a wide range of applications, are discussed below.

DOE-2

Description. DOE-2 was developed by Lawrence Berkeley National Laboratory and sponsored by the U.S. Department of Energy (DOE). It is widely recognized as the industry's standard. Users can calculate hourly and annual whole-building energy performance and life cycle cost of the HVAC systems. Uses include evaluation of the energy efficiency of given HVAC designs, implementation of energy efficiency standards and compliance certification, demand site energy management, and cooling and heating load calculations for multiple zones and a variety of HVAC systems. Programming language of the software is FORTRAN, and it is available for almost all computer platforms including PCs, UNIX, DOS, and VMS. Despite its indisputable strengths, a strong engineering background and a high level of computer skills are required for its use.

Required Inputs to the Program—Outputs. Required inputs include geographic location of building including orientation, building materials and building envelope structure (walls, fenestrations, indoor/outdoor shading, etc.), hourly weather data, operating schedules for HVAC systems, HVAC equipment and control schedules, and utility rates. Manual input of building geometry and other data as well as the absence of a true Windows environment make the input process time consuming. The user has a wide selection of reports including monthly/annual summary reports and hourly energy analysis calculations of multiple zones and HVAC systems.

ESP-r

Description. ESP-r was developed in 1974 by a European research consortium principally located at the Energy Research Unit of the Strathclyde University in Glasgow, Scotland. ESP-r is the European reference building simulation program for energy modeling and also for predicting mass flows, modeling of combined thermal-electrical systems, and daylight utilization within the indoor environment. ESP-r (r stands for Research and EU Reference) allows researchers and designers to assess the manner in which actual weather patterns, occupant interactions, design parameter changes, and control systems affect energy requirements and indoor thermal conditions. Applications include the following:

- *Energy assessment.* Heating, cooling, ventilation, and lighting of buildings
- *Comfort assessment.* Thermal and visual
- *HVAC system simulation.* Equipment critical sizing, control performance prediction
- *Airflow simulation.* Bulk/natural ventilation, detail path/CFD

- *Condensation prediction.* Surface, interstitial, humidity movement
- *Daylighting*

State-of-the art microscopic-type modeling methods including CFD technology have been used to approach all the complex dynamic interactions within the building environment. It simulates many innovative-edge technologies such as combined heat and electrical power generation via photovoltaic technology. Its solar-passive systems make it unique, and it is widely being used in Europe as a research and design tool. Because of its special features, a high level of expertise is required. The programming languages of the software are FORTRAN and C++. Available computer platforms are UNIX, X-windows, and Sun/OS.

Required Inputs to the Program—Outputs. Building geometry is required, which can be defined either by using CAD tools or by using the built-in graphical interface. Built-in libraries can be used to select a variety of materials, HVAC systems, and other entities to create the whole building representation. A graphical interface is available for the analysis of results.

Environmental Comfort Models

The most important objective of a building is to provide a comfortable indoor climate all year round despite the weather changes. Through the centuries humans have continuously attempted to control those climatic parameters that cause dissatisfaction and discomfort. Of course, for the humans of Stone Age, comfort was the equivalent of just staying alive or avoiding freezing conditions. Now, comfort means a total control of the indoor environment including temperature, humidity, lighting, noise, and pollution control; it definitely includes more than just thermal comfort control. That is why the term *environmental comfort* is sometimes used instead of *thermal comfort*.

In the Bibliography, environmental comfort is generally defined as that state that will be considered by a large percentage of occupants (usually at least 80 percent) as acceptable. Thermal comfort particularly is related to the thermal balance of the body and is affected by the so-called thermal parameters, the air temperature, mean radiant temperature, relative humidity, and air velocity. It is also influenced by the occupant's activity level and clothing thermal resistance.

Several research studies have been done in the last decade, including extensive experiments and investigations, to give a mathematical form to this complexity. The most well-known model is Fanger's *comfort equation* and his revolutionary methods Predicted Mean Vote and Predicted Percentage of Dissatisfied, which can be used to define comfort zones for certain thermal parameters. Several thermal comfort standards have been established during the last 20 years based on these models. The most widely used thermal comfort standards are the ASHRAE Standard 55-1992—"Thermal Environmental Conditions for Human Occupancy" and its European equivalent, ISO 1984. It is anticipated that Fanger's methods will be expanded to include other environmental parameters such as air quality, noise, and light conditions.

Indoor Air Quality Models

Indoor air quality models are being used to predict the dispersion of air contaminants within the building environment. Air contaminant concentration can be estimated both spatially and as a function of time. Modeling is a powerful tool that is being used extensively by scientists to investigate air movement and airflow patterns and evaluate the performance of building ventilation systems. Although designers, architects, code enforcement officials,

and other building scientists have been using modeling as a powerful tool to address IAQ issues, more development is needed to increase the accuracy and the validity of the IAQ models. Despite the drawbacks, in the near future computer modeling will be advanced enough to be applied to everyday design and operation.

Macroscopic Models. Several macroscopic models have been developed using the basic mass balance equation for predicting pollutant behavior. The generation and removal of a contaminant in an indoor environment can be mathematically described in the following *mass balance equation*:

$$\begin{aligned} \text{Rate of accumulation} = & (\text{rate of change due to infiltration of outside air}) + (\text{rate of} \\ & \text{change due to generation indoors}) - (\text{rate of change due to exfiltration of indoor air}) - \\ & (\text{rate of change due to indoor removal}) \end{aligned}$$

All parameters defined in the above mass balance equation, such as ventilation, removal, and source emission rates, have to be measured and usually are difficult to obtain.

A single room is usually treated as a single zone or compartment in which no spatial variation of the contaminant concentration occurs (well-mixed air assumption). In this type of macroscopic approach the flow conditions are not parameters of the model. Single-zone models may not be adequate when sources and sinks are not uniformly distributed or perfectly mixed throughout the room. In this case a multizone model may be used by applying the same mass balance concept for every zone.

This approach considers mass concentration alone and addresses the fundamental surface mass transport phenomena in a volumetric fashion. This is inadequate for addressing many important issues concerning indoor air quality problems such as the mass transport of particles at indoor surfaces (deposition), coagulation, and other chemical interactions between particles. Additionally, no information is provided on the spatial distribution of the contaminants. Indoor air flow conditions are also unknown parameters in the model. It is obvious that in cases where the spatial distribution of the contaminant or the other airflow parameters are critical, a microscopic model has to be used. For this type of application a CFD approach is more suitable.

CFD Modeling for the Indoor Air Environment. CFD methods are based on numerical approximation of the Navier–Stokes governing equations of mass conservation, conservation of energy, conservation of momentum, and conservation of species as outlined above. In a CFD approach, the flow domain is divided into small brick-type computational cells or finite control volumes. For each cell an algebraic set of the conservation equations is obtained by integration of the differential equations over the finite volume (discretization process, finite volume method). All those algebraic equations are then solved in an iterative manner to give field values for every dependent variable in every computational cell. Data obtained from such a numerical solution include air velocities, air temperature distribution, pressure distribution, concentration of species, and so on.

CFD modeling has been successfully used, particularly for those indoor air quality applications for which the spatial contaminant concentration distribution or the airflow parameters are needed. Several CFD models have been developed and used successfully for room airflow simulations. Even though there are some difficulties simulating buoyancy flows, turbulence, and other complex flows, as computational power increases, we will be able to use supercomputers to study complex flows and boundary conditions and to incorporate more complicated mass and heat transfer mechanisms into our CFD models.

Applications of CFD in the indoor and outdoor environment include the following:

- Performance analysis of indoor climatic conditions, including air movement and thermal comfort assessment. Typical examples are natural ventilation studies, temperature strat-

TABLE 57.2 Typical Characteristics of Commercially Available CFD Software

Features	Typical applications
Can predict spatial distribution of airflow parameters such as velocity vectors, contaminant concentration, temperature, pressure	Clean room applications, three-dimensional analysis, natural or mechanical ventilation, buoyant airflows, heat transfer problems, temperature stratification
Particle tracking	Track humidity and the motion of particles, aerosol dynamics modeling
Transient and steady state analysis	Fully dynamic analysis to predict time dependency of indoor air environment
Advanced turbulence models	Complex building geometries and boundary conditions for demanding turbulent flows
Multiphase flows, chemical reacting flows	Continuous and disperse multiphase flows for combustion and other chemical engineering applications, advanced IAQ problems such as coagulation, characterization of sink and sources
Advanced numerical methods	Finite volumes, finite elements, advanced grid generation, cartesian/cylindrical systems, complex wall boundary conditions
Graphical user interfaces	Easy creation of geometry, reading of CAD geometries, visualization tools for colorful representation of parameters

ification, and solar gain distribution in large enclosures such as in atria and evaluation of HVAC system performance.

- Indoor air quality assessments including the spread of pollutants and ventilation effectiveness to dilute or remove pollutants. CFD models may also be used to predict thermofluid phenomena in the external environment. Typical applications are the spread of smoke from a fire within the building, clean room applications, isolated intensive care units and other hospital applications, spread of chemical pollutants from chimneys and chemical plants into the atmosphere, and displacement ventilation.

Although CFD modeling was considered quite impractical in the past and was used exclusively for research purposes, recently this type of numerical approach has become commercially available and is considered a powerful design tool. CFD modeling has been successfully used in every application of fluid dynamics in the aircraft, automobile, turbine and pump, and the building industries. Table 57.2 shows the main characteristics and typical applications of the commercially available CFD software.

58.1 INTRODUCTION

Indoor air quality (IAQ) models provide a way to link information about sources, sinks, and building factors to estimate indoor pollutant concentrations. The role of indoor air models in estimating the risk of indoor pollutants is shown in Figure 58.1. Many of the latest indoor air models include exposure modeling and one, RISK (Sparks, 1996), includes risk modeling.

Numerous models have been developed to study indoor air quality. The type of model used depends on the planned uses of the model. The most common uses of IAQ models follow:

- Estimating population exposure to various indoor pollutants
- Estimating the impact of individual sources on pollutant concentration
- Estimating the impact of individual sources and IAQ control options on personal exposure

The nature and structure of a given IAQ model are dictated by the planned use of the model. Models designed to estimate population exposure, for example, use Monte Carlo techniques to estimate exposure distributions. Models designed to estimate the impact of individual sources use mass balance equations. Based on the various uses of IAQ models and on the different techniques used to develop the models, it is convenient to divide models into the categories shown in Table 58.1. Each type of model is discussed in this chapter.

Type of model	General purpose	Example
Statistical	Estimating population exposure	SHAPE, Ott (1984)
Mass balance	Estimating impact of sources	RISK, Sparks (1996), CONTAM, Axley (1988)
Computational fluid dynamics (CFD)	Estimating near-source individual exposure	Brohus (1997)

58.2 STATISTICAL MODELS

Understanding the exposure of the whole population or sensitive subpopulations to indoor pollutants is important for reducing the risk due to pollution. The cost and complexity of determining population exposure experimentally have resulted in the development of several IAQ models. These models provide estimates of the distribution of indoor pollutant exposures for whole populations or sensitive subpopulations. The exposures of interest depend on the nature of the health risks of concern. For example, total lifetime exposure is usually associated with cancer risk. Many chronic and irritant risks are associated with peak exposure.

The total exposure to an environment is defined as the time-integrated concentration encountered by an individual (National Academy of Sciences, 1991) and is given by

$$E_T = \int_{t_i}^{t_f} C(t) dt \quad (58.1)$$

where E_T is total exposure, t_i is the time that the environment is entered, t_f is the time the environment is left, and $C(t)$ is the concentration in the environment at time t . Common units of E_T are microgram hour per cubic meter. The average concentration in the environment between t_i and t_f is

$$\bar{C}_T = \frac{E_T}{t_f - t_i} \quad (58.2)$$

Many of the population exposure models also calculate the potential inhaled dose D_T , defined by

$$D_T = \int_{t_i}^{t_f} B(t) C(t) dt \quad (58.3)$$

where $B(t)$ is the breathing rate at time t . If the breathing rate is constant at $\bar{B}_T$, the potential inhaled dose is given by

$$D_T = \bar{B}_T \cdot \bar{C}_T \cdot (t_f - t_i) \quad (58.4)$$

Databases of concentration as a function of time for various environments, population activity patterns (how much time is spent in each environment), and breathing rates are required for the statistical models. The models generate exposure and potential dose distributions using Monte Carlo techniques to combine the databases. The basic algorithm is as follows:

1. Select an environment
2. Sample the concentration database to generate a concentration
3. Sample the activity pattern database to determine time spent in the environment
4. Calculate exposure in the environment
5. Sample breathing rate database to determine breathing rate
6. Calculate potential dose
7. Repeat steps 2 through 6 to generate exposure distribution for selected environment
8. Repeat steps 1 through 7 until all environments of interest are covered

The time resolution of the statistical models is limited by the time resolution in the databases. The time resolution of the concentration data is generally a limiting factor. Data sources for concentrations of selected indoor pollutants are given in Table 58.2.

One of the best-known statistical models is the Simulation of Human Activity and Pollutant Exposure (SHAPE) model developed at EPA (Ott 1984). This model uses Monte Carlo sampling techniques to build exposure frequency distributions by combining population activity data with concentration distributions for different microenvironments. Although SHAPE was developed primarily for estimating total (24-hour) exposure distributions, it can be used to estimate distributions for indoor environments contributing to total exposure. The Benzene Exposure Assessment Model (BEAM), Behar (1989), uses the basic SHAPE model to study benzene exposures. SHAPE and BEAM use activity patterns from EPA studies in Denver, Col., and Washington, D.C., Akland et al. (1985). Özkaynak et al. (1993) and Pandian et al. (1993) discuss application of statistical models.

Traynor et al. (1989) developed a model to estimate the exposure to pollutants from combustion sources. This model uses databases of housing-stock parameters, type of combustion source, and source-usage parameters to predict indoor pollutant concentration distributions for areas of interest. The model predicts average pollutant concentrations over a 1-week time period.

Carbon monoxide	Residences	Wilson et al. (1993)

The California Population Indoor Exposure Model (CPIEM), Koontz et al. (1998), is an ambitious model designed to allow estimation of the peak and average exposures to indoor pollutants in California. The model uses measured concentration distributions and location/activity patterns to calculate exposure to indoor pollutants. If concentration data are not available, the model can calculate pollutant concentration distributions from user-supplied information on source usage distributions and source emission rate distributions. Example outputs and comparison with measurements from the CPIEM model are shown in Tables 58.3 and 58.4.

The accuracy of the predictions from statistical models is a function of the quality of the data in the various databases and on the validity of the statistical distributions used to sample from the databases. The lack of adequate data on indoor pollutant concentrations and source usage and emission factors is a major limitation of the statistical models. When data needed to drive the models are available, the models provide policymakers with useful information on the exposure of whole populations or subpopulations to indoor pollutants.

58.3 MASS BALANCE MODELS

Mass balance models are designed to allow estimation of the impact of sources, sinks, and IAQ control options on indoor pollutant concentrations. Some of these models, for example Hayes (1989), the Multi-Chamber Consumer Exposure Model (MCCCEM), Koontz et al. (1990) and Koontz and Nagda (1991), and RISK, Sparks (1996), allow estimation of individual exposure.

Mass balance models are based on the principle of conservation of mass. Models may have single or multiple compartments. In a single-compartment model, the entire building is represented as a single space. In multicompartment models, a building is represented by a number of connected spaces. The mass balance for a room is given by

$$V_i \frac{dC_i}{dt} = C_{iIN}Q_{iIN} - C_{iOUT}Q_{iOUT} + R_i - S_i \quad (58.5)$$

where V_i is the volume of the room, C_i is the pollutant concentration in the room, C_{iIN} is the concentration entering the room, Q_{iIN} is the airflow into the room from all locations, C_{iOUT} is the concentration leaving the room, Q_{iOUT} is the airflow leaving the room to all locations,

TABLE 58.3 Comparison of Personal Monitoring Measurements and CPIEM Model Predictions for Nitrogen Dioxide

Statistics	Measured, $\mu\text{g}/\text{m}^3$	CPIEM predicted, $\mu\text{g}/\text{m}^3$
Average	71.7	73.0
Standard deviation	33.8	29.9

R_i is the source term, S_i is the sink and pollutant removal term, and the subscript i refers to room i for a room in a set of multiple rooms, $i = 1, 2, \dots, N$, where N is the number of rooms. The sink and removal term S_i includes pollutant removal by air cleaners and sinks. Note that the source term and the sink and removal term may involve additional differential equations that describe the behavior of the sources and sinks.

If the air in the room is well mixed, $C_{i\text{OUT}}$ equals C_i and Equation (58.5) can be rewritten as

$$V_i \frac{dC_i}{dt} = C_{i\text{IN}}Q_{i\text{IN}} - C_iQ_{i\text{OUT}} + R_i - S_i \quad (58.6)$$

The general equation for the mass balance of room i in a building with N total is

$$V_i \frac{dC_i}{dt} = C_a P t_a Q_{a,i} + C_h Q_{h,i} + \sum_{i=1, j \neq N}^N C_j Q_{j,i} - C_i Q_{i,a} - C_i Q_{i,h} - \sum_{i=1, j \neq N}^N C_i Q_{i,j} + R_i - S_i \quad (58.7)$$

where C_i is the concentration in room i , C_a is the concentration outdoors, Pt_a is the penetration factor for outdoor pollutants entering the indoors ($Pt_a = 1$ means no loss of pollutants and $Pt_a = 0$ means 100 percent loss of pollutants), $Q_{a,i}$ is the airflow from the outdoors into room i , C_h is the concentration in the heating, ventilating, and air-conditioning (HVAC) system, $Q_{h,i}$ is the airflow from the HVAC system into room i , C_j is the concentration in room j , $Q_{j,i}$ is the airflow from room j into room i , $Q_{i,a}$ is the airflow from room i to the outdoors, $Q_{i,h}$ is the airflow from room i into the HVAC system, $Q_{i,j}$ is the airflow from room i into room j , R_i is the source term for pollutants produced in room i , and S_i is the removal term for pollutants removed in room i , including those removed by sinks and air cleaners.

Equation (58.7) is one of a set of equations that must be solved simultaneously in a multiple room model. If the source, sink, and airflow terms in Equation (58.7) are constant for the time interval t_0 to t , the equation can be solved analytically to give

$$C_i = C_i(t_0) e^{-L_i(t-t_0)} + \frac{P_i}{L_i} (1 - e^{-L_i(t-t_0)}) \quad (58.8)$$

where $C_i(t_0)$ is the concentration in room i at time t_0 , t is some time greater than t_0 , L_i is

$$L_i = \frac{Q_{i,a} + Q_{i,h} + \sum_{j=1, j \neq i}^N Q_{i,j}}{V_i} \quad (58.9)$$

and P_i is given by

$$P_i = \frac{1}{V_i} \left[\sum_{j=1, j \neq i}^n Q_{j,i} C_j(t) + R_i - S_i + Q_{a,i} C_a Pt_a + Q_{h,i} C_h \right] \quad (58.10)$$

The L term accounts for airflow out of the room, and the P term accounts for changes in pollutant mass due to airflow into the room, sources, sinks, and air cleaners.

The penetration term Pt_a is important for determining the impact of outdoor air pollution on IAQ. Suggested values of Pt_a for some common pollutants are given in Table 58.5. Note that the values given in Table 58.5 are for penetration through the building shell via cracks and small holes. These values do not apply for entry of outdoor pollutants via open windows or an HVAC system.

In most cases of interest, the sources and sinks terms are not constants. As is discussed in the section on source and sink models, proper modeling of sources and sinks can add additional coupled equations to the set of equations that must be solved. An IAQ model must, therefore, solve the large system of equations resulting from the mass balance numerically. Evans (1996) and Axley (1995) discuss many of the techniques that can be used to solve the set of equations. The CONTAM series of models, Axley (1988, 1990) and Walton (1997), uses finite element techniques to solve the set of equations. The RISK model, Sparks (1996), uses a fast discrete time step algorithm developed by Yamamoto et al. (1988) to solve the series of equations.

Some mass balance models are listed in Table 58.6. Many of these models are continually updated to improve their usefulness. For example, Axley (1995) and Walton (1997) discussed several improvements to CONTAM. Sparks et al. (1999a) added new source models to RISK to improve prediction of the impact of latex paints.

In spite of the differences in these models, they are basically the same in their fundamental underpinning as evidenced by the virtually identical results they produce for a relatively simple situation, Koontz and Rector (1989). The main differences between the models are ease of use and flexibility. Ivnitsky et al. (1996) present a more recent comparison of IAQ models.

A major assumption used in the various mass balance models is that the rooms are well mixed. The well-mixed assumption is valid in the following conditions:

- Time scales of interest are several minutes or longer.
- Concentrations very close to large sources are not of interest.
- There are no local flow disturbances close to the location of interest.

The validity of the well-mixed assumption was verified in several experiments in the EPA IAQ test house, Tichenor et al. (1990), Sparks (1991), Sparks et al. (1999b), and by data reported by Maldonado (1982). Note that the well-mixed assumption applies to the individual rooms in a building. Thus, individual rooms in the building can have different concentrations. Mage and Ott (1996) discuss ways to account for nonuniform mixing.

As can be seen from Equation (58.7), the pollutant concentration in a room is a function of the room-to-room airflows; the airflow between the indoors and the outdoors; and the sources, sinks, and other pollutant removal mechanisms in the room. The room-to-room airflows and the airflows between indoors and outdoors can be dominated by the forced air-flow (such as provided by an HVAC system) or by naturally driven airflows. CONTAM provides a method for calculating the various airflows if sufficient data on openings, temperature differences, HVAC characteristics, and so forth, are provided. COMIS, Feustel (1990), also provides a method for estimating the various airflows. Most other models, for example RISK, require that the various flows be entered as input data. Model predictions are relatively insensitive to the room-to-room airflows.

Because the various models solve the differential equations numerically, it is important that the time step used for the numerical solution is small enough to capture the events, such

as changes in sources on/off status, changes in air exchange rates, and changes in HVAC status, that are being modeled. Most models hide the information on step size from the user but often provide a way to change the step size as part of model setup.

Sowa (1998) discusses methods of introducing stochastic factors into the mass balance models. The addition of stochastic factors allows mass balance models to be used in situations where statistical models are used. Because mass balance models are well suited for analysis of risk management options, the methods suggested by Sowa can provide decision makers with estimates of the population impacts of risk management options that would be difficult to obtain using other methods.

Verification of Mass Balance Models

Sparks et al. (1991, 1999b) and Sparks (1996) discuss the verification of a mass balance IAQ model. Sparks et al. suggest several quantitative factors for assessing the general agreement between the model predictions and the experimental data. Most of these factors are based on recommendations by ASTM (1991).

The first method suggested is the absolute value of the average fractional residual between the measured or observed concentration c_o and the predicted concentration c_p given by

$$\frac{\sum_{i=1}^n \left| \frac{c_{pi} - c_{oi}}{c_{oi}} \right|}{n} \quad (58.11)$$

where c_{pi} is the value of the i th predicted concentration, c_{oi} is the value of the i th observed concentration, and n is the number of observations. The absolute value of the fractional residual gives a general sense of how well the model fits the data. The absolute value of the fractional residual for an ideal model would be of the same order as the experimental error in the data. The other quantitative factors used to assess the general agreement between the model predictions and measurements are those suggested by ASTM (1991).

The correlation coefficient between observed concentration c_o and predicted concentration c_p is given by

$$\frac{\sum [(c_o - \bar{c}_o) \cdot (c_p - \bar{c}_p)]}{\sqrt{[\sum (c_o - \bar{c}_o)^2] \cdot [\sum (c_p - \bar{c}_p)^2]}} \quad (58.12)$$

where $\bar{c}_o$ and $\bar{c}_p$ are the average values of the observed and predicted concentrations, respectively. The correlation coefficient ranges from -1 to 1 , with 1 indicating a strong direct relationship, 0 indicating no relationship, and -1 indicating a strong inverse relationship.

The normalized mean square error (NMSE) is given by

$$\text{NMSE} = \frac{\overline{(c_p - c_o)^2}}{(\bar{c}_o \cdot \bar{c}_p)} \quad (58.13)$$

The NMSE has a value of 0 when there is perfect agreement for all pairs of c_p and c_o and tends toward higher values as c_p and c_o differ. For example, NMSE is near 0.2 for differences between c_p and c_o of 50 percent, NMSE is near 0.5 for differences of about 100 percent, and NMSE is near 8 for differences of an order of magnitude.

The least squares best fit regression line between c_p and c_o provides useful information on how well the model fits the data. The ideal line has a slope of 1 , an intercept of 0 , and a regression r^2 of 1 . The slope b of the line is given by

$$b = \frac{\sum (c_o - \bar{c}_o) \cdot (c_p - \bar{c}_p)}{\sum [(c_o - \bar{c}_o)^2]} \quad (58.14)$$

and the intercept a is given by

$$a = \bar{c}_p - b \cdot \bar{c}_o \quad (58.15)$$

The method used to assess model bias is the normalized or fractional bias (FB) given by

$$\text{FB} = 2 \cdot \frac{(\bar{c}_p - \bar{c}_o)}{\bar{c}_p + \bar{c}_o} \quad (58.16)$$

FB ranges from -2 to 2 with a value of 0 indicating perfect agreement.

The ASTM recommended values of the various quantitative criteria are given in Table 58.7. ASTM recommends that the suitability of an IAQ model be determined by an evaluation of all the quantitative factors. A model may meet one or more criteria and still be inadequate, or a model may fail one or more criteria and still be adequate for the task at hand. The results of the quantitative comparisons presented by Sparks et al. (1991) for the IAQ model EXPOSURE (Sparks 1991) and Sparks et al. (1999b) for the IAQ model RISK (Sparks 1996) are presented in Table 58.8.

Zhao et al. (1998) present comparisons of airflow and pollutant transport predicted by the COMIS model. They compared predictions with observations using a linear regression of the predicted value versus the measured value. The airflow regression had a slope of 0.92 and a correlation coefficient of 0.72 . The pollutant transport regression (measured using SF_6 tracer gas) had a slope of 0.93 and a correlation coefficient of 0.94 . Zhao et al. did not include analysis of actual indoor pollutant sources in their study.

The results of the various comparisons of predicted and measured pollutant concentrations indicate that the mass balance IAQ models can predict indoor pollutant concentrations from a wide range of sources. The accuracy of the predicted concentrations depends primarily on the adequacy of the source and sink models used in the IAQ model. Errors in air exchange rates between indoors and outdoors are less important than those in the source and sink models. Errors in room-to-room airflow have a minor impact on predicted concentrations.

The answer to the question How good are the model predictions? depends on the situation being modeled and the type of data available for model input. Where the source and sinks and the air exchange between the indoors and the outdoors are well understood, the difference

TABLE 58.7 ASTM Recommended Values for Quantitative Criteria for Indoor Air Quality Models

Criterion	Recommended value
Correlation coefficient	>0.9

between measured and predicted pollutant concentrations is of the same order as the errors in the measured concentrations. Where assessment of the impact of a particular source on IAQ is desired, predicted concentrations within ± 100 percent of the measured concentrations can be expected if adequate source and sink models are available. How well the predictions agree with the measurements depends mainly on the source and sink models.

Because of the importance of source and sink models in developing a mass balance model, it is important to understand the various source and sink models. Sparks et al. (1994) discuss the development of source and sink models for use in IAQ models depending on the information needed from the IAQ model. The discussion that follows presents background on the types of source and sink models used in IAQ models and presents some limited information on the parameters for common models. Additional information on source models is provided in the chapter on sources in this handbook.

Source and Sink Models

The usefulness of mass balance IAQ models depends in great part on the adequacy of the source and sink models incorporated into the IAQ model. The interactions between the sources and sinks play a major role in determining the nature of the concentration/time curve (Tichenor et al. 1990). In general, sources determine the short-term pollutant concentration and sinks determine the long-term pollutant concentration. Source models, especially for gas-phase-limited mass transfer, are much better developed than are sink models.

Source Models

Empirical Decay Models. Most common source emission models are obtained using dynamic chamber data (Tichenor 1989). The technique is described by Dunn and Tichenor (1988). Guo et al. (1996) provide a good discussion of the chamber operating and data analysis details necessary to provide good data. ASTM (1990) provides a guide for conducting chamber tests.

The most common empirical model is the first-order decay model:

$$R(t) = R_0 e^{-kt} \quad (58.17)$$

where $R(t)$ is the emission rate as a function of time (mg/h/m^2), t is time (h), R_0 is the initial emission rate (mg/h/m^2), and k is the first-order decay constant (h^{-1}). The total emit-table mass per unit area M_E is given by

$$M_E = \int_0^\infty R(t) dt = \int_0^\infty R_0 e^{-kt} dt = \frac{R_0}{k} \quad (58.18)$$

The emission half life (the time required for the emission rate to decay to $R_0/2$), $t_{1/2}$, is given by

$$t_{1/2} = \frac{\ln(2)}{k} \quad (58.19)$$

An example of the chamber data used to develop a first-order decay model is given in Figure 58.2.

A wide range of sources can be described by the model in Equation (58.17). A constant source, such as moth cakes, can be described by setting R_0 equal to the constant emission rate and k equal to 0. In general, sources with decay constants larger than $0.2/\text{h}$ are limited by gas-phase mass transfer, and those with decay constants smaller than $0.01/\text{h}$ are limited by source-phase mass transfer. Products such as wood stain, varnish, floor wax, and liquid nails are examples of gas-phase-limited sources. Products such as carpet, linoleum, and aged paint are examples of source-phase-limited sources.

FIGURE 58.2 Example of chamber data used to estimate R_0 and k .

The value of k must be considered in setting the time step for the numerical solution of the concentration mass balance equations. If k is large relative to the time step, the source behavior will not be captured. For example, if $k = 1 \text{ h}^{-1}$ and the time step is 1 h, over 60 percent of the emissions will occur in the first time step. If $k = 0.1 \text{ h}^{-1}$ and the time step is 1 h, only 10 percent of the emissions will occur during the first time step.

R_0 and k are estimated by applying nonlinear curve fit techniques to chamber data. The solution to the differential equation governing the change in concentration in a well-mixed dynamic chamber without sinks is

$$c(t) = \frac{AR_0(e^{-kt} - e^{-Nt})}{V(N - k)} \quad (N \neq k) \quad (58.20)$$

$$c(t) = AR_0te^{-Nt} \quad (N = k)$$

where $c(t)$ is the concentration at time t , A is the area of the source, N is the air exchange rate, and V is the chamber volume. R_0 and k can be obtained from chamber data by using nonlinear curve-fitting techniques to fit this equation to the chamber data. A program to perform this fit is provided by Sparks (1996).

Estimates of source terms for several sources are given in Table 58.9. These data are based on experiments conducted in EPA's small chambers and in EPA's IAQ test house (Sparks 1991, 1996; Sparks et al. 1991; and Tichenor et al. 1990).

Table 58.10 from Chang and Guo (1993) provides estimates of R_0 and k for individual organic compounds emitted from wood stain. These estimates are based on test house data.

TABLE 58.9 Emission Rates of Total VOC for Selected Indoor Pollutant Sources

Source	R_0 , mg/m ² · h	k , h ⁻¹
Wood stain	17,000	0.4
Polyurethane	20,000	0.25
Wood floor wax	20,000	6.0

Compound	R_0 , mg/m ² · h	k , h ⁻¹
Nonane	1973	0.89
Decane	1887	0.39
Undecane	181	0.11

Source: Chang and Guo (1993).

In some cases a source has a high initial emission rate that decays rapidly. This high emission rate is followed by a slower emission rate that lasts for a long time. In some cases these emission rates can be described as a sum of several exponential decay rates:

$$R(t) = R_1 e^{-at} + R_2 e^{-bt} + R_3 e^{-ct} \quad (58.21)$$

where R_1 , R_2 , R_3 , a , b , and c are empirical constants. Some authors refer to models of the type shown in Equation (58.21) as multicompartment models. An example of the type of chamber data that can lead to a multicompartment decay model is shown in Figure 58.3, based on data from Mølhave et al. (1997). Techniques for fitting chamber data to multicompartment models are discussed by Mølhave et al. (1997).

Other Empirical Models. Latex paints are an important source whose volatile organic compound (VOC) emissions do not behave in a simple decay manner. Hansen (1974) recommends the following empirical model:

$$R(t) = \frac{R_0}{(1 + aR_0 t)} \quad (58.22)$$

where R_0 is the emission rate at time $t = 0$ and a is an empirical constant for latex paints. An example value of R_0 for total VOCs (TVOCs) is 80 mg/m²-h, and an example value of a is 0.003 m²/mg. A major flaw of this model is that it allows an infinite amount of pollutant to be emitted. A second shortcoming of the model is that over 50 days of data are required to develop reliable estimates of the model parameters.

An empirical model, described by Guo et al. (1996), allows prediction of emission of individual chemicals from latex paint. This model is a combination of the common first-order decay model and a diffusion model with an adjustment factor. The model is

FIGURE 58.3 Multicompartment emission model based on data from Mølhave et al. (1997).

$$R(t) = M_{v0}k_1 \exp(-k_1 t) + \frac{[1 - \exp(-k_1 t)]^2 f_D M_{D0} \exp(-2f_D t^{1/2})}{t^{1/2}} \quad (58.23)$$

where M_{v0} is the initial mass per unit area available for evaporation, k_1 is a first-order decay constant, f_D is the diffusion constant, and M_{D0} is the initial mass per unit area available for diffusion. Note that

$$M_{T0} = M_{v0} + M_{D0} \quad (58.24)$$

where M_{T0} is the total emittable mass per unit area applied. The model parameters for this model are given in Table 58.11. This model fits the experimental data quite well. Over 200 days of data are required to develop reliable estimates of the model parameters.

The constants developed for empirical models are often affected by test conditions. If the total emittable mass is increased, for example by heavy application of a wood stain, R_0 and/or k in the first-order decay model must change. If the mass transfer rate is limited by gas-phase mass transfer, the empirical constants are affected by the air speed over the source. Source testing should be conducted to provide scaling factors for the source model or under conditions similar to those encountered in indoor environments. In some cases a small mixing fan may be required in chamber experiments to provide air velocities over the

TABLE 58.11 Model Parameters for Empirical Latex Paint Emission Model

surface of the source similar to those found in buildings. Guo et al. (1996) provide a good discussion of the factors that must be considered in conducting chamber tests and in analyzing the data from such tests.

Mass-Transfer Based Models. Scaling the empirical models developed from chamber data to real buildings is a major problem with empirical models. This is especially true when the emissions are limited by gas-phase mass transfer processes. In this case, the emission rates are highly dependent on the gas velocity in the chamber and in the building. If the air velocities in the room are significantly different from those in the chamber, the in-building emission rates will be different from those predicted using chamber data.

The general mass transfer process for indoor sources is for pollutants to transfer from the interior of the source to the source/air interface and from the source/air interface to the room bulk air. This physical model is shown in Figure 58.4. In the figure R is the rate of mass transfer, C_i is the gas-phase pollutant concentration at the source/air interface, C_r is the pollutant concentration in the room, m_i is the source-phase pollutant concentration at the interface, and m_s is the pollutant concentration in the bulk of the source. The mass transfer processes in the air and in the source can be described by a driving force divided by a resistance. At steady state the rates of the two mass transfer processes are equal. The overall mass transfer process is limited by the slower of the two mass transfer rates. If the slower rate is due to transfer from the interface to the room bulk air, the overall mass transfer process is said to be gas phase limited. If the slower rate is due to transfer from the interior of the source to the interface, the overall process is said to be source phase limited.

The following discussion is for a source with unit area. The driving force for mass transfer from within the source to the source/air interface is the difference in pollutant concentration at the interface m_i and at the interior of the source m_s . The resistance to mass transfer is $1/k_s$, where k_s is the source mass transfer coefficient. The mass transfer rate R is

$$R = (m_s - m_i) k_s \quad (58.25)$$

Typical units of R are milligrams per square meter per hour, units of m are milligrams per square meter, and units of k_s are hours⁻¹ for indoor sources.

The driving force for mass transfer from the interface to the room is the difference between the gas-phase concentration at the interface C_i and the room concentration C_r . The resistance to mass transfer is $1/k_g$, where k_g is the gas-phase mass transfer coefficient. The rate of mass transfer R is

$$R = (C_i - C_r) k_g \quad (58.26)$$

Typical units of C_i and C_r are milligrams per cubic meter, and units of k_g are meters per hour.

Gas-phase mass transfer rate:

$$R = (C_i - C_r)k_g$$

Source-phase mass transfer rate:

$$R = (m_s - m_i)k_s$$

FIGURE 58.4 Physical model of source.

Equations (58.25) and (58.26) require knowledge of the pollutant concentrations at the source/air interface, which are difficult to obtain. However, bulk-phase pollutant concentrations can be obtained. The bulk-phase concentrations can be used if the equations are rewritten to use overall mass transfer coefficients and equilibrium concentrations (Foust et al. 1960).

The pollutant concentration in the room in equilibrium with the pollutant concentration in the source is

$$C^* = f(m_s) \quad (58.27)$$

where $f(m_s)$ is some function. If the function is linear,

$$C^* = am_s \quad (58.28)$$

where a is a constant with units of meter^{-1} . In the vapor pressure/boundary layer (VB) model of Tichenor et al. (1993),

$$a = \frac{C_{v0}}{M_0} \quad (58.29)$$

where C_{v0} is the initial vapor concentration and M_0 is the initial pollutant concentration in the source. Equations (58.25) and (58.26) can be rewritten using the equilibrium relationship and then added to give

$$R = \frac{C^* - C_r}{(1/k_g) + (a/k_s)} \quad (58.30)$$

for overall mass transfer expressed in terms of gas-phase concentrations. A similar equation can be derived to describe the overall mass transfer in terms of the source-phase concentrations.

The problem of developing a mass transfer-based emission model becomes one of determining both the appropriate mass transfer coefficient and the equilibrium relationship.

Mass Transfer Model for Gas-Phase-Limited Mass Transfer. In most situations, one of the mass transfer resistances is much greater than the other, and the smaller of the two resistances can be neglected. For many important indoor pollutant sources (e.g., wet sources), the gas-phase resistance dominates (i.e., $1/k_g \gg a/k_s$), and a/k_s can be neglected. In these situations a molecule of pollutant is able to move rapidly from the interior of the source to the source/air interface. Equation (58.30) becomes

$$R = \frac{C^* - C_r}{1/k_g} \quad (58.31)$$

Boundary layer theory (Bennett and Myers 1962), and dimensional analysis (Foust et al. 1960), show that gas-phase-limited mass transfer is best analyzed in terms of three dimensionless groups: the Nusselt number, Nu; the Reynolds number, Re; and the Schmidt number, Sc, with $Nu = f(Re, Sc^{0.33})$. The Nusselt number is

$$Nu = \frac{k_g L}{D} \quad (58.32)$$

where L is some characteristic length of the source and D is the diffusivity of the pollutant. The Reynolds number is

$$Re = \frac{Lv\rho}{\mu} \quad (58.33)$$

where v is the gas velocity over the source, ρ is the gas density, and μ is the gas viscosity. The Schmidt number is

$$Sc = \frac{\rho}{\mu D} \quad (58.34)$$

The diffusivity and Schmidt numbers for a range of organic vapors are given in Table 58.12. Note that, except for formaldehyde, there is little variation in the diffusivity and that variations in $Sc^{0.33}$ span a narrow range (1.2–1.5). Within the accuracy of the data, the effects of the Schmidt number can be ignored and data from indoor sources can be correlated as

$$Nu = f(Re) \quad (58.35)$$

for the organic vapors found indoors. Note that all the source-related parameters are contained in Nu, and all the environment- (room-) related parameters are contained in Re. Once the relationship between Nu and Re for a given geometry is determined, the relationship can be applied to all sources of the same geometry where emissions are limited by gas-phase mass transfer. Sparks et al. (1996) determined that the relationship between Nu and Re for gas-phase-limited mass transfer is given by

$$Nu = 0.33Re^{0.67} \quad (58.36)$$

A mass transfer-based model requires knowledge of the mass transfer coefficient and of the equilibrium relation between gas-phase pollutant concentration and source-phase pollutant concentration. The assumed equilibrium relationship is (Tichenor et al. 1993),

$$C^* = \frac{C_{v0}M(t)}{M_0} \quad (58.37)$$

where $M(t)$ is the emittable mass concentration in the source at time t and M_0 is the initial emittable mass concentration (typical units of M are milligrams per square meter).

TABLE 58.12 Diffusivities and Schmidt Numbers for VOC Indoor Pollutants

Pollutant	Diffusivity, m^2/h	Schmidt No. Sc	$\text{Sc}^{0.33}$
P-dichlorobenzene	0.026	2.12	1.28
Formaldehyde	0.06	0.92	0.97
Decane	0.021	2.63	1.38
Benzene	0.028	1.98	1.25
Perchloroethylene	0.03	1.84	1.22
Ether	0.032	1.72	1.20
M-chlorotoluene	0.023	2.35	1.33
Isopropyl iodide	0.032	1.74	1.20
Octane	0.024	2.31	1.32
Dodecene	0.018	3.06	1.45
Toluene	0.029	1.91	1.24
N-butyl acetate	0.021	2.63	1.38

The complete gas-phase-limited mass transfer model for pure compound or total VOC in a mixture is

$$R(t) = k_g \left[C_{v0} \frac{M(t)}{M_0} - C(t) \right] \quad (58.38)$$

This is the VB model of Tichenor et al. (1993). Guo et al. (1998) extended the basic VB model to allow predictions of individual species. The extended model, called the VBX model, is

$$R_i(t) = k_{gi} \left[C_{vi} \frac{M_i(t) m}{M(t) m_i} - C_i(t) \right] \quad (58.39)$$

where $R_i(t)$ is the emission rate of the i th component of the mixture, k_{gi} is the gas-phase mass transfer coefficient of the i th component, and C_{vi} is gas-phase concentration of i th component at the interface and is given by

$$C_{vi} = 10^3 \frac{P_i m_i}{760 v_m} \quad (58.40)$$

where P_i is the vapor pressure for pure component i in millimeters of Hg, m_i is the molecular weight of component i , v_m is the volume of 1 mole of gas under 1 atm at room temperature (at 23°C , $v_m = 0.0243 \text{ m}^3$), and $\bar{m}$ is the average molecular weight of the mixture. Parameters necessary for the VBX model can be obtained from product formulation data and the mass transfer correlation (Guo et al. 1999).

The general effects of environmental and pollutant properties on emission rates can be determined by examining the Nu and Re relationship. Equation (58.36) can be rewritten as

$$k_g = 0.33D \frac{(Lv\rho/\mu)^{0.67}}{L} \quad (58.36a)$$

The mass transfer coefficient for pollutants with high diffusivity is greater than the mass transfer coefficient for those with low diffusivity. The mass transfer coefficient for sources that cover a large area is less than the mass transfer coefficient for sources that cover small areas. The mass transfer coefficient can be increased by increasing the velocity over the source. Increasing the mass transfer coefficient will increase the emission rate.

From Equations (58.37), (58.38), (58.39), and (58.40) it can be seen that pollutants with high vapor pressure have higher emission rates than those with low vapor pressures. Also, because vapor pressure increases with temperature, gas-phase mass-transfer-limited emission rates increase with increases in temperature.

Sparks et al. (1996) provide a relationship between the empirical first-order decay model and the gas-phase-limited mass transfer model. The total emittable mass M_0 in Equation (58.38) is R_0/k , and C_{v0} in Equation (58.38) is R_0/k_g (if $C(0) = 0$).

Source-Phase-Limited Mass Transfer. The emission rate from many sources is limited by mass transfer in the source. These sources are often classified as diffusion-limited sources. The general physical model is that a molecule of pollutant is located inside the source. The molecule has to move through the source to the source/air interface. Once the molecule gets to the source/air interface, it rapidly moves across the interface into the bulk air. The major resistance to mass transfer is in the source. In principle, source-phase mass-transfer coefficients can be calculated if the diffusion coefficient of the pollutant within the source is known. Unfortunately, the data on pollutant diffusivity in sources are limited. Source-phase mass-transfer coefficients have to be developed by experiment.

A mass-transfer-based model can be developed based on the assumption that mass transfer is limited by diffusion from inside the source to the surface. The diffusion equation can be solved to yield a model of the form

$$R = \frac{0.632M_{D0}\sqrt{D}}{\lambda\sqrt{t}} \quad (58.41)$$

where M_{D0} is the initial emittable mass concentration (mg/m^3) in the diffusion-limited source, D is the diffusivity in the source, λ is the depth of diffusion, and t is time. Equation (58.41) can be rewritten as

$$R = \frac{\rho M_{D0}}{\sqrt{t}} \quad (58.42)$$

where

$$\rho = \frac{0.632\sqrt{D}}{\lambda}$$

The diffusion-limited source model has been used to describe the emissions of various pollutants from carpets and other types of flooring; see, for example, Christiansson et al. (1993).

Sparks et al. (1999a) combined the VB model and the diffusion-limited model to describe the emissions of VOCs from latex paint:

$$R(t) = k \left(\frac{C_{v0}M_v(t)}{M_{v0}} - C \right) + \left(1 - \frac{M_v(t)}{M_{v0}} \right)^2 \frac{M_{D0}\rho}{\sqrt{t}} \quad (58.43)$$

where k is the gas-phase mass-transfer coefficient, C_{v0} is the initial vapor pressure, $M_v(t)$ is the gas-phase-limited emittable mass left in the source at time t , M_{v0} is the gas-phase-limited emittable mass at time 0, and C is the in-room concentration. Values of the parameters for the model are given in Table 58.13. The parameters for the model given in Equation (58.43) can be obtained with about 2 days of chamber testing instead of the 200 days required to obtain the parameters for the empirical model, Equation (58.23). Sparks et al. (1999b) use the latex paint source model in an IAQ model to predict indoor pollutant concentrations.

The initial emittable mass due to diffusion M_{D0} is given by

$$M_{D0} = M_A - M_{v0} \quad (58.44)$$

TABLE 58.13 Parameters for Mass-Transfer-Based Latex Paint Model

Pollutant	C_{v0} , mg/m ³	M_{v0} , mg/m ²	ρ , h ^{0.5}
Propylene glycol	1.5	30.4	2.53×10^{-3}
Ethylene glycol	9.47	84.0	2.33×10^{-3}
Butoxy-ethoxyethanol	6.25	75.6	7.77×10^{-4}
Texanol	24.7	487	4.90×10^{-4}
TVOC	43.3	657	1.71×10^{-3}

Source: Sparks et al. (1999a).

where M_A is the total emittable mass applied (mg/m²).

Mass transfer in some sources is limited by both gas-phase and source-phase mass transfer. Emissions of formaldehyde from particle board appear to be such a source. Matthews et al. (1987) and others have published mass transfer coefficients for formaldehyde in particle board. Tichenor and Sparks (1996) suggest a mass transfer model for long-term emissions of formaldehyde in pressed wood product

$$R(t) = k_f \left(\frac{C_0 M}{M_0} - C \right) \quad (58.45)$$

where k_f is the formaldehyde mass transfer coefficient (0.25 m/h), C is the room concentration of formaldehyde (mg/m³), C_0 is the equilibrium formaldehyde concentration (0.3 mg/m³), M is the mass of formaldehyde in the particle board (mg/m²), and M_0 is the total emittable mass of formaldehyde in the particle board (mg/m²). The value of M_0 is difficult to obtain experimentally. A review of much of the data in the literature suggests that a value of 500 mg/m² will give acceptable results. The value of the mass transfer coefficient for formaldehyde indicates that emissions of formaldehyde are limited by processes occurring in the source and in the gas phase.

Sinks. Sinks are materials that absorb pollutants. In many cases the pollutants are reemitted later. This is especially true for VOCs. Most indoor materials act as sinks. Dust particles collected on surfaces or in filters may also act as sinks. The discussion that follows is limited to sinks for VOCs.

Tichenor et al. (1991) suggest a simple sink model based on the Langmuir isotherm. The sink model is

$$R_{\text{sink}} = k_a CA - k_d MA \quad (58.46)$$

where R_{sink} is the net rate at which mass enters or leaves the sink, k_a is the adsorption constant, C is the bulk room air concentration, A is the area of the sink, k_d is the desorption constant, and M is the pollutant mass per unit area collected in the sink ($k_a CA$ is the adsorption rate and $k_d MA$ is the desorption rate). Dunn and Tichenor (1988) provide a method for estimating sink constants from chamber data. Colombo et al. (1993) present data on sinks.

Tichenor et al. report that the Langmuir isotherm works well for ceiling tile and wallboard but that the desorption process for carpet deviates from the Langmuir assumptions. Tichenor et al. reported IAQ test-house experiments demonstrating the effects of indoor sinks on indoor pollutant concentrations. They reported that the Langmuir sink model predicted the sorption of VOCs by indoor materials reasonably well. However, the Langmuir model underestimated the reemissions phase. Sparks et al. (1991, 1999b) and Sparks (1996) recommend that the sink constants shown in Table 58.14 be used. These recommendations are based on a combination

TABLE 58.14 Recommended Sink Constants

Material	Pollutant	k_a , m/h	k_d h ⁻¹
Carpet	TVOC	0.1	0.008
Painted wallboard	TVOC	0.1	0.1
Ceiling tiles	TVOC	0.1	0.1
All surfaces	Ethylene glycol	3.2	0.0001
All surfaces	Propylene glycol	3.2	0.0
All surfaces	Texanol	1	0.0002
All surfaces	p-dichlorobenzene	0.35	0.01

of IAQ test-house and chamber research. Although the model proposed by Tichenor et al. provides useful results, it depends on test-house data for its empirical constants.

Little and Hodgson (1996) discuss models for diffusion-controlled sources and sinks and provide suggestions for chamber experiments to obtain the necessary model parameters. Van Loy and Nazaroff (1998) suggest other sink models for a variety of situations. Axley (1991, 1995) suggests a sink model that accounts for mass transport to the sink/air interface, mass transport from the interface into the sink, and other processes. Axley also provides suggestions for isotherms to replace the Langmuir isotherm used by Tichenor et al. The approaches suggested by Axley are promising. Because reemissions from sinks are an example of source-phase-limited mass transfer, it is likely that some of the source models being developed for source-phase-limited sources can be used to describe the reemissions from sinks. Considerable experimental and theoretical work is necessary to implement and verify these sink models.

Effects of Sinks. An irreversible sink (i.e., a sink that does not reemit pollutants) acts as an air cleaner and reduces exposure for as long as the sink is active. The effects of reversible sinks (i.e., sinks that reemit pollutants) are more complicated because they can have a major impact on the concentration/time history of the pollutants. Reversible sinks generally slightly reduce the peak exposure and greatly extend the time of exposure. The exact effect of a sink is scenario dependent and must be determined by model analysis.

Limitations of Mass Balance Models

Although most of the current IAQ models (RISK and CONTAM for example) model most of the important processes affecting VOCs, they do not model all the important processes affecting particles and semivolatile organic compounds (SVOCs). Axley (1995) and Van Loy and Nazaroff (1998) suggest modification to IAQ models to allow consideration of the poorly modeled or neglected processes. Nazaroff and Cass (1989) provide suggestions for modeling important particle dynamics. Cano-Ruiz and Nazaroff (1993) present suggestions for modifying mass balance models to include reactions of reactive gases with indoor surfaces.

Mass balance models are designed to predict average in-room pollutant concentrations. In many situations the average concentration is the concentration of interest. However, there are situations where the average concentration is not the concentration of interest. For example, if the exposure of a person using a product that is a strong source is of interest, the average in-room concentration is not adequate. In these situations mass balance models may be inadequate.

Furtaw et al. (1995) discuss modifications to the mass balance models to improve predictions near a large source. Their approach is to treat the room containing a source as two

compartments: one compartment contains the source and the other compartment is the rest of the room. The airflow rate between the two compartments varies randomly. Both compartments are assumed to be well mixed. The volume of the source compartment is the volume of a sphere with the source at its center and a radius to the monitoring point of interest. The volume V_{SR} with units of cubic meters is

$$V_{SR} = \frac{4}{3} \pi r^3 \quad (58.47)$$

where r , with units of meters, is the distance from the source to the location where concentration information is desired. The airflow between the source room and the rest of the room is represented by a uniform distribution with mean airflow Q_s with units of cubic meters per minute, given by

$$Q_s = 9\pi r^2 \quad (58.48)$$

Note that Equation (58.48) is a dimensional equation. This model is incorporated in the IAQ model contained in the THERdbASE software package (Pandian et al. 1990).

58.4 COMPUTATIONAL FLUID DYNAMICS MODELS

The modification proposed by Furtaw et al. (1995) may be adequate for many situations. However, there are situations where this modification to the mass balance models does not provide the desired information; these situations involve the necessity to predict a local concentration instead of an average in-room concentration. In such cases, models based on computational fluid dynamics (CFD) may provide the desired predictions.

CFD models differ from mass balance models in two major ways. First CFD models predict air velocity and pollutant concentration at individual points in a room instead of the average concentration predicted by mass balance models. From the model user's perspective, this is the most important difference between the two modeling approaches. If the user is interested in average pollutant concentrations, mass balance models provide the necessary information. If the user is interested in point pollutant concentrations, CFD models provide the necessary information. Because CFD models provide point by point information, the user can have a difficult time interpreting the results of the model.

Second CFD models solve a set of partial differential equations instead of the ordinary differential equations solved by mass balance models. This generally means that CFD models are computationally more expensive than mass balance models. For example, most mass balance models are designed for personal computers (PCs) and most CFD models are designed for mini- or larger computers.

Prediction of personal exposure is an important use of CFD models (Awbi 1996, Brohus 1997, and Brohus and Nielsen 1996). CFD models used for predicting personal exposure can take into account the impact of the person (e.g., thermal effects of the person) on exposure. Rodes et al. (1991, 1995) have shown that the person can have a significant impact on personal exposure.

CFD models are especially useful for studying the distribution of air and air movement in rooms and in buildings. Kurabuichi et al. (1989), Murakami and Kato (1989), Baker and Kelso (1990), and Nho and Kim (1996) discuss use of CFD models for studying airflows in rooms. Nielsen (1995) discusses linking CFD models of airflow with source emission models to predict source emissions and in-room pollutant concentrations.

Both two- and three-dimensional (2- and 3-D) CFD models are available. The 2-D models have the advantages of speed and ease of use. The 2-D models can provide useful information about many cases of interest. For example, Li and Teh (1996) demonstrate the

usefulness of 2-D models for studying flow through large openings. Yamamoto et al. (1990) present a 2-D CFD model for PCs.

Three-dimensional models provide considerably more information about airflow and pollutant concentrations than do 2-D models. The extra information provided by 3-D models comes at the expense of speed and ease of use. Available 3-D CFD models include VORTEX (Gan and Awbi, 1994) and models built using FLUENT (Fluent, 1995), and FLOVENT (Flomerics, 1994).

Three-dimensional CFD models are being used to study the personal exposure to particles indoors. For example, Murakami et al. (1996) and Holmberg and Li (1998) used 3-D CFD models to investigate the effects of a person on personal exposure. The results of these studies show that a personal exposure to particles is not well represented by the average in-room concentration.

Source and sink models are also important in predicting pollutant concentrations with CFD models. If the source and sink terms are not adequately described, the concentration predictions will be inaccurate—even if the airflow predictions are accurate.

58.5 SUMMARY

IAQ modeling provides a way to investigate many IAQ problems without the expense of large field experiments. Where experiments are planned, IAQ models can be used to help design experiments by providing information on expected pollutant concentrations. IAQ models can also provide information on the factors that are important and can help determine what must be measured.

The mass balance models provide the tools best suited for studying general IAQ problems. These models can provide good predictions of pollutant concentrations and individual exposure under a wide range of conditions. The models allow rapid analysis of IAQ control options. Where information on population exposure is desired, the statistical models are useful. And where information on personal exposure very near sources is desired, CFD models are required.

The quality of the model predictions depends on the adequacy of the input data. The most important data for the mass balance models are those necessary to describe source and sink behavior. Source and sink data are not available for many important indoor sources and for important indoor pollutants. Where the data are available, they often are not adequate to provide a detailed description of the variability of the pollutant emissions.

The statistical models require information on pollutant concentrations or sources and on population activity patterns. The available data are from a limited set of cities in the United States. Extrapolation of these data to the whole United States may not be justified. Use of these data for analyzing IAQ in other countries should be done with care.

There are active research programs aimed at overcoming the limitations of the various models. The status of much of this research can be found on the World Wide Web site of the U.S. EPA's National Risk Management Research Laboratory's Indoor Environment Management Branch's home page at <http://www.epa.gov/appcdwww/crb/iemb>. This site provides information on EPA's indoor environment research program and links to other research on indoor air.

CHAPTER 59

APPLICATION OF COMPUTATIONAL FLUID DYNAMICS FOR INDOOR AIR QUALITY STUDIES

Qingyan Chen

Massachusetts Institute of Technology
Cambridge, Massachusetts*

The computational fluid dynamics (CFD) method, is becoming a popular tool to determine pollutant distributions and transport indoors. This chapter discusses the fundamentals of fluid dynamics, CFD techniques, and turbulence modeling choices. Examples of CFD results and comparison to actual flows and concentration distributions are given. The results show that CFD can calculate correctly pollutant distributions and transport indoors, if it is used appropriately. Validation of a CFD program by experimental data is needed.

59.1 INTRODUCTION

By and large, ventilation systems are designed assuming the pollutants and the ventilating air are well mixed within a room, no matter its size. In many instances, this is an incorrect assumption. There are numerous cases where the dispersion of pollutants does not yield well-mixed conditions. For example, in ice skating rinks the exhaust from the machine that scrapes the ice stays near the ice surface due to the negative buoyancy of the cold air and the exhaust fumes. The ventilation air is delivered to the rink at a higher elevation and it is not effective in clearing the exhaust from the rink. When there is a single source of pollution in the room, such as cigarette smoking, the concentration may vary considerably across the room depending on the ventilation design.

In a large open plan office, poor ventilation design can result in a large bypass of intake air to the exhaust. In this case some sections of the office may receive little ventilation and

exhibit high concentrations of unhealthy pollutants. In shelters for the homeless, a ventilation design that does not encourage the mixing of airborne bacteria would help to reduce the spread of TB. The air circulation pattern in aircraft also may play a role in disease spread through the interior.

For some volatile organic compounds (VOCs) given off by paints, varnishes, adhesives, and furnishings, the rate of emission into the air is closely tied to the local air velocity and temperature over the exposed surface. These may be far different from the average velocity and temperature for the entire building space.

59.2 THE NATURE OF AIRFLOW IN BUILDING INTERIORS

The air circulation in building interiors is complicated by the geometry of the interiors. Partitions, furniture, and passageways between rooms all distort the airflow. Air may be entering the interior by way of mechanical vents, leakage around windows, and open entranceways. The air motion in the building may be a strong function of the air velocity (kinetic energy) as it enters. This, in turn, may be a function of the wind flow pattern around the outside of the building or the variability of the fan controls for the mechanical ventilation system. In many building interiors, the airflow may be strongly influenced by buoyancy effects: light hotter air moving up and cooler air moving down. The temperature pattern of the air will change with the temperature of the air delivered by mechanical systems. Equally important may be solar energy entering through windows and temperature patterns on walls due to external weather conditions. Several examples will serve to illustrate the complex nature of the airflow.

Figure 59.1 shows the airflow in a test room under simple natural convection conditions: (Olson et al. 1990). The room is sealed and there isn't any mechanically driven flow. One end wall is heated and the opposite wall is cooled. This might be typical of a solar heated home that has a cooled exterior wall. All other walls, ceiling, and floor are well insulated to minimize any heat gains or losses to the air. The air rises near the heated wall, runs along the ceiling, and flows down the cooled wall. This is what was expected for buoyancy driven flows. Note that a little lower down from the ceiling the air is moving in the opposite direction, from the cold wall back toward the hot wall. A similar reverse flow is seen near the floor. Thus, the flow of pollutants may be considerably enhanced by the reversed flows.

Figure 59.2 (Srebric et al. 1999) shows the experimentally measured flow in a large space separated by a vertical partition. Cool air is mechanically brought into one side of the space and exits through a wall on the same side of the partition surface. The second side has a wall with a cold area typical of a window space in winter. A heater is on the floor under the window. In this instance, the airflow pattern from one side of the partition to the other has a notably complex three-dimensional pattern. On the wall containing the window, there is down flow of air over the cold window and up flow of air along the wall adjacent to the window caused by the floor heater. For public spaces such as atriums or auditoriums with large complex shapes, the airflow patterns may be more complex and are not easily estimated or predicted.

For airflow in building interiors, the dimensions are large, and the air velocity is high enough to produce turbulent flow. Figure 59.3 illustrates the flow from a heat source such as a small flame. The plume initially has a straight streamline laminar flow. At higher elevations, eddies and swirls can be observed, which disrupt the flow and cause lateral mixing between the smoke plume and the surrounding air. The flow is turbulent and the eddies will play a large role in the spread of pollutants. Turbulent flow is much more complicated to deal with.

FIGURE 59.1 Airflow pattern observed in an environmental chamber with a cold wall and a hot wall.

FIGURE 59.2 Airflow pattern observed in an environmental chamber with a partition wall, an air supply diffuser, and a baseboard heater.

59.3 THE LEVEL OF UNDERSTANDING REQUIRED

IAQ problems may involve the building as a whole, considering the transfer of pollutants and ventilation air from room to room. This interroom transfer may be set up by the ventilation system but most likely also involves the exchange of air between different rooms and public spaces in the building. At this level of understanding, a first approximation to the air and pollutant flows may be gained by assuming the gases in each room are well mixed. The flow between rooms is represented as a simple flow resistance between two elements at different pressures. The pressures and driving flows may be set up by the

FIGURE 59.3 Laminar and turbulent flow of a cigarette smoke.

mechanical ventilation systems, wind-driven flows from the outside, buoyancy-driven flows, or a combination of all three.

In many cases, this level of understanding is insufficient to deal with the building design or to solve an existing IAQ problem. The air circulation pattern within an individual space must be understood. The circulation pattern within one space may influence the exchange between neighboring spaces as well as the overall flow for the building.

Two approaches are available for the study of IAQ problems—experimental investigation and computer simulation. In principle, direct measurements of the building interior give the most realistic information concerning IAQ. Due to the nonuniform distributions of the flow and pollutant, measurements must be made at many locations. Direct measurements of the air velocity, flow direction, contaminant concentrations, and air temperature at many locations are very expensive and time consuming. Furthermore, to obtain conclusive results, the airflow and temperature from the heating, ventilation, and air-conditioning (HVAC) systems and the temperatures of room enclosures should be maintained unchanged during the experiment. This is especially difficult because outdoor conditions change, causing the temperatures of the room enclosures and the airflow and air temperature from the HVAC systems to vary with time. For proposed building designs, direct measurements from previous buildings can be misleading. Some information can be gained by experiments carried out on scaled-down models.

An environmental chamber may be used to simulate IAQ, completely isolating the measured system from the external world. Such an environmental chamber, with necessary equipment for measuring air velocity, temperature, relative humidity, and contaminant concentrations, costs more than \$300,000. Also, complete measurements are tedious, time consuming, and costly. This technique is not an efficient way to examine a variety of designs or conditions. Furthermore, it may not be easy to change from one spatial configuration to another in such an environmental chamber. The experimental approach is still used because it is considered most reliable. In many cases, the parameters are normally measured at only a few points in a space.

The computational approach, using computational fluid dynamics, is used most often to study IAQ problems. This involves the numerical solution of the flow behavior using a computer. CFD involves the solution of the equations that govern the physics of the flow. Due to the limitations of the experimental approach and the increase in performance and affordability of computers, CFD provides a practical option for computing the airflow and pollutant distributions in buildings. The next section will describe how the problem is formulated for numerical solution. Succeeding sections will present typical CFD results and describe the future of this technique. Although CFD has become the most popular method of predicting airflows associated with IAQ, it is essential to validate the model results with a few careful experiments carried out over a range of conditions under consideration. Results from CFD techniques that have not been validated should be used with caution.

59.4 FORMULATION OF THE CFD APPROACH

The flow of air and the spread of other gases or particulates are governed by the geometry of the space and the forces present to move the material through the space. To deal with this numerically there are two points of view that could be followed. In the first, one could follow each packet of gas or particles as it moved around the space, like following billiard balls as they collide and move around a table. This turns out to be impractical for room airflows because the packets divide and mix and are constantly changing their location, velocity, and mixture concentration.

A more practical approach is to subdivide the space inside the room into a number of imaginary subvolumes, or elements. These subvolumes usually do not have solid boundaries; rather they are open to allow gases to flow through their bounding surfaces. Each subvolume has a single temperature associated with it; this is the average temperature of all of its contents. It also has a single concentration of air and other components. Finally, it has a single average velocity, although in this case the velocity components in the vertical and two horizontal directions must be included (to account for the velocity magnitude and its orientation in a three-dimensional room). In the beginning of the CFD problem, the temperature, concentration, and velocity are unknown for most of the subvolumes. The values at the boundaries of the room, say at the outlet of a duct or a window, may be known. Similarly, the wall temperatures and the concentration of a pollutant source at its origin may be known. The goal of the CFD program is to find the temperature, concentration, and velocity throughout the room for each of the subvolumes. This will reveal the flow patterns and pollution migration throughout the room.

59.5 GOVERNING PHYSICAL RELATIONSHIPS

To produce a solution the CFD program solves the equations describing the process in the room. For each of the subvolumes this involves the following:

- Conservation of mass
- Conservation of energy
- Conservation of momentum

Figure 59.4 illustrates conservation of mass of air for a subvolume in the room. There is air entering from the neighboring volumes to the side and bottom and, in this example, leaving to enter the neighboring subvolumes above and to the other side. The rate, in say kilograms per second, at which air enters one side is proportional to the velocity of the air leaving the neighboring element or subvolume. Similarly, the rate at which air leaves the volume in question is proportional to the velocity of that volume. The same balance of mass entering and leaving must be made for each subvolume in the room. This results in a number of equations expressing the mass balance. The number of equations is exactly equal to the number of subvolumes. Note that each equation for the conservation of mass involves the velocity of the subvolume in question as well as the velocity of neighboring subvolumes.

Figure 59.5 illustrates conservation of energy. In this case, the balance of energy entering and leaving includes the velocity, to account for energetic air entering or leaving, as well as the temperature, which is a measure of the energy. This results in a series of equations that involve both the temperature and velocity of each subvolume.

Figure 59.6 illustrates conservation of momentum. This is a form of Newton's second law, Force equals Mass times Acceleration, applied to each subvolume. Air leaving the element to the right with a certain velocity or momentum acts like a rocket exhaust pushing the element to the left. Air entering from the left with some momentum tends to push the element to the right. All of these momentum exchanges must be balanced along with external forces on the boundaries of the volume. These include gravity or buoyancy forces. Also included are the forces exerted by air pressure at the boundaries of the element and viscous shear between neighboring elements. The equation for momentum balance of each element involves the velocity, temperature (through buoyancy), and pressure. The full equations for conservation of momentum are referred to as the Navier–Stokes equations.

Because each of the equations for conservation of mass, energy, and momentum involve the velocity, temperature, and pressure of an element and its neighbors, the equations for all of the elements must be solved simultaneously. The smaller the subvolumes are, the more equations that must be solved. For a three-dimensional problem, halving the size of an element's width, length, and height increases the total number of elements by a factor of 8. For speed of calculation, the element size should not be too small. On the other hand, the use of a few large elements, each with a single average velocity, temperature, and concentration, may not capture the true pattern of conditions within the space. In fact, it

FIGURE 59.4 Conservation of mass between neighboring elements.

FIGURE 59.5 Conservation of energy between neighboring elements.

FIGURE 59.6 Forces acting on element and conservation of momentum.

may lead to a very erroneous overall flow prediction, sometimes with air moving in a direction opposite of its true value.

The presence of turbulent flow complicates matters, and improper handling of this is one of the prime causes of inaccurate CFD predictions. Turbulent flow, which exists in most room flow situations, involves a mixture of eddies of widely different sizes. To accurately capture the behavior of the smallest eddies would require a very fine subdivision of the space. The computational resources to solve for the flow this way, known as direct numerical simulation, are stupendous. It is not practical with today's computers. Rather, investigators have adopted a number of ways to approximate the turbulent behavior without using very fine subdivisions. The problem with this approach is the absence of a single approximation for turbulent flow that works well in all situations. Techniques developed for high-speed turbulent flow over airplane wings does not necessarily yield good results in large rooms where buoyancy may be important. Although most commercial CFD codes will yield *a* solution to an IAQ problem, there is no guarantee it is *the* solution.

59.6 CFD TECHNIQUES

The most common CFD techniques are direct numerical simulation (DNS), large-eddy simulation (LES), and Reynolds averaged Navier–Stokes (RANS) equations with turbulence models. Each technique handles turbulence in a different manner.

DNS solves the Navier–Stokes equations without approximations. It requires a very fine grid resolution to catch the smallest eddies in the flow. Figure 59.7 shows the airflow from a round jet. The flow is laminar as it leaves the nozzle. One diameter downstream it shows instability, formation of vortex rings, and transition to turbulence. An eddy, a small element of swirling flow, is typically 0.1 to 1 mm in size in a room with turbulent airflow. To include the smallest eddies in the flow in the computations, the total grid number for a three-dimensional indoor airflow is around 10^{11} to 10^{12} . Current supercomputers can have a grid resolution as fine as 512^3 that is around 10^8 . The computer capacity is still far too small to solve such a flow. In addition, the DNS method solves the time-dependent flow with very small time steps to account for eddy breakup and reforming that occurs in a flow that on average is “steady.” This makes the calculation extremely time consuming. DNS for indoor environment simulation is not realistic in the near future.

LES was developed in the early 1970s by Deardorff (1970) for meteorological applications. He separated turbulent motion into large and small eddies. The theory assumes that the separation between the two does not have a significant effect on the evolution of large eddies. LES accurately solves the large-eddy motion for three-dimensional, time-dependent flow. Turbulent transport approximations are used for small eddies, and the small eddies are modeled independently from the flow geometry, eliminating the need for a very fine spatial grid and short time steps. LES is successful because the main contribution to turbulent transport comes from the large-eddy motion. LES is also a more practical technique than DNS. LES can be performed on a large, fast workstation. Figure 59.8a shows an instantaneous flow field in a room with a cold air supply from the left upper corner and a warm floor calculated by LES. Thousands of the instantaneous flow images can be averaged to obtain a mean flow as shown in Figure 59.8b. Nevertheless, LES is still too time

FIGURE 59.7 Airflow from a round jet.

FIGURE 59.8 Instantaneous and averaged air velocity in a room with a cold jet from the right upper corner and a warm floor computed by large eddy simulation. Arrows show the direction and velocity of the local airflow.

consuming because it calculates time-dependent flow. In addition, such a large, fast workstation is not available in most designers' offices.

RANS is the fastest, but it may be the least accurate method. RANS solves the time-averaged Navier–Stokes equations by using approximations to simplify the calculation of turbulent flow. The approximations can sometimes generate serious problems that will be discussed later. The grid number used for the simulation with RANS is normally much less than that for LES. Most importantly, steady flow can be solved as time independent. Therefore, the computing costs are the cheapest compared to those for LES and DNS. The latest generation of PCs has the speed and capacity to use this CFD technique. The CFD method with RANS is a very promising and popular tool for IAQ prediction. The most popular RANS model is the standard k - ϵ model developed by Launder and Spalding (1974). Recently, the RNG k - ϵ model (Yakhot et al. 1992) has been widely used. A more detailed model comparison is given in Table 59.1.

The computational method can provide informative results inexpensively. Most CFD computations of three-dimensional indoor airflow and pollutant transport can be done on a PC with 64 MB of memory and a Pentium processor. Typically, the costs for a commercial CFD program with a 3-month consultant's license is \$2500 followed by \$2000 quarterly fees when there are active projects. An annually renewable license for a PC version is about \$10,000. The price can be doubled for a perpetual license. The costs for a UNIX workstation are about twice as much as those for a PC.

59.7 VALIDATION OF SELECTED CFD COMPUTATIONS WITH EXPERIMENTAL RESULTS

For new building geometries and ventilation techniques it is essential that the numerical results be validated by comparison with controlled experiments. This section will present examples of the CFD method with RANS to predict indoor airflow and air quality. There are different RANS techniques. The present results are referred to as a renormalization group model from Yakhot et al. (1992). The CFD program was used to calculate the indoor airflow, contaminant concentration, and temperature distributions in a classroom in one example. Experimental measurements were made in an environmental chamber to validate the numerical results. Because the chamber is not large enough to simulate a whole classroom, the investigation uses the chamber to simulate a quarter of a classroom, as shown in Figure 59.9. The limited room geometry is a typical problem with most test chambers.

The CFD computation is also for a quarter of the classroom. There are six persons, overhead lighting, furniture, and so forth, in the quarter of the classroom. The classroom has an exterior wall with an exterior window. A displacement diffuser supplies fresh air from the corner of the classroom at the floor level. The room air is exhausted from the center of the classroom. This is referred to as a displacement ventilation system.

Figure 59.10 shows the flow pattern, observed by using smoke and computed by the CFD method in the midsection (Figure 59.10a and b) and a section through some of the occupants (Figure 59.10c and d). The velocity can be determined from the smoke visualization because the speed is low. However, it is very difficult to observe all of the details of the airflow pattern when the velocity becomes very low. The computed flow pattern agrees generally with the observed one. Due to buoyancy, the cold air from the supply diffuser spreads on the floor level (Figure 59.10a and b). This cold airflow is like a jet and induces the surrounding air. As a result, the induction causes a reverse flow in the layer between 0.5 to 1 m above the floor. The thermal plumes generated by the occupants and computers move upward together with the contaminants generated by the occupants (Figures 59.10c and d).

TABLE 59.1 Comparison of Different Turbulence Models for Predicting Indoor Airflow

	Flow Type									
	Natural Convection				Forced Convection		Mixed Convection		Impinging Jet	
	<i>V</i>	<i>Tu</i>	<i>T</i>	<i>h</i>	<i>V</i>	<i>Tu</i>	<i>T</i>	<i>x</i>	<i>V</i>	<i>T</i>
k-ε	B	C	B	C	C	D	A	C	C	D

RSTM-GY	A	B	B	C	B	C	B	D	B	B
RSTM-QI	A	B	B	C	B	C	B	D	B	C

V = velocity, *T* = temperature, *Tu* = turbulence intensity, *h* = heat transfer, *x* = penetration length; k-ε = standard k-ε model (Launder and Spalding 1974); LB k-ε = low Re number k-ε model (Lam and Bremhorst 1981); 2L k-ε = two-layer k-ε (Rodi 1991); 2S k-ε = two-scale k-ε model (Kim and Chen 1989); RNG k-ε = renormalization k-ε model (Yokhot et al. 1992); RSTM-IP = Isotropization of production Reynolds-stress model (Launder et al. 1975); RSTM-GY = Gibson and Younis (1986) Reynolds-stress model; RSTM-QI = Quasi-isotropic Reynolds-stress model (Launder et al. 1975); A = excellent, B = good, C = fair, D = poor, E = unacceptable.

FIGURE 59.9 A quarter of a classroom used for the experiment and CFD validation.

FIGURE 59.10 Visualized and computed airflow pattern in the classroom at two different sections.

Figures 59.11 to 59.13 present, respectively, the measured and computed carbon dioxide (CO_2), air velocity, and air temperature in the classroom. The measurements were done with nine poles in the classroom as shown in the right bottom portion of the figures. Each pole had ten sensors to measure temperature, six sensors to measure velocity, and six air sampling tubes to measure CO_2 concentration. The vertical axes are dimensionless elevation normalized by room height ($Z = 0$ is the floor and $Z = 1$ is the ceiling). The horizontal axes are dimensionless measured parameters.

Figure 59.11 shows the CO_2 concentration profiles in the classroom. The CO_2 sources were introduced at the head level of the two occupants (the two small squares in the right bottom figure). Because convective flow around the human bodies brings the CO_2 from the occupants to the upper part of the room, the displacement ventilation system creates a better air quality than conventional mixing ventilation. This is clear from the results. The normalized CO_2 concentration in the lower part of the room is less than 1.0, which corresponds to the minimum CO_2 concentration in a classroom with a conventional mixing ventilation system.

The computed CO_2 concentration profiles agree well with the experimental data. However, there are discrepancies in some locations between the computed concentration profile and the measured data. Because the CO_2 is a point source and recirculating flow exists in the upper part of the classroom, the CO_2 concentration in the upper part is not uniform and is very sensitive to the position and boundary conditions. Nevertheless, the accuracy of the computation is acceptable.

Figure 59.12 illustrates that the velocity in most of the space, except near the floor, is lower than 0.05 m/s. The magnitude is so low that the hot-sphere anemometers, commonly used in test chambers to measure air velocity, may fail to give accurate results. Nevertheless, the measured velocity is close to that observed using smoke, and the computed results agree well with the data. The velocity near the floor is larger than that in the center of the room because the diffuser is installed on the floor level.

Figure 59.13 clearly shows that the agreement between the computed temperature profiles and the measured data is excellent. The displacement ventilation system creates temperature stratification because the conditioned air is supplied in the lower part of the room and the system does not mix the room air.

The above example indicates that the CFD method with the RANS model can predict pollutant transport and airflow well in this geometry, although there are some discrepancies between the computed results and measured data. The discrepancies may be attributed to the approximations used in the RANS model or the uncertainties from the measuring techniques or both. Similar comparisons of the CFD model with experimental data must be made for rooms with other conditioning systems and geometries. Several other cases have been investigated by Yuan et al. (1999). For displacement ventilation, the results lead to the same conclusions as above.

59.8 FLEXIBILITY AND RICH INFORMATION FROM CFD SIMULATION

Unlike experimental facilities, the CFD program is very flexible in dealing with changing building geometry and thermal and fluid boundary conditions. For example, the experimental chamber is too small to simulate a full-size classroom, whereas, a full-size classroom can be easily simulated by a CFD program. This section discusses the results for a full-size classroom as shown in Figure 59.14. The classroom has a teacher, 24 pupils, an exterior wall with a window, overhead lighting, and so forth. The classroom uses a displacement ventilation system that has four air supply diffusers in all the four corners and a return exhaust in the center of the ceiling.

FIGURE 59.11 Comparison of the computed and measured CO_2 concentration for the classroom. $C = (CO_2 \text{ in the computed or measure position} - CO_2 \text{ at the inlet}) / (CO_2 \text{ at the exhaust} - CO_2 \text{ at the inlet})$, Z is dimensionless room height. (Symbols = measurement, lines = computation.)

FIGURE 59.12 Comparison of the computed and measured velocity for the classroom. U = velocity in the computed or measure position / velocity at the inlet, Z is dimensionless room height. (Symbols = measurement, lines = computation.)

FIGURE 59.13 Comparison of the computed and measured temperature for the classroom. $\theta =$ (temperature in the computed or measure position – temperature at the inlet) / (temperature at the exhaust – temperature at the inlet), Z is dimensionless room height. (Symbols = measurement, lines = computation.)

FIGURE 59.14 A full-size classroom used for the computation.

Figure 59.15 shows the airflow patterns at the ankle level and section A-A (see Figure 59.15a for the section location). There are similarities between the full-room simulation and the quarter-room simulation. For examples, fresh air from the diffusers moves toward the center of the room. However, Figure 59.15b shows that the airflow in the full classroom is not symmetrical, whereas the quarter-classroom experiment assumed it was symmetrical. Therefore, an experiment on one-quarter of a classroom may not yield proper results for the full space. The validated CFD results for the full space may be closer to the truth. These experimental limitations are especially evident for experiments using scale models, such as wind tunnel models and models of large building interior spaces.

A CFD program can also be used to determine some parameters that are difficult to obtain by experimental measurements. Figure 59.16 shows the distribution of the mean age of air in the full classroom. The mean age of air is the mean time that has elapsed since air entered the room. The younger the mean age of air, the fresher the air is. If experimental measurements were used to obtain the distribution, the experiment would take days. The air in the room must be sampled for a long period with a very small time step to obtain the mean age of air at one position. It is very time consuming to measure the distribution of the mean age of air in such a large classroom.

A CFD program can calculate the distributions of air velocity, temperature, and turbulence intensity. These environmental parameters can be used further to determine comfort criteria such as the percentage of dissatisfied (PD) people due to draft (Fanger et al. 1989). Figure 59.17 shows that the PD distribution at ankle level and section A-A. Because the CFD solves those parameters in thousands of locations, it is easy to obtain more useful information, such as the PD distribution. This is much easier than attempting to measure the PD distributions at numerous locations.

59.9 PROBLEMS ASSOCIATED WITH THE CFD TECHNIQUE

In the past 20 years, the CFD technique has become very useful for numerous projects. However, there have been many problems. There are errors possible due to the particular

FIGURE 59.15 The airflow pattern in the classroom. (a) At ankle level; (b) at section A-A.

turbulence models used in CFD calculations. For example, dry centrifugal cyclone collectors are used to separate particulate matter from gases by forcing the gases to follow a curved path. They are used in industrial gas cleaning and air pollution control. Figure 59.18 shows the prediction of the swirling flows in a cyclone by different RANS models and the corresponding experimental data. The U is axial velocity and the W is tangential velocity. The $k-\epsilon$ model, the most popular RANS model, fails completely to predict the velocity. Although some other RANS models perform better in predicting axial velocity U , they all have problems predicting W in the core region. The cyclone efficiency is directly related to the axial and tangential velocities. Large errors in the predicted velocity make the results useless.

The grid distribution used in the CFD program can also play a significant role in the accuracy of the results. The airflow from a diffuser is one such example. The performance of the air supply diffuser has a major impact on the air circulation pattern and the IAQ. Most CFD computations simulate a diffuser as a simple slot opening. This type of diffuser can rarely be found in practice. The geometry of an air supply diffuser is normally complicated,

FIGURE 59.16 The distribution of the mean age of air in the classroom (seconds). (a) At ankle level; (b) at section A-A.

as shown in Figure 59.19a. When cylinder coordinates are used, the three-dimensional curved boundaries must be represented by small steps instead of smooth lines. The method is straightforward and is the technique commonly used in most CFD programs. Figure 59.19b shows the computed velocity vectors when cylinder coordinates are used with small steps to represent the curved surfaces. The computation predicts a flow pattern that is upward and attaches to the ceiling. This is erroneous; experiments with smoke clearly show a downward flow. The major computational error is due to excessive turbulence energy produced by the small steps used in the cylinder coordinate to represent the curved surfaces.

If body-fitted coordinates or an unstructured grid is used, the results are correct as shown in Figure 59.19c and d. The body-fitted coordinate wrenches the cartesian coordinate into a general grid system to fit the complex geometry in a room. With these geometric techniques, complex geometries can be handled without the use of sharp steps. Body-fitted coordinates are particularly suitable for internal or external flows with smoothly varying nonregular boundaries while keeping many features of cartesian coordinates. The unstructured grid offers geometric flexibility for handling complex geometry. It should be noted that the generation of grids for complex configurations using the body-fitted coordinate or the unstructured grids requires a great deal of labor by the computer programmer.

59.10 APPLICATIONS OF THE CFD TECHNIQUE TO INDOOR AIR QUALITY DESIGN AND EXPOSURE PREDICTION

The results shown here indicate that the CFD technique is a valuable tool for determining pollutant distributions and migration paths through building interiors. With known pollutant

(a)

(b)

FIGURE 59.17 The PD distribution in the classroom. (a) At the ankle level; (b) at section A-A.

sources, the CFD technique is useful to identify a problematic area in a room even before a building is built. The CFD technique can be used to determine the best locations of air supply diffusers and return outlets and the amount of air needed to create an acceptable indoor air quality. The technique can also evaluate different measures for better indoor air quality, such as the effectiveness of a different ventilation system, local air exhaust system, arrangement of spatial partition, and so forth.

Further, the CFD technique can also calculate transient contaminant concentration in a room. The information is very useful for studying exposure risk of the building occupants to pollutants.

FIGURE 59.19 The computed airflow pattern in and around a diffuser. (a) The geometry of the diffuser; (b) with cylinder coordinate; (c) with body-fitted coordinate; (d) with unstructured grids.

59.11 CONCLUSIONS

CFD is a valuable tool for determining pollutant distributions and migration paths through building interiors. It is a powerful tool for studying and improving indoor air quality (IAQ). The CFD with a turbulence model can predict the airflow and contaminant distributions in a room within a few hours on a personal computer. To obtain the same results, an experimental measurement may take many person-months and require an expensive test facility.

Because there is no universal turbulence model available, the results obtained with CFD have some uncertainties. Experimental validation of the CFD results is required for at least one case. A validated CFD program can then be used to study IAQ under various conditions. Note that a CFD program validated for one type of flow, such as natural convection flow, may not correctly predict another type of flow, such as forced convection. The validation is needed for each type of flow. In addition, CFD simulation requires a good knowledge of fluid dynamics and numerical techniques.

Future improvements in computing speed and capacity will allow the use of more accurate CFD techniques and the CFD may not require experimental validation.

PART 6

PREVENTING INDOOR ENVIRONMENTAL PROBLEMS

CHAPTER 60

INDOOR AIR QUALITY BY DESIGN

Hal Levin
Santa Cruz, California

Good indoor air quality happens by design, not by accident. In fact it is simply one aspect of good design.

60.1 INTRODUCTION

Building designers play a major role in determining indoor air quality (IAQ). Primary roles belong to the architect, ventilation system engineer, and interior designer. Major IAQ design concerns include project planning, pollutant sources, environmental control systems, construction, and commissioning. Most architects abdicate responsibility for selection and specification of building environmental control approaches and systems to consulting engineers. Interior designers tend to focus more on appearance than on IAQ and other functional requirements. Some architects now specify “low-emitting materials” without sufficient examination of the nature of their emissions or the life cycle implications for occupant exposure to contaminants. Only when the architect (or other project lead building design professional) takes an aggressive position on IAQ can the achievement of good IAQ be considered likely.

Design Professional Roles in IAQ

As the overall project design team leader, the architect (or other design team leader) is responsible for defining, articulating, and communicating the project goals, including those related to indoor air quality. These goals should be defined in conjunction with the project client, usually the building owner or developer, and sometimes some or all of the intended occupants as well. There is evidence from field studies that buildings with the lowest sick building syndrome (SBS) symptom reporting rates are those whose ventilation characteristics most closely match the original design intent. This suggests that well-defined goals clearly communicated to all relevant parties throughout the building design and construction process is a potentially important key to achieving good IAQ.

The design team leader is responsible for articulating the IAQ goals for the project in a manner that can be understood by all design team members and in terms that are agreed to by the client. Communicating the IAQ design goals is also the team leader's responsibility, and each team member is responsible for identifying any goals that are not clear or any uncertainty about the individual responsibilities for IAQ in the project. Often the communication process itself (or its absence) is the barrier to achieving good IAQ. In the best cases, good communication results in education of all design team members and an open dialog with the client and the contractor, occupants, operating personnel, and other relevant parties.

Building design clients (owners, developers, or major tenants) have begun to request that design professionals ensure good IAQ in their projects. However, unless design professionals advocate and implement a sustained, comprehensive focus on IAQ from project planning through initial occupancy, few buildings will be designed to achieve good IAQ.

This chapter presents the approach to indoor air quality taken by progressive, proactive building design professionals (including architects, building designers, interior designers, and engineers). Not all of the actions described here are appropriate for all building design professionals on every project. But generally, the various actions described in this chapter can be applied by some of the building design team members on most projects. Space limitations allow us only to introduce many of the important concepts of good IAQ by design. Further information is available in a variety of bibliographic references included at the end of the chapter.

Organization of the Chapter

The chapter is organized in four major sections:

1. Major IAQ design strategies
2. Design issues that determine indoor air quality
3. Design services
4. Outline of step-by-step process of good IAQ design

Following these sections is a listing of bibliographic references and a listing of standards and guidelines relevant to IAQ that should be consulted by architects and other building design professionals.

60.2 MAJOR IAQ DESIGN STRATEGIES

Three major strategies are available to designers to improve indoor air quality. They can be affected by design decisions at every stage of project development. Design strategies

should address the major determinants of indoor air quality. These can all be addressed in the design process, the design documents, and the project management services that architects and their consultants provide. They include

- Pollutant source control
- Ventilation and air cleaning
- Occupant and building management activity modifications

Pollutant Source Control

Good indoor air quality is air that is free of pollutants at concentrations that can cause unpleasant or harmful effects. Without pollution sources, there is no pollution. But sources are everywhere and of numerous types, including building occupants themselves. In order to best address sources by design, it is necessary to identify a project's potential sources of pollutants and their characteristics.

Designers must interpret the indoor air quality implications of the architectural program (the client's description of the nature of the building required and the uses it will need to support). Specifically, this involves identifying potential pollutant source activities and spaces to be designed as well as those activities and spaces that will be most sensitive to indoor air pollution.

A pollution prevention approach is generally more cost-effective and environmentally preferable to pollutant removal or remediation of damage after the fact. Rough estimates of the effectiveness of source control indicate that it is at least 4 times less costly than dilution by ventilation to achieve comparable IAQ.

Pollutant sources fall into four general categories: outdoor, building, building contents, and occupants. Pollutants can also be classified according to the timing of their release into the atmosphere, their chemical and physical properties, or their potential effects on people and the environment. Following is a listing of the major pollutant sources that architects must consider during design:

- Outdoor air, soil, and water
- Building envelope
- Building equipment
- Finishes and furnishings
- Machines and appliances
- Occupants
- Occupant activities
- Maintenance and cleaning

For distributed sources such as building materials and furnishings, selection of low-polluting sources is relatively easy, and low-polluting products often cost even less than more polluting ones (<http://www.epa.gov/iaq>). Not all pollution sources can be controlled by design, but many can. Simply by carefully selecting and specifying products and materials, designers can do a great deal to reduce indoor pollution, immediately after construction and throughout the life of a building. Where polluting emitting materials are unavoidable, proper isolation or enclosure of the sources can reduce the emission rates and thereby control airborne contaminant concentrations. Sources of pollution can include not only the emissions from the original building materials but also emissions from the products used to clean, maintain, renew, and ultimately remove materials from a building. Therefore, a good

designer selects low-polluting materials and ones that will require minimal use of polluting products to clean and maintain them throughout their service life.

Ventilation and Air Cleaning

Some pollutant sources are simply unavoidable. These include people and many of the sources related to their activities that are relevant to the reason for construction of the building in the first place. Dilution of contaminant concentrations with outdoor air is the most common approach to indoor air quality control. It is unavoidable unless effective air cleaning and recirculation are used. There are filters and air cleaners capable of removing many indoor air pollutants, but these should be seen as the last resort after other means of pollution control have been exhausted.

When source control by design is impractical, impossible, or of limited effectiveness, designers can reduce concentrations of unavoidable pollutants through dilution ventilation with outdoor air or cleaned, recirculated indoor air. Direct collection and exhaust of pollutants at the source is most effective for point sources or localized sources such as cooking devices and other appliances, office equipment, or other processes and activities that generate pollutants.

Occupant and Building Management Activity Modification

Designers can improve IAQ by their potentially large impact on construction practices as well as the operation and use characteristics of a building. Building material installation procedures, cleaning, maintenance, and product use are all forms of behavior that can be affected by the design professional. By specifying proper product installation procedures with appropriate ventilation, significant reductions can be achieved in pollutant concentrations during the early life of a product or material when strong offgassing occurs.

During the entire period of a building material or product's life, the largest emissions may come from chemicals used for its cleaning, maintenance, repair, refinishing, and, ultimately, removal. Assessing the products not only for their own potential contaminant emissions but also for those of the products necessary for the use of the product over its entire life can result in selection of products with much lower lifetime emissions.

Designers must interpret the indoor air quality implications of the architectural program (the client's description of the nature of the building required and the uses it will need to support). Specifically, this involves identifying potential pollutant source activities and spaces to be designed as well as those activities and spaces that will be most sensitive to indoor air pollution. This information should be analyzed to determine ways in which polluting activities and processes can be eliminated, isolated, or mitigated.

60.3 DESIGN ISSUES THAT DETERMINE INDOOR AIR QUALITY

The major means available to an architect to control indoor air quality are the reduction of pollutant sources, direct exhaust of pollutants at the source, ventilation with clean air to dilute contaminants, and selection of materials and finishes that do not emit pollutants and that can be cleaned and maintained without the introduction of pollutants into the space. Successfully controlling indoor air quality by design requires understanding the major determinants of air quality in buildings. The following section describes the major

determinants of indoor air quality that should be considered by the progressive architect. Table 60.1 lists eight design issues that are addressed by the architect to deliver good IAQ. Rarely are all of them addressed adequately in any particular project. However, a comprehensive approach to control of indoor air quality and climate must address them all.

Site Characteristics: Outdoor and Ground Source Pollutants

The air inside buildings is periodically replaced by outdoor air either by designed mechanical or passive ventilation or by unintended infiltration through small openings in the building envelope. Therefore, the quality of the outdoor air is important. The quality of outdoor air is regulated by federal and state governments, and it is reasonably well documented according to national standards known as the *National Ambient Air Quality Standards* (NAAQS) promulgated by the U.S. Environmental Protection Agency (<http://www.epa.gov/airs/criteria.html>). Nevertheless, during the late 1990s, approximately one-third of all Americans lived in communities in violation of the NAAQS. Most of these violated the ozone limits, and many violated the limits on particulate matter or carbon monoxide. Among the contaminants in outdoor air of greatest health concern are combustion by-products such as particulate matter, nitrogen dioxide, carbon monoxide, and sulfur dioxide. Also important are ozone and lead. All of these are regulated because exposure to high concentrations adversely affects human health (<http://www.lungusa.org>).

Combustion by-products, including particulate matter, nitrogen dioxide, and carbon monoxide brought indoors by ventilation systems, through windows, or by infiltration through cracks in the building envelope, can be important indoor pollutants because of their potential to cause serious health effects. Ozone produced outdoors by photochemical reactions (also produced indoors by some office equipment) is an important pollutant because it reacts with many relatively innocuous chemicals commonly found indoors. These reactions produce irritating and toxic compounds such as formaldehyde and some higher-molecular-weight aldehydes. Ozone is also produced indoors by certain devices such as laser printers and photocopiers.

Air entering buildings from soil gas may contain radon, pesticides, and methane or other decomposition products of organic materials. Radon or chemical contaminants in the soil enter the building through cracks when the portions of the building in contact with the surrounding soil are under negative pressure relative to the soil. High soil-gas pressure, low indoor pressure, or the two combined can produce strong concentrations of soil gas indoors. Pesticides used to treat the soil can enter a building and reach significant concentrations indoors. Negative pressure at the lower portion of a building can occur as a result of the natural stack effect in buildings or the operation of mechanical ventilation. The architect and engineer must adjust building pressure by design and attempt to thoroughly seal all cracks in the envelope in contact with the surrounding soil.

TABLE 60.1 Major Determinants of Indoor Air Quality for Designers

Site characteristics: outdoor and ground source pollutants
Occupant activities: type, schedule, location
Building environmental control concept: ventilation, thermal comfort, pollutant source control
Building materials and furnishings: emissions, durability, maintenance, and cleaning requirements
Appliances and equipment: supplies, lubricants
Construction documents: IAQ requirements, submittals, substitutions
Design observation of construction: material protection, temporary ventilation, commissioning
Building operational manuals: completeness, clarity, IAQ inventory

Ventilation air is used to dilute pollutant concentrations and to replace air that is exhausted from the building. If outdoor air quality is poor, then pollutants are brought into the building. Thus outdoor air may require treatment such as filtration of particles or adsorption of gases before it is supplied to occupied spaces. There are many options available to designers depending on the chemicals that must be removed. Charcoal has been shown effective in the removal of ozone, while its performance is more limited for removal of organic chemicals.

The progressive architect or other designer will investigate the quality of outdoor air and apply a variety of design solutions to minimize the impact of outdoor air pollutants on the indoor environment. The quality of air indoors is highly dependent on that of the air outdoors. Whether natural or mechanical ventilation is used, outdoor air is brought into a building to dilute contaminants and replace contaminated air. If the air outdoors contains contaminants, then the air indoors will be contaminated by the outdoor air.

Occupant Activities: Type, Schedule, Location

The very activities a building is intended to house may also be sources of contaminants. It is important to identify such potential sources and include consideration of the means to isolate these sources from the remainder of the building. There may also be activities or occupants in the building that are sensitive to air pollutants. These should be identified in the programming phase of the architect's services and tracked throughout the design, construction, and initial occupancy period.

The use of a building may be very routinized or very irregular, even in different parts of the same building or in similar buildings occupied by different individuals or groups. Therefore, it is extremely important for the design team to have a clear picture of the planned use of the building, particularly as it indicates the characteristics of potential pollution sources and timing and location of their occurrence.

The program documents should list each space and the expected occupancy and use, including its variability. These will be important data for the design of ventilation to control contaminants and for the creation of an IAQ plan for the completed building-by-building management. They will also form the basis for determining the IAQ requirements for specific spaces within the building.

Building Environmental Control Concept

Environmental control systems produce the ventilation, thermal control, lighting, and acoustic control required for a building's intended use. The design of these systems gets far too little attention from architects who often delegate most of the key decisions to engineering consultants. However, thoughtful design can produce more comfortable, productive, and attractive designs that use less energy and are more susceptible to occupant control of the indoor environment.

As the building shape, layout, orientation, and overall space plan begin to evolve during the schematic design phase, it is essential that the ventilation and source control strategies be integral parts of the planning. Decisions made at this stage of the project can facilitate effective IAQ control by integrating source control and ventilation strategies.

Indoor air quality is often treated by many designers simply as an incidental aspect of the ventilation system design. Many projects are designed by adding a certain amount of outdoor air to the supply air, as required by code or recommended by ASHRAE Standard 62 (<http://www.ashrae.org>). This approach to IAQ control is seriously flawed and results from an inadequate understanding of the role of ventilation in maintaining good IAQ.

Adequate consideration of ventilation for indoor air quality starts by assessing the sources that must be diluted and the activities of the occupants that will require ventilation. Table 60.2 shows a range of ventilation rates with different purposes ranging from the minimum required to sustain human life [0.3 (L·s/p, 0.6 cfm/p (0.3 L/s per person, 0.6 ft³/min per person)] to the amount believed to provide “acceptable” indoor air quality with respect to odors 14–50 (L·s)/p, 28 to 100 cfm/p) depending on the nature of the odor and its intensity.

The wide range of ventilation rates in Table 60.2 shows that there is no magic quantity of outdoor air for ventilation that will provide healthy, safe, or comfortable indoor environments for all people at all times. The key is to match the ventilation rate to the occupants and the source strength. It is also important to consider the concentrations of contaminants in outdoor air that will be brought increasingly into the building as the ventilation rate is increased. Some outdoor contaminants such as ozone can react with chemicals commonly found indoors to form more irritating or toxic chemicals. Ozone is also produced by some devices found in buildings including laser printers, photocopiers, and even some types of air cleaner devices.

Building Materials and Furnishings: Emissions, Durability, Maintenance, and Cleaning Requirements

Building materials and the products used to install, clean, and maintain them are important sources of pollutants, especially during the early days, weeks, and months after installation. Controlling emissions associated with materials and furnishings requires that they be considered over the entire service life, not simply in terms of their initial emissions. It is also important to consider the potential of materials to support microbial growth if they are moistened. The location of the materials and the uses adjacent to them should be examined to determine the susceptibility to water condensation or accumulation on the surfaces (<http://www.epa.gov/iaq/schools/newschool.html>).

TABLE 60.2 Various Recommended and Adopted Ventilation Rates

Rate, L/s*	Basis for recommending or adopting group and year
>0.3	2% CO ₂ (respiration)
>0.5	1% CO ₂ (performance)
>1	0.5% CO ₂ (TLV)
>3.5	0.15% CO ₂ (Pettenkofer rule, body odor), 1858
2.5	ASHRAE Standard 62-1981
3.5	Swedish Building Code, 1980
4	Nordic Building Regulation Committee, 1981

*1 L/s (liter per second) = ~2 ft³/min

Source: Lindvall, T. 1989. Lecture, Advanced course in indoor air quality. Nordic Institute of Occupational Health. Copenhagen. Oct. 16–20, 1989.

There are some basic characteristics of sources that determine their emissions behavior. Wet products tend to emit their volatile contents faster than do dry products. Wet-product emissions from surface coatings such as paints and waxes or polishes are dominated by evaporation processes, so ventilation and air movement immediately above the material surface are important determinants of the emission rates. Wet products generally emit the majority of their total life-cycle emissions during the early portion of their service life. Even so, low-level emissions from adhesives or paints have been shown to last as long as a year or more after installation.

Thin coatings emit faster than do thick materials such as composite wood products and carpets or resilient floor coverings. Thin coatings tend to cure rather quickly and emit the majority of their lifetime emissions early in their service life. Examples are paints, waxes, and varnishes. Most wet products emit the vast majority of their volatile organic compound (VOC) emissions during the first few hours, days, or weeks of life. The surfaces to which these materials are applied and any materials applied over them will affect their emissions life cycle considerably. For example, when latex paints are applied to gypsum board, more than half of the applied mass is absorbed by the gypsum board. On the other hand, a sealant applied to smoothly sanded hardwood will not result in much adsorption and most of the volatile compounds will be emitted directly into the air. Air movement at the surface of a wet material will increase the emissions.

Assemblies of materials behave differently from single materials. Emissions from adhesives and other materials such as carpet cushions that are installed under another product are affected considerably by the materials that cover them. Carpets or wall coverings change the emissions from materials under them by providing a barrier to the emissions from the adhesives used to install them or the materials on which they are applied. This fact can be used to reduce occupant exposure to formaldehyde and other emissions from composite wood products used for casework, for example, by completely encapsulating the substrate with a plastic laminate.

Solid materials such as plywood, particleboard, wood paneling, carpets, resilient floor-coverings, and thermal insulations tend to emit more slowly than do wet products, and their emissions can last for many months or even years. Emissions of formaldehyde from particleboard have been measured several years after the products were installed. Emissions from dry, solid products such as carpets and pressed-wood products are determined more by diffusion processes within the material itself and the material thickness.

Some architects now specify “low-emitting materials” without distinguishing the type or time course of the emissions. Not all VOCs have the same potential to cause odor, irritation, or toxic effects. “Green” or “nontoxic” products often contain lower total VOCs but emit them for far longer than the traditional solvent-based products they replace. Some VOCs emitted by these green products are not listed as VOCs under the USEPA’s definition because they are nonreactive in terms of ozone formation in outdoor air. They are still important for indoor air quality although they will seldom be listed by the manufacturers as VOCs on product information documents, including MSDSs (Material Safety Data Sheets) required by OSHA (<http://www.acgih.org>).

Many of these VOCs that are exempt from outdoor air regulation are important for indoor air quality as they may react with ozone and other oxidants to form aldehydes, including formaldehyde. These chemicals are far more irritating, and some are more toxic than the chemicals they replace. Alkenes that contain unsaturated double bonds react with ozone to form less desirable compounds. New products such as the citrus-based solvents are being used as substitutes for traditional solvents in building materials and cleaning and degreasing compounds because they themselves are less toxic and do not contribute to smog formation outdoors.

Some designers erroneously believe that “natural” products are better for IAQ than synthetic products. In fact, many toxic substances are naturally occurring, including arsenic,

asbestos, formaldehyde, and many others. Many synthetic materials are quite stable and less prone to microbial contamination than are the natural materials they replace. Examples include fibers used for textiles such as carpets or drapes. Nylon and polyethylene are much less susceptible to mold or insect damage than are wool or cotton fibers. Hard plastics are more mold-resistant than is wood or the paper covering on gypsum board.

Ventilation during the strong emissions process will lower the concentration in the space but will increase the actual emissions rate. Thus, ventilation during and immediately after installation of new sources results in less total exposure of occupants. In addition to the emissions during installation and immediately after, the characteristics of a product determine the materials that will be used to protect, clean, polish, or refinish the surface. Cleanability will determine the frequency of replacement of a product and the associated introduction of fresh new sources of emissions.

Surface materials need to be cleaned periodically, and some materials, especially floor and some wall finishes, must be refinished. The cleaning and refinishing processes involve the introduction of products that are often applied wet and have very strong emissions during and shortly after application. Many of the products emit VOCs, some of which are odorous, irritating, or even toxic. Selection of products to limit pollutant contributions to indoor air should be based not only on emissions from the materials when new but also on the life-cycle emissions due to the application of new finishes or of waxes, polishes, lacquers, sealants, and other wet-application products.

Products that are easily cleaned with water or other nontoxic products are vastly preferable to those that require chemical use. While some “natural” paint products have lower VOC emissions while they cure, they may not be easily cleanable and, therefore, will require more frequent repainting. Thus the low-VOC paint may be better initially but over the life of the building may result in more total emissions and, therefore, exposure of occupants to organic chemicals.

Product manufacturers have become increasingly accustomed to requests for such information. Research should not be done with sales personnel but, rather, with the technical staff responsible for the design, formulation, quality control, performance, and environmental compliance of products. Designers should ask sales personnel to identify such technical staff, provide contact information, and notify them that they are assisting on the project. Technical staff can be very helpful in selecting the product with the best potential IAQ performance for a specific project application.

At the end of a product's service life, it must be removed and replaced. The removal itself might result in pollutant emissions, either from chemicals used to aid in the removal or from mechanical damage to existing materials (e.g., insulation) and the release of particles and vapors to the air (<http://www.naima.org>).

It is obvious that the longer the service life of a product or material, the less often it must be replaced. Durability is important for indoor air quality as well as overall environmental sustainability. The service life of a product is the denominator in any calculation of sustainability.

Appliances and Equipment

Devices that use fuel or supplies tend to emit pollutants. Office equipment such as photocopiers, laser printers, and fax (facsimile) machines emit gases and particles with large variations depending on the types of processes, the rates of printing, and the time history relative to periodic maintenance and cleaning. EPA studies of photocopiers show that their ozone emissions increased severalfold from the rates immediately after servicing to the rates at the end of the service period. Kitchen appliances, especially cooking devices, are sources of moisture and contaminants. Gas-fired appliances, like any combustion device,

produce by-products such as particulate matter, nitrogen dioxide, carbon monoxide, and water vapor that must be controlled.

Equipment and appliances that are known sources of contaminants should be placed carefully so that their emissions do not enter the circulating air indoors. They should be exhausted directly to the outdoors. They also tend to be sources of heat and need to be located where the thermal conditions will be controlled to comfortable levels.

Construction Documents

Construction documents (CDs) can specify both IAQ-related performance requirements as well as prescriptive requirements for materials, products, and systems. They can also include requirements for submittals of information about the chemical content of and pollutant emissions from products and materials. Criteria for emissions can be established in the CD. The procedures for installation can be specified to reduce exposure to occupants from emissions.

Designer Observation of Construction

Many construction specifications include details that could ensure good indoor air quality if followed. Examples are the requirements for ductwork in the manuals of SMACNA, the Sheet Metal and Air Conditioning Contractors of North America (<http://www.smacna.org>). The SMACNA specifications for duct assembly are usually included but rarely implemented in most projects. The care with which joints are created in the assembly of ductwork can have a large impact on the indoor environment by reducing leakage and noise and reducing the accumulation of particulate matter on fibrous duct insulation materials.

It is not uncommon for products selected for their IAQ performance to be substituted out of a project by a contractor. Designers must hold fast to the IAQ criteria and refuse to accept substitutes that do not meet those criteria.

Ventilation is essential during installation of strong sources of pollutants to avoid a large sink effect. As concentrations of chemicals rise in the air, some of the molecules of any chemical deposit on surfaces and then can be re-released at a later time when air concentrations decrease. This process can result in higher occupant exposure to contaminants for longer periods. Research has shown that the sink effect can account for the majority of emissions in a minimally ventilated building for many weeks or even months after the introduction of a source. Ventilation during construction reduces the sink effect and therefore reduces subsequent occupant exposure by keeping air concentrations low and by exhausting chemicals from the building.

Ventilation systems, especially ductwork, should be protected during construction to prevent buildup of dust (e.g., from drywall finishing) or of chemicals (e.g., from paints and adhesives). Ductwork should be sealed until it is ready to be made operational and should not be allowed to carry contaminated air during construction. If such exposure is unavoidable, then ductwork should be cleaned before occupancy.

Building Manuals

One of the design team's most important functions to ensure good IAQ is to assemble the building manuals that will be used by building management and engineering personnel to operate the building. These manuals, together with the as-built drawings, will identify the products and materials used as well as the intended procedures for operation and maintenance of

equipment. The building manuals should also include complete documentation of the commissioning process (<http://www.eheinc.com>; <http://www.peci.org>; www.ashrae.org).

60.4 DESIGN SERVICES

Every phase of the architect's work is important to indoor air quality. Table 60.3 is a checklist of all the building project phases where explicit attention to IAQ is necessary. Specific examples of considerations in these phases are given in Sec. 60.3.

TABLE 60.3 Checklist of All Building Project Phases Where Explicit Attention to IAQ Is Necessary

Project planning phase
Programming: identifying project goals, requirements, budget, schedule
Assembling the design team
Site evaluation
Site planning and design
Building schematic design: emphasize environmental control scheme
Design development
Construction documents
Bidding process
Source control
Selection of building materials
Furnishings
Space planning for isolation of pollutant source activities
Emissions testing and interpretation
Moisture exclusion
Cleaning and refinishing surfaces
Ventilation and comfort control
Conceptual design for environmental control: basic ventilation, heating, cooling, illumination scheme
Planning of adjacencies for sensitive locations and pollutant-generating activities
Location of air intakes and building openings
Location of windows and skylights
Passive cooling and heating strategies
Load-based ventilation system design
Construction process
Bid documents
Bidding process
Submittal requirements
Substitutions
Controlling dust and fiber accumulation during construction
Control of sink effects during construction
Temporary ventilation
Commissioning process
Assembling the project manuals
Initial occupancy and start-up operations
Testing for acceptability
Initial ventilation strategies
Transitional ventilation
Final clearance and acceptability

60.5 OUTLINE OF STEP-BY-STEP PROCESS OF GOOD IAQ DESIGN

This section follows the sequence of a typical design project by phases and lists questions that should be asked or items that should be identified and checked by the architect or other lead designer.

- I. *Determine IAQ project goals.* Establish IAQ goals for the project.
 - A. Determine overall purpose and level of IAQ required. This could range from ensuring outstanding IAQ for special need locations to avoiding most likely sources of problems. The IAQ goals will determine the scope and depth of the IAQ-related design concerns and the level of effort and resources required to achieve the goals. Absence of clear statements of these goals will result in wasteful efforts or failure to accomplish project goals, or both. Questions to answer to help define these project IAQ goals.
 1. List the concerns and identify what the client (agency) is willing to do to achieve good IAQ. (*Comment:* Answering these questions will help establish the project IAQ goals.)
 2. Determine whether the client agency wishes to provide standard, above average, or outstanding indoor environmental quality. If yes, then
 - a. Identify the specific IEQ concerns of the client:
 - (1) Reduce employee SBS symptoms
 - (2) Reduce employee absenteeism
 - (3) Reduce employee odor-related complaints
 - (4) Reduce employee allergic or asthmatic responses
 - (5) Reduce health risks related to:
 - (a) Legionnaire's disease and Pontiac fever
 - (b) Colds and flu
 - (c) Hypersensitivity pneumonitis
 - (d) Other?
 3. Determine how the client agency will participate in the project planning and design process:
 - a. Does the client attend regular periodic project meetings?
 - b. Review project meeting notes and comment.
 4. Determine whether the client agency is willing and able to acquire supra-normal budget resources to construct and operate a high-IEQ facility. If yes, identify and document the estimated extra budget allocated to high IEQ.
 - B. Determine whether there are spaces requiring special protection for good IEQ.
 1. Determine whether sensitive populations will occupy the building. If so, determine the characteristics of the special populations and where they will be working in the building.
 - a. If so, will they be visitors or normal occupants?
 - b. Will they need access to the entire building or only to certain spaces?
 - c. What are the sensitivities, and what do they require in terms of special consideration in design and operation?
 - C. Determine whether certain spaces are likely to be sources of contaminants.
 1. What functions will be performed? List all major and routine activities, and identify the potential pollutant emissions from the materials, equipment, and processes used.
 2. What types of materials will be brought into the building from the outside, and are any of them potential sources of indoor air contaminants?

3. Will pollutant sources be brought into the entire facility, or can they be limited to certain spaces? If so, identify the spaces and tag them on building plan diagrams and space planning diagrams during the design process.
 4. Are there hazardous or toxic chemicals that will routinely, periodically, or episodically be brought into the building in connection with the building occupant's normal functions? If so, identify them and place them on the list for design consideration and to inform local fire or other hazardous-materials response agencies.
- II. *Site characteristics.*** Identify site characteristics relevant to IAQ. Determine preferable locations and orientations for outdoor air intakes, requirements for air cleaning and filtration, and scheduling issues related to short-term outdoor air pollutant concentration excursions (e.g., heavy-traffic periods).
- A. Adjacent or nearby sources of contaminants**
 1. Are there any industrial activities (manufacturing, processing, waste handling, agriculture, etc.) that might be sources of pollutants?
 2. Are there any commercial activities that might be sources of pollutant emissions? (Examples are dry cleaning, food preparation, and health care.)
 - B. Soil or groundwater as potential sources of contaminants**
 1. Is there a history of industrial or agricultural activity on the site or on adjacent or nearby sites? If so, is there information on potential contamination of soil by industrial chemicals such as solvents, oils, pesticides, or fertilizers?
 2. If there is a shallow groundwater table, is there information on the pollutant content of that groundwater?
 - C. Prevailing wind conditions**
 - D. Traffic patterns**
 - E. Ambient-air quality.** (Check with the local air pollution authority and examine the surrounding area for potential contaminant sources.)
- III. *Conceptual environmental design.*** Determine overall concept and approach to environmental control (ventilation, illumination, heating, cooling, and acoustic control).
- A.** Will ventilation be all mechanical, hybrid mechanical and natural, or all natural?
 - B.** How will ventilation air be brought into the building and distributed to spaces?
 - C.** How will building air be returned to air handlers or exhausted to the outside?
 - D.** Will illumination be significantly dependent on daylight strategies intended to provide more productive and energy-conserving environments?
 - E.** Will occupants be able to control illumination or override automatic lighting controls?
 - F.** Will heating and cooling be through ventilation air or other means?
 - G.** Will occupants be able to affect thermal conditions and their control?
 - H.** Will noise control be through soft or fleecy surfaces, through shaping space enclosure, or other?
 - I.** Will occupants be able to affect the noise levels in their individual workspace?
 - J.** Will acoustic privacy be provided to workspaces? If not, how will private and confidential communication be supported by the building design and operation?
- IV. *Schematic design.*** Determine general building massing, layout, and exterior openings. Indicate general ventilation system flows, equipment locations, locations of major pollutant point sources, exhausts of ventilation system, cooling towers, outlets from combustion exhausts, toilet and other plumbing exhausts, and so on.
- A.** How will air be supplied to occupants?
 - B.** Where are outdoor pollutant sources?
 - C.** Can air intakes, including HVAC inlets, building doors, and operable windows, be located away (and not downwind) from pollutant sources?
 - D.** Where will mechanical ventilation equipment be located?

- E. Will drift from cooling towers potentially contaminate intake air?
- F. Will exhaust from toilet stacks, kitchens, trash, biological/chemical hoods potentially contaminate ventilation air intake?
- G. How will ventilation be controlled? Will occupants be able to affect the quantity of air and the thermal properties of supply air?
- H. Will occupants be able to control important aspects of their individual work environment?
- V. *General materials pallet.* Include this in the schematic design phase. Given the project type and budget, what are the likely dominant materials?
 - A. Can major interior floor and wall surfaces be easily cleanable with nontoxic materials?
 - B. Will floorcovering materials require minimal periodic coatings (wax, polish, sealant, lacquer) for appearance and extended service life?
 - C. Will concealed spaces used to circulate air be easily accessible, cleanable, and renewable?
 - D. What will be the major materials? Have alternatives been considered in terms of low-emitting and low-maintenance requirements?
- VI. *Determine ventilation system options and evaluate.* Conduct box model analysis of generic schemes to isolate best alternatives. (This is part of the design development phase of the architectural services contract.)
 - A. Evaluate various major options for ventilation system(s).
 - 1. Are there options for user control of ventilation?
 - 2. Are there options for energy efficiency?
 - 3. Are there options for improved indoor air quality?
 - 4. Will passive or natural ventilation be adequate?
 - 5. Can a hybrid natural-mechanical system provide good IAQ and occupant control?
 - 6. Is heat recovery important? What will be the IAQ issues related to heat recovery systems?
 - 7. Can displacement ventilation reduce occupant exposure to contaminants?
- VII. *Identify target materials for IAQ evaluation.*
 - A. From the complete bill of materials, select those that are of IAQ importance.
 - B. Use the material quantity takeoffs from the cost estimate normally done as part of the architectural design services contract during the design development phase.
 - C. Use the quantity takeoffs to prepare a spreadsheet analysis of the area and mass of major materials per unit of volume in the spaces to which they relate.
 - D. Use this process to identify the high-use materials and prioritize the material evaluation activities.
 - E. Add major wet products even though they may not rank high in terms of mass or area, such as seam sealers, glazing compounds, and caulks.
 - F. What materials have the largest interior total surface area?
 - G. What materials have the greatest mass?
 - H. Except for concrete, masonry, metal, stone, tile, and glass, what are the major interior surface materials?
 - I. Do any of these materials have the potential to be strong emitters of pollutants in the short term? (These might include adhesives, paints, caulks, sealants, and other "wet" products.)
 - J. What are the surface areas of the target materials?
 - K. What are the masses of the target materials?
 - L. Multiply the emission factors obtained for target materials times the areas or masses as appropriate to prepare estimates of the impact that emissions will have on indoor concentrations.

- VIII.** *Obtain information on the chemical contents and emissions of IAQ target materials.* Request information from product manufacturers. Use products only from those manufacturers who provide the requested data.
- A.** Have product data sheets and volatile organic chemical (VOC) emissions tests been provided for dry products such as composite wood products?
 - B.** Have chemical contents lists been requested of manufacturers of wet products?
 - C.** Have all major “target” products been reviewed for their chemical contents and potential emissions?
 - D.** Can any of the “wet” products be eliminated or their use reduced?
 - E.** Can installation of necessary “wet” products occur with temporary or permanent ventilation system operation?
 - F.** Will there be extensive use of composite wood products? If so, have low-emitting products been selected?
 - G.** Are composite wood products sealed, laminated, or otherwise isolated from indoor air?
 - H.** Is carpet specified? If so, is it required to meet the Carpet and Rug Institute’s “green label” criteria? Can carpet be eliminated in any cases of its use?
- IX.** *Obtain information on cleaning and maintenance (C&M) requirements.*
- A.** Request product manufacturers’ instructions or guidelines on cleaning and maintenance of the major surface area materials (floors, walls, ceilings). Identify chemical products required and obtain chemical composition of these products.
 - B.** Include these C&M products in the assessment of emissions under steps X through XII below.
- X.** *Review chemical data for presence of strong odorants, irritants, acute toxins, and genetic toxins.*
- A.** Use standard references (e.g. Sax, NIOSH RTECS, EPA IRIS, California OEHHA, ACGIH TLVs, OSHA PELs) to determine status of chemicals that will be emitted at significant rates (to be defined). Useful information is available from <http://www.chemfinder.com/>. There are listings on that Website for a very large number of government and other databases and information sources on chemical properties including odor, irritation, and toxicity. Information on over 600 common chemicals is also available from USEPA’s Integrated Risk Information Service (IRIS) database on the Web at <http://www.epa.gov/ngispgm3/iris/>.
- XI.** *Calculate concentrations of dominant emissions*
- A.** Use a basic indoor air model to calculate emissions of worst-case chemicals at 24 h and 30 days. (Such a model is available at no cost from USEPA’s Website <http://www.epa.gov/iaq/iaqinfo.html#IAQINFO> or by contacting Sparks.Les@epa.gov.)
 - B.** Another IAQ model is available from the National Institute for Standards and Technology (NIST) www.bfrl.nist.gov/863/contam.
 - C.** Compare various sources and focus on those with the largest impact on IAQ.
- XII.** *Evaluate calculated concentrations and total potential emissions against criteria.* Use the following sources for criteria concentrations.
- A.** *Odor.* See Devos et al. (1990); multiply threshold by factor of 2.
 - B.** *Irritation.* Use ACGIH TLVs for current year for irritants only; divide TLV by 40.
 - C.** *Cancer.* Use latest lists from NTP, IARC, USEPA, and CalOEHHA. Exclude known carcinogens, using concentration or total potential emissions criteria to be established by City of Oakland.
 - D.** *Toxicity.* Use CalOEHHA, IRIS, and the Danish National Institute of Occupational Health VOCBase lists.

- XIII.** *Assess total potential emissions (alternative to steps X and XI above).* Multiply mass present in the product times the vapor pressure for chemicals to get a dimensionless number. Multiply this number by the reciprocal of $1/40$ TLV. Select from among the candidate products the one(s) with the lowest ratio.
- XIV.** *Select products and write installation specifications.* For selected products, write specification for acquisition, storage, transport, handling, and installation.
- A.** *Acquisition.* This should include criteria used for selection in the specification.
 - B.** *Storage.* Ensure that storage includes moisture and dust protection, adequate ventilation, absence of direct sunlight, moderate temperatures (freeze protection), and relative humidity.
 - C.** *Transport.* This should include the same criteria as storage.
 - D.** *Handling.* This should include protection against mechanical damage or chemical contamination.
 - E.** *Installation.* Specify the installation of a quantity of wet products (paints, adhesives, caulks, sealants, surface preparation materials, etc.) no greater than that required for the application and use of the product or material in question.
 - F.** *Ventilation.* For all “wet” products and major floorcovering products, specify no less than 3 ACH (air changes per hour) during the installation and for 72 h afterward.
- XV.** *Ventilation system specifications*
- A.** Outside air quantity determination for design at full- and part-load conditions
 - B.** Outdoor air intake locations
 - C.** Filter type and efficiency determination and guidelines
 - D.** Air-cleaning specifications, if required by outdoor air quality conditions
 - E.** Coil and drip-pan access and drainage requirements
 - F.** Use of fleecy duct linings limited to absolute minimum
 - G.** Air distribution system characteristics to ensure adequate distribution under heating and cooling, full- and part-load conditions
 - H.** Return-air system specifications (ducted, cleanliness, access, etc.)
 - I.** Building automation system (BAS) characteristics, variables to monitor, algorithms for operator alerts
 - J.** Sensors for input to BAS
- XVI.** *Ventilation system construction*
- A.** Protect materials and components from adverse weather. Dry thoroughly before use and inspect for water damage and fungi.
 - B.** Ensure that there are no friable surfaces or edges when using internally lined ducts.
 - C.** Leak-test to ensure finishing details on joints, fittings, and other components.
 - D.** Assure access for inspection, maintenance, and cleaning.
- XVII.** *Commissioning completed facility.* Follow ASHRAE Guideline 1 and *SMACNA Commissioning Manual*.
- A.** Has a single commissioning authority been designated to oversee the commissioning process?
 - B.** Have relevant facts been documented beginning with the design phase and on through the occupancy phase of the project?
 - C.** Are all relevant parties aware that a commissioning process is being conducted?

60.6 CONCLUSION

By taking a proactive role in addressing IAQ concerns, the architect or other lead design professional can significantly improve IAQ in the completed building. The client's goals

and the nature of the project will determine the appropriate design response. The entire life cycle of the building must be considered to reduce occupant exposure to harmful or annoying substances. Many means are available to improve IAQ, and the progressive architect will use the design process to implement them throughout the design services period.

CHAPTER 61

BUILDING COMMISSIONING FOR MECHANICAL SYSTEMS

John F. McCarthy, Sc.D., C.I.H.

Michael J. Dykens

*Environmental Health & Engineering, Inc.
Newton, Massachusetts*

61.1 INTRODUCTION

The American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. (ASHRAE) published its original guidance document on commissioning heating, ventilating, and air-conditioning (HVAC) systems in 1989 (ASHRAE 1989). The document presents a framework in which to view the commissioning process and general requirements that can be adapted to various projects. While this is still the most widely cited guideline on commissioning, many commissioning projects involve building systems beyond those for heating, ventilating, and air conditioning. In this manner, a well-conceived commissioning program can serve as an overall quality assurance measure for integrating complex building systems. These additional building systems could include the building envelope, mechanical and electrical systems, power and communication systems, occupant transport systems, fire and life safety systems, water systems, specialized control areas, and building management systems.

Commissioning has been defined as a systematic, documented, collaborative process to assess the ability of a building and its component systems to meet design intent and the needs of its occupants. This process begins in the design phase and should last at least a year after the completion of construction. Properly executed, the process includes the training of operating staff and ensuring through documented verification that all building systems perform interactively according to the design intent and the owner's operational needs (PECI 1996). Commissioning is most valuable when system performance is evaluated

under the full range of load and climate conditions. The ability to assess system performance under part-load or extreme conditions is often the best way to discover problems in buildings and correct them before occupancy.

This process has proved so successful that several states are promising to include it in revisions to their codes. For example, Massachusetts will require specific construction documents which will include

- Design intent
- Basis of design
- Sequence of operation
- System operation
- Testing
- Operations and maintenance manuals
- Record drawings

Benefits

The value of commissioning projects is most often cited with respect to new building construction projects. Part of HVAC design intent is formally documenting performance objectives; basing the criteria of acceptability on these performance objectives, from construction through to system operation, results in a better functioning building. As useful as these procedures are for new construction, they can be equally valuable in renovation projects and energy-conservation programs. Many times, the start-up, control, and operational problems that occur as a result of “minor” changes made in localized areas can often compromise the performance or efficiency of entire buildings. Furthermore, when one considers the impact that HVAC systems that are deficient in operation can have on indoor air quality, the benefits of incorporating proper building commissioning activities in all HVAC-related projects is obvious.

The benefits that can be realized from a complete commissioning program include

- Higher-quality building systems and the knowledge that the facility operates in a manner consistent with the original design intent and meets occupant needs.
- Identification of system faults or discrepancies early in the construction process so that they can be resolved in a timely manner while appropriate contractual entities are still on the job. This will reduce the number of contractor callbacks.
- Improved documentation, training, and education for operators and facility managers to ensure longer equipment life and improved performance.
- Increased equipment reliability by discovering system problems during construction. In this way, commissioning prevents costly downtime due to premature equipment failure, and also reduces the wear and tear on equipment by ensuring that the equipment operates properly.
- Reduced operation and maintenance costs.
- Improved occupant comfort and indoor air quality. Managing these factors effectively can reduce employee absenteeism and improve productivity and morale. Furthermore, the reduction in occupant complaints of discomfort minimizes service calls to building operators during the life of the building.
- Reduced potential for liability and litigation. This is true for minimizing both liability of owners due to occupant personal injury cases and litigation of engineers and contractors due to claims from owners.

Building owners who have had their buildings commissioned overwhelmingly cite energy savings and the assurance that systems will operate correctly as the important reasons. Figure 61.1 shows the results from follow-up interviews with owners involved in some 175 projects.

Selection of a Commissioning Authority

Commissioning involves a variety of technical expertise, such as engineering, controls, and life safety, as well as the ability to assess interactions. It does not fall under the purview of any single discipline. Therefore, a separate commissioning agent, or as ASHRAE now prefers to designate the role, *commissioning authority* (CA), should be part of the project team and carry out these required evaluations and documentation. For this function to be effective, it is generally most appropriate that the CA be independent in nature and report directly back to the building owner. Figure 61.2 shows a possible reporting structure that emphasizes the CA's role of coordination among the various parties.

The following list describes the various options that have been proposed to fill the role of CA and the pros and cons for using each one.

- *The owner.* The owner might appear to be an obvious choice for commissioning authority since this person has a vested interest in ensuring that the building is specified, constructed, and operated as envisioned. Utilizing in-house staff, the owner might control the commissioning process to ensure that the contractor delivers the building properly. Assigning staff to deal with commissioning, however, could delay construction and divert efforts from other projects. Staff might encounter a conflict of interest

FIGURE 61.1 Why owners commission their buildings. (Copyright Portland Energy Conservation, Inc. Portland, Oregon. Reprinted with permission.)

FIGURE 61.2 Role of the commissioning agent.

between timely completion of a construction project and the need for modifications, risking delays. In-house staff may lack the appropriate expertise to effectively serve as a CA.

- *An outside expert.* The owner can still act as a commissioning authority by hiring an outside expert to serve in the role of the CA. The expert would report directly to the owner on the contractor's performance and provide effective monitoring of the commissioning progress. This also requires that the outside consultant be given appropriate authority to coordinate outside subcontractors for the many commissioning activities that are required. For this program to be effective, the line of authority from the owner to the commissioning authority must be clearly defined.
- *General contractor.* It is logical that the contractor be held accountable for quality control, which takes into account many of the activities required for effective commissioning of a building. Furthermore, it is the general contractor who is responsible for construction sequencing and who should effectively police the quality of work on the job. The general contractor has a stake in the successful completion and timely delivery of the entire project. There is also direct financial benefit if the general contractor can reduce warranty and service calls in the future. Of course, the major drawback is the possible conflict of interest since the contractor would be responsible for replacing any items found to be deficient. To try to avoid this conflict of interest, owners should retain the prerogative of approving or disapproving the work of the general contractor as commissioning agent by performing spot-checks and providing quality assurance of the contractor's commissioning efforts. However, by doing this, the owner may generate animosity and ill will since the exercising of this authority will directly undermine the activities of the general contractor as commissioning agent.
- *The engineer of record.* Advantages in using the design engineer as a commissioning agent include the fact that the engineer has full knowledge of the system design and is intimately familiar with its sequence of operation. This could be seen to achieve significant economies. However, there is a potential conflict of interest since the design engineer may not acknowledge problems that are in fact design errors since they would be his responsibility. Also, a major benefit of commissioning, that of outside peer review, is lost in this approach. Areas of design that could be deficient may not be captured since the engineer may not see them as deficient.

61.2 THE COMMISSIONING PROCESS

The commissioning process can be undertaken in phases which best start at the design phase and can be carried through to the occupation and operational phases of a building. Of course, much benefit can be gained by performing the functional performance tests on the systems before owner acceptance and occupancy. However, costs to rectify design deficiencies discovered at this point could be more costly to correct.

Phase I: Programming Review

The building/HVAC commissioning process begins by

- Designating a commissioning authority (CA)
- Establishing the parameters for design and acceptance
- Designating the responsibilities of the various parties
- Delineating the documentation requirements for the entire project

The CA, design team, and owner review the building program and identify the information required for effective design and performance criteria for building acceptance.

Phase II: Design Review

The CA is often thought of as a quality control element of the design team. As such, the CA would be responsible to review and document discrepancies between architectural/HVAC design and specifications and the owner's building system performance criteria. As the design review proceeds, the CA would also be responsible to review proposed value engineering options for conformance to codes, occupant needs, and system optimization, and to provide an opinion regarding resulting limitations. Early in the design phase, the CA is responsible for preparing and distributing a commissioning plan that identifies the responsibilities of each key member of the team and the scheduling of commissioning activities and deliverables. This should be in sufficient detail so that the required submittals designate parties and instrumentation that will need to be present for each test. In addition, the master construction schedule should include the schedule of commissioning activities and link them with other construction activities.

The CA must ensure that the design team takes explicit responsibility to document the following items:

Design Criteria and Underlying Assumptions. The design criteria should include all of the following environmental considerations:

Thermal conditions
Humidity
Occupancy (hours and levels of activity)
Lighting
Noise
Vibration
Total and outside air requirements

Code requirements and impact on design

Special loads

Air quality design criteria

Pressurization and infiltration requirements

Fire safety

Life safety

Energy efficiency

Maintainability

Functional Performance Test Specifications for Mechanical Systems. Test specifications are developed during the design phase and allow the design team to better anticipate the commissioning process requirements. These specifications are required at a minimum to

- Describe the equipment or systems to be tested. The description of the HVAC system includes type, components, intended operation, capacity, temperature control, and sequences of operation.
- Identify the functions to be tested. Operation and performance data should include each seasonal mode, seasonal changeover, and part-load operational strategies as well as the design setpoints of the control systems with the range of permissible adjustments. Other items to be considered include the life safety modes of operation and any applicable energy-conservation procedures.
- Define the conditions under which the test is to be performed. It is important to consider all possible operating modes, such as full and partial loads, and the extremes of operating temperatures and pressures. The documentation that will be provided to support this is critical for it will clearly show the completeness of the engineer's design.
- Specify acceptance criteria. It is essential that the acceptance criteria be presented in clear, unambiguous terms. Where possible, the acceptance criteria should be quantitative with accuracy and precision requirements consistent with the limitations of the equipment and system design.

Phase III: Construction Oversight

During the construction phase, the CA is responsible for on-site inspection of materials, work quality, and installation of HVAC system and components, including pressure tests of piping and duct systems. The CA should also observe and/or independently audit testing, adjusting and balancing, and calibration of system components.

Other activities that an effective CA performs during the construction phase include (1) review of warranty and retainage policies prior to construction, (2) obtaining copies of contractor's approved equipment submittal for review, (3) ensuring that effective construction containment techniques are used, and (4) documenting and reporting discrepancies for the owner.

Finally, it is essential that personnel who will be responsible for operating the completed system receive adequate training prior to system acceptance. This is best done during the construction phase. The CA should take responsibility to ensure that this training is provided by appropriate personnel (often equipment manufacturers through the design engineer) for the numerous components that make up the HVAC system.

Phase IV: Acceptance Phase

The acceptance phase should follow the commissioning plan established during the design phase. The functional performance test specification forms the basis for documenting the acceptability of the installed systems. The CA certifies performance either by conducting tests personally or by observing the appropriate parties testing the functional performance of each system. This testing should start at the lowest reasonable level, specifically, system components, then on to subsystems, then finally systems, until every piece of equipment has been tested. The CA must also ensure that all essential activities have valid performance tests (e.g., hydrostatic testing; testing, adjusting, and balancing work; and calibration of automatic controls), and that the tests have been completed to a satisfactory level prior to starting the acceptance verification procedures. As stated earlier, it is critical that testing be done in all modes of system operation, including full-load and emergency conditions.

All required documentation should be compiled to form the basis of the system operations manual. Furthermore, as-built documents should be revised to ensure that accurate plans are available showing all relevant control points and values.

Prior to final acceptance, the CA will produce and distribute to the appropriate parties a document detailing all discovered deficiencies in the form of an action list. After required work has been completed, the CA will revisit the site and perform follow-up performance testing where required to verify that all action list items have been successfully resolved.

Phase V: Postacceptance Phase

The postacceptance phase can best be thought of as an ongoing audit function of the building systems and the building's occupancies. Periodic retesting, especially during the first year, is often advisable. This can be particularly important during extreme seasonal variations from the original commissioning period or during design extremes. The CA should also document the building operator's adjusted setpoints to ensure that they are consistent with original design. Where differences exist, the CA should evaluate the impact and reconcile them in a written report.

61.3 COST AND OFFSETS

There is currently no standard approach to costing commissioning services. Some of the more common methods are:

1. Budgeting a percentage of the total mechanical/electrical cost of a project. A range of 2.0 to 6.0 percent is generally considered reasonable; the higher percentages generally are utilized for those projects that are smaller in scope or those that are more complex in nature.
2. Setting up a separate commissioning budget that is independent of the project budget. This is often useful in a case where the owner has an ongoing construction program, such as that found in many hospitals. Setting aside a commissioning budget that represents \$0.10 to \$0.28 per square foot allows the work to be carried out over a number of projects over a year's time. Most owners utilize an operations budget, although some do capitalize this work.
3. Utilizing a payment schedule based on time estimates provided by the CA to the owner. In such projects, it is important that all parties agree in writing as to what constitutes a completed plan, as well as an appropriate payment schedule.

No matter what budgeting approach is selected, it is imperative that contracts with the general and specialized contractors specify their financial liabilities. Although the CA is initially paid by the owner, additional charges incurred by the CA will be paid by the contractors if systems fail or cause delays to the schedules established for the commissioning.

Commissioning a building with the intent of improving performance can save owners and tenants tens of thousands of dollars over the operating life of the building. The Department of Design and Construction (DDC) for the City of New York developed *High Performance Building Guidelines* in 1999, which included commissioning as an essential component (New York DDC 1999). They are described as easy-to-implement requirements that can achieve 10 to 30 percent reductions in energy and water use while improving productivity. Commissioning agents today must inform their clients of these potential savings as listed in Table 61.1 and described in more detail in the *NYC Department of Design and Construction 1999* report. Substantially greater savings are possible if the owner desires “green design” involving a systematic analysis of the HVAC demand, lighting, material content, recycling of waste, and water use, among other components. New guidance documents, such as the U.S. Green Building Council’s Leadership in Energy and Environmental Design (LEED) program, require commissioning of buildings to ensure optimum performance of installed system. Designing green buildings to reduce ecological consequences is a subject of Chap. 5.

Although commissioning is often seen as an added cost to a project, owners experienced with commissioning do not find an overall cost increase in constructing buildings. The costs provided above compare favorably with several other cost parameters normally associated with building construction. For example, the 2 to 6 percent of M/E (mechanical/electrical) project cost compares favorably with the range of change orders and claims generally encountered on capital projects, which can typically range from 9 to 18 percent.

In addition to the benefits cited earlier, experience shows that an effective commissioning program can also reduce mechanical change orders and claims by 10 to 50 percent, pro-

TABLE 61.1 Cost and Potential Savings Projected for NYC Buildings if High-Performance Guidelines Are Implemented

Facility or service	Cost	Savings
Energy	\$1.50–\$2.00/(ft ² ·year)	\$0.30–\$0.80/(ft ² ·year) \$70,000 for 100,000 ft ²
Water	\$0.0025–\$0.0050/(ft ² ·year)	NYC could save \$625,000/year if leaks were fixed
Waste	\$40–\$100/ton	\$0.17/(ft ² ·year) Recycling could capture \$30–\$80/ton; 10% recycling would save \$3 million/year
Maintenance	\$1.00–\$1.50/(ft ² ·year)	\$0.11–\$0.77/(ft ² ·year)
Labor	\$200–\$300/(ft ² ·year)	1% increase in productivity \$2–\$5/(ft ² ·year)
	\$500 for medical safety personnel	\$500,000 for 100,000 ft ² 1% reduction in absenteeism \$1–2/(ft ² ·year) \$100–\$200 million/year for NYC

Source: New York DDC. April 1999. *High Performance Building Guidelines*. New York: Department of Design and Construction.

vide significant energy savings in the first year of operation, and reduce overall system maintenance costs during the first year in an amount comparable to or often exceeding the cost of the commissioning program.

Figure 61.3 demonstrates the payback period for various activities undertaken in typical commissioning projects.

Levin (1997) lists the benefits reported by a Portland Energy Conservation, Inc., survey, including 146 case studies. The results are reproduced in Tables 61.2 to 61.4. The data reported in these tables clearly indicate that commissioning programs provide important economic and operational benefits to the construction process.

While readily available data may not exist to demonstrate improvements in worker productivity, or illness rates due to commissioning activities, many groups have extensively evaluated the impact of commissioning and on implementing energy-conservation or energy-efficient measures. Piette and Nordman (1996) studied the commissioning of energy-conservation programs in 16 buildings in the Pacific Northwest and found that the investment in commissioning was cost-effective in terms of energy savings alone. Figure 61.4 shows the range of the present value of the total savings from commissioning compared to the cost of commissioning for each building. The range is based on the high and low lifetime value. These data clearly indicate that the benefits exceeded the costs, sometimes significantly, in the majority of cases.

61.4 RECOMMISSIONING OF EXISTING BUILDINGS

Many terms are used to describe the process of getting occupied buildings back into optimal operation. All essentially use the process of auditing the functional performance of a

facility and comparing it to some standard of acceptability. *Recommissioning* is viewed as a means to assure owners that their building still meets design intent and the acceptable performance standards that were detailed in the original occupancy commissioning document. Recommissioning can also serve as part of a QA process to ensure that the results of major renovations are still in conformance with the design intent of the original construction.

Recommissioning can also refer to the process of comparing the performance of previously uncommissioned buildings to an appropriate, newly established standard of acceptability (often called *retrocommissioning*). Alternatively, it can mean that a building's

FIGURE 61.4 The savings from commissioning compared to the total cost of commissioning. (Copyright American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. From M. Piette and B. Nordman. 1996. *Costs and benefits from utility-funded commissioning of energy efficient measures in 16 buildings*. ASHRAE Trans. Vol. 102, Part 1. Reprinted with permission.)

intended use has significantly changed, and that current building performance must be measured against other criteria of acceptability.

61.5 RECOMMISSIONING: A CASE IN POINT

The impact of a thoughtful recommissioning program can be extremely beneficial to both occupant acceptance and operating cost. An example is a 200,000-ft², four-story medical research building in the Northeast. Originally designed and constructed as an administrative building, it has undergone many renovations and use changes since the mid-1970s. Current occupants complained of odor migration, improper temperature control, and ruined experiments, while the owner complained of excessive energy costs and continuous demands on maintenance staff.

The renovations called for 15 ACH (air changes per hour) to be delivered to the laboratories; 50 percent of this was to be outdoor air tempered by chilled water from a central facility. Each laboratory had a separate fan coil unit to help control the heat load from the laboratory equipment, primarily as design days were approached.

What Was Found

Problems were first reported during the construction of an adjoining building. Fearing a reduction in chilled-water supply at the new construction site, the designers installed booster pumps, which, through an installation flaw (due to lack of space in the mechanical

room), effectively sent the chilled water back to the chiller plant, unused. This resulted in an energy penalty of approximately \$100,000/year. Since the outside air was not being thermally conditioned, the fan coil units were required to operate constantly during the summer months, resulting in higher electrical costs and additional service calls. This also resulted in air with a high moisture content that induced mold to grow in many areas. To try to maintain temperature during the summer, the operating staff reduced the amount of outside air, causing the building to become extremely negative and disrupting pressure relationships as originally established. Furthermore, the energy management system was disabled and the mechanical system was operated manually.

It was found that design intent was not being met because of the cumulative impact of several operational problems due to a design or installation defect. Renovations were undertaken to correct these problems, generating savings of nearly \$160,000 a year in energy usage and \$70,000 in service costs.

Recommissioning a building is a very straightforward process. To analyze the functional performance of a building, it is essential that the commissioning engineer meet with the building owner and the operating engineer to clearly define the operational goals of the building. This also presents an opportunity to understand how well the building is achieving these goals. This is generally accomplished through developing an understanding of a building's historic and current problems and maintenance issues, reviewing existing documentation relative to alterations and renovations, and examining operating cost and energy use.

On the basis of the information described above, a functional performance and diagnostic testing program can be implemented. This can involve documenting current system capabilities and comparing them with the operational goals defined earlier. The data collected in this part of the study should also be used for comparing current operation against relevant benchmarks. The final report should contain recommendations to help existing systems meet the owner and occupants' performance goals. This information also serves as a benchmark of ongoing performance, to modify operations and maintenance schedules, and/or serve as a basis for future infrastructure master planning.

Because buildings are designed, operated, and managed as long-term investments, recommissioning is essential to ensure that systems are working as intended, that the original design can meet the demands of the current occupants, and that the owner's goals are being realized.

61.6 CONCLUSION

Commissioning is a systematic and detailed process that requires the mutual commitment of the owner, contractors, and commissioning authority to ensure its success. The goal of commissioning is to turn over to the owner a building that meets the design intent with the appropriate safeguards (such as operator training and required documentation) to ensure that it will continue to function properly. As owners, contractors, architects, and engineers have begun to see the benefits of commissioning, they are incorporating it into their building projects. Although there are many definitions of commissioning, it is important to bear in mind that this is the ultimate quality assurance program in the life of a building. As such, it must clearly and unequivocally set the standards of acceptability. The commissioning authority has a responsibility to the owner and to the community of professionals involved in the building process to ensure that the highest standards are met and that a building performs according to its design intent and its occupant needs.

CHAPTER 62

PREVENTION DURING REMODELING RESTORATION

Kevin M. Coghlan, M.S., C.I.H.
Environmental Health & Engineering, Inc.
Newton, Massachusetts

62.1 INTRODUCTION

Conducting renovation and remodeling work in today's work environment poses special challenges with respect to occupant health, safety, and comfort. Our reliance on ventilation systems to maintain and control our environment has become more critical as a result of the increased time spent in these environments. The type and variety of building materials used and the general complexity of building operations all contribute to this challenge. This chapter explores the nature of IAQ during renovation and remodeling work in occupied environments. The elements of an effective mitigation program are highlighted and discussed. Unique environments, such as hospitals, are given special treatment, and operating issues, such as cost considerations, are explored.

This chapter should help building operators or managers, engineers, designers, and health and safety professionals address the following critical questions:

1. What factors influence IAQ during remodeling and renovation activities?
2. How does one effectively manage the impact on IAQ during renovation and remodeling in occupied environments?
3. What are the essential elements of any mitigation plan?
4. How does one monitor the ongoing renovation and mitigation activities to document that occupant health, safety, and comfort are being maintained throughout the process?

Nature of the Problem

There was a general downward trend in new construction for the period between 1985 and 1995 (U.S. Bureau of the Census). The construction of new commercial office space has declined further, and prime real estate in economic centers is a diminishing resource. These

are some of the economic factors influencing the move toward increased renovation and alteration activity in occupied environments.

Technology has also played a role. The need for better and faster computing systems requires significant upgrades to existing facilities. In the late 1980s, asbestos abatement activities often forced upgrades of building systems and components. In addition, the rising expectations of occupants of what constitutes a safe and comfortable work environment have also forced building owners, operators, and managers to upgrade building systems. In a survey conducted by the International Facility Managers Association (IFMA), IAQ and thermal comfort were the top operational issues in all buildings (Tatum 1998). According to a telephone survey of building tenants commissioned by the Building Owners and Managers Association (BOMA), Washington, DC, "control and quality over air" was the fourth most important criteria for attracting and retaining tenants. The study also shows that quality HVAC is even more important for retaining tenants (BOMA 1999). One paper that reviewed the impact of the physical environment on worker productivity found that it could be enhanced between 3 and 15 percent (Lomonaco and Miller 1997). Together, economic, technological, and building occupant issues are behind the increase of alteration and renovation activity in occupied settings.

The amount of time individuals spend indoors is an important consideration for understanding the importance of IAQ during renovation work. Estimates state that people spend about 90 percent of their time indoors, with about one-third of that time at work (Tucker 1998). This provides more opportunity for occupants to be exposed to materials used or generated as a result of renovation activities.

Building materials have become more complex. Veneers, sealants, treatments, and composites are just some of the advancements in building materials. A wide selection of furnishings and flooring systems is also available. These products introduce new and, in some cases, more intense emissions into the indoor environment.

We have become much more dependent on the performance of mechanical systems, and HVAC systems in particular. More demands are placed on these systems to control sensitive environments (operating suites, cleanrooms, etc.). Computer-controlled HVAC systems are commonplace. The added flexibility and performance provided by these control systems also bring an increased level of complexity to building operations.

Economic factors are encouraging more renovation and alteration work to take place, frequently in occupied facilities. Technological issues, occupant expectations, and productivity concerns are all factors that influence the pace and extent of renovation activity. A wider selection of materials and furnishings is available, which increases the variety and amount of emissions into the indoor environment. Ventilation is increasingly more important for controlling the indoor environment, and these sophisticated systems demand a greater level of knowledge to effectively operate a building, especially during remodeling activities.

The Classic Industrial Hygiene Paradigm: A Solution to the Challenge

Despite the challenges of renovating in an occupied facility, the potential problems can be managed effectively. Industrial hygienists have been involved in the anticipation, recognition, evaluation, and control of workplace hazards for a century. This profession has developed and used a standardized approach to mitigating hazards in the workplace (DiNardi 1997). The paradigm shown in Table 62.1 has been used successfully over the years to identify and prioritize opportunities to improve the health and welfare of workers.

The classic industrial hygiene (IH) paradigm can be applied to IAQ issues during renovation activities in occupied environments. Table 62.1 outlines the equivalent IAQ elements. The following information explores, in more detail, the equivalent IAQ elements. The next section provides guidance on how to utilize these program elements effectively and how to manage potential IAQ problems associated with renovation and remodeling activities proactively.

TABLE 62.1 Industrial Hygiene Paradigm and the Equivalent Elements for IAQ

Classic IH paradigm	IAQ equivalent elements
Product substitution	Material selection
Substitute with less hazardous materials	Select less hazardous product, lower emissions
Engineering controls	Engineering controls
Local exhaust ventilation, remove the hazard	Work area isolation
General ventilation, dilute the hazard	Depressurization
Protective equipment, hazard barrier	General exhaust ventilation, containment
Work practices	Work practices
Training to minimize exposure to contaminants	Training to minimize transfer of contaminants out of work area
Administrative controls	Administrative controls
Worker rotation, limit time exposed	Project scheduling, off-shift work

62.2 MATERIAL SELECTION

General Considerations

Any renovation or remodeling project has the potential to generate contaminants. Activities outside the building can impact the interior through the ventilation system, open windows, or leaks in the building envelope. Demolition activities indoors generate high levels of organic (i.e., fungal spores) and nonorganic (i.e., glass fibers from insulation) particulate due to the presence of dust reservoirs common in many buildings, or through the destruction of building materials. Dispersal of these contaminants may be uniquely associated with construction or remodeling activities. This potential source of emissions dissipates shortly after the completion of the project and can be controlled by using some of the strategies discussed in Sec. 62.3. However, the installation of new materials presents a unique source of contaminants to the indoor environment that can emit compounds into the indoor environment long after the remodeling has been completed.

The proper selection of building materials and furnishings is important in order to control emissions from this source. The goal of any material selection process should be to identify a product that meets the needs of the planned renovation program and introduces the lowest possible hazard into the indoor environment. Four principal parameters should be addressed as a part of any selection process:

- *Hazard rating.* What are the toxicological or physical hazards inherent in the material, considering its potential for occupant exposure?
- *Performance criteria.* Will the material do the job, and what are its physical, aesthetic, economic, and environmental qualities?
- *Compatibility and application.* Can the material be used safely with other materials, and is the application appropriate without introducing any new hazard?
- *Odors and irritation.* What type of odors and/or irritation can be expected and with what intensity and duration?

Hazard Rating. The most common resource for determining the hazards of a material is the Material Safety Data Sheet (MSDS). Manufacturers are required to provide MSDSs with shipment of their product if it contains one or more chemicals referenced in the OSHA *Hazard Communication Standard* (29 CFR 1910.1200) and is present in

NFPA DIAMOND

HMIS System

0-4	Health
0-4	Flammability
0-4	Reactivity

§Verbal descriptors from NPCA *Hazardous Materials Identification System*, 2d. ed., *An Employee's Guide to the HMIS*.® Labelmaster, Chicago, 1996. LC_{50} lethal concentration 50, the concentration of the target gas or vapor that causes death in 50 percent of the population test animal species.

TABLE 62.3 Screening Method to Assess Potential Hazards for Building Products

8-h exposure standard or guideline, ppm	Qualitative hazard rating
>1000	Very low toxicity
100–1000	Low to moderate level of toxicity
10–100	Moderate level of toxicity
1–10	High level of toxicity
<1	Extremely toxic

quantities greater than 1 percent by weight or volume. The threshold for chemicals that are listed as carcinogens is 0.1 percent by weight or volume.

The MSDS typically rates the hazard presented by the product on the basis of the properties of one or more of its hazardous constituents. It is unusual to have a product formulation tested for specific hazards. The product is usually rated with one of two rating systems, the *National Fire Protection Association* (NFPA) *Diamond* (www.nfpa.org) or the *Hazard Material Identification System* (HMIS) developed by the National Paint and Coatings Association (NPCA, www.paint.org). A summary of the two systems follows.

The two systems (see Fig. 62.1 and Table 62.2) are comparable, with some minor differences in hazard determinations. Both of these schemes offer a good initial look at the potential hazards inherent with a material or product. However, care must be taken when using these systems for IAQ purposes as the hazard rating schemes were developed for shipping and firefighting purposes and to guide emergency response to spills and environmental releases. The schemes tend to identify the acute hazards presented by the product and may not adequately identify the hazards associated with chronic exposure to the materials released by the product once installed. However, the HMIS system was modified in 1996. This revision incorporated information on chronic hazards presented by different materials, so the HMIS scheme may be more appropriate for an IAQ screening program.

Another approach to hazard rating is to use and compare published occupational and public health guidelines for the particular chemical constituents (see Table 62.3). An efficient screening mechanism compares the published guidelines and standards in this fashion.

The advantage of this rating system is that chronic exposures are considered as well as lower-level toxic effects, such as mucosal irritation that is reversible. However, care must be taken to consider the amount of any individual compound in a material as this can affect the overall toxicity rating of the product. The American Conference of Governmental Industrial Hygienists (ACGIH) has developed a formula for assigning a threshold limit value (TLV) for chemical mixtures (ACGIH 1999). The toxicity for each compound and the composition of the product are both included in this assessment.

$$\text{TLV}_{\text{mixture}} = \frac{1}{f_a/\text{TLV}_a + f_b/\text{TLV}_b + \dots + f_n/\text{TLV}_n} \quad (\text{mg}/\text{m}^3) \quad (62.1)$$

where f_a represents the weight fraction of chemical a in the mixture or solution and TLV_a is the threshold limit value (exposure guideline) for chemical a in the air. TLVs can be developed for different products and compared to each other so that the relative level of hazard posed by the different products can be assessed.

The following two products can be compared.

Product A		Product B	
Component and % by weight	TLV, mg/m ³	Component and % by weight	TLV, mg/m ³
Xylene (50%)	434	Toluene (50%)	188
111 trichloroethane (45%)	1910	Methyl ethyl ketone (45%)	590
Benzene (5%)	1.6	Methylene chloride (5%)	103
Calculated TLV for mixture [using Eq. (62.1)]	31	Calculated TLV for mixture [using Eq. (62.1)]	256

From this example, product A is clearly more toxic than product B. Its TLV is about 8 times lower than product B's TLV, and the composite TLV for product A is determined largely by the low-level presence of one highly toxic compound, benzene. In fact, benzene contributes about 95 percent to product A's composite TLV, yet it only comprises 5 percent of the mixture by weight. If benzene were removed from this product and replaced with more 1,1,1-trichloroethane, the resulting product TLV would be approximately 700 mg/m³; about 2.5 times less toxic than product B. In this case, product A would be the material of choice, everything else being equal.

A note of caution regarding this hazard rating scheme is worth mentioning. It is designed for chemical mixtures that target the same organ system and have similar physiological effects. The combined effects for the constituents in the chemical mixtures are assumed to be additive. This system should not be used for chemicals that target different organ systems or have different toxicological endpoints, or be used for materials that contain known or suspected sensitizing or potentially allergenic agents (e.g., isocyanates). In addition, the volatility of a product must be considered to complete the evaluation process. For instance, toxic metals (lead, mercury, etc.) are likely to be bound in the product matrix and do not constitute the same exposure potential as does volatile benzene. The more volatile a chemical constituent, the more likely it is to become airborne and expose workers and/or occupants.

Regardless of the hazard scheme used to rate different products, it is how, where, and when the product will be used that can significantly influence the potential hazards associated with the use of that product. For example, a product used in a confined space may present serious health and fire hazards, whereas that same product may be acceptable if it were used in an open environment with adequate ventilation. The evaluation form shown in Fig. 62.2 is an example of an instrument that can be used to incorporate many of the elements discussed earlier so that the appropriateness of a selected product can be evaluated.

Performance Criteria. Typical resources for product performance information include product bulletins or technical data sheets (cut sheets) developed by manufacturers (see example in Fig. 62.3). Information regarding the performance of a product is typically

Benjamin Moore & Co.
PROFESSIONAL COATINGS

PRISTINE®
Eco SPEC™
Interior Latex Flat 219

Features

- ▲ Low Odor.
- ▲ Low VOCs.
- ▲ Quick return to service.
- ▲ 100% Acrylic.
- ▲ Dries quickly to a beautiful, washable, and uniform flat finish.
- ▲ Spatter-resistant.

General Description

A low odor, low VOC, 100% acrylic latex flat that provides high hiding, excellent touch up, and a uniform flat finish. Pristine Eco Spec is ideally suited for commercial, facility management, and residential applications.

Pristine Eco Spec does not have the odor of conventional paints that contain ingredients known as Volatile Organic Compounds (VOCs).

Recommended For:

New or previously painted interior wallboard, plaster, ceilings and masonry, as well as primed or previously painted wood and metal.

Use Pristine Eco Spec Interior Latex Primer (231) as a first coat when a low odor, solvent free Primer / Finish system is desired.

Limitations:

- Do not apply when air and surface temperatures are below 50°F (10°C).

Product Information																																									
Colors: —Standard: 219 01 Pure White (May be tinted with up to 2.0 fl. oz. of Benjamin Moore & Co. colorants per gallon.) —Tint Bases: Benjamin Moore & Co. bases 1B & 2B (Over 900 custom colors can be made using the Benjamin Moore & Co. color system.) —Special Colors: Contact your Benjamin Moore & Co. representative Certification: Formulated without lead or mercury. Formulated without Volatile Organic Compounds (VOCs) or solvents. Technical Assistance Available through your local authorized independent Benjamin Moore & Co. dealer. For the location of the dealer nearest you, call 1-800-826-2623, see www.benjaminmoore.com, or consult your local Yellow Pages.	<table> <tr> <th>Technical Data</th><th>White</th></tr> <tr> <td>Vehicle Type</td><td>100% Acrylic Latex</td></tr> <tr> <td>Pigment Type^o</td><td>Titanium Dioxide</td></tr> <tr> <td>Volume Solids^o</td><td>32%</td></tr> <tr> <td>Theoretical Coverage At Recommended Film Thickness</td><td>400–450 Sq. FIGURE 62.3 Sample of Product Technical Bulletin.

PRISTINE® ECO SPEC™ Interior Latex Flat (219)

Surface Preparation

Surfaces to be primed must be clean, dry, and free of wax, grease, dust, mildew, water soluble materials, and scaling paint. Glossy areas should be dulled. Apply Pristine Eco Spec Interior Latex Primer (231) before and after filling nail holes, cracks, and other surface imperfections. Sand when dry. New plaster or masonry surfaces must be cured before priming.

Primer/Finish Systems

For best hiding results, tint the primer to the approximate shade of the finish coat, especially when a significant color change is desired.

A primer is not required on previously painted surfaces in good condition and similar color.

Benjamin Moore® offers a number of specialty primers for use over difficult substrates such as bleeding woods, grease, crayon markings, hard glossy surfaces, galvanized metal, or other substrates where paint adhesion or stain suppression is a particular problem. Your Benjamin Moore dealer can recommend the right problem-solving primer for your special needs.

Wood, New:

Primer: Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Wood, Repaint:

Primer: Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Plaster/Drywall, New: All plaster surfaces must be thoroughly cured. Drywall surfaces must be free of sanding dust.

Primer: Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Plaster/Drywall, Repaint: Remove any peeling or scaling paint and sand these areas to feather edges smooth with adjacent surfaces. Greasy walls and ceilings must be washed with a strong detergent solution.

Primer: Spot prime as needed with Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Masonry, New:

Rough Masonry:

Primer: Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Smooth Poured or Precast Concrete:

Primer: Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Masonry, Repaint: Remove all peeling and scaling paint by scraping or use of power equipment. All surfaces must be free from greasy or oily deposits. Glossy surfaces must be dulled.

Primer: Spot prime as needed with Pristine Eco Spec Interior Latex Primer (231)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Ferrous Metal, New: All ferrous metal surfaces must be wiped with mineral spirits to remove oily, greasy residue. Solvent and rags should be changed frequently. When shop coat is abraded and rust has developed, remove by sanding or wirebrushing to a sound surface.

Primer: IronClad® Latex Low Lustre Metal and Wood Enamel (363) or IronClad Alkyd Low Lustre Metal and Wood Enamel (C163)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Ferrous Metal, Repaint: All surfaces must be free of grease and oil, and cleaned in accordance with SSPC-SP1 "Solvent Cleaning," followed by removal of all loose, scaling paint by hand scraping, or by use of power tools. Rusted surfaces to be cleaned in accordance with SSPC-SP2 "Hand Tool Cleaning" or SSPC-SP3 "Power Tool Cleaning." Glossy surfaces should be dulled. Where heavy rust, corrosion and deteriorated coatings exist, the surface should be abrasive blast cleaned in accordance with SSPC-SP6 "Commercial Blast Cleaning." The surface should be blown off with compressed air to remove traces of blast products, and must be primed within 24 hours.

Primer: IronClad Latex Low Lustre Metal and Wood Enamel (363) or IronClad Alkyd Low Lustre Metal and Wood Enamel (C163)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Galvanized Metal, New: All new galvanized metal surfaces must be thoroughly cleaned with mineral spirits.

Primer: IronClad Latex Low Lustre Metal and Wood Enamel (363)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Galvanized Metal, Repaint: All surfaces must be free of grease, oils and industrial contaminants, cleaned in accordance with SSPC-SP1 "Solvent Cleaning." Peeling or scaling paint must be removed by scraping, sanding, or wirebrushing. Rusty surfaces must be wirebrushed and sanded free of rust and spot primed.

Primer: IronClad Latex Low Lustre Metal and Wood Enamel (363) or IronClad Alkyd Low Lustre Metal and Wood Enamel (C163)
Finish: 1 or 2 coats Pristine Eco Spec Interior Latex Flat

Application

Stir thoroughly before use. Apply by brush, roller, or spray. Apply generously, using short overlapping strokes, brushing or rolling from unpainted areas into painted areas. Avoid excessive brushing and rolling. Let paint dry before touching up any missed spots. Do not apply when air or surface temperatures are below 50°F (10°C).

Spray, Airless: Fluid Pressure—1,500 to 3,000 PSI;
Tip—.018 Orifice; Filter—50 mesh.

Spray, Conventional: See Thinning/Cleanup

Thinning/Cleanup

Thinning is unnecessary, but if required to obtain desired application properties, a small amount of clean water may be added. Never add other paints or solvents.

Wash brushes, rollers, and other painting tools in warm soapy water immediately after use. Spray equipment should be given a final rinse with mineral spirits to prevent rusting.

USE COMPLETELY OR DISPOSE OF PROPERLY. Dry, empty containers may be recycled in a can recycling program. Local disposal requirements vary; consult your sanitation department or state-designated environmental agency for more information on disposal options.

Environmental & Safety Information

Use only with adequate ventilation. Do not breathe spray mist or sanding dust. Avoid contact with eyes and prolonged or repeated contact with skin. Wear eye protection and gloves during application or sanding. A dust/particulate respirator approved by NIOSH should be worn when sanding or spraying. Close container after each use.

FIRST AID: If you experience difficulty in breathing, leave the area to obtain fresh air.

IN CASE OF SPILL: Absorb with inert material and dispose of as specified under Thinning/Cleanup

FIGURE 62.3 (Continued)

included in these documents. Other performance criteria that relate to IAQ are drying times, cure rates, and application guidelines. These can be used to assess the impact of the planned use of this product on IAQ. Table 62.4 outlines specific selection criteria for a product.

A material's environmental and physical properties are most significant for IAQ-related issues. Specifically, emission rates of the material's constituents are very important with respect to the intensity and duration of emissions. Emission rates vary and they are proportional to "the vapor pressure of the substances, the amount of vaporizable material, surface area, diffusivity through materials and local environmental conditions" (Kuehn 1996). The emission rate, as determined by these factors, must be considered with the hazard rating to understand the impact on the indoor environment.

The "sink" properties of the material are determined by its adsorptive characteristics. Certain materials will readily adsorb chemicals and odors because of their construction and large effective surface area (i.e., carpeting). Chemicals and odors can then be reemitted back into the environment and act as a low-level reinforcing source of contaminants into the renovated space long after construction has been completed.

Floor and ceiling treatments and finishes are good examples of material that cover large areas (typically 100 percent of floor area) inside buildings and can be both primary and secondary sources of contaminants (emission, sink, and reemission). Work surfaces represent only 15 to 35 percent of the total floorspace, whereas office partitions have a large "virtual" surface area that covers as much as 200 to 300 percent of the total floorspace (Maroni et al.). These furnishings are usually covered with a fleecy fabric that can readily adsorb and reemit contaminants. These office furnishings should not be installed until the very end of a renovation program when emission rates from the new materials and furnishings have greatly declined.

Compatibility. Issues of product compatibility can be found in the MSDS as well as the manufacturer's product cut sheets. Compatibility can impact both product performance and IAQ. Reactions with incompatible products should be avoided, as potential toxic emissions can occur. Products must be reviewed to ensure that they are compatible with other materials that will be used on a project, or potential harmful emissions may result.

It is important to adhere to application instructions. In order to control product emissions, one must understand the interaction of physical parameters (e.g., substrate characteristics) with environmental factors (temperature, relative humidity, ventilation, etc.).

TABLE 62.4 Selection Criteria for Indoor Materials and Desirable Characteristics

Attributes	Example	Desirable characteristics
Physical	Strength, durability, heat transmission, light transmission, maintainability, effectiveness	Nonsorbent ("sink" properties), not reemitting
Aesthetic	Color, texture, odor, noise	As needed for application
Economic	Initial cost, maintenance cost, operating cost (e.g., energy)	Reasonable
Environmental	Emission to air, other releases, support of microbial growths, life-cycle impacts	Low emission rates, low toxicity of emissions, nonnutrient base to prevent microbiological growth

Source: Adapted from M. Maroni, B. Seifert, and T. Lindvall (Eds.), 1995, *Air Quality Monographs*, Vol. 3, *Indoor Air Quality: A Comprehensive Reference Book*, Elsevier Science, Chap. 31. Tables 31.8 and 31.9.

Uneven, rough substrates will greatly increase drying times for wet materials (Clausen 1993). High relative humidity levels increase emission rates in some materials, such as wood products and ceiling tiles, while low relative humidity levels increase emissions from other building products, such as concrete and gypsum board (Kuehn 1996).

Odors. The problem of odors and irritants and indoor air covered in other parts of this handbook should be reviewed. Please review these chapters for more detail on odors. Odors are an important consideration, even though toxic levels of a compound may never be reached. Depending on the nature of the odor, a space may become uninhabitable until the odors have dissipated. In some cases, this can be on the order of weeks and months, greatly impacting both the tenant and the building owner. Irritation, while seldom accompanied by serious lasting health effects, interferes with occupant comfort and may affect productivity or require relocation of the affected occupants.

Research has identified odor and irritation thresholds for a number of chemical substances. In one published study as well as in Chap. 20, several conclusions are made regarding odor and irritation (Cometto-Muniz and Cain 1994):

- Odor thresholds are usually several orders of magnitude below irritation (pungency) thresholds.
- Odor thresholds are inherently more variable and vary greatly by compound.
- Generally, the longer the carbon chain (and less volatile), the lower the pungency and odor thresholds.

The importance of these observations is that if the odors are controlled, irritation from these same chemicals is not likely to occur. Odor control is challenging, given the inherent variability of odor thresholds among chemical compounds and people. Individuals tend to associate an odor with a hazardous exposure, generating fear and concern among the occupants. There is also no clear link established between emission levels or rates and odor perception. Materials with high emission rates may not be perceived as objectionable, while other materials with more moderate emission rates may be perceived as very objectionable. In one study, it was determined that the floorcoverings used for that study produced the highest sensory response (decipols) and were only moderate VOC emitters (Oie et al. 1993).

Source Control

The importance of source control cannot be overstated. It is the preferred method for reducing and controlling emissions in the indoor environment. The importance of source control can be seen in the steady-state equation

$$C = \frac{G}{Q} \quad (62.2)$$

where C = contaminant concentration, mg/m³

G = generation rate, mg/min

Q = volumetric flow rate of “clean” replacement air, m³/min

From this equation, it is clear that the space concentrations increase directly with increases in the generation rate. Therefore, if the generation rate can be lowered, the space concentrations will also be lowered for the compounds in that product.

There has been increased recognition that the emissions of building products and materials can contribute to complaints, leading some manufacturers to address the “source term.” The Carpet and Rug Institute (CRI) has developed voluntary standards for emissions

that manufacturers can adopt. The emissions are limited to a few select materials. Table 62.5 outlines the emission standards for carpets, adhesives, and cushions or pads.

The Carpet and Rug Institute combines this voluntary testing program with a labeling program to assist purchasers in selecting low-VOC-emitting products. This work is one example of a collaborative effort by industry, the government and academia to improve IAQ.

Product Emission Testing. Product emissions can be characterized under carefully controlled laboratory conditions. These tests are known as *environmental chamber testing studies*, where a product's emissions are evaluated in an inert, nonreactive vessel under controlled environmental conditions. The emissions from a product are determined over a specified period of time and compared to established standards, or these data are used in IAQ models to predict space concentrations. ASTM has developed a protocol for small environmental chamber testing (ASTM 1999). It is beyond the scope of this chapter to review the science and technology behind this protocol. Other chapters in this book discuss the use of emission data and IAQ models to predict space concentrations.

Environmentally Friendly Products. More attention is being paid to the selection of products used in buildings. The American Institute of Architects (AIA) has developed a comprehensive reference that can assist designers and installers of various building products in selecting those materials that have minimal environmental impact while meeting the performance needs (AIA 1994). Although much of the focus is on sustainable development and minimizing the impact to the environment, there is a section devoted exclusively to IAQ for each product category. For example, in Sec. 0900 of the *Building Materials Guide*, a discussion of the IAQ effects of carpet, cushions, and adhesives is offered. In this discussion, the "carpet policy dialog" was presented and a summary of an independent laboratory study of carpet emissions was provided. Briefly, this study showed little variation in emissions based on carpet fabric and treatment; carpet emissions were considered low compared to other building materials. Carpet adhesives are potentially significant contributors to TVOCs in the indoor environment (49 mg/m³ concentration over a 24-h period, according to the study).

Product manufacturers have recognized the important connection between product formulation and indoor environmental quality. For example, Benjamin Moore has introduced a new line of paints that are of low toxicity and low odor, called *EcoSpec*.

TABLE 62.5 Emission Criteria for Carpets, Adhesives, and Cushions Published by the Carpet and Rug Institute, Dalton, GA

Parameter	Emission criteria, mg/(m ² ·h)*		
	Carpets	Adhesives	Cushions
Total volatile organic compounds (TVOCs)	0.5	10.0	1.00
4-Phenylcyclohexene (4-PC)	0.05	NA†	0.05
Formaldehyde	0.05	0.05	0.05
Styrene	0.4	NA	NA
2-Ethyl-1-hexanol	NA	3.0	NA
Butylated hydroxytoluene (BHT)	NA	NA	0.30

*Emissions of a particular parameter by weight in milligrams per square meter of test specimen every hour, mg/(m²·h).

†Not applicable.

Source: The data in this table are available from Website <http://www.carpet-rug.com>.

However, all claims about low environmental impact should be investigated. One manufacturer of a floor mastic product had an environmentally friendly claim on the label. This was because the product did not contain any chlorofluorocarbons—known to deplete the stratospheric ozone layer. The product contained some very volatile solvents and under certain conditions, could pose a health hazard for indoor applications. Claims on product labels should not be used exclusively to qualify a product for use. The product contents, application, associated hazard rating, and emission information should be understood prior to selection and use.

62.3 ENGINEERING CONTROLS

The previous section described ways to control emissions at the source by utilizing various product evaluation and selection techniques. This section presents procedures that help reduce and/or prevent exposures to building occupants by utilizing several proven engineering methods.

Work Area Isolation

One of the most important engineering controls is isolation of the work area from adjacent occupied spaces (see Fig. 62.4). This clearly delineates the work zone and prevents unauthorized personnel from entering the work area. It also provides additional safety and security for the worksite.

FIGURE 62.4 A temporary isolation barrier constructed of plastic sheeting and wood framing to isolate work area from occupied spaces.

Isolation methods can vary; however, they should be selected based according to the requirements of the project. Short-term projects with low traffic may be able to use 6-mil plastic sheeting sealed with duct tape as an isolation barrier. Longer-term projects with higher traffic levels may require solid partitions and/or thicker plastic sheeting in order to maintain the integrity of the isolation. Local building and fire codes need to be considered when selecting certain materials to be used as barriers. For example, in some localities, only fire-retardant plastic sheeting may be used. Changes to emergency egress need to be evaluated, and interim life safety measures may be necessary if changes to exit passages are made.

The important considerations for any isolation barrier is that it must effectively define the work area, limit and control the movement of people and equipment from the work area, and support the other engineering controls that will be used (e.g., negative pressurization, ventilation).

General Ventilation

General ventilation, also known as *dilution ventilation*, can be an effective tool in controlling exposures to a very diffuse array of sources (i.e., product emissions). Both worker and occupant health and safety can be protected with this method of contaminant control. The basic concept is to dilute the concentration of pollutants by introducing “clean” air into the space and exchange the air within the space to reduce contaminant levels below health standards and guidelines.

Earlier in this chapter, the dilution ventilation equation was presented in discussing material selection and source control [see Eq. (6.1)]. According to this equation, the more ventilation added to the space, the lower the resulting steady-state concentration.

The greatest benefit of general ventilation is provided by the first few air changes. This is demonstrated in Fig. 62.5.

Increasing the ACH from 1 to 2 results in a 50 percent reduction of the contaminant level (assuming perfect mixing)—from 84 to 42 mg/m³. Doubling the ACH to 4 further reduces the contaminant to approximately 25 percent of its original value, an additional reduction of only 21 mg/m³. As the room ventilation is increased, the magnitude of contaminant reduction decreases. Above 10 ACH, there is no measurable reduction in contaminant levels. In asbestos abatement projects, 4 ACH is typically specified as an air exchange rate.

Air exchange rates between 4 and 6 ACH offer the maximum benefit in terms of reducing contaminant levels while minimizing the associated costs of providing this type of ventilation. Capital costs are reduced by limiting the number of fans needed to provide the ventilation air, and operating costs are minimized by controlling the amount of energy consumption for heating and/or cooling the “clean” replacement air. Another approach to achieving the necessary air changes is to use air treatment/cleaning equipment. (See apparatus in Fig. 62.6.) As long as the device has a relatively high efficiency for contaminant removal, this approach can be as effective as increasing the amount of clean supply air to the work zone. In some cases, a combination of approaches is necessary to obtain the desired results. The drawback to air-cleaning equipment is that it needs to be maintained to prevent the cleaning efficiency from degrading. Whether air-cleaning equipment and/or dilution ventilation is used to control airborne contaminants, surfaces of VOC-containing products need to be exposed and ventilated to facilitate drying.

Pollution Pathway Mitigation

The purpose of pollution pathway mitigation is to prevent and/or reduce the potential exposure of occupants to air contaminants. This is achieved by controlling air movement into

FIGURE 62.5 Effect of varying room ventilation rate on contaminant levels under steady-state conditions.

and out of the work areas. Air transfer is the principal exposure vector for airborne contaminants.

Air transfer is controlled by the establishment and maintenance of appropriate pressure relationships between the work zone and the surrounding occupied areas. Air will flow from areas of higher pressure to areas of lower pressure. The amount of airflow into a work area is determined by the pressure gradient created by exhaust fans in the workspace. By exhausting air out of a work zone, air will flow from surrounding spaces into the work area and prevent contaminants from migrating into adjacent spaces.

This technique is referred to as *depressurizing a space* or *placing a space under negative pressure* (see Fig. 62.7). It is important to note that *pressurization* as it is referred to in this section is relative. Simply exhausting air out of a work zone does not ensure that the work zone will be negative with respect to all surrounding spaces. If an adjacent space is more negative than the work zone, a portion of the work zone air will flow into the adjacent space. Again, the amount of airflow into the adjacent space varies directly with the pressure gradient and the amount of free or open area between the two spaces. Some engineers recommend maintaining a pressure differential of 5 to 10 pascals (Pa) between the construction zone and the adjacent spaces (Turner 1998).

Pressure imbalances between the work zone and surrounding spaces can result from a number of factors, including natural stack effect, wind pressures, and competing mechanical systems such as lab exhausts. Pressurizing adjacent spaces in addition to depressurizing the work zone is an effective approach to minimizing the influence of these factors on pressure differentials (Turner 1998).

Absolute containment (see Fig. 62.8) of all contaminants is seldom necessary, and some amount of airflow out of a work zone may be acceptable. For example, if the control of

FIGURE 62.6 An in-room air-cleaning device that can be used to filter particulate and/or vapors within a room.

objectionable odors were the principal issue, then airflow out of the work zone must be less than that which would produce an odor in the adjacent spaces. This can be confirmed with air monitoring or empirically by detecting odors outside the work zone.

To control odors in the adjacent occupied space, a sufficient amount of dilution air would be required to reduce the contaminant levels below their respective odor thresholds. According to Eq. (62.2), the steady-state concentration of a contaminant can be reduced by lowering the contaminant's evaporation (generation) rate or increasing the supply rate of dilution air to the space. Flushing a neighboring space with dilution air can reduce the odor levels in that occupied space.

The level of containment should be determined by the relative toxicity of the contaminants, odor thresholds and perceptions, occupant demographics, and exposure duration, frequency, and intensity. In fact, there is most likely at least one phase in every remodeling effort where absolute containment is not required to achieve the objectives of an IAQ program. However, there are some notable exceptions, including work in hospitals, where infection control is the primary endpoint. Also, work that occurs near areas occupied by sensitive individuals (e.g., pregnant occupants), or work with products that contain allergens or sensitizers may require absolute containment throughout the process to prevent any adverse exposures.

Pressurization is a global approach to pollution pathway mitigation. It can be effective but also costly, given the capital costs associated with the equipment and the operational costs associated with running the equipment and conditioning the makeup air. If contaminants are captured at the source (i.e., welding fumes), less dilution air is needed to reduce contaminant levels. (See apparatus in Fig. 62.9.) The associated costs of providing general ventilation and depressurization of the work zone are reduced.

FIGURE 62.7 HEPA-filtered fan unit in construction zone used to depressurize the work-space. Exhaust is vented to building's exhaust system.

Exposure Modeling

Exposure modeling techniques can be used to determine acceptable levels of contaminants in the air according to certain application and ventilation parameters. Modeling can be used to predict levels of airborne contaminants during renovation activities. However, it is most useful in determining at what point a space is ready for occupancy.

The technical basis for modeling is treated in depth in several other chapters in this book (Chaps. 57, 58, and 59). For a more detailed analysis of this topic, please refer to the appropriate chapters.

FIGURE 62.8 Sample containment setup to control dust and odor emissions generated during construction and renovation programs.

62.4 WORK PRACTICES

The successful implementation of the engineering controls is determined by the work practices. An aware, trained workforce is necessary to effectively implement most of the items discussed in this chapter. Poor work practices can compromise the effectiveness of the engineering controls, especially those that rely on the workforce to implement and maintain them. When renovations are contracted, facility managers should expect compliance with control practices and material application specifications. Authorization of construction site shutdown for noncompliance should be stated in the contract.

FIGURE 62.9 Welding fume extraction device used to capture and filter wet or dry fumes at their source.

Housekeeping

Contaminants can migrate out of a work area on a worker's clothing, shoes, materials, and equipment. Dust, glues, mastics, and other compounds that workers come into contact with can all be inadvertently transported out of the work zone. These residues can be resuspended or offgassed outside the work zone, without the benefit of the enhanced ventilation controls.

One simple and effective way to mitigate this problem is to enforce an effective housekeeping policy. When dirt and debris is allowed to build up, the likelihood of transporting material outside the work zone increases. The following are some recommendations for reducing the transport of residues out of the work zone.

- Containerizing demolition debris
- The use of wet methods to remove dusty materials
- Frequent floor mopping in commonly traversed areas
- The use of walkoff mats (see Fig. 62.10) to remove dust and residues from workers' shoes

One of the least understood cleaning techniques is *dry sweeping*. It is an effective way to collect bulk dust and debris; however, dry sweeping does not necessarily control fine dust and residues. The action of sweeping actually resuspends the finer dust, which later settles out on surfaces that may have already been cleaned. The use of sweeping compounds can reduce this effect. However, since the fine dust cannot be removed from the floor by sweeping and is potentially a greater source of IAQ problems than coarse dust, it needs to be controlled. A housekeeping program needs to include some form of wet cleaning techniques, especially in common paths of travel in the work zone.

Material and Waste Transport

The movement of equipment, materials, and waste into and out of the work zone can be a significant source of contamination and should not be overlooked in any IAQ program. There are a number of ways to containerize waste to minimize the impact on IAQ during transport.

FIGURE 62.10 Temporary isolation barrier constructed of wood and plasterboard. Note use of walk-off mat. These dust control devices require maintenance, or they can be a source of dust and microbiologicals outside the contained area.

Waste chutes are effective at eliminating the potential contamination of a building's interior with dust and debris generated during transport. Reducing the reliance on interior transport systems (e.g., elevators) can also enhance work efficiency. The siting of the waste receptacle is the main issue with regard to the use of chutes. Considerable dust can be generated when the material is dropped through the chute. To reduce dust generation during impact, the waste can be containerized in plastic bags prior to being dropped down the chute. Alternatively, the receptacle can be covered and placed under negative pressure if more stringent dust control is warranted.

The work area is most likely under negative pressure during this phase of the project, and the chute can act as a significant pathway for makeup air into the work zone. This could result in introducing dust-laden air back into the work zone. Ventilating the chute with mechanical exhaust, preferably at the waste receptacle to maximize dust capture, can control the reflux of dust-laden air into the work zone.

If waste chutes cannot be used, fully enclosed waste containers are good transport vehicles. Regardless of the waste transport system, waste load-outs should be scheduled for off-peak or unoccupied periods where possible to minimize potential exposures to the occupants.

Training and Education

Any IAQ construction program must include a training and education element if it is going to be successful. Responsibilities need to be clearly outlined and all parties must understand their role in maintaining and preserving IAQ during their work activities. Table 62.6 outlines a suggested training program.

TABLE 62.6 Recommended IAQ Training Program for Renovation and Remodeling Activities in Occupied Facilities

Trainee	Training level and content
Occupants	Awareness level, occupants must be provided with a point of contact; communication may be achieved with a 1–2-page summary and a meeting to discuss impact on occupant activities; project-specific Web sites may also be used to communicate progress and to demonstrate the effectiveness of dust and vapor controls in an interactive and real-time fashion.
Occupant representative	Same as above, point of contact for construction manager; should attend scheduled project meetings and/or obtain weekly updates; communicates status to other occupants
Construction manager and supervisors	Understand IAQ plan and defined responsibilities prior to construction start-up, including Engineering controls Submittal approval process Work practices Administrative controls/schedules Communication plan
Workers and subcontractors	Task-specific training provided by supervisors through “tailgate” meetings in field; provided with a copy of plan for review and reference

Prior to the start of the project, a coordinator should be designated and a telephone hot-line set up so that a clear communication chain is established. Occupant communications are most effective if they are short, direct, and timely. Using a predeveloped format can assist to this end. A simple communication is shown in Fig. 62.11.

62.5 SENSITIVE ENVIRONMENTS

Most of the discussion so far in this chapter has been targeted at general commercial office space. These same concepts can be more broadly applied to other environments; however, additional considerations must be given to the unique requirements of certain sensitive environments or any location where asthmatics or occupants with chronic conditions are in the adjacent workspaces. Sensitive environments present a unique set of challenges that must be met to successfully conduct renovations in these facilities while they are occupied.

Hospitals

Hospitals, by definition, typically house occupants whose health status is more fragile than that of the general population found in commercial office buildings. As a result, this subset of the population may be more sensitive to dust and debris generated during renovation activities. This “raises the bar” for any renovation or construction program conducted in this environment. For example, asthmatics may be extremely susceptible to dust exposures. Patients who are immunocompromised are particularly sensitive and susceptible to biological agents such as mold and bacteria. Chemotherapy, bone marrow transplant, and organ transplant patients are among the most susceptible to infection from exposure to mold and bacteria that may be resident in dust. In fact, nosocomial infections in bone marrow transplant patients have been reported to be in proportion to the mean ambient *Aspergillus* spore content of hospital air (Rhame 1991). Given a reported fatality rate for invasive aspergillosis of 75 percent, control of dust containing mold spores is of paramount importance in hospitals.

A study conducted by Overberger et al. during renovation activities in a hospital demonstrated the effectiveness of proper work area isolation techniques, engineering controls, and work practices in controlling airborne dust and mold spores (Overberger et al. 1995). In this 30-week study, concentrations of viable spores reached 335 colony-forming units (cfu)/m³ in the construction zone compared to a high of 20 to 25 cfu/m³ for viable spores measured in the adjacent patient areas for the same period.

A special risk may be present in some hospitals and health care facilities. The use of latex products, particularly gloves, is widespread because of universal precautions. This has resulted in a constant exposure for health care workers to latex proteins over many years, resulting in an elevated incidence of latex allergy for this population. Estimates for the latex sensitivities in health care workers range from 8 to 20 percent (Hamann 1993). This is an important statistic since latex dust reservoirs may be disturbed during renovation activities. One study has demonstrated that potentially high levels of latex allergen residues may exist in building dust, especially if high-allergen powdered gloves were used previously (Weeks 1997). The latex allergens resident in the settled dust can become airborne when these surfaces are disturbed, exposing a potentially sensitive population to the allergen. Special consideration must be given to this issue.

Environmental Update

Odors Caused by Sprinkler Work 4th Floor, B Building

September 2, 1995

Foul-smelling odors detected in the A/B Stairwell today were associated with sprinkler work conducted on the Fourth Floor of the B Building. The source of the odor was a recently opened sprinkler pipe located in the Fourth Floor stairwell. This pipe opening has been sealed to prevent further odors from migrating into the stairwell and any adjacent spaces. In addition, supplementary ventilation has been installed to eliminate the odors.

Sprinkler systems, like the one on the Fourth Floor, contain reservoirs of water that are released when a fire is detected in the building. When the system is not used, the water becomes stagnant. These odors are likely due to the presence of microbiological organisms that produce foul-smelling metabolic by-products.

The odors attributed to these metabolic by-products are typically noticeable at levels far below health-effect guidelines. It is unlikely that exposure to microbiological organisms occurred in the sprinkler because the water was not sprayed into the air.

The corrective measures should greatly reduce the odors caused by the sprinkler work. Thank you for bringing this matter to our attention. We appreciate your cooperation and patience.

FIGURE 62.11 Sample of environmental update.

Laboratories

Laboratories have unique ventilation requirements that challenge the standard engineering approach used for IAQ construction programs. Specifically, labs must be maintained under negative pressure and continuously operate the fume hoods to vent potentially toxic vapors to the outdoors. When working in these spaces, maintaining the work area under negative pressure may be difficult. In some research-and-development (R&D) laboratories, solid chemicals are used in formulations. The use of these powders increases the potential for dust exposures, especially if changes to the established airflow patterns occur.

62.6 SPECIAL SITUATIONS

Asbestos

Asbestos is a heavily regulated compound in today's environment. Detailed engineering controls, work practices, administrative controls including strict training requirements, and a comprehensive testing protocol have been specified by a number of agencies and organizations. Because of the regulatory-driven nature of dealing with this common building material, the control measures are among the most stringent required for renovation work in occupied facilities. Table 62.7 highlights some of the critical regulations

TABLE 62.7 Summary of Key Asbestos Regulations and Requirements

Agency	Reference	Comments
USEPA	40 CFR 763, Subpart E— <i>Asbestos Containing Materials in School</i> (AHERA)	Governs ACM in schools and, sets specific training requirements, work practices, engineering controls, and testing protocols
	40 CFR Part 61 (NESHAP)	Governs the release of asbestos to the environment, including labeling and packaging requirements; no visible emissions criteria
OSHA	29 CFR 1910.1001	Sets specific performance goals to reduce worker exposure to ACM; PEL is 0.1 f/cm ³
State agencies	29 CFR 1926.58	Same as above, except covers construction trades
	State-specific regulations	States responsible for certifying ACM workers in accordance with USEPA AHERA requirements; may have additional requirements for work practices and controls depending on state; also, may certify testing labs and consultants
Local authorities	Local specific regulations	May have notification requirements in addition to state and federal requirements
NVLAP	—	Volunteer program that certifies labs to analyze ACM bulk samples under AHERA regulations.

Abbreviations: USEPA—United States Environmental Protection Agency; OSHA—Occupational Safety and Health Administration; NVLAP—National Voluntary Laboratory Accreditation Program; AHERA—Asbestos Hazard Emergency Response Act; NESHAP—National Emissions Standards for Hazardous Air Pollutants; ACM—asbestos-containing material; PEL—permissible exposure limit—based on an 8-h exposure; f/cm³—fibers per cubic centimeter of air.

that detail requirements for dismantling or disturbing asbestos-containing building products.

Any asbestos work must be handled carefully to ensure that building occupants are protected and that all relevant health, safety, and environmental regulations are appropriately considered and addressed.

Lead

Lead is heavily regulated in certain settings. Conducting lead abatement work or disturbing lead-containing products or finishes in residential or commercial environments that house children will trigger certain lead regulations, including inspection and testing protocols, abatement measures, and clearance and reoccupancy criteria. Although there are a variety of uses for lead in building products, the most commonly encountered lead-containing product is paint. The Department of Housing and Urban Development (HUD) has developed a lead paint guidance document that details state-of-the-art protocols, from the identification and characterization of the hazard through the abatement of any hazard and clearance and reoccupancy standards.

Many states that have adopted lead regulations rely heavily on this document for guidance, and it represents the current state of knowledge regarding the handling of lead paint hazards. Table 62.8 outlines some of the key lead regulations and requirements.

Prior to conducting any lead-related work, the HUD guideline should be reviewed, as it provides the most comprehensive resource for this type of work (HUD 1995). In addition, state requirements listed in regulations or guidelines should be consulted to ensure that the work is in compliance with the relevant regulatory framework.

TABLE 62.8 Summary of Key Lead Regulations and Requirements

Agency	Reference	Comments
USEPA	40 CFR Part 50, (NAAQS)	Governs the release of lead into the environment, $1.5 \mu\text{g}/\text{m}^3$ averaged over a quarter
	Title X, <i>Residential Lead-Based Paint Hazard Reduction Act of 1992</i> (Public Law 102-550)	Specific training requirements for contractors, workers, supervisors, inspectors, and risk assessors
OSHA	20 CFR 1910.1025	Sets specific performance goals to reduce worker exposure to lead; PEL is $50 \mu\text{g}/\text{m}^3$
	29 CFR 1926.62	Same as above, except covers construction trades, addresses problems with lead-based paint
State agencies	State-specific regulations	States responsible for certifying workers in accordance with USEPA requirements; may have additional requirements for work practices and controls depending on state; also, may certify testing labs and consultants
HUD	Title X, <i>Residential Lead-Based Paint Hazard Reduction Act of 1992</i> (Public Law 102-550)	Requires HUD to publish guidelines and provide information on lead abatement, identification, and characterization

Abbreviations: USEPA—United States Environmental Protection Agency; $\mu\text{g}/\text{m}^3$ micrograms per cubic meter; OSHA—Occupational Safety and Health Administration; NAAQS—National Ambient Air Quality Standards; HUD—Department of Housing and Urban Development.

Microbiologicals

Fungi and bacteria are a normal part of our natural environment. However, under certain conditions (e.g., water incursion), these natural organisms can proliferate indoors and colonize building products. Disturbing contaminated materials is likely to release spores into the indoor environment, exposing those nearby. These exposures may be particularly problematic for sensitive or allergic individuals and should be avoided.

Rautiala and coworkers describe fungi, bacteria, and total dust levels before, during, and after renovation repair work in seven buildings with water damage and mold contamination. In the study, no attempt was made to alter the ventilation systems. Specifically, the study demonstrates an increase in mold and bacteria concentrations during demolition in the subject room and in an adjacent noncontaminated room. Total fungal levels (viable and nonviable) averaged 5.9×10^4 counts/m³ before demolition in the subject space and reached an average value of 1.3×10^6 counts/m³ during demolition, with an average 20-fold increase in fungal levels during demolition for all buildings (Rautiala et al. 1996). Viable fungal levels increased almost 100 times the predemolition levels in the subject room and about one order of magnitude over predemolition levels in the adjacent noncontaminated room. According to the authors, this increase in viable fungi reached statistical significance at the *p* .05 level. One additional finding worth noting is that although particulate concentrations increased 100- to 1000-fold over predemolition levels, the absolute levels varied between 0.1 and 2.9 mg/m³. This is significant because particle levels in this range do not necessarily represent visibly dusty conditions, and work area isolation controls may be relaxed on the basis of these visual observations. This action may be premature, especially if working in a hospital or health care setting where the control of airborne microbiologicals is of paramount importance to avoid infection.

This chapter demonstrates that microbiological levels in the air can rise dramatically during handling of mold-contaminated materials and can also cause a rise in adjacent spaces if specific control measures are not implemented. One particularly problematic contamination issue is building material colonized by *Stachybotrys chartarum* (*atra*). This fungus, among many others, is capable of producing potentially toxic metabolic by-products, which can become airborne if disturbed. Please refer to Chap. 45 of this book for more discussion of this issue.

In 1993, the New York City Department of Public Health developed provisional guidelines for cleanup of building materials contaminated with the fungus *Stachybotrys atra*. The control measures for large contaminated surfaces mirror asbestos abatement protocols. These measures included work area isolation, depressurization and HEPA filtration, worker protection (full-face respirators, coveralls, gloves, etc.), and surface cleaning with bleach solution. The remediation protocol consisted of three levels for surface contamination and a separate level for HVAC contamination.

In 2000, the New York City Department of Public Health, Bureau of Environmental and Occupational Disease Epidemiology, issued a revision to the 1993 protocols (NYC DPH 2000). The revised guidelines depart from the notion that *Stachybotrys* warrants special attention as a microbiological contaminant and, therefore, requires unique remediation protocols. The guidelines are expanded to include all fungi since many are capable, under certain growth conditions, of producing mycotoxins, and all fungi are potentially allergenic. These guidelines have been relaxed for smaller and/or contained surface contamination. Bleach solution is no longer specified for surface cleaning; rather, a soap and water solution is now recommended. Some other important revisions to the 1993 guidelines include the elimination of the occupant evacuation guideline of 1000 to 10,000 colony-forming units of *Stachybotrys* per cubic meter of air sampled, and retraction of the recommendation to use ozone and chlorine dioxide as a remedial compound in HVAC systems. Table 62.9 summarizes the new, revised guidelines for remediating fungal contamination in buildings.

TABLE 62.9 Summary of Remediation Guidelines for Materials Contaminated with Fungi

Level	I	II	III	IV	V
Description	Small isolated area; <10 ft ² (e.g., ceiling tiles)	Midsized isolated area; 10–30 ft ² (e.g., single dry wall panel)	Large isolated area; 30–100 ft ² (e.g., >1 drywall panel in occupied area) (utilize this level only if low dust generation is expected; otherwise use level IV methods)	Extensive contamination; >100 contiguous ft ²	Contaminated HVAC systems (>10 ft ²) (If <10 ft ² of contamination, shut down HVAC system, utilize level II methods, remove contaminated porous material, e.g., insulation, clean and/or disinfect as required)
Personnel	Trained building maintenance staff	Trained building maintenance staff	Personnel trained in handling hazardous material (e.g., asbestos)	Personnel trained in handling hazardous material (e.g., asbestos)	Personnel trained in handling hazardous material (e.g., asbestos)
Engineering controls	Vacate work area No other special controls necessary	Vacate work area No other special controls necessary	Isolate work area with plastic, including ducts and grills	Isolate work area with plastic sheeting and duct tape Use HEPA-filtered exhaust unit to depressurize work area Construct decon. unit with airlocks Vacate work area	Isolate work area with plastic sheeting and duct tape Use HEPA-filtered exhaust unit to depressurize work area Construct decon. unit with airlocks Vacate work area Shut down and isolate affected HVAC system

Unfortunately, there are no “closeout” guidelines for microbiologicals as there are for reoccupying spaces after an asbestos abatement.

62.7 MONITORING DEVICES

Although IAQ instrumentation is covered in Chap. 51, it is worth summarizing what instruments are of value in documenting the conditions during an IAQ renovation program. When selecting a device, it is important to understand the goal of the sampling. This will define the operational needs (real-time vs. time-integrated), the performance criteria (detection limits, precision), and the functional requirements (battery-powered vs. AC/DC power). At some level, real-time screening devices, such as particle counters and pressure monitors, are necessary to document the ongoing effectiveness of the controls and to quickly note deficiencies in the work practices or engineering controls. The principal disadvantage of this type of instrumentation is that it lacks specificity. For example, although particle concentrations may be recorded, it may be important to distinguish between inert, nonorganic particles and microbiological particles, such as fungal spores. For this reason, supplementary sampling may be required to document actual exposures to particular chemical or biological agents, whereas real-time devices are better used as performance indicators and provide immediate feedback on the effectiveness of the controls. Table 62.10 highlights some equipment and the various characteristics of each.

62.8 SUMMARY

Remodeling activities in occupied buildings are likely to increase with time, given the economic realities facing commercial office buildings and the rapid pace of technology that constantly require upgrades in infrastructure. Adhering to the basic tenants of industrial hygiene can help avoid safety and health problems associated with renovation work in occupied environments. Proper planning of these activities should occur well before the work begins. Selecting the least hazardous (toxic) and the least volatile materials for the job is the critical first step. There are several techniques available to make this determination; however, the context in which these materials will be used is as important a consideration as the hazard ranking of the material.

A number of off-the-shelf control technologies can be used to maintain a safe environment both inside and outside the work area. The extent of work area isolation, depressurization, dilution ventilation, air cleaning, and work practices will depend upon the project objectives, the “exposed” population, the size and scope of the work, and any physical constraints or limitations. The effectiveness of the controls can be monitored through the use of real-time instruments to measure performance and the collection of time-integrated samples to document contaminant levels. All these elements should be part of an overall plan that clearly outlines roles and responsibilities and establishes accountability for implementation. The key to success is effective, consistent, and frequent communications with occupants, workers, supervisors, and personnel, especially if violations of the established plan are noted.

Vigilance in enforcing the control plan is especially important when working with special products or materials (e.g., asbestos, lead, sensitizers) or if work is occurring in sensitive environments (e.g., hospitals, labs) where hypersensitive subpopulations may exist.

There are a few cases where control of odors and dust can be difficult to achieve. Roofing projects typically utilize very odorous products and materials (petroleum-based

TABLE 62.10 Summary of Real-Time Environmental Monitoring Equipment

Instrument	Operation	Performance	Functional requirements	Comments
Particle counter	Light scattering	Range typically between 0.01–100 mg/m ³	Battery or AC/DC power, datalogging, costly device	Excellent screening device and good for record; not particle-specific, use surrogate dust reference for weight measurement
PID or FID vapor analyzer	Photo- or flame ionization of various hydrocarbons	Range typically between 1 and 10,000 ppm; precision usually $\pm 3\%$ or 3 ppm in field devices	Usually battery-powered, size varies from pocketsize to larger shoulder-mounted units, prices can vary widely depending on performance	Good for source identification and quick exposure screening; not chemical-specific, must use surrogate chemical for concentration measurement
Pressure monitor	Pressure transducer	Range typically between 0.01–0.5 in H ₂ O for field units	Handheld or wall-mountable units, battery-powered with datalogging, costs vary with performance criteria	Excellent for document isolation of work area via negative-pressure ventilation; provides excellent record; may need recalibration in field; limited to two monitoring locations per unit
CO monitor	Electrochemical cell	Range typically between 1 and 1000 ppm for most field units, precision typically $\pm 3\%$ or 3 ppm	Handheld, battery-powered, datalogging, requires calibration, modest expense	Specific to CO, although may experience interference from other vapors (e.g., ethanol); electrochemical cell needs maintenance and requires periodic replacement
Smoke tubes	Stannic chloride mixes with moisture in air to create irritant fume	Qualitative device, requires moisture in air, used to document airflow patterns	Inexpensive, handheld, easy operation	Very effective to document airflow in and around work area; good demonstration tool; fume is irritating; care must be exercised in disposal

Abbreviations: mg/m³—milligrams per cubic meter; PID—photoionization detector; FID—flame-ionization detection; ppm—parts per million; in. H₂O—inches of water; CO—carbon monoxide.

products). In addition, many buildings obtain some, if not all, of the outdoor air supplied to the building from the roof level. The outdoor air dampers can be temporarily closed to reduce the influx of roofing chemicals into the building; however, this may not be possible when the building is occupied. Petroleum-based products also have low odor thresholds and are fairly potent irritants, further complicating the execution of this work. Therefore, this work (or the most odorous work sequence) may need to be carried out when the building is unoccupied or underoccupied. This will allow certain control measures to be implemented, such as temporarily closing the outdoor air damper. If the work schedule will not permit off-hours application, then enhanced filtration or temporarily reconfiguring the outdoor air intake will be required and will add expense to the project.

The use of new materials that are not well-characterized challenges the model posed in this chapter. In this special case, professional assistance may be required to adequately assess the potential health and safety concerns associated with the application of these materials.

Implementing a sound control program during remodeling activities need not be onerous add significant expense to the project. Proper planning, scheduling of activities during unoccupied times, and developing a concise plan that is enforced will go a long way to reducing hazards associated with renovating in occupied environments while ensuring that the objectives of the planned renovations are met.

CHAPTER 63

PREVENTION AND MAINTENANCE OPERATIONS

Tedd Nathanson, P. Eng.
Indoor Air Quality Consultant
Ottawa, Ontario

63.1 INTRODUCTION

A well-designed, -commissioned, -operated, and -maintained HVAC system is a fundamental requirement for the provision of good indoor air quality (IAQ) to maintain a comfortable and productive indoor environment. The definition of good IAQ (USEPA 1991) includes: the introduction and distribution of adequate ventilation [outside] air, the control of airborne contaminants, and the maintenance of acceptable temperature and relative humidity (thermal comfort). In most buildings, these elements are provided by mechanical HVAC systems or air-handling-units (AHUs).

Air supplied to the occupied space passes through a series of central and terminal mechanical systems and components; outside air is mixed with return air, filtered, cooled or heated, humidified or dehumidified, and transported through ducts, dampers, and other additional air-conditioning systems (induction units, fan coil units, variable-air-volume boxes, etc.). Each component in this chain has to be regularly and properly maintained to perform as intended so that healthy and comfortable conditions are provided in the workplace.

New buildings require proper system design and commissioning to achieve good IAQ. This process confirms that the building systems perform as intended, are tested, adjusted, and balanced (TAB), and that documentation, training, and an operation-and-maintenance (O&M) plan are complete. Postoccupancy, all of the parties involved—the building owner, the property manager, and the O&M staff—must continue this commitment to

provide a well-maintained system. Over time, as changes occur—new office layout, different occupancy levels, new equipment, different job activities, changing work periods—recommissioning of the building's systems should be done in order to reflect these changes.

It has been demonstrated that providing good IAQ and maintaining a productive indoor workplace is cost-effective for both the property manager and the employer. Well-designed systems have a cost-payback of under 2 years (National Energy Management Institute 1994). As salary expenses are several hundred times higher than building system operations costs, changes in productivity are highly sensitive compared to issues relating to the provision of good IAQ and a comfortable workplace. Typical labor charges can range from \$250 to \$500 per square foot of office space (the upper range reflective of multishift operations such as health care, public safety, hightech, etc.), while cooling and heating costs are approximately \$1/ft². Therefore, a 1 percent decrease in productivity far exceeds any additional charges for a well-designed, well-operated, and well-maintained HVAC system.

Improving IAQ with good system design, operation, and maintenance may increase the cost of energy; however, the net benefits would again far outweigh the costs. Energy consumption depends on a variety of factors, notably building and system design, interior heat load, and climate. There are a variety of computer simulation models to estimate building operational expenses. Good design benefits both the building owner and the occupants. For example, systems can be designed using an economizer cycle where natural cooling is provided by using outside air. Energy costs are reduced, thermal comfort is achieved, and the ventilation rate is increased. Using high-efficiency filters is also cost-effective as it improves the performance of the cooling and heating coils and the supply-air fan, and keeps the ducts, diffusers, and ceilings cleaner. It also reduces indoor airborne and surface particulate levels, resulting in a cleaner work environment with good IAQ.

The cost of building repair and maintenance depends on many factors. The Building Owners and Managers Association (BOMA) International tabulates these costs and other income and expense items for cities in the United States and Canada in an annual *Experience Exchange Report* (BOMA 1999).

From BOMA, the following average range of costs per square foot, in 1998, for the U.S. private-sector buildings (first figure) and U.S. government buildings (second figure) are as follows:

Cleaning	\$1.15–\$1.28
Repair and maintenance	\$1.36–\$1.39 (includes elevator, HVAC, building, etc.)
Utilities	\$1.78–\$1.50 (includes heating, cooling, and lighting)
Base rent	\$15.98–\$12.30
Average work area per maintenance worker	81,624–45,760 ft ²

These typical figures again demonstrate the two-orders-of-magnitude difference between building cleaning, repair and maintenance, and utility costs compared against salary costs.

Systems and controls have become more complex, and it is imperative that property managers understand how the HVAC system affects IAQ. Building operators must also have the expertise and resources to properly operate and maintain the building's systems. Several professional associations and companies provide training programs and checklists for maintenance and preventive maintenance [USEPA, ASHRAE, Sheet Metal and Air Conditioning Contractors' National Association (SMACNA), equipment manufacturers, consulting firms].

Negative publicity from having a "sick building" can result in a higher vacancy rate and increased liability (legal) problems. As a proactive approach to IAQ is much easier than a

reactive approach, a commitment to diligent system operation and maintenance is paramount.

63.2 STATISTICS ON THE CAUSE OF IAQ PROBLEMS

Improper design, operation, and maintenance of HVAC systems have been the cause of approximately half of all IAQ problems. The National Institute for Occupational Safety and Health (NIOSH) has gathered statistics from over 500 building studies and found that the HVAC system was the primary cause of air quality problems in 53 percent of the buildings (Crandall and Sieber 1996). Public Works and Government Services Canada (PWGSC) studies in 95 “problem” buildings indicated that HVAC system deficiencies were the primary cause in 48 percent of the cases [Nathanson 1994].

NIOSH recognized that most problem buildings have multiple environmental deficiencies rather than a single cause. In a detailed analysis of 104 office buildings, it was found “that 93 of the 104 building evaluation reports contained at least one recommendation concerning HVAC design, operation, or maintenance deficiencies.” Eight categories of indoor environmental deficiencies and problems were reported, and the total number of multiple problems noted within each building was 442, broken down as follows:

HVAC maintenance	107
HVAC operation	94
Building and facilities	79
HVAC design	57
Occupant comfort	33
Contaminant, inside	33
Contaminant, outside	23
Ergonomic/physical agents	16

63.3 PREVENTION

Prevention of IAQ problems in facilities can be achieved through good system design, commissioning, operations, and maintenance. Several of these issues are described in other chapters but are included here for completion. Chapter 60 discusses guidelines for incorporating IAQ in building design; HVAC systems and pollutant source specification, as well as other aspects, are presented. In Chap. 61, commissioning is described in detail. Chapter 62 describes how to maintain acceptable IAQ during renovation and remodeling. Filter types and performance ratings are described in Chap. 9.

Design

ASHRAE has published IAQ and thermal comfort standards (ASHRAE 62-1999, 55-1992), HVAC system handbooks (*Fundamentals*, *HVAC Systems and Equipment*, *HVAC Applications*), and guidelines on *Preparation of Operating and Maintenance*

Documentation for Building Systems (ASHRAE 4-1993), *Guideline for Commissioning of HVAC Systems* (ASHRAE 1-1989), and guidelines on filter efficiency rating (Standard 52.2P).

Other IAQ and system design documents have been published by the U.S. Environmental Protection Agency (USEPA 1991), the Sheet Metal and Air Conditioning Contractors' National Association (SMACNA 1998), the Trane Company (Trane 1994), and the International Society of Indoor Air Quality and Climate (ISIAQ 1996, 1998).

The HVAC system comprises components that ventilate, filter, cool, heat, humidify, dehumidify, and distribute air within the occupied space. Not all HVAC systems have the same components; some buildings have no mechanical cooling, many do not provide humidity, while others have heat recovery systems. The features of the system will depend on several factors, including

- Age of building
- Climate
- Building codes in effect at the time of design
- Project budget
- Planned use of building
- Owner's and designers' concept
- Subsequent modifications

All mechanical systems have an impact on IAQ. It is therefore prudent to consider the following good design practices with regard to AHUs, filters, humidification systems, heating/cooling coils, fans, and the interior space.

Air-handling units

- Locate air intakes away from pollutant sources, such as exhausts, drains, standing water, garbage compactors, loading docks, bus stops, bird roosts, water towers, and condensers.
- Ensure that a screen covers the outdoor air intake to capture debris, such as leaves and papers.
- Stagnant water should not be present within the mechanical system. Drain rain or snow in the outdoor air intake.
- Ensure that interior acoustic or thermal insulation is not porous, and is cleanable. Exposed fiberglass should be covered and all seams sealed. Protect insulated floors that will be walked on.
- Ensure that the outdoor air damper controls are functioning; at the minimum ventilation rate, dampers should not be completely closed.
- Access should be provided to all system components for routine inspection and maintenance. Access doors or panels should be sealed to prevent air leakage.

Filters

- Distance the filter bank from the outdoor air intake so that it cannot be wetted by rain or snow.
- Position the filters after the return air mixing plenum and before system components.
- Have a well-racked filter system with no air bypass.
- Maximize filtration performance. Small systems, because of space limitations should use pleated filters with a minimum dust-spot efficiency of 30 percent. Larger AHUs

should have roll, panel, or pleated prefilters and ≥ 85 percent efficiency pleated or bag filters.

- Electronic filters are also an option as a secondary filter. The prefilter will collect larger size particles. Electronic filters work best at airflow velocities from 150 to 350 ft/min.
- A pressure-drop indicator should be installed across the filter bank; a differential-pressure gauge is easier to use and calibrate than an inclined manometer.

Humidification systems

- Steam systems require less maintenance than do water-spray units and have less potential for microbial contamination. Wetted media humidifiers are applicable for warm dry climates; periodic maintenance and water treatment are required.
- Steam humidifiers should have a dedicated boiler or steam generator that supplies clean steam, or use a steam-to-steam converter. Hot-water and heating system boilers use chemically treated water to inhibit corrosion, and these chemicals, which include amines, can become airborne if this steam is used for humidification.
- Maintain relative humidity according to the ASHRAE thermal comfort range (ASHRAE 55-1992), 25 to 60 percent during occupied periods, 70 percent maximum during unoccupied periods. (Usually air is humidified to RH 25 to 45 percent during the winter and dehumidified to $R < 60$ percent during the summer.)
- Total evaporation (absorption) within the humidification system enclosure is required. Moisture should not pass through into the fan enclosure or into the supply ductwork. Water systems may require drift eliminators. Wet interior system walls and insulation must be avoided.
- Reservoirs and condensate pans must be able to drain properly, and trap depth and height differentials between the inlet and outlet must be designed to overcome the system static pressure (positive or negative). This is especially critical if the fan is run 24 h/day. Traps with a continuous water bleed will also eliminate the reverse flow of sewer gas.

Cooling and heating coils

- Ensure access to both sides of all coils for cleaning.
- Condensate pans should not be insulated on the inside (interior perimeter and ceiling fan coil units included), and should be sloped to a drain. Avoid stagnant water.
- Individual finned-tube coils should be no deeper than eight rows to facilitate cleaning.

Fans

- Fans should be sized and located so that no moisture is pulled through into the fan enclosure and adjacent ducts.
- The system should be designed for compliance with the ASHRAE ventilation standard (62-1999) and also have a fan capable of providing the recommended number of air changes per hour (ACH). For an office building this usually ranges between 4 and 6 ACH, resulting in a circulation rate of 0.7 to 1 ft³/min per square foot of floor area.
- The building's interior should be under a slight positive pressure (10 percent more supply than exhaust, or 0.025 to 0.05 in. water gauge) to operate under controlled exfiltration, rather than uncontrolled infiltration with unconditioned outside air.

- Pressure relationships should be used to control airflow between interior zones; air should flow from clean to less clean areas (office areas toward washrooms, labs, printing facilities, loading docks, etc.).
- Stack effect in buildings, where hot air rises, can have negative effects on IAQ (temperature differences, uncontrolled interior air flow, infiltration of outdoor air. The building and system design should be able to counterbalance this effect.

Interior space

- Supply-air diffusers should be located away from return-air slots to prevent short circuiting.
- Diffuser design should incorporate an effective means of delivering air to the occupants in the workplace, considering office design and layout.
- Pollutant source control is more effective than dilution by ventilation. Position contaminant-generating equipment under returns; place in enclosed areas. Remove strong contaminants at the source using separate exhaust.
- Building envelope assemblies—walls, roof, and glass—must have proper insulation coefficients to avoid surface condensation at maximum relative humidity conditions. Missing or reduced insulation will produce a cold spot (thermal bridge) where condensation may form.
- An integral building envelope vapour barrier is necessary to avoid moisture infiltration and migration, from both inside and outside the building.
- It is not good practice to use unbonded fiberglass as acoustic insulation in the ceiling return-air plenum. Not only is this not effective, but fibers will migrate to the workplace.
- Thermostats should control areas having similar thermal requirements. The perimeter zone of an office will have needs different from those of the interior. Each side of a building will have different solar gains and radiant-heat transfer.

Commissioning

Commissioning provides procedures and methods for documenting and verifying the performance of HVAC systems so that they operate in conformity with the design intent. The provision of good IAQ for new and renovated buildings is dependent on both proper system design and a comprehensive commissioning process.

The ventilation system is designed for anticipated occupancy levels and activities, and these assumptions and drawings should be maintained in order to assist the building owner when modifications are required in the future.

New and renovated buildings will require specific operational and maintenance processes to ensure a comfortable, odor-free workplace.

The following procedures should be incorporated:

- During construction periods where quantities of dust are generated, the return-air system should be blocked off and the HVAC system should be protected from contamination. Do not operate the HVAC system without filters. Prior to occupancy, replace the (pre) filters.
- During fit-up, run the system 24 h/day to ventilate the offgassing of volatile organic compounds (VOCs) from carpets, wallcoverings, furnishings, equipment, window blinds, and so on. The system may need to be run continuously several weeks after occupancy, depending on whether odors are still present. During this time, maximum outside air (ventilation) should also be provided.

- Establish a communication channel between the occupants and the building manager or operator. Areas may have to be fine-tuned.

The importance of the commissioning process for good IAQ must be emphasized. ASHRAE Guideline 1-1999 focuses on the mechanical system performance and operation. Starting with a system that works, that is balanced with respect to occupancy and equipment requirements, where the operators are trained and procedures are documented, and where the IAQ is in compliance with good practice is the right of all building occupants.

The *commissioning* process as it applies specifically to IAQ prevention and maintenance operations for all new Canadian Office Facilities, has been incorporated in a revised *Canada Labour Code*, Part II, *Canada Occupational Safety and Health Regulations* (*Canada Labour Code* 2000). The following elements are included:

- *Records.* The employer shall keep a record of design intent, normal hours of occupancy, and the types of occupant activities
- *Operation, inspection, testing, cleaning, and maintenance.* Every employer shall appoint a qualified person to set out, in writing, instructions for the operation, inspection, testing, cleaning and maintenance of the HVAC system and the calibration of probes and sensors on which the system relies....The employer shall insure that the qualified person or persons...have been instructed and trained in the specific procedures to be followed in the operation, inspection, testing, cleaning and maintenance of the HVAC system and the calibration of probes or sensors on which the system relies....The employer shall post, in a place readily accessible to every employee, the telephone number of a contact person to whom safety or health concerns regarding the indoor air quality in the work place can be directed.
- *Investigations.* Every employer shall develop, or appoint a qualified person to develop, a procedure for investigating situations in which the safety or health of an employee in the work place is or may be endangered by the air quality.... Every employer shall keep the records of every indoor air quality complaint and investigation for at least five years.

Following these basic commissioning elements will prevent many of the postoccupancy problems endemic to new or refitted buildings.

A new trend in commissioning is “commissioning for IAQ” where a specialist reviews the building and systems design to ensure compliance to current codes and guidelines, monitors the selection of construction and fit-up materials and furnishings to minimize pollutant sources, collects all material safety data sheets, and emissions data, and measures IAQ parameters both pre- and postoccupancy while establishing the ventilation requirements to purge the facility of contaminants. Results are communicated to the future occupants and IAQ becomes part of the information package on the benefits of the new workplace. This has resulted in better initial perceptions and increased satisfaction with the indoor environment. It also demonstrates to the occupants that both the building manager and the employer care about the well-being of the employees.

Operations and Maintenance

Building systems must be operated properly and require scheduled maintenance and preventive maintenance to keep functioning as intended in design. The building owner or property manager has a responsibility to train O&M personnel to understand how the systems function and their impact on IAQ. There should be a policy to react promptly to IAQ complaints. “The expertise and effort required to prevent most IAQ problems is much less than the expense and effort required to resolve problems after they develop. Many IAQ problems can be prevented by educating facility management, staff, and occupants about the factors that create such problems” (USEPA 1991).

Each system component should have a recommended cleaning and maintenance procedure, and it is necessary to coordinate these requirements into a “maintenance plan,” taking into account a host of variables such as the equipment manufacturer’s specifications, the operational work schedule, system and component downtime, season, special maintenance or calibration of equipment required, and the need to contract out specialized tasks. It is also necessary to customize the O&M plan for the building; each facility has a unique assembly of components and IAQ parameters. ASHRAE Guideline 4-1993, *Preparation of Operating and Maintenance Documentation for Building Systems*, presents a comprehensive and systematic approach for the preparation of O&M documentation.

There are also specific operational and maintenance procedures to be followed in the event of a system component failure. This could be a water leak from a valve or a blocked condensate pan on a perimeter fan coil unit, a broken fan belt, or an uncalibrated sensor. While occupants may alert the maintenance staff to certain problems, others can be found using a computerized building management program. Some problems might not be easily found and may be discovered during an annual building audit or walkthrough or during an IAQ survey. Ideally, system failures are minimized by having a good preventive maintenance program.

Although buildings and systems vary in complexity, there are certain generally accepted rules and good engineering practices with regard to system operation and maintenance.

In the mechanical room

- Inspect the HVAC system components monthly (outdoor air intake, screen, dampers, mixing plenum, filters, humidifier, coils, fan, etc.); clean and repair if necessary.
- Schedule routine maintenance according to the O&M manual.
- Water-spray humidifier reservoirs and cooling coil condensate pans should be cleaned monthly; during downtime, drain, brush with a bleach solution, and rinse.
- If the mechanical room serves as a return-air plenum, do not store or mix chemicals in this area.
- Replace prefilters and secondary filters according to specified pressure drop (prefilters are usually replaced several times a year and secondary filters are replaced after 12 to 18 months). Change filters that have become wet.
- Visually inspect covered or nonporous internal and external acoustic and thermal insulation for dirt buildup, tears, and mold growth. Clean dirty surfaces using a HEPA-filtered vacuum, seal broken surfaces, and remediate the mold problem. [There are many good sources for information on microbial contamination and remediation: the American Industrial Hygiene Association (AIHA), Eastern New York Occupational and Environmental Health Center, New York City Department of Health, Canada Mortgage and Housing Corporation, and Health Canada, to name only a few.]
- The use of encapsulants and biocides, sprayed on internally insulated ducts to control microbial growth, is not recommended. Keep surfaces dry and clean; discard porous materials that are contaminated.
- Do not allow condensate to form on cold pipes and ducts; these should be insulated. Valves, gauges, regulators, and other components should not drip on porous material to avoid damage and microbial growth.
- Monitor water quality in reservoirs and limit the concentration of salts, minerals, chemicals, and pollutants by the addition of potable water and a continuous water bleed. The rate of “blowdown” will vary with city water quality and will serve to minimize microbial growth and keep the coils clean and unscaled (with minimal or no use of chemical additives). It is usual to limit the “cycles of concentration” to under five. Certain locations may require deionized water.

- Monitor water quality in reservoirs, water towers, evaporative condensers, etc. on a regular basis for bacteria (*Legionella*) and other bioaerosols. Although chemical treatment for water towers is usually required, it is imperative that vapors or mists from the treated water not be reentrained into the outdoor air intake. Chapter 48 describes the operation of cooling towers and procedures to control *Legionella*.
- Unless the building is occupied 24 h/day, it is seldom necessary to operate the HVAC system continuously. The exception occurs on very hot or cold days when loss of thermal control may occur, if the building is new or has been renovated and is still offgassing VOCs, or if there are strong pollutant sources within the facility. The hours of operation are dependent on several factors such as occupancy levels, pollutant loads, ventilation rate, and building envelope tightness. The optimum operating period is when indoor CO₂ and pollutant levels approach outdoor ambient levels at the start of the workshift.
- Pollutant source control is a far better, cost-effective option for good IAQ than is increasing the ventilation rate. Adding more outside air simply dilutes levels of indoor contaminants. The HVAC system itself may be a source of contamination (microbial amplification site, unbonded fiberglass, outdoor pollutant entrainment, etc.).
- It is prudent to keep a log of maintenance activities, incidents, and records of occupants' complaints and how the issue was resolved.

In the occupied space

- Clean perimeter convection, induction, or fan coil units annually. Control and minimize the use of water if a pressure washer is used. Vacuum all excess water immediately after cleaning each unit. Do not leave water in the channels. If a vacuum cleaner is used for cleaning, it should have a HEPA filter to reduce the reentrainment of particulates into the workplace.
- The air delivery system should be rebalanced to reflect changes in occupancy, activity, or layout. The air supply in existing zones should be verified every 5 years. The minimum and maximum flow performance of variable-air-volume boxes should be tested and reset at least every 5 years (CSA 1994).
- Be aware of the potential negative effects that cleaning products, waxes, glues, paints, caulking, pesticides, and other substances can have on IAQ and building occupants. Often the impact can be minimized by proper product selection, time of use, ventilation, confinement, and—last but not least—communication. Informed occupants who feel they have a measure of control over their work environment are more supportive.
- Occupant intervention of the air-handling systems; taping or adding deflectors to ceiling diffusers, blocking the grates of perimeter units, opening ceiling tiles, etc., may be an indication of poor system performance in this area.
- The use of personal humidifiers should not be allowed in the workplace. These are seldom cleaned and can become contaminated.
- Where possible, schedule office refit (new carpets, painting, new furnishings, etc.) during the spring or fall season when the ventilation rate can be maximized (free-cooling, economizer cycle).
- Wetted interior surfaces, such as walls, carpets, and ceilings, require prompt remedial action. First, find and correct the cause, then dry, clean, or replace the penetrated area. If mold growth is evident or odors persist, refer to specific remediation guidelines or seek expert advice.
- Inadequate housekeeping may cause IAQ problems. Dirty, fleecy materials such as carpets, partitions, or chairs, may harbor allergenic particulates such as dust,

spores, dander, or mites. Using a high-performance, multifiltered vacuum will collect more dirt and reexhaust less airborne particles. Chapter 64 discusses this subject in detail.

- When renovating a section, isolate the work area to confine contaminants. This area should be placed under negative pressure and the returns should be blocked to prevent pollutants being recirculated within the entire building.

There are often specific requirements to treat gaseous IAQ contaminants using gas sorption compounds. Although gas sorption technology can be successfully applied, it is difficult to monitor the effectiveness of the process, it can be costly, it increases the system pressure loss, and not all gases are absorbed. Gas-phase air cleaners need careful design and monitoring. Ozone generators are not effective air cleaners; ozone itself is a pollutant that has negative health implications, and generators should not be used in the occupied space (Nathanson 1998).

There may be infrequent occasions when the outside air is more contaminated or odoriferous than the inside air; examples are periods of roof repair, construction, smog or pesticide use, and nearby industrial stacks. During these episodes, the IAQ in the occupied space would be better served with a reduced (zero) ventilation rate. The supply air would simply recirculate return air. If this is acceptable to the occupants, the system can be operated in this fashion for no longer than 4 h/day. Longer periods will require treatment to reduce the outdoor pollution levels.

Finally, with regard to air supply duct cleaning, both USEPA (1991) and SMACNA (1998), provide good advice on determining the need for cleaning. Basically, the amount of dust and particulates within the duct depends on many factors such as the age of the building, the filtration efficiency, past construction and refit cleanup practices, and level of system maintenance and housekeeping. It is important to have visual access to ducts to assess their condition. While some amount of surface dust does not indicate a problem (or a reduction in airflow or system pressure), duct interiors that have damaged liners or loose fiberglass insulation, or are wet or have microbial growth, require remediation. Often, the return-air systems are more dirty than the supply-air systems. Central, terminal, and perimeter air-handling systems require routine maintenance and cleaning. Efforts to establish duct-cleaning standards and guidelines are currently being prepared by various authorities.

63.4 CONCLUSION

The provision of good IAQ is contingent on a building's design and HVAC system performance, operation, and maintenance. By definition, good IAQ in the workplace is achieved through proper ventilation, air distribution, thermal comfort, and control of contaminants. It is well established that good IAQ results in a more comfortable and productive work environment, a review of the literature indicates a strong relationship between IAQ and health symptoms such as respiratory disease, fatigue, allergy, and asthma.

It has been estimated that the benefits of HVAC system improvements can result in a 4 percent reduction in office workers reporting sick building symptoms, and a 2 percent reduction of building-related diseases (*Canada Labour Code* 2000).

It is therefore incumbent on the building owner and property manager to have a comprehensive O&M program and a basic understanding of the factors influencing IAQ. Generalized IAQ walkthrough and HVAC system checklists have been developed which can serve as guidelines (USEPA 1991, SMACNA 1998, PWGSC 1990), and there are numerous associations providing training courses.

Almost every aspect or issue relating to IAQ is increasing in public view; consider the following incomplete list—questions relating to the health effects of microbial contamina-

tion in homes, schools, and offices; the increase in reported cases of asthma, allergies, multiple chemical sensitivity, and environmental hypersensitivity; changes in legislation to accommodate persons with environmental “disabilities”; the increase in litigation, where, in the absence of standards, courts set the precedent; and the number of building failures. There remains much to be done in the field of IAQ!

CHAPTER 64

PREVENTION WITH CLEANING

Jan Kildesø, M.Sc. (Eng.), Ph.D.
Thomas Schneider, M.Sc.

*National Institute of Occupational Health
Copenhagen, Denmark*

64.1 INTRODUCTION

There are a number of important reasons for cleaning the indoor environment. Even though there are exceptions, most people seem to prefer clean and tidy surroundings without possessing detailed knowledge of hygiene, microorganisms, allergies, and other factors. A clean environment is associated with good aesthetics. However, only very little knowledge exists on how the quality of cleaning affects people in the indoor environment. Cleaning is also an important part of maintenance, as lack of cleaning or application of wrong cleaning methods might contribute to the surface deterioration.

Costs related to cleaning are high. According to the American Building Owners and Managers Association, the actual costs of cleaning in average buildings amounts to 13 percent of the total expenses for a private-sector building in the United States. The annual cleaning costs were estimated at \$1.09/ft² in 1995. The question is what the building management actually gets in return for this expense with respect to indoor air quality, cleanliness, and healthiness and productivity of the employees.

Cleaning practices differ by building type even when only human occupancy is considered. In general, the cleaning program has to be designed for the materials and layout of the building. For instance, the needs in a day-care center with children playing on the floors will be different from those of an office building. The routine cleaning regimen usually consists of daily cleaning of the most important objects, weekly cleaning of less accessible areas, and deep cleaning (window cleaning, etc.), say, 4 times a year. Besides routine cleaning, special cleaning of the HVAC system and cleaning after fire or flooding is of importance to indoor air quality and the elimination of important sources for future pollutants.

It is a plausible hypothesis that the indoor air quality is more affected by infrequent, inadequate, or absent cleaning than by the actual cleaning method applied to the surfaces cleaned at regular intervals. An exception is, however, where the cleaning method leaves considerable residues of cleaning agents on the surface. Wolkoff et al. (1998) gave a broad introduction to exposures related to cleaning with regard to both cleaners and room

occupants, focusing on the constituents of cleaning agents. It has long been known that detergent residue remaining in carpets after shampooing could cause respiratory irritation (Kreiss et al. 1982).

64.2 INDOOR SURFACE POLLUTANTS

Areas with difficult access accumulate major deposits of dust. This may have a negative impact on the indoor air as microorganisms may grow in such deposits, if the humidity is sufficiently high (Kalliokoski et al. 1996). A number of different volatile organic compounds (VOCs) are also adsorbed in the dust (Gyntelberg et al. 1994, Wilkins et al. 1997). Dust deposits can be avoided if the rooms are kept tidy and deep cleaning is performed regularly.

Most air pollutants of indoor surfaces deposit on the surface in the form of particles. This may be in the form of solid particles or droplets of condensed volatile compounds. On the floors, people's shoes are probably the most important transport mechanism for pollutants. Especially close to entrances, the track-in of dust and dirt from outside may be considerable. Spillages, waste, and other contaminants on horizontal surfaces are also important contributions to surface pollution.

The choice of cleaning agents to be applied and the selection of methods in the routine cleaning will depend on surface materials, function of the surface, access to the surface, and the rate at which dust and dirt builds up (the *soiling rate*). This again depends on the number of people present, the working process, and the ventilation system. The choice will also depend on the surface materials used for construction and for repair work. Conversely, proper choice of surface materials and design of buildings and rooms can facilitate cleaning. Using the correct method of cleaning and maintaining surfaces is important for the lifetime of surface materials and their condition.

Another source of pollutants in new buildings is residue from the construction process, such as particles inside the HVAC system. If a high level of cleanliness is maintained during the construction of a building, the building will stay cleaner once it is occupied. This also applies to remodeling and repairs. Special attention should be given to cleanliness when hazardous materials, such as asbestos or building materials contaminated with growth of fungi, are involved in the work.

64.3 DUST SOURCES

Particles found indoors, such as house dust and airborne aerosols, consist of a number of minerals, metals, textiles, paper, building materials, fibers from insulation, particles from combustion processes (including tobacco smoke), office machines, organic material from various biological sources (e.g., skin scales from people, animal allergens, growth of microorganisms, and pollen), and chemical substances with well-known adverse health effects [e.g., polycyclic aromatic hydrocarbons (PAHs)]. Table 64.1 lists the major dust sources.

The relative contributions of each of these sources depend on the activities and materials within the building. In each category listed in Table 64.1, particles affecting health may be found. The known effects are mostly on the respiratory system, but effects on the eyes (ophthalmologic effects) have also been reported (Hauschildt et al. 1996).

TABLE 64.1 Examples of Dust Sources

Source	Examples
Building materials	Concrete, wood, plaster
Furniture	Upholstery, wood dust, old painting
Textiles	Carpets, dividers, curtains
Persons	Skin scales, clothes, dirty shoes, and physical activities
Outdoor air	Soot particles, plants, fungi, pollen, insects, soil-derived particles, seawater salt
Track-in from areas outside the entrances	Sand, soil, grass (large particles which may abrade the floor covering)

64.4 TRANSPORT MECHANISMS

The transport of dust and particles in the indoor air is quite complex. Figure 64.1 illustrates the different transport processes. Most important for the indoor air quality is the concentration and composition of airborne particles and the resulting the exposures of the room occupants and the cleaning staff during cleaning. The amount of outdoor particles, such as pollen, soot, and road dust, is determined by ventilation and penetration and can be partly controlled by filtering the outdoor air. The amount of particles generated in the indoor environment depends on the sources as described above.

Dust on surfaces in the indoor environment is a source of both airborne particle exposure (if resuspended) and dermal exposure. Of particular importance is the floor dust in day-care centers where small children playing on the floor are at risk of ingesting the dust. Cleaning is thus needed to control surface dust levels. However, the cleaning activity in itself may also resuspend dust to the air. Figure 64.1 illustrates the relationship between airborne particles, dust on surfaces, and cleaning. As illustrated, these parameters affect the personal exposure to particulates. One study showed that vacuum cleaners may emit large numbers of fine particles (Liroy et al. 1999). In that study, the motors of 11 different vacuum cleaners were tested and found to emit 0.3- to 3- μm particles at an estimated rate of 0.028 to 176 $\mu\text{g}/\text{min}$ (mean: 58.3 $\mu\text{g}/\text{min}$). The collection efficiency in the particle size range 0.3 to 0.5 μm varied from 29 to over 99 percent.

Whether airborne or deposited on a surface, one key parameter of a particle is its size. The size determines how quickly the particle will settle, to what extent it will follow the movements of the air, the probability that it will deposit in a given part of the human airways, and, to some extent, how easily it will be resuspended from a surface on which it has been deposited. This is illustrated in Chap. 39. The size may be measured in several ways, but the most frequently used method when health effects are of concern is determination of the *aerodynamic diameter*, defined as the diameter of a spherical particle with unit density settling at the same speed as the particle in question.

The penetration factor for outdoor particles penetrating into residences in the PTEAM study (Özkaynak et al. 1996) was found to be approximately 1 for particle masses $\text{PM}_{2.5}$ and PM_{10} . A similar result was found by Thatcher and Layton (1995).

Thatcher and Layton (1995) measured the average deposition velocity of particles to all indoor surfaces by raising the indoor air concentration while simultaneously measuring the air infiltration rate and decay rate of airborne particle concentration. The deposition

FIGURE 64.1 Illustration of the transport of dust on surfaces and airborne particles in the indoor environment.

TABLE 64.2 Dust Buildup on Surfaces and Airborne Particle Concentration in Offices in Boston

Office	Average buildup, % dust area (24 h ⁻¹)	PM _{2.5} , μg/m ³	PM ₁₀ , μg/m ³	Buildup (PM ₁₀) ⁻¹ , [% dust (24 h) ⁻¹] (μg/m ³) ⁻¹
1	0.112	5.68	8.03	0.0140
2	0.074	4.98	7.33	0.0101
3	0.226	4.97	9.24	0.0245
Average	0.137	5.21	8.20	0.0167

Source: Adapted from Kildesø et al. (1999a).

velocity was found to increase from approximately 0.028 cm/s for 1-μm particles to approximately 0.125 cm/s for 10-μm particles. Raunemaa et al. (1989) found a deposition velocity of 0.003 cm/s for sulfur-containing particles. Edwards et al. (1998) measured the deposition of house dust in homes onto surfaces 0.3 and 1.5 m above the floor and found a mean deposition rate of 0.37 ± 0.13 μg/cm² per day during summer and 0.22 ± 0.13 μg/cm² per day during winter. Kildesø et al. (1999a) measured the build-up of dust on surfaces in offices (see Table 64.2). The measurements were based on a sticking gelatine foil method and the measure was the dust covered area of the surface as a percentage. The average result was 0.137 percent-dust area in a 24-h period.

The resuspension of dust particles depends on the adhesion force between the particle and the surface and on the lift force on the particle caused by the airflow. These two forces depend on the particle size, shape, airflow, electrical forces, humidity, and composition of surface and particle. Resuspension of particles has been studied (Sansone 1987, Ziskind et al. 1995), and in general the smaller the particle, the less likely is resuspension. Thatcher and Layton (1995) found that particles smaller than 1 μm are not likely to be resuspended. They measured the increase in particle concentration by various physical activities in a private residence (see Fig. 64.2). The activities tested were cleaning, 2 min walking about by one person, 5 and 30 min of normal activities performed by four people, and one person walking into and out of the living area. Cleaning resuspended the largest quantity of dust.

For particles between 1 and 5 μm , the airborne particle concentration measured by an optical particle counter after cleaning was increased by a factor of 3.6, and for particles in the 5 to 10 μm size range, the concentration increased by a factor of 11.4 as illustrated in Fig. 64.2. For all the tested activities, the resuspension increased with increased particle size up to 25 μm , which was the upper size limit of their measurements.

Typically, the resuspension factor is expressed as the concentration becoming airborne divided by the concentration on the surface. The unit will be $\text{m}^{-3}/\text{m}^{-2}$ or m^{-1} , where common values will be in the range 10^{-2} to 10^{-8} m^{-1} (Sansone 1987) depending on the type of activity. A few examples from the review by Sansone (1987) are given in Table 64.3.

Other factors, such as humidity, which can affect the electrostatic charge of surfaces, may also explain the flux of particles from air to surfaces and from surfaces to air. Kivistö and

FIGURE 64.2 Resuspension of particles in a residence. [Adapted from Thatcher and Layton (1995).]

TABLE 64.3 Examples of Resuspension Factor for Different Conditions

Contaminant	Conditions	Resuspension factor
I-labeled brick and plaster dust	Active work in open unventilated space	$1.8 \times 10^{-6} \text{ m}^{-1}$
Uranium	Floor vacuuming	$0.2\text{--}5.9 \times 10^{-5} \text{ m}^{-1}$
PuO_2	No movements; 10 air changes/h	$0.1\text{--}5 \times 10^{-8} \text{ m}^{-1}$
Microorganisms	Walking	$2.3 \times 10^{-3} \text{ m}^{-1}$
Beryllium	2 workers sweeping vigorously in an unventilated room after vacuuming	$1.0 \times 10^{-2} \text{ m}^{-1}$

Source: Sansone (1987).

Hakulinen (1981) performed experiments in a chamber with an artificial foot walking on a carpet containing some dust. They found that, for $RH < 50$ percent only relatively little dust was resuspended. They suggested that this was due to electrostatic forces. At $RH > 85$ percent also relatively little dust was resuspended, which was explained as an effect of the humidity itself. The maximum resuspension was found for relative humidity around $RH 70$ to 75 percent. Measurements were performed with a microscope and a particle counter.

Surface dust need not be resuspended to cause problems in the indoor environment. For instance, dust buildup, especially in carpets, may act as a growth medium for microorganisms if the humidity is high. Furthermore, dust has been shown to be a reservoir for VOCs (Wolkoff and Wilkins 1994).

64.5 HEALTH EFFECTS

Several sick building syndrome (SBS) investigations and building surveys have reported an association between symptom frequency and being in a dusty environment. Symptoms associated with SBS have been correlated with a number of factors related to cleaning in the Danish Town Hall Study (Skov et al. 1990). These factors were the fleece factor (expressed as the area of textile surfaces such as carpets, curtains, and seats divided by the volume of the room), the shelf factor (expressed as the length of all open shelves and cupboards divided by the volume of the room), and the amount of macromolecular organic floor dust (potentially allergenic material in the dust).

Gyntelberg et al. (1994) performed a cross-sectional study of the relationship between the qualitative, physical, chemical, and biological compositions of dust from offices and the symptom prevalence. The study included 12 Danish town halls and the participation of 870 persons. A significant correlation between the concentration of gram-negative bacteria and general symptoms such as fatigue, headache, dizziness, concentration problems, and irritation of the mucous membrane and the upper respiratory tract was found. Symptoms associated with mucous membrane irritation were also correlated with the particle count per unit area. There was a correlation between the total volatile organic compounds present in the dust and difficulties of concentration. Potentially allergenic materials in the dust or the macromolecular components were significantly correlated to the prevalence of headaches, general malaise, and dizziness. Table 64.4 summarizes some of the main results from Gyntelberg et al. (1994).

The indications that dust influences the prevalence of certain SBS symptoms have been supported by other studies. Raw et al. (1993) reported that treatment of surfaces with liquid nitrogen, to mitigate dust-mite infestation, reduced the frequency of reported symptoms. Sundell et al. (1994) reported that the frequency of floor cleaning was associated with an overrepresentation of skin symptoms among videodisplay terminal workers. Hauschildt et al. (1996) found significant effects on the eyes from dust exposure in a climate chamber. Furthermore, Pan et al. (1999) reported irritation and dryness of eye and nose due to 3 h of exposure to 0.39 mg/m^3 of dust in a chamber. Effects due to high dust loading were also found in an Australian study (Kemp et al. 1998) where a cleaning intervention significantly reduced the level of airborne respirable particles by approximately 80 percent and the symptoms of eye and throat irritation among room occupants were reduced by approximately 30 percent.

A possible productivity gain of \$10 to \$20 billion in the United States has been estimated from reduced SBS symptoms (Fisk and Rosenfeld 1997). The abovementioned studies suggest that a high dust loading will influence symptoms and that an improved cleaning quality will improve the well-being of room occupants. Therefore, the cost of improved cleaning in a building should also be related to the likely gain in productivity.

TABLE 64.4 Some of the Main Results from Gyntelberg et al. (1994)*

Symptom	Number of gram-negative bacteria	Relative particle amount in fine fraction of dust	TVOCs in fiber sample	Number of VOCs in fiber sample
Excessive fatigue	<i>0.61</i>	<i>0.54</i>	<i>0.57</i>	<i>0.56</i>
Heavyheadedness	<i>0.60</i>	<i>0.69</i>	<i>0.67</i>	<i>0.72</i>
Headache	<i>0.66</i>	<i>0.64</i>	<i>0.37</i>	<i>0.49</i>
Indisposition/dizziness	<i>0.39</i>	<i>0.39</i>	<i>0.53</i>	<i>0.55</i>
Concentration problems	<i>0.38</i>	<i>0.72</i>	<i>0.90</i>	<i>0.85</i>
Dryness, smarting, or irritation in eyes	<i>0.49</i>	<i>0.75</i>	<i>0.45</i>	<i>0.58</i>
Dry and irritated, blocked, or running nose	<i>0.46</i>	<i>0.87</i>	<i>0.47</i>	<i>0.55</i>
Dry and irritated throat	<i>0.65</i>	<i>0.69</i>	<i>0.48</i>	<i>0.64</i>
Hoarseness, sore throat	<i>0.69</i>	<i>0.22</i>	<i>0.69</i>	<i>0.69</i>

*Correlation coefficients between symptoms and some parameters measured in dust sampled from floors. Significant correlations are in italics.

64.6 CLEANING METHODS

Cleaning is performed in a number of different ways. A brief introduction to the most widespread methods in professional routine cleaning methods for offices, schools, private homes, and other buildings follows.

Cleaning Programs

The cleaning program must specify what the cleaning service has to include in terms of types of surfaces and facilities to be cleaned, the frequency of cleaning, and the cleaning method. The cleaning program usually forms part of the contract between the cleaning service provider and the building management. It must include all cleaning and related activities. Typically, the cleaning program will include a description of the activities to be performed. However, the most interesting aspect to the customer is the result of the cleaning. Therefore, a specification of the cleaning quality to be maintained is an alternative way of describing the performance of the cleaning program. This necessitates a flexible cleaning program which can be adjusted according to the activities performed in the building and to where the cleaning effort should be adjusted to the actual needs in different rooms. A method for assessing the cleaning quality is also necessary and must be specified in the contract.

Cleaning Agents

There are a large number of cleaning agents on the market, and the appropriate selection and use for a given task is very important. If the cleaning agent is too weak, it may not clean adequately. If the cleaning agent is too strong, it may wear the surface unnecessarily, leave

residues, and expose the cleaner or occupants to unnecessarily strong cleaning agents or by-products from interactions between terpenes in the cleaning agent and ozone (Weschler and Shields 1999). If the cleaning frequency is reduced and stronger cleaning agents used instead, both the indoor environment and the occupational health of the cleaners will be affected negatively. Another issue of equal importance is the correct dosage of the cleaning agent.

The active components in cleaning agents are detergents and *tensides* which enhance the effect of cleaning by reducing the surface tension of water. Acidic and alkaline substances dissolve calcium and fatty substances, respectively. Water softeners will dissolve and bind calcium and metal ions, which may otherwise reduce the effect of detergents and tensides.

Disinfectants are used for eliminating living microorganisms, whereas solvents such as alcohols are used for dissolving fatty substances. Wolkoff et al. (1998) described the composition of cleaning agents and their known effect on humans.

Floor Cleaning

For hard floor surfaces, different types of mops are the most commonly used cleaning tools. Dry or semidry (meaning spin-dried or only slightly wet) mops are often used for the daily cleaning or frequent floor cleaning combined with more thorough washing, say, once a week depending on the load on the floor. Dry or semidry mops have the advantages of using smaller amounts of cleaning agents, wetting the floors to a lesser extent, and generating less wastewater. Semidry mop systems may use either water or oil. The surfaces of hard floors will be worn over time, and maintenance with polish, wax, or varnish—depending on the surface material—is necessary to avoid destruction of the materials, which would make cleaning more difficult in the future.

For textile floorcoverings, the use of vacuum cleaners is the basic method. It is important to apply vacuum cleaners with effective filter systems without leaks which also remove the submicrometer particles from the exhaust air. The mouthpiece of the vacuum cleaner is important for the effectiveness in terms of removing dust and dirt. The use of rotating brushes within the mouthpiece increases the release of dust and dirt from the carpet. However, the mouthpiece may also stir up dust which is not captured. This possibility has to be considered in the selection of mouthpiece.

For all cleaning methods, but especially the cleaning of floors, particles are resuspended during the cleaning process. The consequence for the indoor air quality has to be considered if rooms are cleaned while occupied. An efficient ventilation should be maintained during the cleaning process to reduce exposure and to reduce settling of resuspended dust (Schneider et al. 1999).

Furniture Cleaning

In most offices, cleaning of furniture and equipment will take up 40 to 60 percent of the cleaning time. It is therefore important to ensure that the surfaces which are to be cleaned are easily accessible to the cleaner.

Furniture surfaces are usually cleaned using dry and semidry methods, which have the advantage of being less harmful to the surface than wet methods. A relatively new strategy is to provide the cleaner with a number of moist cloths in a green bag. The cleaner takes one cloth from the green bag, uses it, and, disposes of it in a red bag when it gets dirty, thus eliminating the need to carry around water. All used cloths in the red bag are sent for central washing after cleaning.

Microfiber cloths have become very common as their cleaning results have turned out to be very satisfactory. However, care should be taken not to scratch softer surface materials such as vinyl and painted surface materials. On metals and ceramics, microfibers will clean more effectively without the use of cleaning agents. The friction of a microfiber cloth moved on a surface is higher than for traditional cloths.

Other Surfaces and Special Areas

Fine particles will also adhere to vertical surfaces and the ceiling. Therefore, these surfaces should also be included in the cleaning program. Sanitary installations and kitchen facilities need special attention in cleaning. In such areas cleaning must be of a high hygienic standard.

Duct Cleaning

Dust may build up inside the HVAC ducts over time and be a source of indoor air pollution. Considerable buildup will also affect airflow in the ducts. The following three methods for duct cleaning are commonly used: (1) vacuum cleaning with special vacuum cleaners, (2) sweeping with compressed air upstream and vacuuming downstream to remove the debris, and (3) using rotating mechanical brushes moving down the ducts with an air filter at the end for collection of debris. It still remains to be shown how important the cleanliness of the HVAC system is to the indoor air quality. [See, e.g., USEPA report, EPA-600/R-97-137 (1997).]

64.7 ASSESSMENT OF CLEANING QUALITY

Sampling or measuring of dust on surfaces is important when an analysis of the dust as part of indoor air quality evaluations is required or when assessing the cleanliness, for example, when different cleaning methods are to be compared or for control of the cleaning quality.

One frequently applied method for the sampling of floor dust for further analysis is the *high-volume small surface sampler* (HVS3), in which 99.4 percent of the sampled dust is collected in a cyclone. This method was developed for the USEPA, and ensures controlled sampling with a sampling efficiency of 85 to 87 percent from bare floors and approximately 70 percent from carpets. The air is drawn through a nozzle which is moved at a fixed distance from the floor. Analysis of dust sampled by the HVS3 has been compared to analysis of dust collected from the bags of different standard vacuum cleaners (Colt et al. 1998). Both methods detected a number of chemical compounds in 15 homes. Also, the concentration of the compounds were equivalent. This indicates that in some situations the collection of vacuum cleaner bags may be an inexpensive alternative to performing dust sampling. However, differences in the sampling efficiency of different vacuum cleaners handled by different people makes it difficult to relate a measured compound to a surface area, which is a possibility with the HVS3.

The *VacuMark vacuum cleaner mouthpiece* (Petersen Back, of Bjerringbro, Denmark), also called the ALK sampler mouthpiece for the sampling of dust from surfaces on a filter for subsequent analysis, has been used in a number of studies [e.g., Gyntelberg et al. (1994), Kildesø et al. (1998)], where microbiological analysis is to be performed. The airflow through the mouthpiece is ensured by a vacuum cleaner. This method is not very accurate

for quantitative sampling of the surface dust, but is widely used for sampling of dust for further analysis.

In a *wipe test*, a white cloth is moved a given distance along the surface using a constant pressure. The amount of dust collected by the cloth is quantified by evaluating how gray the cloth becomes. This “gray level” may be found by visual comparison to a gray scale or by measuring with a chromameter. This method is used for the assessment of cleaning quality but is not suitable for the sampling of dust for further analysis.

The *SMAIR* sampler is a small inverted tunnel-like sampler which is placed tightly on the surface. Air is drawn from the tunnel through a filter. Replacement air flows through small holes, generating small jets of air directed at the surface. This resuspends dust which is sampled on the filter. The filter can be weighed, or the dust sampled on the filter can be analyzed. This method was originally developed for the nuclear industry for the measurement of removable radioactive surface contamination.

Agar plates pressed against a surface may be used for quantification of viable microorganisms on the surface measured as colony-forming units (cfu). This method is widely used in the food industry where a high level of hygiene is essential.

For the measurement of dust on horizontal surfaces, an objective method quantifying the concentration of dust on such surfaces has been developed in Denmark. This method has been described by Schneider et al. (1996) and is based on the sampling of dust on adhesive gelatine foils and subsequent measurement of the dust covered area in a laser-based instrument, the BM-Dustdetector (see Fig. 64.3).

The dust is sampled from the surface onto the adhesive foil by placing the foil on the surface and rolling a roller 3 times across the foil. The roller has a spring system which ensures a force of 1 kp [corresponding to the force of a 1 kg weight (= 9.8 N)]. The relative area covered with dust particles is quantified by measuring the light extinction of the particles. Before sampling the dust, a reference measurement must be made for each individual foil. The dust-covered area, which is calculated on the basis of the difference in light extinction, is given as a percentage of the surface area. The foil may also be analyzed by microscopy and image processing (Kildesø and Nielsen 1997).

The method may be applied to assess the dust levels in different buildings as part of indoor air studies to evaluate how clean different types of surfaces really are, to compare different cleaning methods, and to control the cleaning quality. The dust detector method has been applied in a number of cleaning studies (Aulanko 1996, Kildesø et al. 1998).

The method is closely linked to a sampling strategy suggested by Schneider et al. (1994a). Samples should be taken from five different types of horizontal surfaces. There are three types of surfaces on furniture:

- *Close-to-person surfaces.* These are surfaces close to the people working in a room, within a 1-m distance (desks, etc.).
- *Easily accessible surfaces.* These are surfaces in the room below 1.8 m from the floor, such as shelves or windowsills.
- *Other surfaces.* These are highly placed surfaces or other surfaces with limited access; typically, surfaces cleaned at a low frequency.

On the floors there are two types of surfaces:

- *Walking zones.* These are areas where people walk, but are not too close to door openings. There should be an open space on the floor of at least 2 m.
- *Nonwalking zones.* These are areas where people do not walk, including corners where furniture, office machines, electric wires, and other equipment or furniture make access difficult.

FIGURE 64.3 The BM-Dustdetector with roller and gelatin foils.

The time for measurement is selected with respect to the purpose of the study:

1. If the quality of one cleaning event is to be assessed, the measurements are performed immediately after the cleaning.
2. If the average dust level on surfaces is to be assessed, the measurements are performed at randomly selected times in the course of a workday.
3. If the daily dust loading in a room is to be assessed, the measurements are performed at the end of the workday but before the cleaning.

The different measuring positions on each type of surfaces have to be selected at random and at a ≥ 10 cm minimum distance between two positions.

Samples from carpeted floors may be taken by means of the *Carpettester*, which is a special vacuum cleaner nozzle moved on wheels over the carpet. Downstream of the inlet nozzle, a gelatin foil is inserted over a slit opening in the pipe. Part of the dust collected during a test vacuum cleaning will be deposited on the foil, which is subsequently measured in the BM-Dustdetector. The result of this measurement is a relative dust index. The number of measurements will be lower when using the *Carpettester* as the area of the surface covered in one single measurement is larger.

An improved instrument for measuring the potential resuspension of dust from carpets, the *STEPP-tester*, has been developed (Kildesø et al. 1999b). This instrument is also moved on wheels over the carpet with a weight falling and resuspending dust from the carpet. The air containing the resuspended particles is drawn through a sampling pipe and is collected and analyzed as in the Carpettester.

Three quality levels for the dust level on surfaces are applied: 1, 2, and 3. Level 3 is the highest level, also termed the *indoor environment quality*; level 2 is termed *improved quality*; and level 1 is termed *baseline quality*. The quality level will depend on the cleaning frequency, the cleaning method, and the dust load of the rooms. For each quality level, Table 64.5 gives the maximum mean value in the dust-covered area percentage for each of the five types of objects.

A very high spatial variance of the dust concentration on a surface is also considered unacceptable. Therefore, another condition for the acceptance of the cleaning quality at a certain level is that only a given number of the measurements may exceed the mean value multiplied by a factor of 1.5. The maximum number of measurements which may exceed this level is given in Table 64.6.

Two different strategies may be applied for the evaluation of the cleaning quality of a building: to evaluate the building or a floor as a whole or to evaluate individual rooms or smaller areas. The latter strategy will, of course, require a larger number of measurements.

TABLE 64.5 Dust-Covered Area (%) on a Foil Measured with the BM-Dustdetector

Type of surface	Quality level		
	3	2	1
Close to person	1	2	4
Easily accessible	1.5	3	6
Other	5	10	15
Walking zone	3	7	12
Nonwalking zone	5	10	18
Walking zone (carpet)*	5	10	20
Nonwalking zone (carpet)*	8	15	30

*Dust index measured by the Carpettester.

TABLE 64.6 Maximum Number of Measurements which May Exceed a Limit Defined by a Factor of 1.5 Multiplied by the Maximum Mean Level Given in Table 64.5

Number of measuring positions	1–3	4–9	10–14	15–19	20–23	24–28
Maximum measurements to exceed	0	1	2	3	4	5

Evaluation of an Entire Building or Floor in a Building

The number of measurements are selected in accordance with Table 64.7. The possible number of measuring positions is found by counting the number of objects to be measured, such as the number of desks. The result is multiplied by three measuring positions for each object.

TABLE 64.7 Number of Rooms or Measuring Positions in which Measurements Need to Be Performed

Total number of room/positions	<6	6	7–9	10–14	15–26	27–50	>50
Number of room/positions to be measured	All	5	6	7	8	9	11

The maximum number of measurements that may exceed the limit of 1.5 multiplied by the maximum mean value is given in Table 64.6.

Evaluation of Individual Rooms or Small Parts ($\leq 40 \text{ m}^2$) of Large Office Areas

Measurements are performed in a number of rooms or areas selected at random. The number will depend on the total number of rooms or areas and is given in Table 64.7. Special rooms such as bathrooms and kitchens must be omitted from this selection process.

In each room or area, five measurement positions have to be selected on each of the five types of surfaces, for example, five measurements on one desk. If a type of surface is not present in the room, the five measurements for that particular type of surface are omitted.

The limit of 1.5 multiplied by the maximum mean value may be exceeded in only one of the five measurements. If this limit is exceeded by more than one measurement or if the mean value is exceeded, the quality level is not met in the room for that particular type of surface.

By using the Carpettester, the number of measurements is reduced to one in the walking zone and one in the nonwalking zone.

64.8 CLEANING RESEARCH

The number of studies on the effect of cleaning is not large. Michael Berry has covered the present knowledge on cleaning in relation to indoor air and health in his book (Berry 1993). Only a few later studies are summarized here.

The effectiveness of different dry and wet cleaning methods for cleaning of furniture and hard floors was studied by Schneider et al. (1994b). High cleaning effectiveness was obtained with certain dry floor cleaning methods. On furniture, a wet cloth proved better at high dust levels, but at low levels, the relative differences between dry and wet methods were low. The use of dry cleaning methods is encouraged, because they are as good as the wet methods in many situations, while their potential for damaging the surfaces is lower and they do not leave behind residues of cleaning agents.

Franke et al. (1997) performed a cleaning intervention study in a 2700-m² building and found that very thorough deep cleaning can reduce the relative content of fungus spores, bacteria, endotoxins, and condensed VOCs of the dust. At the same time, the concentration of dust, both on surfaces and in the air, was reduced after the deep cleaning. The non-problematic, non-complaint-generating, and multiuse building was monitored for a total of 12 months.

In a cleaning intervention study in Denmark (Kildesø et al. 1998), various improvements of a cleaning method were tested to clarify whether they reduced the concentration

of airborne dust or of dust on surfaces, or whether the concentration of various microbiological components in the dust was reduced. The interventions were focused on improved floor cleaning methods and improved cleaning of easily accessible surfaces. One finding was a reduction in the dust concentration on easily accessible surfaces. Correlations between surface dust and airborne dust were also found. Furthermore, correlations between the measurements and factors such as activity during the day were obtained. The cleaning improvements tested had to be cost-neutral and therefore included only limited changes. This was the reason for the relatively small number of effects found.

In a Finnish study (Aulanko 1996), the differences in the tendency of various surface materials to become dusty was investigated. Eleven different surface materials were tested. Specimens were put in five different places with two groups in each. One group was dusted with a dry microfiber cloth and the other, with a slightly damp viscose cloth. The amount of dust was measured once a week for 6 weeks. Uncoated linoleum tiles were found to collect the largest amount of dust, and no difference in cleaning effectiveness between the two cleaning methods was found (see Fig. 64.4).

Nilsen et al. (1997) investigated a number of different microfiber cloths and found their cleaning effect to be generally excellent under both dry and damp conditions, but that the cloths scratched plexiglass surfaces.

Kildesø et al. (1999a) measured the buildup of dust on surfaces in offices and found a significant correlation between the 5-day accumulation rate of particles on surfaces and the airborne concentration of coarse particles (the difference between PM_{10} and $PM_{2.5}$). For data also presented in this study, a significant correlation was found between subjective evaluations of the dust amount on a surface and subsequent measurements by the BM-Dustdetector method. An equivalent finding was presented by Özkaynak et al. (1996), in which the cleanliness of a home as perceived by measuring technicians was found to correlate significantly with the airborne particle concentrations.

In an Australian study (Kemp et al. 1998), interventions with improved carpet cleaning and improved cleaning of hard surfaces were performed in a six-floor office building con-

FIGURE 64.4 The mean dust levels on six types of surface materials cleaned with a dry microfiber cloth and a slightly damp viscose cloth. The cleaning method did not have any significant effect, but uncoated linoleum accumulates more dust than the other materials. [Adapted from Aulanko (1996).]

structed in 1965. The interventions reduced the initially high levels of airborne respirable particles (average: $245 \mu\text{g}/\text{m}^3$) by approximately 80 percent. A questionnaire survey revealed reduction in symptoms related to eye, throat, and nose irritation.

64.9 CLEANING AS A SOURCE OF INDOOR AIR POLLUTANTS

As illustrated in Fig. 64.1, the cleaning process also contributes to the pollution of the indoor air. This pollution will be in the form of resuspended particles and volatile matter from the cleaning agents. As an example, Schneider et al. (1994b) measured the resuspension of particles during different cleaning activities and found a distinct pattern for particles larger than $3 \mu\text{m}$ in relation to the cleaning activities. The mobility of the cleaners seemed to be of major importance.

Lawless et al. (1996) tested the particulate emissions during vacuum cleaning in a chamber and measured an initial burst of particles when the vacuum cleaner was turned on. This burst is likely to come from soil on the floor and already present in the filter bag. It indicates that it is preferable to vacuum continuously instead of turning the vacuum cleaner on and off. As mentioned above, vacuum cleaners may emit large numbers of fine particles, and different vacuum cleaners have very different collection efficiencies (Lioy et al. 1999).

Vejrup (1996) established the presence of detergents in dust sampled from offices (up to 1500 ppm). The likely sources were claimed to be residues of cleaning agents left on surfaces during cleaning and detergents left in washed textiles. Vejrups (1996) also measured the evaporation of cleaning agents and polish from the floor in a 41-m^3 climate chamber. It was found that the peak levels of VOC started to decline 2 h after the polishing of floors, with a dilution ventilation of 0.5 to 1.5 h^{-1} . This indicates that polishing should be performed after working hours.

64.10 OCCUPATIONAL HEALTH OF CLEANING WORKERS

In Denmark it is estimated that 130,000 people or 2.5 percent of the entire population work with professional cleaning. Within the European Union countries there are an estimated 3 million full- or part-time cleaners. The typical cleaner is a woman with limited education. The work hours are often early in the morning or late in the evening, and many jobs in this sector are part-time jobs. In the United States, many of the cleaning jobs go to unskilled labor and are contracted services, where records are not well maintained. The cleaning is often hard work, and early retirement is common. The occupational exposures in cleaning work may be divided into four main groups: physiological, chemical, airborne dust, and psychosocial.

Physiological exposures depend on the cleaning tools and methods applied, the design and construction of the rooms and furniture, and the organization of the work. The effect on the individual cleaner depends on that individual's personal capacity and health status. *Chemical exposures* depend on the choice of cleaning agents and the methods by which they are applied. The time in which the skin is in contact with the cleaning agents is important, as is the ventilation in the rooms during cleaning, due to the exposure to vapors and gases. *Airborne dust* exposure may be high when vacuum cleaners with ineffective filters are used or when very dusty rooms are cleaned. Ventilation is also of importance in this connection. *Psychosocial* exposures are difficult to quantify. They are caused by combinations of physically hard work, time pressure, monotonous tasks, and unusual work hours.

In a Danish questionnaire study, described by Nielsen (1995), in which 1166 adult female cleaners participated, the most prevalent health problems were psychosomatic symptoms, musculoskeletal complaints, skin irritation and allergy, and respiratory symptoms. Occupational health should always be considered when cleaning methods, tools, and agents are selected or developed.

Also, in the design phase of buildings, facilities, and furniture, the cleaning process should be taken into account. The longer time it takes to clean a given area, the less cleaning quality is obtained at a given cost. Design must include sufficient storage space around the building for cleaning equipment. It must be easy to get around with the equipment. If areas need to be crowded or cluttered with furniture or other equipment, more time should be planned for cleaning these areas. Surface materials should be selected so that cleaning is easy.

65.1 INTRODUCTION

In many ways, hospitals are similar to commercial and residential buildings and yet are so unique and distinct that they must be treated in a class by themselves. Hospital facilities have evolved from palliative hospices to complex multifunctional facilities. In these facilities, the most susceptible of our population is cared for. Sophisticated technology, advanced therapeutic treatments, and intensive personal interaction are used to improve an individual's well being. The need to meet increasingly stringent requirements of health care provision places intense pressure on the facilities themselves and the health care workers (HCWs) that occupy them.

In addition to the environmental issues common to all buildings discussed previously in this book, hospitals by their very nature as treatment and healing facilities present many potential hazards that require constant vigilance to maintain a safe and healthful environment. Close control of the hospital environment is complex but absolutely essential due to the following:

- The increasing acuity and oftentimes susceptibility of patients being treated in hospitals
- The presence of pathogenic agents such as hepatitis-B and mycobacterium tuberculosis (MTB)
- The need to use various chemical agents to disinfect and sterilize medical devices, equipment, and surfaces
- The presence of other chemical, physical, or biological agents used for treatment

In distinct contrast to the dramatic advances in equipment and treatment that distinguish modern health care delivery, the design, operation, and maintenance of most hospital facilities have generally not evolved as rapidly. The need for advanced isolation, increased ventilation effectiveness, and environmental control has stressed many hospitals' existing mechanical systems. Furthermore, the continuous occupancy of most areas, requiring systems to operate 24 hours a day, 7 days a week, presents challenges to preventive maintenance, repair, and system upgrades.

The treatment and ancillary support areas of a multiservice medical center include laboratories, clinical treatment areas, operating and intensive care units, emergency and triage areas, pharmacies, morgues, patient care, provision of food, laundry, waste treatment, and a variety of other functions. It is rare when a hospital complex is not undergoing some form of renovation. New surgical or treatment procedures, diagnostic equipment, expanded patient services, requirements to isolate patients, or a general need to modernize are among the reasons why the hospital environment undergoes more renovation than many other types of buildings. As a result, hospitals are often extended construction sites that may reroute traffic, modify ventilation systems, deliberately or accidentally change pressure relationships, introduce new materials, and create unique exposures in their indoor environments.

This chapter presents an overview of the environmental risks present in the hospital setting. The opportunities to improve provision of health care to patients also present new challenges for building performance and environmental control. The maintenance of a safe and healthful hospital environment depends on the continuous review of new procedures and the rapid assessment of possible environmental hazards. However, through anticipation of potential risks, thoughtful intervention, effective communication, and integrating environmental concerns into facility design, hospital environments that support the ideals of health for all occupants can be developed and maintained.

65.2 EXPOSURE TYPES

As discussed earlier, certain types of indoor exposures are more prevalent in hospital settings. It is also important to assess the risk these various exposures may present for the different classes of building occupants such as patients, employees, and visitors—those in direct contact and those who receive a secondary or attenuated contact. An appropriate exposure/risk assessment is critical in developing effective control strategies. The following sections describe some of the common exposures.

Sensitizing and Allergenic Agents

A number of materials commonly found in hospitals have strong sensitizing and allergenic properties. Some of these include histamines, glutaraldehyde, formaldehyde, latex allergen, hexachlorophene, and psyllium laxatives. Sensitization has been shown to occur during the preparation of pharmaceutical products, especially antibiotics. Kern and Frumkin (1989) found that the respiratory therapists in their study reported significantly higher asthma rates than matched control subjects. Although the specific sensitization mechanism has not yet been discovered, these results have been replicated (Christiani and Kern 1991).

Methylmethacrylate, which is commonly used as bone cement in orthopedic surgery, is an irritant as well as a sensitizing agent. It appears that the major route of exposure is through contact rather than through inhalation (Williams and Syderham 1996), although there is a noticeable odor associated with evaporation of the resin.

Latex allergen has been shown to elicit various dermatologic and systemic reactions via Type I immune mechanisms. This is discussed in more detail under “Substitution” in Section 65.4.

Irritants

Several compounds or mixtures of compounds, such as cleaning/disinfecting agents, environmental tobacco smoke (ETS), formaldehyde, and volatile organic compounds (VOCs), have been shown to be highly irritating. Common sites of irritation can be the eyes, skin, and the upper airways. For example, glutaraldehyde, a strong irritant, has many sources in the hospital environment; it is a component of x-ray film developing solution, is found in some cleaning compounds, and is used as a cold disinfection solution for medical equipment. Wellons and colleagues (1998) report glutaraldehyde's irritation threshold to be about 0.3 parts per million (ppm) and its odor threshold to be 0.04 ppm. Many different irritating VOCs can be released from solvents, multipart forms, photocopying machines, caulking compounds, floor adhesives, and floor finishes. Certain irritants associated with accelerators, stabilizers, antioxidants, and other chemical additives found in rubber and plastic products have been shown to cause contact dermatitis. Finally, aldehydes, including acrolein and formaldehyde, VOCs, and polynuclear aromatic hydrocarbons, are some of the irritating and odorous compounds produced during laser surgery (Ott 1993).

Direct Toxins, Mutagens, and Teratogens

The hospital environment is replete with materials that, given sufficient exposure periods at high enough concentrations, will elicit direct toxic effects on individuals. For example, at elevated concentrations, many anesthetic agents have demonstrated toxic effects on organ systems in certain categories of health care workers. A variety of effects have been examined, including cancer, renal and hepatic disorders, nervous system effects, and reproductive effects (Buring et al. 1985; Mazze and Lecky 1985).

Many antineoplastic agents have been reported to be carcinogenic, mutagenic, and teratogenic (Selevan et al. 1985). At one time, it was common for HCWs to prepare the agents in areas without hoods. However, mutagenic agents have been found in the urine of workers preparing the agents in horizontal laminar flow hoods to protect product quality (Anderson et al. 1982). This emphasizes the need for careful selection of control devices. Furthermore, selection and use of appropriate gloves is essential. Nitrile has been shown to be far less permeable to many chemotoxic drugs than either the latex or polyvinyl chloride gloves used previously.

Implementation of specific work practice guidelines will minimize the potential for exposure. These recommendations include that antineoplastic agents be mixed in environmentally controlled settings by pharmacists. Furthermore, strict protocols must be developed and adhered to for the administration and disposal of antineoplastic drugs, including cleaning up spills.

Ribavirin is a synthetic nucleotide that is delivered to the patient as an aerosolized medication for the short-term treatment of severe respiratory syncytial virus (RSV) infections. Although Ribavirin has not been linked to fetal abnormalities in humans, the teratogenic potential demonstrated in several animal species requires that avoidance to Ribavirin prior to pregnancy and during pregnancy and lactation be strongly recommended (Waskin 1991). Specific engineering controls and personal protective equipment have been shown to be effective in controlling exposure (NIOSH 1992).

Ethylene oxide (EtO) is used in many hospitals to sterilize medical devices and equipment. It is very effective in the sterilization of heat- and moisture-sensitive items that cannot be sterilized by steam. At high doses, EtO has induced dominant lethal mutations and has caused embryotoxicity in rodents. EtO in air at concentrations of approximately 200 ppm can irritate the eyes, nose, and throat of most people. Higher concentrations can cause coughing, lung irritation, breathing difficulties, and chest pain. Angerer and colleagues (1998) have documented some short-term peak exposures to EtO during the unloading of sterilizers ranging from 0.2 to 8.5 ppm in the workplace air.

Infectious Aerosols

There are many examples of infectious aerosols affecting occupants of health care facilities. It is essential to understand the sources of these infectious agents, so that appropriate controls can be implemented. As may be expected, patients are often the primary source of infectious agents, and their presence is a potential hazard to other patients and to employees. Certain infectious diseases such as tuberculosis, chicken pox, measles (Rubeola), and German measles (Rubella) can be spread easily in the air (Eickhoff 1993). Respiratory syncytial virus and adenoviruses have been shown to be spread via the airborne route in pediatric wards (Hall 1981).

Employees and visitors can also become significant sources of airborne infection among patients. Airborne droplets often carry bacteria such as *Staphylococcus aureus* (*S. aureus*), *S. epidermidis*, and gram-negative rods, which are common causes of postoperative wound infections.

Casewell (1998) reports that *S. aureus* is one of the most important causes of surgical site infection in the United States. Furthermore, development of methicillin- and vancomycin-resistant strains of *S. aureus*, termed MRSA and VRSA, respectively, has seriously complicated treatment. Although MRSA is generally thought to be spread through direct contact, it is felt that patients can release droplets and contaminate the surfaces in their environment, thereby requiring better isolation techniques.

Other infectious diseases can be easily transmitted by ventilation systems, during renovation, or by plants. Cases of nosocomial infection with *Aspergillus* have been reported in immunocompromised patients (Rhame 1991). Furthermore, activity such as building construction and renovation that may be removed from the patient care area has been shown to increase the airborne concentration of fungal spores and the incidence of aspergillosis in immunocompromised patients (Overberger et al. 1995, Dewhurst et al. 1990). Table 65.1 shows relationships of airborne concentrations of *Aspergillus fumigatus* to infection rates under various conditions. Spores may also enter a patient's room from clothing, potted plants, or infiltration through windows.

TABLE 65.1 Airborne Concentration of *Aspergillus Fumigatus* and Infection

Study	Conditions	Concentration, cfu/m ³ *	Infection rate, %
Lentino et al. 1982	Baseline	<1.0	0.0
Lentino et al. 1982	During construction	†	1.6
Arnow et al. 1991	Baseline	<0.2	0.3
Arnow et al. 1991	Epidemic	1.1–2.2	1.2
Rhame et al. 1984	During construction	0.9	5.4
Sheretz et al. 1987	Baseline	0.009	0.0

*cfu/m³ = colony-forming units per cubic meter.

†Surface concentration on window air-conditioner filter ranged between 400 and 2800 spores/cm².

65.3 EMERGING HAZARDS

Latex

It is widely recognized that exposure to latex allergen can cause local reactions such as urticaria upon contact. Because latex allergen can trigger Type I immune mechanisms, it can cause allergic rhinitis, conjunctivitis, wheezing, and bronchospasm upon inhalation. With severely sensitized people, exposure to latex allergen can cause anaphylactic or systemic effects, such as tachycardia, hypotension, and bronchial constrictions.

The estimates of latex allergy risk for HCWs range from approximately 3 to 10 percent (USFDA 1991, Grzybowski et al. 1996), whereas that for the general population (non-HCW) is generally less than 1 percent. A dramatic increase in the number of HCWs that acquired sensitivity to latex proteins in the early 1990s is apparently related to the increased use of various latex glove products required by implementation of universal precautions in 1988.

Detailed evaluations of latex aeroallergens in medical centers have been published by several investigators (Swanson et al. 1994, Heilman et al. 1996) and covered in more detail in Chapter 41. High levels of latex allergen (ranging from 14 to 208 ng/m³) were consistently found in areas where powdered, latex gloves were used in high numbers (e.g., operating rooms, urology areas, orthodontics clinics and blood bank clinics), as opposed to areas where glove use was minimal (concentrations <2 ng/m³). Personal samples were generally 8 to 10 times higher than area samples collected concurrently.

Exposures can be effectively controlled by substituting powder-free, low-allergen latex gloves or nonlatex gloves for the high allergen content gloves. Generally detailed cleaning of high glove-use areas is also required after the glove conversion to remove reservoirs that may remain (e.g., above ceilings, in and around ductwork, and on equipment surfaces) to ensure that extremely sensitive individuals can remain at work. Additionally, it is important to develop latex guidelines in conjunction with the occupational health department to provide effective management of sensitized employees (Sussman and Gold 1996).

Surgical Smoke

Lasers are widely used in a number of surgical applications. Lasers can reduce trauma to surrounding tissue and promote healing by cauterizing small blood vessels. With the increased practice of laparoscopic procedures, lasers are being used more frequently for microsurgical operations. Lasers also find use in various dermatological procedures and more recently in a number of dental procedures.

Because lasers work by transferring electromagnetic energy into tissue, a heated plume containing particles, gases, and tissue debris is released from the point of incision. The heating and burning of flesh will release a wide variety of acrid smelling and irritating gases and particles. Aldehydes, including acrolein and formaldehyde, volatile organic compounds, and polynuclear aromatic hydrocarbons, are among some of the odorous and irritating compounds released into the breathing zone of the surgical team. Mucous membrane irritation has also been reported from the high concentrations (e.g., >8 mg/m³) of respirable particles that are released as well.

Concern regarding organic debris in the laser plume has been debated for over 10 years with no definitive resolution. The potential for aerosolization of malignant cells, bacteria, and viruses has been assessed by many investigators. Bellina and colleagues looked at the potential hazard to operating room personnel when irradiating tumors with a carbon dioxide (CO₂) laser (Bellina et al. 1982). Metabolic and cytologic examination of cellular debris showed there was no cytoplasmic or nuclear activity detected. Nezhat and colleagues characterized the smoke plume extracted from the abdominal cavity of patients undergoing laser endoscopic

treatment for endometriosis and adhesions (Nezhat et al. 1987). They concluded that viable cancer cells could not exist in the plume.

Walker and colleagues inoculated strips of human skins with viable bacilli (Walker et al. 1986). Using both pulse and continuous CO₂ lasers, they demonstrated dissemination of viable particles. This has implications for treatment of infectious lesions as well as for dental and dermatological procedures that may be done in an outpatient clinic that may not have the high ventilation rates of surgical operating rooms.

Baggish (1991), Garden and colleagues (1988), and Sawchuck and colleagues (1989) provide evidence that particles, mutagens, and viral materials exist in laser plumes. Therefore, there is sufficient evidence to consider laser and electrosurgery procedures as potential risks for patients and medical personnel. It is important that appropriate smoke extraction systems be used to control the plume at the source. Furthermore, surgical teams should consider upgrading their personal protective equipment to include full face shields and improved respiratory protection (i.e., a 95 percent efficient mask/respirator).

Anesthetic Gases

Exposure to anesthetic gases is a significant concern at all medical institutions. The six anesthesia agents presented in Table 65.2 represent the major agents used in the United States today.

Several studies have indicated that exposures by second- and third-trimester pregnant women to nitrous oxide at levels exceeding guideline values can increase the risk of spontaneous abortions, stillbirths, and congenital abnormalities in their children. There are also several epidemiological studies that indicate exposure to nitrous oxide might also be responsible for increases in hepatic and renal disease (Buring et al. 1985, Rogers 1986, Cohen et al. 1991).

The health effects reported for the other halogenated anesthesia agents listed in Table 65.2 include psychomotor difficulties and hematopoietic, central nervous, hepatic, and renal system diseases and dysfunction.

HCWs are typically exposed to anesthetic agents as a waste gas stream or as a fugitive gas. A waste anesthetic gas (WAG), for example, is exhaled by an anesthetized patient either during or after a procedure, or WAG can leak from the exhaust side of the anesthesia administration apparatus. A fugitive anesthetic gas is gas that has escaped from any system that is functionally upstream of the patient (i.e., the vaporizer/ventilator, the high pressure nitrous oxide supply system outlets, or an HCW's poor work practices).

TABLE 65.2 Major Anesthetic Agents Used in the United States and Relevant Exposure Limits

Agent	Limit, ppm	Reference*
Nitrous oxide	50	ACGIH 8-h TLV-TWA
	25	NIOSH 8-h REL-TWA
Halothane	50	ACGIH 8-h TLV-TWA
	2	NIOSH 60-min REL-C
Enflurane	75	ACGIH 8-h TLV-TWA
	2	NIOSH 60-min REL-C
Isoflurane	No established guideline	
Methoxyflurane	2	NIOSH 15-min REL-C
Suprane	No established guideline	

*TLV = threshold limit value; TWA = time-weighted average; REL = recommended exposure limit; C = ceiling value (never to be exceeded).

Waste anesthetic gases can be effectively controlled by the proper use of a vacuum scavenging system that is typically situated in the anesthesiologist's station (Gilly et al. 1991, Burkhart and Stobbe 1990). WAGs that are emitted in surgical recovery units are potential sources of exposure to HCWs, especially near the breathing zone of patients immediately after their arrival in the recovery area. In this situation, general room ventilation is used to control exposures. Therefore, it is imperative that there be adequate amounts of outside air supplied to effectively reduce WAG concentrations and to ensure that there is no "short-circuiting" or dead spaces in the room.

Fugitive anesthetic gases are best controlled by elimination at the source (i.e., tightening fittings, reducing leakage around seals, and improving work practices). Routine evaluations must be performed to determine the presence of these leaks. Generally the high ventilation rates found in operating rooms (i.e., 15 to 20 air changes per hour) are sufficient to control low-level leaks to below threshold limits. Exposure concerns arise in the area directly adjacent to the leak or if ventilation system deficiencies reduce the effective ventilation rate.

Aerosolized Medications

A wide variety of medications are being supplied as aerosols and delivered via the inhalation route because of increased efficacy in treating various diseases. Materials such as Ribavirin, Pentamidine, Amphotericin, Colistin, DNase, Gentomycin, and Tobramycin, among others, are given routinely in many hospitals across the United States. Although much information may be available regarding efficacy of the medication as treatment, there is generally little information regarding impacts of exposure on HCWs. Control of aerosolized medications is worthy of additional discussion.

Ribavirin is an antiviral agent used for the treatment of RSV infection. The drug has been shown to be teratogenic in some animal species (Kochar et al. 1980, Fernandez et al. 1986, Kilham and Ferm 1997), and therefore, detailed policies regarding administration have been developed to minimize HCW exposure. No occupational exposure standard has been recommended by OSHA, NIOSH, or the American Conference of Governmental Industrial Hygienists (ACGIH). The California Department of Health Services has recommended a limit of $2.7 \mu\text{g}/\text{m}^3$ as an eight-hour time-weighted average (TWA). This was based on taking the no-observed-effect level (NOEL) in the most sensitive animal species and applying a safety factor of 1000 (CA DOHS 1988). NIOSH (1992) during a Health Hazard Evaluation at a Florida Hospital found airborne concentrations of Ribavirin ranging from nondetectable to $28.2 \mu\text{g}/\text{m}^3$ during patient administration using a variety of engineering controls.

Minimization of HCW exposure requires a combination of administrative and engineering controls be employed (NIOSH 1992). Ideally a fully enclosed scavenging system will minimize release into the general room environment. All rooms in which Ribavirin is administered should conform to American Institute of Architects (AIA) guidelines for total air exchange rates and be negative with respect to adjoining spaces during and following administration. People entering the room should wear appropriate personal protective equipment, including high-efficiency particulate air (HEPA) filtered respirators, nonsterile gloves, a disposable jumpsuit, hair and foot covers, and goggles. Most importantly, appropriate training must be provided to HCWs to educate them about the potential risks of Ribavirin and the appropriate methods to control and minimize exposures.

Other aerosolized medications do not have the same health effects data that Ribavirin does. Very little is known about the mutagenic or teratogenic effects of certain medications. However, anecdotal reports indicate that some HCWs experience symptoms of scratchy throat, burning eyes, rashes, and irritation and exacerbation of certain allergies under prolonged exposure to these aerosols.

As with Ribavirin, appropriate engineering controls can be very effective in limiting exposure. Until a specific medication can be conclusively shown not to have health effects, a cautious and protective approach to using aerosolized medical therapies must be followed. Nebulizers should have absolute filters on their exhaust leg and HCWs must wear N-95 respirators or better as well as gloves, eye protection, and precaution gowns when administering aerosolized medications.

65.4 ENVIRONMENTAL CONTROLS

Hospitals, by virtue of their unique functions both as a healing service environment and as a nurturing social environment, pose significant challenges for controlling contaminant exposures. When considering control strategies and interventions, approaches beyond dilution with ventilation air must be considered. Innovative solutions may be employed, but they must be well designed and tested because reliability is critical. The modern health care modality is to improve patient outcome through the use of technology, thereby placing significant pressure on controls because more acute patients may require more aggressive treatment. Nevertheless in applying more advanced control systems to protect workers and patients, it remains useful to consider the hierarchy of environmental control, which is substitution, isolation, ventilation, and personal protection. Many times these techniques are employed in combination to ensure the maximum protection under an often informal “risk-benefit” analysis. Development of a better risk assessment/risk management process is becoming increasingly important in the highly complex and evolving hospital environment to ensure adequate resources and appropriate levels of information are provided to occupants.

Substitution

Although there have been many successful examples of product substitution in the medical environment, perhaps the most significant, current example is the substitution of nonpowdered latex or alternative glove products for powdered latex glove products. This product substitution action has resulted in many hospital environments seeing an immediate and dramatic reduction, often to levels $<1 \text{ ng/m}^3$, of airborne concentrations of latex allergen.

Another effective substitution program involves replacing glutaraldehyde, used as a cold sterilant, with equipment that uses periacetic acid in a closed system. This process has generally been found to be capable of disinfecting approximately 90 percent of instruments used in an operating room, thereby dramatically reducing the amount of glutaraldehyde used.

Material substitution, although often highly effective, must be carefully considered before implementation. Sometimes there can be significant unforeseen and detrimental impacts on patient care, personal protection, or equipment stability when alternative products are substituted. Having appropriate review from user groups, occupational health, infection control, health and safety and materials management, among others, can often help in avoiding problems.

Isolation

Being able to reduce or eliminate exposure to harmful materials through the manipulation of physical space is a very effective means of control. Isolation as it is commonly used in hospitals has the following two different yet related definitions:

1. Positive Pressure

- a.** Protective isolation is used to reduce the exposure of highly susceptible individuals to contaminants of concern. This is most commonly used in controlling exposures to fungal contaminants in those who are immunosuppressed such as lung transplant or bone marrow transplant (BMT) patients or other such susceptible populations through the use of some or all of the following techniques: maintaining positive pressure in patient rooms, use of anterooms and/or air-locks, use of HEPA filtration and or laminar flow in patient rooms. These techniques have been shown to be extremely effective in controlling exposures to invasive aspergillosis in susceptible populations (Streifel 1996).
- b.** Specialized activity areas. Many hospitals utilize laminar air flow (LAF) areas for preparation of specialized medication, such as the laminar flow hood, commonly found in pharmacies, and in certain procedure areas such as in operating rooms.

Operating rooms are designed to be positively pressurized, have a high air exchange rate, and provide highly filtered (>95 percent) air vertically directed toward the surgical site (ASHRAE 1995). The goal of this design is primarily infection control where bacteria from the surgical team's activities is dispersed with clean air, and bioaerosols from adjacent spaces and outdoors are prevented from entering. Although the concept is straightforward, maintaining the flow field is difficult in practice due to numerous factors including impediments to flow and thermal buoyancy around the surgical site due to high-intensity lamps, people, and equipment. Luscuere and colleagues (1993) demonstrated through computational fluid dynamics that the area under the high-intensity lamps, generally the wound area, is often one of the most contaminated areas in the room due to disruption of the downflow field by the physical obstruction and thermal gradients cause by the lamp.

2. Negative Pressure

- a.** Negative pressure isolation rooms are used for patients who have infectious diseases that can be transmitted through the air. A well-known use for these rooms is to house patients that have infectious TB. To maintain negative pressure between these rooms and adjoining spaces requires them to be well sealed and have exhaust exceed supply by approximately 15 percent. Air should be exhausted directly to the outdoors and care taken to avoid possible inadvertent exposures by reentrainment through outside air intakes. Any air from these rooms to be recirculated should pass through HEPA filters prior to reintroduction. Of course, great care must be taken to ensure that the filters meet their required performance as installed. CDC (1994) recommends a minimum of 12 ACH for new or renovated spaces. Table 65.3 presents a summary of pressure and airflow recommendations for TB isolation. Supplemental, local controls such as UV lights and portable filters may also be used to reduce airborne bacteria levels in these rooms. Chapter 47 presents more in-depth information on the effectiveness of various TB exposure control measures. However, even with these supplemental controls in place, personnel must use appropriate personal protection while in the room, and it is essential that these rooms be maintained at negative pressure to minimize exposures to those in adjacent spaces.
- b.** Specialized containment areas are used more and more in today's advanced hospitals. As with the previous description of control measures, they commonly use a combination of pressure differentials, localized controls, and appropriate ventilation rates to provide effective controls of these special use areas. Examples include special procedure rooms where certain medicated aerosols, such as Ribavirin, are administered or where bronchoscopy is performed. Often these can be accommodated through the use of negative pressure isolation rooms. The use of supplementary controls, such as containment hoods or "demisters," stand-alone HEPA filters, or isolation booths can be useful but need to be carefully evaluated for efficacy for various applications.

TABLE 65.3 Summary of Pressure and Airflow Recommendations and Requirements for TB Isolation Rooms in the United States

	ASHRAE (1995)	Centers for Disease Control and Prevention (CDC 1994a)
Negative pressure	Yes	Yes 0.25 Pa (0.0001 in. H ₂ O)
Exhaust to outside	Yes	Yes
Air recirculation	No	No (In existing facilities: yes with HEPA filtration)
Minimum total air changes per hour (ACH)	6 h ⁻¹	Existing facilities: 6 h ⁻¹ ; new or renovated facilities: 12 h ⁻¹
Minimum outside ACH	2 h ⁻¹	None stated
Airflow recommendations	None	Exhaust: 10% or 24 L/s (50 ft ³ /min) greater than supply

General Ventilation

In addition to maintaining thermal comfort, general ventilation is used in hospitals to dilute odors, improve general hygiene conditions, and as an adjunct to various treatments. For example, burn patients benefit from a warm and humid environment whereas cardiac patients benefit from a cooler environment. In the United States, hospital ventilation design guidelines and standards are provided by the AIA (1993), ASHRAE (1999) in its applications chapter and in *Guidelines for Acceptable Indoor Air Quality* (ASHRAE 62-1999), and the Centers for Disease Control (CDC 1994a, 1994b). Table 65.4 provides a comparison of the current guidelines.

As has been demonstrated in this chapter, ventilation systems play a critical role in controlling diverse environments throughout the hospital. The complex interaction between different areas places stringent demands for well-thought-out and implemented design, operation, and maintenance programs.

Operating a hospital ventilation system is costly, but efforts to conserve energy should not compromise patient health and comfort or protection of HCWs, the very objectives for which they are specified. For example, variable air volume (VAV) systems are commonly found in hospital settings. Because room temperature is maintained by adjusting supply airflow, there can be a degradation in air quality when thermal conditions are met and the VAV units go to a minimum set point, thereby reducing general dilution. Furthermore, if not carefully designed, installed, and operated, VAV systems can adversely affect maintenance of appropriate pressure relationships between adjacent areas.

Personal Protection

Personal protective equipment can mean many things in the hospital setting. It can involve the use of respirators to supplement engineering controls to minimize exposure to various agents such as Ribavirin and EtO, the use of appropriate gloves as barrier protection in handling potentially contaminated body fluids or medications such as various antineoplastic agents, and the use of face shields, goggles, and so forth, to eliminate exposure through splashback of contaminants or to protect eyes from electromagnetic radiation during laser usage. What is critical is to ensure that appropriate procedures are followed to provide the maximum level of safety for HCWs.

TABLE 65.4 A Comparison of Current Ventilation Guidelines in the United States

Area	ASHRAE Standard 62-1999			ASHRAE Handbook (1999)			AIA Guidelines (1993)		
	Outdoor air, L/S/person	Estimated maximum occupancy, P/100 m ²	Outdoor air calculated,* ACH	Min. OA, ACH	Min. total air, ACH	Pressure relationship†	Min. OA, ACH	Min. total, ACH	Air required to be exhausted directly to outdoors

Negative	N/A	N/A	N/A	2	6	N	2	12	Optional

*Calculated by assuming typical dimensions and given occupancy.

†P = positive; N = negative; E = equal; ± = continuous directional control not required.

The use of personal protection in the health care field is an essential component of a health and safety program but should be viewed as an adjunct to engineering and administrative controls, not as a substitute. Furthermore, the unique nature of the health care field often complicates the selection of certain pieces of personal protective equipment. For example, in operating rooms a simple half-face respirator cannot be used when a TB-positive patient is being operated upon due to the possibility of contamination of the surgical site by bacteria released through the exhalation valve. Another example has to do with selection of appropriate glove material when handling certain chemicals such as antineoplastic agents in the OR. Steps must be taken to ensure the barrier effectiveness is maintained to control exposures to both bloodborne pathogens and the chemical being used.

65.5 CONCLUSION

The health care industry in the United States is changing dramatically. There is a resurgence of some old diseases and the emergence of new viruses. New technologies, treatment protocols, and medicines are being introduced and employed in health care facilities to improve patient care. Work patterns are changing, with many HCWs working longer shifts and often bearing greater responsibilities. The pattern of patient occupancy is also changing, generally toward those patients with increased acuity, which also has the impact of increasing the demand on the health care workers and the health care system.

After 40 years of responding to antibiotics, some bacteria have mutated to drug-resistant strains, requiring implementation of special precautions to limit their spread in the hospital population. The increased prevalence of atopy has accompanied the proliferation of antibiotics in medicine. Sensitization to materials such as latex allergen or glutaraldehyde and complex exposures to other contaminants makes the health care work environment different from others.

New procedures or requirements in one area may have unforeseen impacts in another (e.g., the institution of universal precautions dramatically increasing latex glove usage and thereby increasing the risk of sensitization). It is essential that health care institutions maintain vigilance in actively tracking symptoms and trends to be able to avoid unnecessary exposures for health care workers, patients, and visitors. In addition to evaluating building systems, a deeper understanding of personal, microenvironmental exposures to occupational hazards that are so important in the health care industry must be developed.

These emerging problems will also increase the demand placed on the physical environment. Hospital ventilation systems may have to be more flexible and reliable in the future. For effectiveness reasons, hospital ventilation systems must be integrated into an overall environmental management program that includes advanced environmental surveillance programs, material and product review and selection, and utilization of comprehensive diagnostic procedures. Previously, the emphasis was on patient care and infection control. As we move into the twenty-first century, hospitals must now also see the overall healthfulness of the indoor environment for both patients and health care workers as a primary concern.

CHAPTER 66

RESIDENTIAL EXPOSURE TO VOLATILE ORGANIC COMPOUNDS FROM NEARBY COMMERCIAL FACILITIES

Judith S. Schreiber, Ph.D.

Bureau of Toxic Substance Assessment
Troy, New York*

66.1 INTRODUCTION

Residences and commercial facilities may be in close proximity. This chapter addresses the resulting exposures to residents of nearby housing. Elevated levels of tetrachloroethene, a solvent used in dry cleaning, have consistently been found in residences located in the same building as dry-cleaning facilities. Many other facilities use volatile organic compounds (VOCs) in mixed commercial/residential areas. Such facilities include furniture refinishing and upholstery shops, automobile painting and auto body repair shops, beauty shops, printers, and repair shops. When facilities are small and use limited quantities of VOCs, they are exempt from pollution control requirements and often use no emission controls. Air samples from 11 facilities, residences, and commercial neighbors showed elevated concentrations in the indoor air of residences and businesses located in the same building as the commercial facility. Highly elevated levels of methylene chloride were found in the indoor air of neighbors of furniture refinishing and textile screen printing facilities. Other VOCs found to be elevated in the indoor air of neighboring residences and businesses were tetrachloroethene (textile screen printing), hexane (shoe repair shop), toluene (furniture refinishing and shoe repair), and 1,1,1-trichloroethane (photoprocessing/camera repair shop and a nail salon). Methylene chloride, hexane, and 1,1,1-trichloroethane all have high odor thresholds, so people can be exposed to high levels of these VOCs without smelling them. VOC levels in outdoor air and the indoor air of residences not located in the same buildings as the study facilities were, with a few exceptions, similar to background levels reported in other studies.

Facilities using VOCs may release chemicals via fugitive and vented emissions in sufficient quantities to significantly increase the VOC concentrations in the air of residences and

businesses located in the same building as the commercial facility. A number of studies have focused on the contribution of indoor air to VOC exposure. The USEPA Total Exposure Assessment Methodology (TEAM) study (Wallace 1987) found that in randomly selected U.S. residences the indoor air concentrations of VOCs almost always exceeded the concentrations of VOCs in outdoor air. New York State Department of Health (NYSDOH) studies of indoor air quality in residences and businesses near dry-cleaning facilities (Schreiber et al. 1993, NYSDEC/DOH 1993) have found highly elevated concentrations of tetrachloroethene, the dry-cleaning solvent, in both indoor and outdoor air at these locations. Indoor air concentrations almost always exceeded outdoor air concentrations in the same area. Also, most people spend the majority of their time indoors, at home or at work (USEPA 1990a). Therefore, indoor air is likely to contribute more to VOC exposure than outdoor air.

The first NYSDOH investigation on tetrachloroethene levels in residences near dry-cleaning facilities began in response to odor complaints by a family with an infant who lived in an apartment directly above a dry-cleaning facility. The investigation found tetrachloroethene concentrations up to $200,000 \mu\text{g}/\text{m}^3$ in the indoor air of the residence.

A more extensive study of apartments in dry-cleaner buildings in the Albany, NY area in 1991 by NYSDOH and the New York State Department of Environmental Conservation (NYSDEC) also found clearly elevated tetrachloroethene concentrations up to $55,000 \mu\text{g}/\text{m}^3$ (Schreiber et al. 1993). Both day and night 12-h indoor and outdoor air samples were significantly elevated compared to controls. Subsequent NYSDOH investigations in New York City and elsewhere in the state also revealed elevated levels of tetrachloroethene in almost every apartment studied that was in the same building as an operating dry-cleaning facility. Elevated levels of tetrachloroethene were found even on floors distant (e.g., on the 12th floor of an apartment building) from the dry-cleaning facility operating on the first floor.

Businesses other than dry cleaning may also release enough VOCs to increase neighbors' exposure. In 1992, a NYSDOH investigation in a residential apartment above a small shoe repair shop found elevated levels of hexane ($1030 \mu\text{g}/\text{m}^3$) and toluene ($1500 \mu\text{g}/\text{m}^3$), which are solvents in the glues used for shoe repair. These concentrations were measured after some remedial measures had already been taken at the facility and odors were no longer detectable in the residence.

Many other facilities use VOCs in mixed commercial/residential areas. Such facilities include furniture refinishing and upholstery shops, automobile painting and body shops, beauty shops, printers, and machine shops. When facilities are small and use limited quantities of VOCs, they are exempt from pollution control requirements and seldom use emission controls. Such facilities are also often in residential areas where there is a rapid turnover of tenants and correspondingly less chance of complaints to local health departments. Some of the VOCs have high odor thresholds, so people can be exposed to high levels of certain VOCs without smelling them. As a result, residents may be exposed to high VOC concentrations without their knowledge.

Numerous studies have investigated indoor residential VOC levels related to personal activities within the home, such as smoking, cooking, cleaning, use of deodorizer, painting, arts and crafts, and storage of dry-cleaned clothes, in addition to other factors such as the presence of an attached garage or the residents' occupation (Thomas et al. 1991, 1993; Wallace 1987; Howard and Corsi 1998; Clobes et al. 1992). Many studies have also measured VOC exposures in occupational settings such as shoe manufacturing (Periago et al. 1993), furniture refinishing (Shusterman et al. 1990), and gasoline stations (Backer et al. 1997, Mannino et al. 1995). However, there is very little published information on the impact of small commercial or industrial facilities on the indoor and outdoor air quality of neighboring residences. One study (Heudorf and Hentschel 1995) measured benzene, toluene, ethylbenzene, and xylene levels outdoors and inside 32 apartments, some near gas stations, in Frankfurt, Germany. Mean and maximum levels of benzene were higher in apartments near gas stations. The other compounds were not elevated in apartments near gas stations, but toluene was elevated in apartments near paint stores.

66.2 NEW YORK STATE DEPARTMENT OF HEALTH INDOOR AIR STUDIES

Selection of Facilities

Facilities were selected for study according to the potential to cause occupational and residential exposure to VOCs. Other than NYSDOH dry-cleaning facility studies, we found no published information on the relationship between workplace VOC concentrations and resultant residential indoor air concentrations. Locations were identified on the basis of several of the following criteria:

- Industries reported by the U.S. Occupational Safety and Health Administration (OSHA) in which workplace measurements of VOCs exceeded 50 percent of the permissible exposure limit (PEL)
- Industries which use VOCs that have poor warning properties [odor threshold higher than the PEL or threshold limit value (TLV)]
- Industries located in the Capital District of New York State (Albany, Schenectady, Rensselaer counties) with residences in the same building

To evaluate chemical use by industry, we used data from the U.S. Occupational Safety and Health Administration (OSHA 1989, IMIS 1992). OSHA lists chemicals used in each industry by Standard Industrial Classification (SIC) category, but does not provide quantities of chemicals used. Each individual facility within the SIC code may not use all of the chemicals reported for that SIC code. Chemicals used by small businesses may be under-represented since businesses may not be required to report small quantities to OSHA.

The chemical characteristics that were evaluated were toxicity (indicated by TLV or PEL) and warning properties (odor threshold). Chemicals with a relatively low TLV or PEL and high odor threshold concentration in air are of particular concern because substantial exposure can occur without the residents detecting an odor. Neighbors may be exposed to elevated concentrations but are not likely to complain about odors. Chemicals meeting this criterion for which the threshold odor concentration exceeds the TLV include benzene, carbon tetrachloride, hexane, methylene chloride, and methyl chloroform (1,1,1-trichloroethane).

Occupational exposure was assessed with the OSHA Integrated Management Information System (IMIS 1992), which provides data by SIC code on measured 8-h time-weighted average (TWA) workplace exposures to specific chemicals in relation to the permissible exposure limit. Many of these chemicals are associated with adverse human health effects, including noncancer endpoints and carcinogenic effects. Few of the measurements made in these workplace inspections exceeded the PELs. Industries for which chemicals used in the workplace exceeded the PEL are more likely to impact the air quality of proximate residential or business neighbors. However, on the basis of previous experiences with evaluation of dry-cleaning facilities, a facility may have air contaminant concentrations below the PEL and still have an adverse effect on air quality in proximate residences.

Industries where IMIS (1992) reports that the PEL has been exceeded in the workplace include the following: SIC 2512, *reupholstered household furniture*; SIC 2751, *commercial printing*; SIC 3471, *plating and polishing*; SIC 2891, *adhesives and sealants*; SIC 1721, *painting and decorating*; and SIC 7641, *furniture stripping*. Industries where some percentages of the TWA samples measured in the workplace exceed 50 percent of the PEL include the following: SIC 7332, *blueprinting and photocopying*; SIC 7539, *auto body repair shops*; SIC 7395, *photofinishing labs*; SIC 2753, *engraving and polishing*; SIC 2752, *commercial printing and lithography*; SIC 7219, *laundry/garment services*; SIC 7699, *repair services*;

SIC 7299, *miscellaneous personal services* (which includes nail salons). Category 7219 facilities were studied in previous NYSDOH investigations [see Schreiber et al. (1993)].

Facility location was determined by field surveys. To first determine which industries were located in the study area, information on the numbers of businesses in the selected SIC industrial categories was obtained from the New York State Department of Economic Development. In addition, the staff reviewed the Yellow Pages of the NYNEX telephone books for the Capital District. We found many businesses using VOCs listed in the Yellow Pages.

In fall 1993, under the guidance of the NYSDOH, students at the State University of New York at Albany (SUNY Albany) conducted site surveys of facilities identified from the Capital Region Yellow Pages to determine which were located near residences. The facilities surveyed included auto body, commercial printing, photoprocessing, and shoe repair shops. The students used a site survey form which included the following information: building construction (brick, wood frame, or concrete), number of floors, number of apartments in the building, location of emission stacks, location of sensitive populations (hospitals, schools, day-care centers, and senior citizen housing), neighborhood setting (residential, commercial, industrial, or mixed), and number of apartments in adjacent structures. NYSDOH staff surveyed other industry types, including nail salons, furniture refinishing, and textile screen printing as well as additional auto body repair, commercial printing, photoprocessing, and shoe repair facilities in the Albany area not previously surveyed by the SUNY Albany students.

On the basis of the criteria noted above and the results of field surveys, the industries in Table 66.1 were selected for study.

Contact with Study Participants

After completing the site surveys, NYSDOH staff requested facility owners and/or operators, building owners, and residential and/or business tenants to participate in the study. In

TABLE 66.1 Summary of the Number of Facilities Surveyed and Sampled by Facility Type

	Furniture stripping/ repair	Photo-finish	Shoe repair	Nail salon	Textile screen printing*	Offset printing†	Auto-body repair	Totals
Facilities listed in Yellow Pages for Capital Region	14	48	29	40	26	130	154	441
Facilities surveyed	14 (100%)	26 (54%)	15 (52%)	23 (58%)	6 (23%)	65 (50%)	74 (48%)	223 (51%)
Facilities surveyed with residences	1 (7%)	2 (8%)	8 (53%)	5 (22%)	2 (33%)	3 (5%)	0 (0%)	21 (9%)
Facilities sampled	1	1	1	1	2*	3†	2	11

*One textile screen printer was located outside the New York State Capital District.
†One of the three offset printing facilities sampled had apartments in the same building.

most cases, facilities with residences in the same building were selected. Auto body repair shops colocated with residences in the same building were not found. For auto body repair shops, adjacent residential buildings and/or nearby large apartment buildings were selected. While selecting potential auto body shops, the staff noted the location of outdoor vent stacks in relation to the neighboring residences to select those residences most likely impacted by outdoor emissions from these facilities. The other facility types all had residences located in the same building. The 11 facilities listed in Table 66.2 agreed to participate in the study.

Product Inventories

Prior to sample collection, staff conducted an inventory of the facilities to identify chemicals used. When available, the following information was recorded for each product: product name, product number, manufacturer, manufacturer address and phone number, chemical ingredients, CAS (Chemical Abstracts Service) number, and percent weight of each chemical. For products with missing chemical information, staff contacted the manufacturer for Material Safety Data Sheets (MSDSs). During the product inventories, they interviewed the facility operator/owners to determine which products were used most often and during which processes.

Air Sampling

When residents were contacted to schedule a sampling date, an explanation of the sampling procedure was provided by NYSDOH personnel. Residents were asked not to introduce freshly dry-cleaned clothes or furnishings into the dwelling during the week before the sampling date. We recommended that the use of other VOC-containing consumer products be avoided during the week before the sampling date, including the use of tobacco products. The sampling protocol stipulated that windows and doors should be closed for the 24-h period prior to sampling. The facility operator was notified of the sampling date and time and was requested to operate processes that use VOCs during the sampling period.

TABLE 66.2 Summary of Study Facilities and Residential/Business Neighbors

Facility code	Facility type	Residences same building	Residences separate building	Other businesses same building

AB-2	Auto body repair	0	9	0

*Not applicable.

Air samples were collected with 6-L evacuated stainless-steel SUMMA canisters with flow controllers using EPA compendium method TO-14 (USEPA 1988). One indoor air sample was collected in the study facility and in each nearby residence or business that participated. One outdoor air sample was collected near each facility, except for the auto body facilities, where outdoor samples were collected between the facility and each of the two neighboring residential buildings. Sample locations within residences and neighboring businesses were based on where odors were strongest or where, if ever, they had been reported in the past. All air samples at a facility and its neighbors were collected during the same 4-h time period. During this period, NYSDOH staff checked to ensure that the facility was operating a process that used VOCs. At one facility (photoprocessing/camera repair), air samples were collected for formaldehyde analysis using method APC-29a (NYSDOH 1981).

During sample collection, NYSDOH staff used portable flame and/or photoionization detectors (FID/PID) to monitor total VOC levels at all sampling locations. The FID/PID monitors were also used to investigate potential pathways for fugitive emissions from the facilities to nearby residences and businesses such as pipe chases and hallways.

Field Questionnaires

On the sampling day, NYSDOH staff completed both facility and residential questionnaires. The facility questionnaire includes information about facility operations such as permit requirements, chemical use and disposal, process and emission control equipment, building construction, and ventilation. Also, the staff noted activities in the facilities at the time of sampling and recorded the quantity and type of products used. The residential questionnaire included information on building characteristics (airtightness and heating/cooling system); household activities prior to and during sample collection; location, type, and intensity of any chemical odors; and a list of chemical products used in the home. The staff also sketched floor plans for both the facility and residences and site maps for the auto body facilities showing the location of the outdoor samplers in relation to any exhaust vents in the facility.

Sample Analysis

All samples were analyzed by the Wadsworth Center of the NYSDOH. The canister samples were analyzed by gas chromatography–mass spectrometry according to procedures in *USEPA Compendium Method TO-14* (USEPA 1988). Air samples from the first nine facilities were analyzed for 13 VOCs: chloromethane, methylene chloride, hexane, chloroform, carbon tetrachloride, benzene, trichloroethene, toluene, tetrachloroethene, ethylbenzene, *m/p*-xylenes, *o*-xylene, and 1,1,1-trichloroethane. The analysis was expanded to 40 VOCs for the last two facilities studied (the nail salon and a textile screen printer). The detection limits ranged from 1 to 7 $\mu\text{g}/\text{m}^3$. Formaldehyde in samples from the photo processing facility were analyzed by method APC-29a (NYSDOH 1981).

66.3 NYSDOH AND USEPA RESULTS

Tables 66.3 through 66.9 summarize the results of the canister samples. Each VOC shown in those tables was detected at an elevated level compared to the USEPA median background level in at least one sample. Other analytes are not shown in the tables; most were

not detected, and some were detected at levels similar to or below USEPA median background levels.

Residences and businesses located in the same building as the facilities using VOCs had elevated indoor VOC levels compared to background levels found in other studies by the NYSDOH and the USEPA. In buildings with furniture refinishing and textile screen printing facilities, indoor levels of methylene chloride in neighbors were 100 to 1000 times higher than median background levels. Indoor levels of other VOCs in neighbors of photoprocessing-camera repair, nail salon, and shoe repair facilities were 10 to 100 times higher than median background levels. Indoor VOC concentrations were not as elevated in neighbors of offset printers and auto body repair shops, but some indoor concentrations of VOCs were above median background concentrations. In contrast, most indoor VOC levels in neighbors that were not in the same building as the facility were similar to background levels.

Air samples for formaldehyde were collected at the photoprocessing/camera repair facility. The results were similar to USEPA background levels with $11 \mu\text{g}/\text{m}^3$ in the facility, $21 \mu\text{g}/\text{m}^3$ in the residence, and not detected ($<12 \mu\text{g}/\text{m}^3$) outdoors.

With a few exceptions as noted below, outdoor VOC levels at all facilities were similar to background levels. Some chemicals identified by product inventory at certain facilities (e.g., methyl methacrylate and acetone at the nail salon, and most photoprocessing chemicals) could not be analyzed by method TO-14.

Furniture Refinishing

Fourteen furniture refinishers in the Capital District were identified, and one had five apartments in the same building. The facility operator used a commercial-grade paint remover which contained significant quantities of methylene chloride (77 % by weight). The liquid paint remover was sprayed on several wood items and scraped off after being allowed to solidify. Later, the operator finished the items with wood stain containing petroleum distillates (85 % by weight). The work area had minimal ventilation via one floor fan, an open door, and a small exhaust fan vented outside the building. Heavily soiled carpet was present throughout the facility. Elevated levels of methylene chloride, toluene, ethyl benzene, and xylenes were measured in the facility, all three apartments tested (second and third floors), and the other business (upholstery) located in the same building (see Table 66.3). Methylene chloride levels in the neighboring residences and businesses were over 1000 times higher and toluene levels were over 10 times higher than background levels. The upholstery business used a small quantity of spray lacquer, which likely contributed to the levels of toluene measured in the building.

Textile Screen Printers

Of the six facilities surveyed, two had apartments in the same building. One was evaluated. Another facility was evaluated in western New York as a result of an odor complaint from a residential tenant in the same building. Both printers use a silk screening process with plastisol inks to apply lettering, logos, and insignia to sportswear such as T-shirts, jackets, and baseball caps. After silk screening, the printed items are placed in a special curing oven and "baked" for several minutes to harden the inks. The screen printers use a number of products that contain petroleum distillates such as silk screen openers, paint thinners, and washer solvents. They also use plastisol ink removers, which contain methylene chloride and tetrachloroethene. The ink remover is sprayed to remove ink smudges from textile items. Both facilities had inadequate exhaust ventilation in their work areas. One facility had a local

exhaust for the curing oven only. The other facility had an exhaust fan only for the general air within the facility.

Levels of methylene chloride and tetrachloroethene were highly elevated in the facilities and in the upstairs apartments (see Table 66.4). Methylene chloride levels in the residences were 200 to 300 times higher, and tetrachloroethene levels were 10 to 100 times higher than median background levels. Trimethylbenzenes were elevated in one of the residences (the air from the other residence was not analyzed for trimethylbenzenes), probably resulting from the use of petroleum-containing products.

Shoe Repair

Many of the shoe repair facilities in the Capital District are located with residences in the same building. Fifteen shoe repair shops were surveyed and the owners asked to participate, but only one agreed. The shoe repair shop used small amounts of cement and cement thinner, products which contained significant quantities of hexane and toluene (18 to 51 percent by weight). Additional products used in the shoe repair shop included shoe polish, leather dyes, and silicon spray products. There was no exhaust ventilation in the facility and the carpet was soiled.

Hexane and toluene concentrations were elevated in the facility and in the upstairs apartments compared to background indoor air levels reported by the USEPA (see Table 66.5). Hexane levels in the indoor air of the residences were over 100 times higher than background. These results are consistent with a previous NYSDOH investigation of residences above a shoe repair shop. Elevated levels of toluene and methylene chloride were found in the outdoor air sample. The outdoor air level of toluene was consistent with the shoe repair shop as a source, but the methylene chloride level outdoors was much higher than inside the shoe repair shop, and may not have been related to processes in the facility.

Offset Printers

The majority of offset printers in the Capital District were located in commercial areas; three were in buildings with residences. Of these three, only one facility agreed to participate. Two other offset printers with residences within 50 ft were also evaluated. Two types of printing processes—offset and screen—were identified during our survey. Different inks and solvents are used in the offset and screen printing processes. The three offset printers examined in this study used a variety of products which contain VOCs including inks, petroleum-based blanket wash, and alcohol-based fountain solutions, conditioners, and cleaners. One printer (PR-3) does both offset and screen printing, but during the sampling period did offset printing only. None of the offset printers had exhaust ventilation dedicated to the offset printing process or an exhaust for the general air within the facility. Two of the printers had soiled carpeting.

Slightly elevated levels of some VOCs (ethyl benzene, xylenes, toluene, 1,1,1-trichloroethane, and methylene chloride) were found in several businesses above the printers (see Table 66.6). Ethyl benzene and xylenes were elevated in the printers. In one of the buildings evaluated, the levels of many of these VOCs were higher in a neighboring business than in the offset printer shop. The neighboring business was a business machine repair shop and also used many products containing these VOCs, and likely contributed to the VOC levels found in the building. The residences sampled had levels of VOCs similar to background indoor air levels reported by the USEPA and were most likely not being impacted by the facilities.

Auto Body Repair Shops

Seventy-four auto body repair shops were identified in the Capital District, but none had residences in the same building. Two auto body shops located near five residences (30 to 50 ft away) were selected for study. Both facilities did limited auto body spray painting during sampling. The spray painting is a three-step coating process which was completed in the spray booth with local exhaust fans venting to the outside. A primer coat, a color coat, and multiple coats of clear urethane finish were applied. The vehicles were left to air-dry in the spray booth with the exhaust fan running. Toluene levels in the facility and outdoors were elevated compared to background outdoor air levels reported by USEPA (see Table 66.7). However, toluene levels in the residences were only slightly above background.

Other Facilities

Twenty-six photoprocessing facilities and two shops had residences in the same building. The one evaluated had both photoprocessing and camera repair services. Of the 23 nail salons surveyed, five had residences in the same building and one was evaluated. Air samples were collected in the two facilities and in apartments above both facilities. Many of the chemicals used in the nail salon (such as methacrylates) and in the photoprocessing facility could not be analyzed by method TO-14. The photoprocessing/camera repair shop used a spray degreaser containing 1,1,1-trichloroethane. The facility had no exhaust ventilation. The nail salon used an adhesive activator containing 1,1,1-trichloroethane. The facility had an exhaust for only the general air within the shop.

Levels of 1,1,1-trichloroethane and benzene were elevated in the photoprocessing/camera repair shop and the apartment above (see Table 66.8). Levels of 1,1,1-trichloroethane and toluene were elevated in the sculptured nail salon and in the apartment above (see Table 66.9). In residences above both facilities, levels of 1,1,1-trichloroethane were over 10 times higher than background levels. Benzene was slightly elevated and at similar levels in the photoprocessing/camera repair facility, the residence, and outdoors, making it difficult to determine the source of the benzene. No products containing benzene were found in the photoprocessing/camera repair facility.

66.4 DISCUSSION

Elevated levels of VOCs were found in several residences and businesses located in the same buildings as facilities using these VOCs. It was clear, in most cases, that elevated VOCs in neighboring apartments and businesses came from these commercial operations. Many facilities had inadequate ventilation for the processes that they were using. Few had exhaust hoods dedicated for processes using VOCs. Local exhaust ventilation drawing air directly from the process area to the outside could help to reduce VOC levels in the facility. Several facilities (furniture refinishing, shoe repair, offset printing) had soiled carpeting on the floor. VOCs absorbed into the carpet or other building materials can continue to offgas over a long period of time. The most obvious factor is that these facilities, excluding the auto body shops, all have a neighbor in the same building. There was little, if any, impact of facilities on neighbors not in the same building. Studies of dry-cleaning facilities have shown that despite attempts to better ventilate, enclose processes, and use proper maintenance, storage, and disposal practices, residences with dry-cleaning facilities in the same building continue to have elevated levels of tetrachloroethene in indoor air. It may be difficult to locate any facility using VOCs in a building without affecting the neighbors' indoor air.

¶Not reported.

Currently there are only limited data to characterize the potential impact of VOC-using facilities on their neighbors' indoor air. The sampling and analytic methods used to date did not evaluate all the VOCs used by facilities of these types. For example, methacrylate compounds used in nail salons and several chemicals used in the photoprocessing facility need to be assessed. Also, such facilities do not always operate at full capacity or use all the processes that they are capable of using. Therefore, data presented in this chapter should be considered as only a single "snapshot" for the facility. A larger or more in-depth study may be able to more fully characterize the impact of facilities using VOCs on their neighbors' indoor air.

Chemicals with a relatively low TLV or PEL and high odor threshold concentration in air are of particular concern because substantial exposure can occur without odor detection. Methylene chloride, hexane, and 1,1,1-trichloroethane all have poor warning properties (the threshold odor concentration exceeds the TLV), and all were highly elevated in the indoor air of residences in the same building as facilities using these VOCs. As a result, even though neighbors were exposed to elevated concentrations, they did not complain about odors. Except for one textile screen printing facility, none of the neighbors had complained to local health departments about odors from the facilities studied.

Facilities that use small quantities of VOCs are generally not required to have pollution control devices. In many cases, building codes and zoning laws do not prohibit the location of a facility using VOCs in the same building as a residence or other business. OSHA regulates worker exposure to VOCs, but there are no standards or guidelines for most VOCs in residential indoor air. In the absence of any other regulation, local health departments have attempted to mitigate such exposures by enforcing public health nuisance laws, with varying degrees of success. It may be more effective for zoning and building codes to be updated to recognize the hazards posed by locating such facilities in the same building as residences or other businesses.

66.5 CONCLUSIONS

Although based on a small number of samples for any one facility, the following conclusions can be made:

1. Small commercial facilities which use VOCs can impact the air of residences and businesses located in the same building. When compared to background indoor air levels cited in other studies, the following VOCs were found to be elevated in the air in the residences and/or businesses located the same building as these facilities:
 - a. Furniture refinishing: methylene chloride and toluene
 - b. Textile screen printing: methylene chloride and tetrachloroethene
 - c. Shoe repair: hexane and toluene
 - d. Photoprocessing/camera repair: 1,1,1-trichloroethane
 - e. Nail salon: 1,1,1-trichloroethane
2. Residents may not complain about odors even though VOC levels are elevated. In 10 residences and businesses where elevated levels of VOCs with poor warning characteristics (high odor thresholds) were found, only one resident had complained of odors to a local health department.
3. Some of these facilities had characteristics in common (such as inadequate ventilation, soiled carpeting, and a neighbor in the same building) that may contribute to elevated VOC levels in their neighbors' indoor air.
4. Neighbors not in the same building as the study facilities did not appear to be impacted. VOC levels in the indoor air of residences not in the same building as a study facility

were similar to background levels. However, only a small number of residences were studied during a relatively short period of time at a limited number of facilities. One cannot conclude, from this limited study, that a residence must be located in the same building as a facility using VOCs in order to be impacted.

ACKNOWLEDGMENTS

The NYSDOH investigation was designed, managed, and reported by Judith S. Schreiber, principal investigator. The cooperation of numerous other individuals was essential to its completion. In addition to the authors, Stanley House and Michael Hughes contributed many hours to collect samples, tabulate data, and provide contributions to earlier versions of this report. Staff of the Albany and Schenectady County Departments of Health and Herkimer District Office assisted us by securing cooperation of the various businesses involved in the study and assisting in building assessment and sample collections. Under the direction of George Eadon, Kenneth Aldous, Rajendar Narang, and Michael Force conducted all the analyses related to the NYSDOH investigations reported here. Ronald Miller and his graduate students of the State University of New York at Albany conducted the preliminary identification of study sites and surveys. We acknowledge the contribution of the facility owners, residents, and businesses who allowed us to collect samples from their businesses and homes. The NYSDOH study was supported by a NYSDOH internal preventive health block grant.

CHAPTER 67

RECREATION BUILDINGS

Michael Brauer, Sc.D.

*School of Occupational and Environmental Hygiene
The University of British Columbia
Vancouver, Canada*

67.1 INTRODUCTION

Several types of buildings used by the general public have special indoor air quality characteristics or concerns associated with them due to the function of the building, the particular occupants, and unique air quality requirements. This section will discuss recreational buildings in which indoor air quality has been identified as a particular concern. The first part of the section will focus on recreational buildings in which indoor air quality presents a risk to the human users of the building. Ice arenas and some other indoor sports facilities use indoor vehicles that have combustion emissions, whereas indoor swimming pools emit byproducts of disinfectants into the surrounding air. This section will also discuss indoor air quality in restaurants and bars, with particular emphasis on environmental tobacco smoke. The second part of the section describes specific requirements that libraries and museums have to preserve their collections. Unique exposures of relevance to human health that may be present in libraries are also described.

Poor indoor air quality in the above locations is of particular interest to the public because, as recreational locations, people expect them to be comfortable, pleasant, and healthy environments. Further, children and others who may be more susceptible to the impacts of poor air quality than the general public often frequent them. Additionally, ice arenas and swimming pools are environments where individuals exercise, thereby increasing their breathing rates and consequently their uptake of airborne pollutants.

67.2 ICE ARENAS

Problem Description

In indoor ice skating facilities the operation of equipment powered by internal combustion engines to clean and resurface the ice can lead to elevated concentrations of combustion products. Reports indicate that high concentrations of carbon monoxide (CO) in ice rinks leads to

toxicity (Anderson 1971; Spengler et al. 1978, 1984, 1986; Miller et al. 1989; Levesque et al. 1990). More recently, acute respiratory illness due to nitrogen dioxide (NO_2) exposure has also been reported at indoor ice rinks (Dewailly and Allaire 1988; Hedberg et al. 1989; Morgan 1995; Karlson-Stiber et al. 1996). Substitution of propane for other fuels (typically gasoline) has led to the expectation that air quality problems in ice arenas have been eliminated (Soparkar et al. 1993). However, emissions of NO_2 from propane are greater than those of gasoline, and consequently NO_2 has emerged as a problem (Brauer and Spengler 1994). CO is also still a problem, as evidenced by reports of poisoning incidents such as a recent poisoning in Seattle where a CO level of 354 ppm was measured in an ice arena (Hampson 1996). As a result of CO exposure, 78 people went to emergency rooms with symptoms of fatigue, dizziness, and headache. Two people were treated on-site by paramedics for acute respiratory distress.

Case Reports

Other incidents have been reported in the public health literature (approximately 25 reports between 1970 and 1996) and in the media. Selected examples are discussed below. Perhaps the best-known incident occurred at a high school hockey tournament in Minnesota in 1987. Players, cheerleaders, and spectators reported acute cough, hemoptysis (blood in sputum), and difficulty breathing during and within 48 hours of attending a hockey game. Cough lasted for an average of 16 days. Of those players with asthma, 90 percent indicated that their symptoms worsened after playing at the arena. Ninety-two players sought medical attention after the incident (Hedberg et al. 1989). In Quebec, five referees, three arena employees, and one player experienced symptoms 2 to 6 hours after exposure, which persisted for 12 to 48 hours. Symptoms included difficulty breathing, coughing, hemoptysis, and a suffocating feeling. Difficulty breathing was also noted in most other players who had been in the arena. Other individuals had headaches, nausea, and vomiting, suggesting both NO_2 and CO poisoning (Dewailly and Allaire 1988).

In Wisconsin 11 students who had played in a high school hockey game were treated in emergency rooms for acute respiratory symptoms: cough, hemoptysis, chest pain, and difficulty breathing. Two players were hospitalized. Symptoms suggestive of CO exposure were also reported: headache, dizziness, sleepiness, nausea, and vomiting. Of the 131 people who attended the game, 18 percent reported acute respiratory symptoms, 5 percent of the symptoms were suggestive of CO exposure and 26 percent suggested both types of symptoms. Acute respiratory symptoms occurred 1 to 32 hours after exposure (average: 4 hours) and CO-type symptoms occurred 1 to 24 hours (average: 2 hours) after the game began. Simulation tests the day after the game indicated NO_2 levels of 1.5 ppm (parts per million) and CO levels of 150 ppm (1992).

Pollutant Concentrations

These and other case reports of acute CO and NO_2 poisoning in ice rinks demonstrate that exposure in this setting can lead to illness, although these occurrences appear to be relatively infrequent (three to five reported incidents per year in North America) and are associated typically with a combination of factors, including high resurfacer emissions, poor ventilation of the rink building, and prolonged exposure of individuals. In addition to these poisoning incidents, it is also possible that there are less severe health effects associated with skating in ice arenas that are operating without any known problems. A survey of NO_2 concentrations in 70 arenas in the northeastern United States (Brauer and Spengler 1994) identified NO_2 concentrations (average = 0.36 ppm, range: 0.003–2.14 ppm) in excess of World Health Organization (WHO) guidelines (0.213 ppm) in many facilities. Pennanen

and colleagues describe results of a survey indicating high levels of NO_2 and CO in five ice arenas in Finland (Pennanen et al. 1997b).

To evaluate the distribution of NO_2 concentrations in these facilities and to identify practices that may be associated with increased NO_2 concentrations, indoor air NO_2 concentrations were measured in 332 ice arenas in nine countries, including Canada and the United States (Brauer et al. 1997). The mean NO_2 level for all rinks in the study was 0.228 ppm, with a range of 0.001 to 2.68 ppm, based on a sample collected adjacent to the ice surface. Estimates of short-term NO_2 concentrations indicated that as many as 40 percent of the sampled rinks would have exceeded the WHO 1-hour guideline value of 0.213 ppm NO_2 . In rinks where the main resurfacer used propane, the NO_2 concentrations were higher than in those using gasoline, which were higher than in those using diesel. Rinks where the main resurfacer was electric had the lowest NO_2 concentrations, similar to levels measured outdoors. Increased ventilation or reduced resurfacer operations were partially effective. Higher NO_2 concentrations were associated with the absence of a catalytic converter on a resurfacer and with the use of an ice edger. There were also indications that decreased use of mechanical ventilation, an increased number of resurfacings per day, and smaller rink volumes were associated with increased NO_2 levels. The results suggested that the most effective control strategy was the use of an electrically powered ice resurfacer. Alternative strategies (increased ventilation or reduced resurfacer operation) may also be partially effective. New strategies such as the use of a three-way catalyst to reduce emissions from propane-fueled resurfacers may be the most effective, although these were not evaluated in this survey because they were not in widespread use at the time.

Control Measures

Although inadequate ventilation is often believed to be the root cause of poor air quality inside arenas, increasing the rate of fresh air supply to adequate levels has proven to be impractical and expensive. The current American Society of Heating, Refrigeration and Air-Conditioning Engineers (ASHRAE) standard for ice arenas or stadiums do not explicitly consider the possibility of emissions from internal combustion engines. For a typical community ice arena with a surface area of approximately 2100 m² and a volume of 16,000 m³, the ASHRAE standard ventilation rate for ice arenas of 0.5 cfm/ft² is equivalent to approximately 1.2 air changes per hour (ACH). In practice, however, this level of ventilation is neither obtained nor is it adequate to dilute resurfacer emissions to acceptable levels (Pennanen et al. 1997b). Depending upon the season and on the outdoor climate, increasing the amount of outdoor supply air may also require significant dehumidification heating or cooling. Because of these concerns regarding the ability to provide adequate ventilation, a simple economic analysis of control measures concluded that for North American facilities, the most feasible long-term control strategy was to replace internal-combustion-engine-powered resurfacers with electric or battery-powered machines (Brauer and Spengler 1994), although at the time the authors did not consider the retrofitting or purchase of resurfacers with advanced emission controls such as three-way catalytic converters with oxygen sensors and feedback mechanisms.

Lee and colleagues evaluated the effectiveness of several simple mitigation techniques to reduce indoor CO and NO_2 levels (Lee et al. 1993). No single measure, such as the use of an exhaust pipe extension, full operation of the mechanical ventilation system, or reducing the number of resurfacing operations per day, was effective in lowering the NO_2 concentrations. However, a combination of full operation of the ventilation system and reducing the number of resurfacings did lower the mean NO_2 concentration from a peak value of approximately 0.7 ppm to below 0.1 ppm. CO concentrations dropped from peak values of 15 ppm to approximately 2 ppm. Although this strategy was effective, the authors concluded that these methods were impractical and probably not cost effective for most facilities.

More recently, the retrofit of existing ice resurfacers with state-of-the-art emission control technology has proven to be an economically feasible and successful way to reduce emissions. CO and NO₂ concentrations in an ice arena were evaluated before and after a three-way catalytic converter and fuel management system was added to a 7-year-old ice resurfacing machine (McNabb et al. 1997). Monitoring before and after the retrofit indicated an 87 percent reduction in NO₂ concentrations (Figure 67.1) and a 57 percent reduction in CO levels. These findings indicate that there is a practical and affordable solution to reduce NO₂ and CO concentrations in ice skating facilities that can be used with other measures to improve air quality. Similar findings have been reported for Finland in which a countrywide program was initiated to purchase new electric resurfacers, retrofit existing resurfacers with three-way catalytic converters, and to improve ventilation in ice arenas (Pennanen et al. 1997a).

Standards and Guidelines

Because skaters are often young children, occupational standards based on a healthy adult worker are not appropriate. Pribyl and Racca surveyed the health departments of 50 states and found that only two states (Minnesota and Rhode Island) have laws specifically regulating toxic gases in indoor ice areas. Interviews with sports medicine doctors and hockey team physicians also indicated that most were unaware of the potential problems associated with exposure to air pollutants in ice arenas (Pribyl and Racca 1996). Minnesota's air quality standards for ice arenas (Minnesota 1985) stipulate that immediate corrective action must be taken when CO is >34 ppm or NO₂ is >0.5 ppm (1 hour average) and require rinks evacuation when CO is >125 or NO₂ is >2 ppm. This standard protects against accidents where immediately dangerous levels of pollutants are present, but it is insufficient to provide a margin of safety to protect susceptible subgroups, such as asthmatics or children. For adult ice skaters, both Levesque and Lee (Levesque, Dewailly et al. 1990; Lee, Yanagisawa et al.

FIGURE 67.1 Reduction in NO₂ concentrations measured in an ice arena before and after three-way catalytic converter and oxygen sensor with feedback control was retrofit to ice resurfacer.

1994) have made measurements of carboxyhemoglobin in hockey players and recommended that concentrations be kept below 20 ppm for the duration of a 90-minute skating session. Because children may breathe in more of the pollutant relative to their body weight than adults do, elevated carboxyhemoglobin levels may result at lower levels of exposure.

The increased awareness of air quality in ice arenas prompted the development of a series of guidelines for ice arenas in British Columbia (Recreation Facilities Association of British Columbia, RFABC, 1996). These guidelines, designed to protect the health of all arena users, are also being applied in other provinces in Canada. The main elements are air quality guidelines (Table 67.1) and a code of practice for arena managers.

Code of Practice

1. *Training.* Arena managers train staff on air quality health effects and symptoms, operating procedures to improve air quality, and air quality testing procedures.
2. *Measurement.* Regular measurement of air quality 1 day per week (twice per day) within 30 minutes of resurfacing for CO and NO₂ with techniques sensitive enough to measure ≤ 0.25 ppm NO₂, 11 ppm CO. Results recorded.
3. *Ventilation.* Ventilated resurfacer warm-up prior to use. If ventilation available, operate ventilation continuously whenever rink is occupied.
4. *Emissions.* Monitor resurfacer emissions during engine tuning. Regular servicing of ice resurfacing equipment. Install three-way catalytic converter with oxygen sensor and feedback control on existing fuel-powered resurfacers. Plan for purchase of new resurfacers to be electric or battery powered. Subsequent to the development of these guidelines new occupational exposure regulations now require that all new purchases of indoor vehicles in British Columbia be equipped with a three-way catalytic converter and oxygen sensor with feedback control (Workers Compensation Board of British Columbia 1998).

TABLE 67.1 Air Quality Guidelines for British Columbia Ice Arenas

Zone*	CO (ppm), 1 hour average	NO ₂ (ppm), 1 hour average
Target	≤ 11	≤ 0.25
Action	$> 11-50$	$> 0.25-1.5$
Danger	> 50	> 1.5

*Target zone = levels assure adequate health protection to facility users (including children) and staff. Action zone = potential health hazard. At these levels some individuals may experience symptoms. Immediate action is required to reduce to target zone levels (i.e., ventilation improvements, resurfacer servicing). Public health officials must be notified within 1 hour of detecting high concentrations. Danger zone = immediate corrective action required (i.e., evacuation, ventilation). Public health officials must be notified immediately.

67.3 OTHER INDOOR VEHICLE EXPOSURES

Similar, although less frequent, exposures to combustion products have also been associated with indoor recreational events such as tractor pulls, demolition derbies, motocross events, and indoor go-kart and motorcycle facilities. The Cincinnati Health Department evaluated CO levels during tractor pulls, monster-truck jumps, and a mud race event held in an indoor arena with a seating capacity of approximately 16,000 persons. Even though the ventilation

system was operating maximally during the events, mean CO levels of 79 to 140 ppm were measured in the arena. Results of multiple measurements indicated that higher CO levels were measured at lower seating levels within the arena. Increasing the time between vehicle operation during each event did not lower CO levels (Boudreau, 1994).

Precautions taken during a recent motocross competition exemplify the increased awareness of the potential for elevated exposures during such events. Concentrations of CO and of NO₂ were monitored continuously during a motocross competition in an indoor skating rink. Initially, exposure limits were set at 50 and 2 ppm, respectively, for CO and NO₂. If excesses were to occur, activities would be interrupted until the levels decreased to less than 25 ppm for CO and 0.5 ppm for NO₂. NO₂ was not detected during the event. However, CO concentrations generated by motorcycles forced the competition to be interrupted seven times. Statistical analysis revealed that the initial CO concentration, the event duration, the motor size, and especially the number of motorcycles on the track were all positively associated with levels of CO at the end of the race (Levesque, 1997).

67.4 SWIMMING POOLS

Problem Description

Swimming pool water is treated chemically to disinfect it in the interest of public health. Indeed there are numerous examples of transmission of infectious diseases by inadequately treated pool water. In some instances, however, the disinfection processes are associated with poor air quality in indoor swimming facilities. In particular, the medical literature contains several references describing respiratory health problems among users of indoor swimming pools. Chlorine gas, volatile chlorinated hydrocarbons, and chloramines (especially nitrogen trichloride, also known as trichloramine) are often suggested as potentially being responsible agents. Chloramines are a product of the reaction of free chlorine with urea and creatinine introduced into the pool water by swimmers. The presence of irritant compounds in the air of swimming pool enclosures is particularly unfortunate because asthmatics are frequently encouraged to participate in swimming as an exercise, which is less likely than others are to exacerbate their condition. The potential for the development of respiratory health problems may be most significant for competitive swimmers who train for as much as 30 hours per week and who swim at breathing rates of 100 L/min, as well as for lifeguards who spend many hours at poolside (Potts 1996).

Case Reports

Mustchin and Pickering describe reversible airways disease in three swimmers and symptoms in many others at a newly opened pool. It was suggested that these responses might have been associated with a release of chlorine gas from chlorine dioxide, which was the principal water disinfectant (Mustchin and Pickering 1979). Penny describes a case of severe coughing in a patient following swimming at a pool with a heat reclamation system that recirculated the air inside the pool building (Penny 1983). The symptoms were attributed to nitrogen trichloride exposure. In this report, Penny indicates that prior to the use of the heat recovery system and in an older pool with no such system symptoms complaints did not occur.

Several recent studies have indicated a high prevalence of bronchial hyperresponsiveness among elite swimmers and suggest that this may be the result of exposure to air surrounding chemically treated pool water (Zwick et al. 1990, Helenius et al. 1998). Helenius

and colleagues found that elite swimmers more often had significantly increased bronchial responsiveness than control subjects. Sputum from swimmers contained a higher percentage of irritant cells and higher concentrations of inflammatory mediators than sputum from controls. Zwick found that competitive swimmers had higher prevalence of allergic sensitization and bronchial hyperresponsiveness than a control group (Zwick et al. 1990). Potts found that over 60 percent of competitive swimmers demonstrated bronchial responsiveness compared to 12.5 percent of controls. In a larger survey of 738 competitive swimmers, high prevalences of symptoms were reported following training sessions. All of the symptoms were associated with increased amounts of training time as well as years of swimming. Nearly 75 percent of the swimmers reported smelling strong chemical odors at swimming pools and as many as 40 percent of the swimmers associated their symptoms to the chemical odor (Potts 1996).

A case study of four young athletes who participated in heavy swimming exercise reported symptoms of exercise-induced asthma (EIA). Three of the subjects started to develop the symptoms after several years of training and had no former history of asthma, whereas the fourth subject had asthma but the EIA-symptoms were exacerbated by swimming. All four experienced more symptoms when the air in the swimming pool was warm or when there was a strong odor. Two of the athletes reported having no symptoms when they swam in outdoor pools and had only minor symptoms, or none at all, when they did other forms of physical exercise, including running. In all four their swimming performance was hampered by their respiratory symptoms. The cases suggest that an irritant may provoke asthma symptoms in susceptible swimmers. Volatile compounds from chlorination of the pools were suspected as possible irritant agents (Fjellbirkeland et al. 1995).

Pollutant Concentrations

Although rare, there are reports of acute chlorine toxicity at swimming pools (Shaw 1987, Decker 1988). Spas and whirlpools have been implicated in numerous outbreaks of Legionellosis, Pontiac fever, and *Pseudomonas*, although it is recognized that these incidents are largely due to inadequate disinfection (Shaw 1987, Potts 1996). The irritating effects of indoor pool atmospheres have generally been attributed to chloramines, most notably nitrogen trichloride (trichloramine).

Hery et al. developed a method for airborne trichloramine monitoring and applied it to a survey of 13 swimming pools in France (Hery et al. 1995). Hery et al. suggest that trichloramine is a likely compound to be responsible for reports of eye and respiratory irritation in swimming pool atmospheres. Area sampling indicated that higher trichloramine levels were associated with lower air exchange rates and with the presence of fountains, bubbling baths, waves, and so forth, in the pools. The same trichloramine sampling method was later applied to a survey of respiratory health involving 334 lifeguards. As indicated in other studies, trichloramine levels were higher in leisure than in public swimming pools. This difference is suggested to be due to higher water temperatures, greater air recirculation, and the use of mechanical water surface disturbances (wavepools, waterslides, fountains, etc.) in leisure pools. The mean trichloramine levels were associated with acute irritant eye, nose, and throat symptoms but not with chronic respiratory symptoms or bronchial hyperresponsiveness. In the public pools trichloramine levels were generally below the 0.5 mg/m³ (0.10 ppm) limit proposed by Hery et al., whereas nearly all of the leisure pools exceeded this level (Massin et al. 1998).

The impact of agitation systems in leisure pools on the generation rate of airborne chemicals has also been discussed by Lawrence (Lawrence 1990), who indicates that the ventilation systems in pool enclosures are generally designed to consider the rate of water evaporation from the pool surface, not the much greater rate from agitation. To supply sufficient makeup

air to agitated pools would require much greater amounts of outside air. Lawrence also reports that airborne chlorine concentrations were greatest in the areas of greatest water agitation.

Measurements of chlorine gas levels at poolside indicate levels that are generally well below occupational exposure limits when the chlorine concentrations in the water are within normal values (0.5–2 mg/L free chlorine). However, once the increased ventilation rates of swimmers are considered, the chlorine-inhaled doses of swimmers would be similar to those of workers inhaling chlorine at the occupational exposure limit. Airborne chlorine levels were correlated with the number of swimmers using the pool per square meter of pool surface area and with the volume of the indoor enclosure (Drobnic et al. 1996).

Indoor swimming pools have also been investigated for their potential for chronic health risk due to chlorinated hydrocarbon exposure. The use of chlorinated water produces elevated chlorinated hydrocarbon levels in the water and air of swimming pools. Chloroform is often cited as the major chlorinated hydrocarbon component present in the air of swimming pool enclosures, whereas ethanol, carbon disulfide, acetone, toluene, and tetrachloroethylene have also been detected. In a survey of 23 indoor pools, chloroform levels (2.5–54 ppm) were as much as 500 times higher than outdoor air levels. Chloroform levels in air were approximately twice as high in pools with no ozone (O_3) purification relative to those with O_3 purification (Mannschott et al. 1994).

A study in Korea measured indoor air chloroform levels in three indoor swimming pools using both sodium hypochlorite and O_3 for water disinfection. Despite water chloroform levels that were comparatively lower than pools using sodium hypochlorite exclusively, the mean air chloroform concentrations were about 70 to 240 times higher than the corresponding outdoor air chloroform levels. The total dose (dermal, inhalation, and ingestion doses) of chloroform from a weekly swim was estimated to be higher than the upper range of the weekly dose of chloroform from the use of chlorinated water in the home (ingestion and showering). The dermal dose of chloroform was estimated to be about 2.5 times the inhalation dose of chloroform for the same swim (Jo 1994).

Aggazzotti and colleagues measured plasma and alveolar air samples of individuals attending indoor swimming pools. For both measurements, chloroform levels were higher in those with more frequent use of swimming pools and were correlated with the chloroform levels in the water and in the surrounding air (Aggazzotti et al. 1990, 1993).

Control Measures

The report of Penny supports a requirement for adequate air exchange levels within enclosed pool buildings (Penny 1983). Shaw reports on an incident at a large swimming pool in which a new ventilation system reduced the air exchange rate from 1.8 hour^{-1} to 0.6 hour^{-1} . During peak load periods, swimmers and staff experienced symptoms, especially during intensive training. Increasing the air exchange rate to 1.5 hour^{-1} alleviated all symptoms. Shaw indicates that this rate of ventilation ($625 \text{ m}^3/\text{hour}$ per person) is more than 10 times higher than normally considered adequate (Shaw 1987).

The recommended ventilation requirements for swimming pools as determined by the European Union are discussed by Trianti-Stourna et al. (1998). The pool area rate of $10 \text{ m}^3/\text{hour}/\text{m}^2$ of pool water surface (the ASHRAE 62-89 limit is equivalent to $9 \text{ m}^3/\text{hour}/\text{m}^2$) normally produces an overall total of approximately five air changes per hour in a typical swimming pool enclosure, although it is apparent from limited information on the literature that these levels are rarely met (Shaw 1987).

Other control measures emphasize changing the disinfection process itself to limit emissions of volatile compounds. In contrast to the use of chlorine as a disinfectant, chlorine dioxide does not produce chloramines (Shaw 1987). Alternatively, the use of O_3 as the primary disinfectant is reported to oxidize the organic contaminants (creatinine and urea) and therefore eliminate the production of the irritant chloramines and chloroform (Shaw 1987,

Jo 1994, Mannschott et al. 1994). Further, the work of Lawrence indicates the relatively large impact of agitated water (from water slides, fountains, wavepools, etc.). Directing control efforts to these areas or to facilities with these attributes may prove most beneficial.

Standards and Guidelines

Based on measurements and on symptoms recording by pool staff, Hery et al. report that irritation symptoms were first reported when the trichloramine levels reached approximately 0.10 ppm and that 0.14 ppm levels provoked 100 percent reporting of symptoms. Accordingly, a standard of 0.10 ppm trichloramine, measured using the same method as Hery et al. is recommended.

67.5 RESTAURANTS AND BARS

Problem Description

Restaurant and bar smoking restrictions and smoking bans are being implemented with increasing frequency in North American municipalities. Despite extensive analysis indicating that smoking restrictions do not have any negative impacts on restaurant sales (Sciacca and Eckrem 1993, Glantz and Smith 1994, Sciacca 1996), there is often resistance within the hospitality industry and within segments of the population to increased restriction or elimination of smoking in public eating establishments. Although compliance with a total smoking ban will certainly eliminate exposure to environmental tobacco smoke (ETS) in restaurants, claims are often made that less restrictive policies are also effective. Because the introduction of smoking restrictions in restaurants is currently an issue of important public health policy, it is surprising how little data are available to indicate the effectiveness of various levels of smoking restrictions on ETS exposures.

Pollutant Concentrations

Several surveys have indicated that restaurants and bars present high levels of ETS, although there is considerable variability among establishments. Due to the complex chemical nature of ETS, most measurements have focused on particulates, often combined with one of several tracers for ETS. Carbon monoxide levels have also been measured in several surveys, although levels are generally not significantly higher than ambient concentrations and appear to be less important as potential health hazards than particulates. Siegel summarized measurements of respirable suspended particles (RSP) in bars, restaurants, offices, and residences with at least one smoker (Siegel 1993). Levels of ETS in restaurants were 1.6 to 2.0 times higher than in offices and 1.5 times higher than in residences with at least one smoker. Levels in bars were 3 times higher than in restaurants. Siegel concluded that ETS was a significant occupational health hazard for food-service workers. Miesner and colleagues measured fine particulate matter smaller than $2.5\text{ }\mu\text{m}$ ($\text{PM}_{2.5}$) in restaurants and bars as well as various other public places (Miesner et al. 1989). In most of the public facilities and office buildings where there was no smoking, particulate concentrations were less than $30\text{ }\mu\text{g}/\text{m}^3$, whereas restaurants and bars had levels of 30 to $140\text{ }\mu\text{g}/\text{m}^3$.

Collett and colleagues measured vapor phase nicotine and respirable suspended particulates in 13 nightclubs, 8 taverns and 10 neighborhood pubs (Collett et al. 1992). Nightclubs were characterized by higher occupant density, whereas taverns offer less extensive food service than neighborhood pubs. Mean RSP levels were 151, 93, and 95

$\mu\text{g}/\text{m}^3$ for the nightclubs, taverns, and neighborhood pubs, respectively. Nicotine levels in neighborhood pubs were lower than in taverns, which were lower than in nightclubs. The higher RSP and nicotine levels in the nightclubs were associated with higher occupant densities, higher cigarette counts, and higher CO_2 concentrations. Measurement of CO_2 as an indicator of ventilation adequacy suggested that ventilation levels did not meet ASHRAE 62-1989 levels designed to provide "acceptable indoor air quality."

Lambert and colleagues compared RSP and nicotine levels in the nonsmoking and smoking sections of seven restaurants (Lambert et al. 1993). The mean concentrations of respirable suspended particulates and nicotine were 40 and 65 percent lower, respectively, in the nonsmoking than in the smoking sections. The authors concluded that the simple separation of smokers and nonsmokers may reduce, but does not eliminate, the exposure of nonsmokers to environmental tobacco smoke.

A cross-sectional survey of the impact of smoking restrictions conducted by Brauer and 't Mannetje also found that smoking restrictions resulted in significantly lower ETS levels (Brauer and 't Mannetje 1998). In this survey fine particulates and particulate cadmium were measured in 20 restaurants and bars in Vancouver, British Columbia. The restaurants were divided into three categories based on their smoking policy: five nonsmoking restaurants, eleven restaurants with both nonsmoking and smoking sections (restricted smoking), and four bars (with food service) where smoking was unrestricted. Regulations at the time of this study required at least 40 percent of seating to be nonsmoking in restaurants, whereas there were no restrictions applicable to bars. High particle concentrations were measured in all restaurant types (5-minute average peak $\text{PM}_{2.5}$ concentrations above $400 \mu\text{g}/\text{m}^3$). Fine particle concentrations were significantly higher in establishments with no smoking restrictions (mean $\text{PM}_{2.5}$ concentration = $190 \mu\text{g}/\text{m}^3$, range: 47–253) than in restaurants with partial smoking restrictions (mean $\text{PM}_{2.5}$ concentration = $57 \mu\text{g}/\text{m}^3$, range: 11–163). Concentrations in nonsmoking restaurants were reduced by an additional 20 to 30 percent. Measurements of cadmium, a more specific tracer of environmental tobacco smoke than $\text{PM}_{2.5}$, implicated environmental tobacco smoke as the major source of indoor particulate in restaurants where smoking was allowed, with cooking as an additional source.

The contribution of additional sources other than ETS to particulate levels in restaurant was also suggested by Crouse et al., who (in collaboration with the tobacco industry) conducted a survey of 42 restaurants without smoking restrictions (Crouse et al. 1988). Vapor phase nicotine, ultraviolet particulate matter, and RSP were measured. One-hour average RSP levels of 16 to $221 \mu\text{g}/\text{m}^3$ (mean concentration of $81 \mu\text{g}/\text{m}^3$) were measured. Because nicotine levels were not significantly correlated with RSP levels, the authors suggested that other sources in addition to ETS contributed to the high RSP levels.

In perhaps the most important study of smoking restrictions in restaurants conducted to date, Ott and colleagues measured RSP inside a sports tavern before and after the prohibition of smoking (Ott et al. 1996). During the smoking period, the average RSP concentration was $57 \mu\text{g}/\text{m}^3$ above the outdoor concentration, and it decreased by 77 percent to $13 \mu\text{g}/\text{m}^3$ above the outdoor concentration after the prohibition of smoking. There was no change in the number of customers following the smoking restriction. It is noteworthy that this tavern had a relatively high air exchange rate of 7.5 hour^{-1} , indicating that a volume of air equal to that of the tavern was replaced every 8 minutes. This work estimated that each cigarette contributed, on average, $37.5 \mu\text{g}/\text{m}^3$ to the RSP ($\text{PM}_{3.5}$) concentration of this 521-m^3 tavern. This contribution was similar to the $25\text{-}\mu\text{g}/\text{m}^3$ $\text{PM}_{2.5}$ increase attributable to each cigarette reported by Brauer and 't Mannetje for a series of restaurants and bars of different volumes (Brauer and 't Mannetje 1998).

The ASHRAE 62-89 standard presently does not consider restaurants or bars to be much different from other indoor environments. For example, the ventilation requirement for restaurants is similar to that of conference rooms in office buildings. A somewhat increased ventilation rate is specified for bars due to their higher occupant density.

67.6 LIBRARIES

Problem Description

Although there are numerous reports of occupant complaints in libraries and several detailed case investigations have been conducted (Elliott et al. 1989, Berglund et al. 1990, Yeung et al. 1991, Lundin 1993), to date there have been relatively few general surveys of library air quality. Libraries are suspected of providing an optimal environment for the growth of fungal organisms due to their often humid conditions and the large quantities of natural materials stored in libraries that can serve as potential growth media (Hay 1995). Some types of fungi appear to readily digest cellulose and other materials present in libraries (Gambale et al. 1993). Further, exposure to air within libraries has been associated with the provocation of rhinitis or asthma, although the general symptom pattern has yet to be explained (Burge et al. 1978, Hay 1995).

Case Reports

Several case reports describe high fungal exposures originating from library books that incur significant water damage (Kolmodin-Hedman et al. 1986, Light et al. 1989) and suggest that the cleaning of porous water-damaged materials, such as books, is ineffective and that it may be necessary to replace these items (Light et al. 1989).

A major investigation was undertaken in the Madison Building of the U.S. Library of Congress in the mid 1980s in response to employee complaints of poor indoor air quality. A systematic study was designed to assess the nature of employee health symptoms and comfort concerns and to attempt to correlate these with a large number of environmental measurements. The primary associations observed were between health symptoms and both the perception of thermal comfort and the perception of odors. Few associations were demonstrated between symptom occurrence and any of the environmental measurements. No environmental contaminants were identified at levels above any relevant criteria or standards (Anonymous 1991).

A similar evaluation was undertaken of possible poor air quality in a large new library in Florida. Soon after the building was opened, workers began to complain of eye and upper airway irritation, difficulty in breathing, and headaches. On a floor where government documents were housed, employees suffered allergylike symptoms. The building had repeated problems with the heating, ventilation, and air-conditioning system, and numerous rainwater leaks occurred. Some documents had visible growths of mold on their covers. However, air samples indicated very low counts of mold. Formaldehyde was also found in air samples at low levels (0.01–0.07 ppm). Carbon dioxide measurements in some places in the library approached the point that indicated that inadequate quantities of fresh air were being distributed to an occupied space. Although the investigation report concluded that the employees' symptoms were not the result of exposure to molds, work with historical documents did appear to be related with the health complaints of the workers (Elliott et al. 1989).

Pollutant Concentrations

Burge et al. evaluated the levels of airborne fungi in 11 university libraries. Library spore levels were generally low and were lower than corresponding outdoor levels. Air-conditioned libraries had lower spore levels, whereas the handling of books during sampling was associated with increased spore counts, especially in non-air-conditioned libraries. This investigation also documented the association between water-damaged books and mold

growth, a relatively common problem for libraries. The observation of increased fungal spore counts during the handling of books indicates that books themselves serve as substrates for fungal growth, despite the absence of visible molds. The authors conclude that the overall low spore levels and lack of a distinctive spectrum of library mycoflora suggest that other sources should be sought for library-based respiratory symptoms (Burge et al. 1978).

A similar survey of fungi was undertaken in 28 university libraries in Brazil and indicated that the airborne fungi isolated in libraries are likely to be found anywhere in the city of São Paulo, but they are likely to be present in higher concentrations in libraries. Measurement of fungi on deteriorated books indicated the presence of *Cladosporium*, *Penicillium*, *Trichoderma*, and *Aspergillus*. As part of this study 314 librarians were questioned about the presence of asthmatic or rhinitic symptoms and the relationship between these symptoms and their work at libraries. Forty-nine percent of the librarians reported symptoms and of these, 80 percent related them to their place of work. As a follow-up to the symptom survey, librarians underwent intracutaneous tests against the 20 fungi most frequently isolated in the libraries. Eighteen (6 percent) of the librarians presented positive tests, 12 of whom reported rhinitis and 6 of whom were asymptomatic (Gambale 1993).

Fantuzzi and colleagues surveyed volatile organic compounds (VOCs), formaldehyde, and total dust in 16 university libraries in Italy, all with openable windows and natural ventilation. In general, indoor levels were similar and related to outdoor measurements and suggested no major problems related to indoor pollution. Formaldehyde was detected 10 of the 16 libraries (range: 0.002–0.055 ppm; mean: 0.027 ppm). VOCs were present in all the libraries investigated with an average total VOC (TVOC) value of 433 $\mu\text{g}/\text{m}^3$ (range 102–936 $\mu\text{g}/\text{m}^3$) (Fantuzzi et al. 1996).

67.7 MUSEUMS

Problem Description

Although the effects of humidity on museum objects has been appreciated for some time, only since the 1980s have conservators addressed gases and particulates as potentially damaging agents (Ayres et al. 1990). In contrast to most other indoor environments where human comfort and health risk motivates concern, air quality in museums has received attention primarily because air pollutants can damage articles of museum collections. For the long-term preservation of objects in museums and libraries, pollutants at concentrations far below those of concern to public health may cause significant damage over an accumulated period of time. The principal pollutants of concern are those originating outdoors, in particular oxidant and acidic gases. Therefore, museums located in areas with higher levels of ambient air pollution may be more susceptible to damaging effects. Examples of indoor sources contributing to the deterioration of objects have also been reported (Debock et al. 1996, Roshanaei and Braaten 1996). Brimblecombe (1990) provides a review of the impact of indoor air pollutants on materials in museums, art galleries, and libraries and suggests that knowledge is limited because measurements have only been made for a relatively limited number of gaseous compounds (Brimblecombe 1990).

Pollutant Concentrations

Much of the research on indoor air quality in museums has been undertaken in southern California, where the primary pollutant sources of concern is the infiltration of polluted

ambient air. A survey of several selected air pollutants in nine southern California museums and libraries indicated that for most museums indoor concentrations of NO_2 , peroxyacetyl nitrate (PAN), and nitric acid (HNO_3) were comparable to outdoor levels and closely followed outdoor variations, thus indicating rapid indoor/outdoor air exchange. The measured indoor levels were 0.120 ppm for NO_2 , 0.014 ppm for PAN, 0.010 ppm for HNO_3 , and more than 0.012 and 0.03 ppm for tetrachloroethylene and trichloroethane, respectively. At six of the nine institutions surveyed, indoor levels of chlorinated hydrocarbons were higher than outdoor concentrations, thus pointing to indoor sources such as solvents used in cleaning of archaeological pieces or other cleaning products. The presence of a heating, ventilation, and air-conditioning (HVAC) system had little effect on the indoor levels of air pollutants. Indoor concentrations were nearly equal to outdoor levels. Of the three museums equipped with HVAC and chemical filtration systems, only one yielded low indoor pollutant concentrations and low indoor/outdoor ratios (Hisham and Grosjean 1991a). Additional measurements of sulfur dioxide (SO_2) at three southern California museums indicated an average indoor:outdoor SO_2 ratio of 0.89 (Hisham and Grosjean 1991b).

Eleven museums, art galleries, historical houses, and a museum library in southern California were monitored during summer periods to determine whether high outdoor O_3 concentrations are transferred to the indoor atmosphere of museums. The rate of air exchange was found to be strongly associated with the infiltration of outdoor O_3 . Museums having conventional air-conditioning systems show peak indoor O_3 concentrations about 30 to 40 percent of those outdoors, whereas buildings where the HVAC system included an activated carbon filtration system had indoor levels that were approximately 10 to 15 percent of outdoor levels. Indoor O_3 concentrations as high as 0.143 ppm were found in one museum that lacked a chemically protected air-conditioning system. For purposes of comparison, the recommended O_3 level in places where works of art and historical documents are stored ranges from 0.013 to 0.001 ppm, depending on the authority cited. A mathematical model was used to study the O_3 concentrations within these buildings to confirm that the differences in indoor O_3 levels between buildings can be explained in terms of building and ventilation system design (Druzik et al. 1990).

Nazaroff and colleagues provide detailed information on the impact of airborne particles in museums, based on measurements conducted in three southern California museums. For these measurements, the only major particle source was infiltration of outdoor air. Based on these measurements and a model that was developed, it was estimated that deposition of particles onto vertical surfaces can lead to appreciable soiling that is dependent primarily upon the rate of air exchange and particle filtration as well as particle size and density. For soiling, particles of approximately 0.1- μm diameter were the most important, and it is recommended that filtration systems be designed to effectively remove particles of this size range. For walls and ceilings elemental carbon was a more significant soiling agent than soil dust, whereas the opposite was true for floors. Perceptible soiling was estimated to occur at 1 to 40 years and 3 days to 3 years for walls, and floors, respectively (Nazaroff et al. 1990). In a different situation, indoor aerosols, likely those originating from the deterioration of plaster walls, were identified as major contributors to the soiling of paintings in a museum (Debock et al. 1996).

Lanting presents results of a survey of SO_2 , NO_2 , and O_3 levels in three archives and three museums in The Netherlands. As found in other investigations, indoor levels, although low, were highly correlated with outdoor levels. Although low indoor air levels were observed, the indoor to outdoor ratios were independent of the outdoor concentration and suggested that deposition processes inside the buildings were major factors in lowering the concentration levels. For example, NO_2 and O_3 were efficiently transmitted within the HVAC system with little drop in concentrations. However, measurements within a storeroom supplied by the same ventilation system were considerably lower, resulting in cleaner air leaving the room. Accordingly, the greater the percentage of recirculated air supplied to the storeroom, the lower the air concentrations of the gases. SO_2 was

absorbed efficiently within the ventilation system. Because occupancy of many museum storerooms is low, a high rate of recirculation can be maintained, and galleries can sustain high recirculation rates during periods when museums are closed (Lanting 1990).

Control Measures

Materials stored in cases are generally well protected from air pollutants, although they are more susceptible to pollutants generated within the case itself. In contrast, materials stored in open rooms will be more sensitive to air pollutants due to their lower surface area to volume ratios. Although HVAC systems present in most museums will lower the infiltration of ambient pollutants, there has also been concern regarding the chemical transformations of air pollutants present inside museum atmospheres. Nazaroff and Cass applied a photochemical air pollution model to an art gallery and found that homogeneous chemistry within buildings may occur where glass walls allow for high photolytic rates, leading to increased production of oxidant gases and nitric acid, which can subsequently damage museum materials. Reactions occurring on indoor surfaces may also be important in the production of nitric, nitrous, and formic acids (Nazaroff and Cass 1986).

Standards and Guidelines

A number of air quality standards have been designed to protect historical records, specifically paper materials, from the deteriorating effects of air pollutants (Table 67.2). In practice, these levels are often difficult to achieve, depending upon the surrounding ambient air quality. Ayres et al. (1990) review the literature recommending filtration of outdoor air to result in acceptable indoor air quality for museum collections. Particle removal on the order of 85 percent efficiency and the use of activated charcoal filters for gaseous pollutant removal are recommended.

TABLE 67.2 Air Quality Guidelines Applicable to Museums, Archives, and Libraries for the Preservation of Historical Records

Pollutant	Level
SO ₂	0.0004 ppm ¹ 0.004 ppm ²
HNO ₃	BAT* ¹ 0.004 ppm ²
NO ₂	BAT ¹ 0.005 ppm ²
O ₃	0.001 ppm ^{1,2}
Particulate matter	30% Filtration for prefilter (outside air only)† 80% Filtration for intermediate filter (supply and recirculated air)† 90% Filtration for fine filter (supply and recirculated air)†

*BAT = Best available technology.

†Filtration efficiency determined by ASHRAE Atmospheric Dust Spot Efficiency Test.

67.8 CONCLUSION

This section has discussed examples of several types of recreational buildings in which indoor air quality has been identified as a particular concern, either for the potential health risks of building users or employees or for the maintenance of materials housed in the building. Although this section emphasizes those recreational facilities with the most available knowledge, it is likely that indoor air quality problems will be identified in different types of recreational buildings in the future. Just as likely is the future development of new types of indoor recreational facilities, some with poor air quality. For example, many activities that historically were undertaken outdoors are now being attempted indoors: indoor go-kart facilities; theme restaurants that recreate a simulated environment; “mega malls,” which include indoor amusement parks, zoos, and water parks; and so forth. Architects and building engineers should be aware of the potential for poor air quality associated with the use of these facilities and with the potential susceptibilities of the particular user groups. Unfortunately, the progress of efforts to improve indoor air quality is often slow. Despite 20 years of research regarding poor air quality in ice arenas, currently, new facilities are constructed with little or no ventilation, nor is the purchase of electric resurfacers common.

As the many examples described in this section indicate, control of the pollutant sources is the most effective method of control. Relying on ventilation systems to achieve acceptable air quality has proven to be ineffective for many types of recreational facilities. Further, emphasis on source control and the use of alternative technologies to reduce emissions will likely be less expensive and less energy intensive in the long term. For ice arenas, priority should be placed on the use of electric resurfacers or combustion engine resurfacers with advanced emission control technology and combined with routine air monitoring. For swimming pools, use of ozone pretreatment to minimize the amount of chlorine in the water is suggested. For restaurants and bars, smoking restrictions and partitions have proven to be at least partially successful without adversely affecting sales, although evidence suggests that air quality in many restaurants would also benefit from improved ventilation. For libraries, frequent inspection of materials for water damage and attention to potential sources of humidity and water leakage should be high priorities. Along with these considerations and with the use of activated carbon and particulate filtration of ambient air, museums should promote efforts to improve the ambient air quality in their communities. New museums might consider locating in areas that have lower levels of ambient air pollutants.

68.1 INTRODUCTION

Exposure Principle and Proximity to Source

Exposure is a combination of the concentration of an agent at a body boundary and the duration of the contact. Population-based exposure estimates combine distributions of concentrations contacting individuals and time-activity patterns that result in contact within that population. The primary exposures to chemicals associated with transportation are (1) inhalation exposure to emissions from fuel combustion or evaporation when people spend time in or near mobile vehicles (2) dermal exposures when fuel splashes onto skin or clothing during fueling activities, and (3) ingestion exposure if food is eaten after handling fuel. This chapter considers only inhalation environmental exposures, since the other two routes are considered small for the general population, although they have not been well studied. Occupational exposures also exist during transport, transference, and storage of fuel and during driving that are typically greater than for the general population but will not be discussed in this chapter. The air concentrations of pollutants resulting from exhaust and evaporative emissions of fuel is often higher in and near vehicles (automobiles, buses, trains, airplanes, ships, sidewalks, parking lots, etc.) than in other microenvironments because of proximity of these microenvironments to the source and the enclosed nature of vehicles. Exposures to compounds prevalent in both combustion engine exhaust and evaporative emissions of fuel have been measured for a variety of transportation modes. The pollutants measured include carbon monoxide, nitrogen oxides, volatile organic compounds (VOCs; predominantly hydrocarbons and fuel additives), aldehydes, and particulate matter. Gasoline and diesel fuel are petroleum distillates containing hydrocarbons between C4 and C12, and between C10 and C19, respectively. The Clean Air Act Amendments of 1990 specify the allowed VOC emissions from gasoline, gasoline's benzene content, and the minimum oxygen content of fuel (Sawyer 1993). These regulations have resulted in the introduction of reformulated gasoline designed to reduce emissions of compounds that promote photochemical formation of ozone and smog, oxygenated fuel to reduce CO

emissions during the winter, and alternate fuels to reduce reliance on petroleum. The specific composition of fuel results in exposures containing different proportions and types of compounds from automobile and truck emissions.

Time-Activity Patterns

The most recent time-activity pattern database that includes the amount of time spent in or near vehicles by geographic location, age, and gender that used a probabilistically based population sampling technique is the National Human Activity Pattern Survey (NHAPS) (Klepeis et al. 1996, Tsang and Klepeis 1996). The overall daily mean amount of time spent by the U.S. population, for those individuals who were in a vehicle on the day questioned, was 95 min or 6.6 percent of a day and for those who spend time near a vehicle, was 78 min or 5.4 percent (Klepeis et al. 1996). The amount of time spent in these two microenvironments was lognormally distributed; the median, 90th percentile, and 99th percentile for the time in a vehicle were 70, 190, and 570 min per day, respectively, and the median, 90th percentile, and 99th percentile for being near a vehicle were 30, 200, and 675 min per day, respectively. A total of 7743 people of the 9386 responders to the survey indicated that they were in a vehicle. A smaller number, 2825 people, indicated that they were near a vehicle. Males spent slightly more time per day in vehicles than did females (mean 103 min compared to 92 min), but more than twice the amount of time near a vehicle (mean 111 min compared to 50 min). Adults spent more time in vehicles than did children (ages 1 to 4, 68±75 min; ages 5 to 11, 71±77 min; ages 12 to 17, 82±80 min; ages 18 to 64, 104±111 min; ages >64, 91±94 min). The greatest amount of time spent in a vehicle occurred in the Midwest, although the geographic differences were not large (Northeast, 99±107 min; Midwest, 101±115 min; South, 96±98 min; West, 94±104 min). Little differences were observed in the amount of time spent in vehicles by day of week (weekday, 94±101 min; weekend, 103±112 min) or across seasons (winter, 94±101 min; spring, 100±110 min; summer, 98±104 min; fall, 97±104 min). Within the NHAPS database, traveling in a car (6560 people) was more prevalent than in a truck or van (1296), buses (469), trains or subways (116), or airplanes (53). Individual activities near vehicles included walking (1639), riding a motorcycle (32), riding a bicycle (115), being on a sidewalk (896), being in a parking lot (226), and visiting a service station (191). Since the same individual could have engaged in more than one of the activities listed above in a single day, the sum of the individual components is greater than the values provided for the in-vehicle or near-vehicle activities. As expected, the majority of the time spent in or near vehicles occurred during the day, from approximately 6 A.M. through 11 P.M. During weekdays a trimodal pattern was observed, with peaks at 7:30 A.M., 12:30 A.M., and 5:00 P.M., times when people commute to and from work or school or go to lunch. On the weekend the time of day when people were in a car was more evenly distributed during the daylight hours than on the weekday, although some skewness toward the latter part of the day was evident. The observed time distribution indicates that a greater number of vehicles were on the road at specific times of the day. This pattern results in an increase in the source strengths during specific time periods and therefore greater potential exposures to exhaust and evaporative fuel emissions than if the average emission rate were constant throughout the day.

68.2 AUTOMOBILES

Carbon Monoxide

As described above, the most common mode of transportation in the United States is the automobile. Since cars drive near other cars and near trucks and buses and the interior air

of automobiles is primarily from penetration of roadway air, the concentration of components in automotive exhaust emissions (carbon monoxide, nitrogen oxides, and uncombusted gasoline), evaporative emissions from gasoline (volatile aromatic and aliphatic hydrocarbons and volatile gasoline additives), and diesel exhaust emissions (long-chain aliphatic hydrocarbons, and particles containing polyaromatic hydrocarbons) are typically elevated within the cabin of the automobile compared to the ambient air.

Carbon monoxide was the first air pollutant studied within automobiles and continues to be used as a marker of automotive exhaust emissions (Akland et al. 1985, Cortese and Spengler 1976, Flachsbart et al. 1987, Ott et al. 1988, Ott and Willits 1981). The frequency distribution of CO exposures to representative, nonsmoking urban populations was determined in Washington, DC and Denver using personal exposure monitors (Akland et al. 1985). More than 10 percent of the residents of Denver and 4 percent of those in Washington, DC were exposed to CO levels above 9 ppm for 8 h during the winter of 1982/83, although the ambient air monitoring stations had lower concentrations. The mean CO exposure levels measured with personal monitors were similar to the composite of the monitoring sites and the monitoring site with the highest CO values in both Washington, DC and Denver, but the 90th and 98th percentile concentrations measured with personal monitors for the exposed population were higher than the concentrations measured at the ambient monitoring sites (Akland et al. 1985).

Carbon monoxide concentrations were measured within test vehicles driven in Washington, DC along eight prescribed automotive commuter routes, four bus routes, and three rail routes using a microenvironmental study design to assess commuter exposures (Flachsbart et al. 1987). The routes were selected to represent the major commuter routes of the city. Different parameters which could affect roadway CO levels were evaluated. (Examples are: street traffic density, parking garage use, presence of roadway tunnels, street canyons, and expressways.) Automobiles that were parked in indoor garages, where elevated CO concentrations occurred, had higher CO levels during their return trip than the morning trip. The authors explained this by residual pollutant concentrations from the indoor parking garage remaining in the car's interior during a portion of the trip home. They also noted that there was an inverse relationship between driving speed and CO concentration, indicative of an air exchange between the car's interior and surrounding roadway air which resulted in the cars' interior concentrations being equivalent to the surrounding roadway's air concentrations as the trip progressed. The average difference between the A.M. and P.M. routes was ~15 percent (Flachsbart et al. 1987) while the interior of the garages had CO concentrations twice the average value in the automobiles during commuting (Akland et al. 1985). If the elevated concentrations observed during the P.M. commute did arise from residual levels, those elevated concentrations needed to remain in the car's interior for 15 to 20 percent of the return trip or 8 min of a 40-min commute. That could occur if the car were being driven slowly while waiting to exit the garage and leaving the city center. In addition, the actual CO air concentration in the garage while the car was exiting could have been higher than the average indoor garage air concentration as a result of both buildup during the day and being near other cars attempting to exit the garage at the same time. If this were the case, the residual would need to remain in the car for a shorter time period than 8 min for a 40-min trip indicated above to cause the observed difference in A.M. to P.M. commute. The commuters in Washington, DC who used an automobile were exposed to average CO concentrations of 9 to 14 ppm during a 40- to 60-min period, twice a day. The mean CO concentrations measured on 2 days in the four microenvironments designated as transportation were automobiles (7.6/4.4 ppm), buses (8.2/10 ppm), trucks (6.8/7.7 ppm), and motorcycles (13.2/11.1 ppm). These concentrations exceeded the values measured in the other 18 microenvironments examined, except for 4 high-exposure microenvironments which were locations frequented by automobiles (parking garages, service stations, within 10 ft of a road) and a manufacturing facility (Akland et al. 1985).

Concentrations of CO in cars driven along a single Californian arterial highway were measured by Ott and coworkers in 1980/81 and again in 1991/92 to determine long-term temporal variations (Ott et al. 1993). To assess what controlled CO concentration in cars, the Californian in-car CO concentrations were used as the dependent variable in a regression analysis with roadway, automotive, and meteorological parameters. The regression model indicated that the surrounding vehicle counts and season were predictive of the CO interior concentration. The trend in declining CO exhaust emissions from automobiles due to increased regulations was more predictive of the magnitude in the decline in CO exposure in cars than was the decline in ambient CO air concentrations. The strong association between declining emission rates and in-car CO air concentrations is because of the strong influence of near source emissions, the tailpipes of the surrounding automobiles, on in-car concentrations and therefore driver exposures to compounds in automotive emissions.

A variety of exposure models have been developed to estimate general population exposures to different environmental contaminants, including CO and other automobile emissions. These include: Simulation of Human Activity and Pollutant Exposure (SHAPE) (Ott et al. 1988), Benzene Exposure Assessment Model (BEAM) (BEAM 1992), National Ambient Air Quality Standard (NAAQS) Exposure Model (NEM) (McCurdy 1995), a probabilistic version of NEM (pNEM) (Johnson 1995), Hazardous Air Pollutant Exposure Model for Mobile Sources (HAPEM-MS) (Johnson 1995), and Benzene Exposure and Absorbed Dose Simulation (BEADS) (MacIntosh et al. 1995). One of the first attempts to evaluate population exposures to air pollutants was for CO with the SHAPE model using the exposure data collected in Denver during the winter of 1982/83 with personal samplers (Ott et al. 1988). The model results were generated using a Monte Carlo simulation based on Denver microenvironmental concentration data coupled with activity patterns simulated from actual activity patterns from Denver. According to the authors, reasonable agreement was obtained between the model predictions and actual measurements. The logarithmic-probability plot suggests that the SHAPE model underpredicted the top 5 to 10 percent of the measured population and overpredicted the bottom 5 to 10 percent (Ott et al. 1988).

More recent microenvironmental studies on CO exposures within automobiles and/or population distribution models have been done in Germany (Rudolf 1990); Boston (Chan et al. 1991b); California (Ott et al. 1993, 1994); Tapei, Taiwan (Liu et al. 1994); New Jersey (Lawryk et al. 1995); Paris (Dor et al. 1995); Mexico City (Fernandez-Bremauntz and Ashmore 1995); Amsterdam (van Wijnen et al. 1995); and Nottingham, United Kingdom (Clifford et al. 1997). Reviews of these and other data published in reports have shown a decline in ambient and in-vehicle CO levels since the 1970s (Flachsbart 1995). Overall, in-vehicle CO concentrations are elevated compared to ambient air. The values measured in the United States during the 1990s are lower than in other countries with median (and 90th percentile) CO concentrations in automobiles driven on suburban and urban commutes of 2.3 (5.9) ppm and 1.9 (6.9) ppm, respectively, while the average CO concentrations in the urban settings of other countries are between 7 to 20 ppm for the European cities and Tapei, and 40 ppm for Mexico City. In-vehicle CO air concentrations in rural regions which have limited traffic were lower in all studies. Linear regression models of CO exposure concentrations within automobiles based on central monitoring stations have shown only moderate predictive power (Fernandez-Bremauntz and Ashmore 1995), with the ambient monitoring stations typically underestimating the exposure levels (Liu et al. 1994). Therefore, extrapolation of ambient-air CO concentrations underestimates the exposure to automotive-derived compounds to commuters.

Two other inorganic gases associated with automotive emissions have also been measured within automobile cabins, ozone and NO₂; the former is a secondary pollutant formed in the atmosphere. The ozone levels within the automobile cabin in Raleigh, North Carolina across the three routes measured—urban, interstate, and rural (7, 9, and 42 ppb, respectively)—were lower than at ambient-air monitoring stations (42, 49, and 72 ppb, respectively)

(Chan et al. 1991a). The lower in-cabin ozone concentrations measured in heavier traffic areas were presumably due to reactions with NO emitted from the surrounding exhaust emissions which rapidly converted the ozone to oxygen. No consistent trends in the median NO₂ concentrations were observed with traffic density among the three routes (83 ppb urban, 75 ppb interstate, and 102 ppb rural) as was found of CO (13 ppm urban, 11 ppm interstate, and 4 rural) (Chan et al. 1991a). The mean 1-hr time-weighted-in-vehicle NO₂ concentration measured in Amsterdam was 277 µg/m³ or 146 ppb (van Wijnen et al. 1995). The NO₂ level was not correlated with CO, suggesting that its concentration within vehicles was not strictly a function of exhaust emissions, consistent with the results from North Carolina. The lack of a correlation may be a function of the time period required to convert NO to NO₂ and other chemistry that may be occurring between emissions and the penetration of the NO_x into the vehicle's cabin.

Many of the in-cabin automotive studies done during the 1990s have focused on the measurement of exposure to volatile organic compounds (Chan and Lin 1994; Chan et al. 1991a, 1991b; Dor et al. 1995; Jo and Choi 1996; Lawryk et al. 1995; SCAQMD 1989; van Wijnen et al. 1995; Weisel et al. 1992). This is because of the health concerns associated with these compounds and new analytic methodologies for VOCs that provided adequate sensitivity to measure air samples collected in automobiles. VOCs are either volatilized from the gasoline during evaporative losses or emitted in the exhaust as incomplete combustion products and have been found to be elevated in the interior of automobiles. Benzene and other aromatic compounds were the most frequently quantified compounds, although some studies have measured alkanes and fuel additives. The vehicle's interior concentrations are 5 to 10 times higher than the ambient atmosphere for many of these compounds and 2 to 3 times higher than indoor values (Table 68.1).

Several studies have tried to identify the major factors that influence the VOC contaminant levels within the automobile. The location of the route—urban, suburban, or rural—along with the time of day had the largest influence on the concentration (Chan et al. 1991a, Lawryk et al. 1995). Route and time of day are determinants of the traffic density and therefore the number of cars immediately around the test vehicle. The number of surrounding cars was shown in the CO studies to be an important contributor to the CO air concentration within automobiles (Ott et al. 1988). This is particularly evident in the measurements made while driving through a tunnel, which had the highest concentrations measured in New Jersey (Lawryk et al. 1995). Increased ambient VOC air concentrations are also associated with automotive emissions within and near tunnels (De Fre et al. 1994, Tsai et al. 1997). Window position, ventilation, and meteorological conditions had smaller but determinable influences on the in-vehicle VOC concentrations.

Because of logistic considerations, the general approach taken in all except one study has been to use a small number (<10) of cars operated by the investigators over predetermined routes selected to be representative of a specific type of traffic pattern, usually commuting. The exception was a study conducted in Los Angeles. The samples in this study were collected by providing 140 employees of a Californian state agency with air samplers for use during their normal commute over two seasons (SCAQMD 1989). The samples were analyzed for VOCs, formaldehyde, and particulate metals. The mean VOC in-vehicle concentrations measured in Los Angeles were higher than the other concentrations measured in the United States, although not higher than those measured in other countries (Table 68.1). Substantial variability in the in-vehicle concentrations was observed in the Los Angeles study, reflecting the different routes and automobiles that were sampled. A second factor that could be associated with the high variability in the in-vehicle air concentrations measured in Los Angeles was the inclusion of vehicles being driven by the study population without exclusion criteria based on mechanical or body integrity problems and the age of the vehicles. Vehicles with carburetors and that have malfunctions could result in self-contamination of VOCs in the automobile's interior as a result of evaporative emissions of gasoline within the engine com-

partment. Such an effect was observed in New Jersey, where one of the cars had a fuel-injected engine while the other had a carburetor engine (Lawryk et al. 1995). The car with a fuel-injected engine had a significantly lower concentrations of all compounds studied even though both were driven along the same route at the same time. The higher levels in the carburetor-powered vehicle indicated that uncombusted gasoline from the carburetor was penetrating into the cabin of the automobile. Further, on two occasions there were malfunctions of one car in New Jersey (a valve which did not open fully and a pinhole leak in a hose), which resulted in increased gasoline evaporation within the engine and significantly elevated concentrations of the VOCs in the malfunctioning car's interior. Proper maintenance of automobiles should optimize fuel combustion and reduce the amount of evaporative gasoline releases, thereby reducing potential exposures to both VOCs and CO to individuals in and near the automobile being maintained properly. These results suggest a relationship between the high-end exposures to emissions from automobiles in the population and maintenance of their automobiles. One study (Rodes et al. 1998) conducted in California revealed lower in-

cabin concentrations of selected VOCs and particle mass ($PM_{2.5}$) than reported a decade earlier in Los Angeles (SCAQMD 1989). These results indicate that the emission controls on automobiles and on gasoline during the 1990s have reduced the exposures to VOCs to commuters in Los Angeles.

Formaldehyde, a probable human carcinogen, is emitted in the exhaust. Its emission rate is increasing with greater use of alternate, oxygenated, and reformulated fuel. Formaldehyde concentrations in the cabin of automobiles [5 to $17 \mu\text{g}/\text{m}^3$ in Boston, Los Angeles, and Sacramento (CA)] are similar to levels measured in subways, while walking and bicycling (4 to $20 \mu\text{g}/\text{m}^3$) (Chan et al. 1991a, SCAQMD 1989, Rodes, et al. 1998) and in ambient air ($19 \mu\text{g}/\text{m}^3$), but lower than measured indoors ($60 \mu\text{g}/\text{m}^3$) (Zhang et al. 1994). Indoor air concentrations are elevated because formaldehyde is emitted from pressed-wood products and some synthetic products used in residential and commercial furnishings. The lower air formaldehyde concentrations in vehicles compared to indoors, combined with the greater amount of time spent indoors, results in a small percentage of the total daily formaldehyde exposure occurring in vehicles. No information on exposure to other aldehydes within vehicles has been reported, but will be measured as part of a study currently being conducted in Elizabeth, N. J., Houston, Texas, and Los Angeles, Calif, by the Environmental and Health Science Institute, Piscataway, N.J. and funded by the Health Effects Institute, Cambridge, Mass.

Several studies have been done to assess potential exposures to methyl *tert*-butyl ether (MTBE) (Liroy et al. 1994, White et al. 1995), a gasoline additive that is the single largest component (up to 15% volume basis) in many fuel blends and for which adverse health claims have been made (Mehlman 1996). MTBE is emitted as part of evaporative releases and in exhaust emissions when incomplete combustion occurs. MTBE has been found to be elevated inside automobiles relative to other microenvironments (Liroy et al. 1994). Evaporative emissions were identified as the primary source to MTBE in vehicle concentrations since higher concentrations were identified after filling the gasoline tank, and the automobile with the highest evaporative emission rate had the highest interior MTBE concentration.

An additional compound associated with automotive exhaust that has not yet been analyzed inside the automobile cabin, but of potential health concern, is 1,3-butadiene. This compound is present in exhaust emissions from automobiles (Ye et al. 1997) and has a high cancer potency. It has the highest cancer unit risk factor of 38 nonmethane hydrocarbons, including benzene, measured in the air around a tunnel which was highly impacted by automotive emissions (Duffy and Nelson 1996).

Particle exposures within automobiles have been reported by only a limited number of investigators (Buckley and Ott 1996, Ptak and Fallon 1994, SCAQMD 1989). Diesel engines found in most buses and trucks produce large numbers of particles during the combustion process, particularly polyaromatic hydrocarbons (PAHs). More than 90 percent of particles within automobile cabins are $<1 \mu\text{m}$ in diameter. Particles are also generated by mechanical abrasion within the motor, from brakepads and the road surfaces. The average total suspended particle air concentrations in a vehicle driven along an urban route in Madison, Wisconsin was $105 \pm 30 \mu\text{g}/\text{m}^3$ (Ptak and Fallon 1994). In-vehicle particle levels were higher when the traffic density was greater, although roadway air concentrations exceeded the in-cabin concentration because of removal of particles by the ventilation system of the cars. Within cars driven in North Carolina and California, real-time measurements of PAHs on particles smaller than $1 \mu\text{m}$ and CO were both elevated compared to ambient levels. The concentrations range from baseline levels of $<200 \text{ ng}/\text{m}^3$ and $<2 \text{ ppm}$ for PAH and CO, respectively, to short-term spikes of $>1000 \text{ ng}/\text{m}^3$ and 10 ppm , respectively, when individual trucks and buses drove past the automobiles containing monitors (Buckley and Ott 1996). The $PM_{2.5}$ and PM_{10} concentrations were 6 to $22 \mu\text{g}/\text{m}^3$ in automobiles driven in Sacramento and 29 to $107 \mu\text{g}/\text{m}^3$ in Los Angeles (Rodes et al. 1998).

The ambient-air concentrations measured for these two particle size fractions were much greater than in the cabins of automobiles.

Fuel additives can contribute to particulate loadings in exhaust emissions and alter the composition of particles generated. Lead exposure from gasoline emissions, when tetraethyl lead was used as an octane enhancer and antiknock agent in the United States, was a major source of lead exposure to the general U.S. population but also could increase lead exposures while driving an automobile. Lead is no longer added to gasoline in the United States. However, lead's continued addition to gasoline in developing countries in Latin America and Asia is still a major health concern, and plans to decrease reliance on tetraethyl lead as an octane enhancer have and are being developed (Onursal and Gautam 1997, Walsh and Shah 1997, Lovei 1998). While it is critical that developing countries plan to decrease and eventually eliminate the reliance on lead additives in gasoline, the potential adverse health effects of other octane enhancers, such as high levels of aromatic hydrocarbons, resulting in increased benzene emissions, methylcyclopentadienyl manganese tricarbonyl (MMT), and oxygenated compounds (methyl *tert*-butyl ether, ethyl *tert*-butyl ether, and methanol), need to be considered when choosing an appropriate substitute (Menkes and Fawcett 1997). MMT has been used in Canada and has been proposed for use in the United States as an antiknock gasoline additive. The use of MMT may have resulted in increased fine-particle manganese levels in remote areas (Wallace and Slonecker 1997), although it is unclear whether an elevated signal in background manganese levels was observable in Canadian cities or increased the general-population-based exposure (Loranger and Zayed 1994, Loranger et al. 1994, Pellizzari et al. 1999). Elevated levels of particulate manganese were measured for taxicab drivers compared to office workers in Toronto, Canada, indicating that in-cabin levels of particulate manganese are elevated compared to ambient and indoor air when MMT is used as an additive in fuel (Zayed et al. 1996).

Air Exchange Processes and Meteorological/Car Conditions that Control Concentrations

Continuous CO measurements were used to evaluate air exchange rates (AERs) within automobiles and to evaluate temporal CO concentration changes (Ott et al. 1994, Ott and Willits 1981). The in-vehicle CO concentrations decreased exponentially with time when an automobile was distant from the exhaust of other vehicles. As expected, shorter time constants were calculated when a window was open and with increasing vehicle speed. The air exchange rate ranged from 0.023 air exchanges per minute when the vehicle was parked to 1 to 2 air exchanges per minute when it was driven at 20 mph (mi/h). Similar results for a stationary vehicle were obtained when the windows were closed, although higher AERs (0.5 air exchange per minute) were measured when the windows were opened and mechanical ventilation was on (Park et al. 1998). The AER increases with increasing car speed and for stationary vehicle is a function of wind speed across the car, heating effects, and sheltering of the car.

The AER affects the concentration of compounds entering or residual compounds leaving an automobile. Even with the high AERs reported for a moving vehicle, it has been observed that if the initial CO concentration in an automobile starts at background ambient levels, such as during a morning commute, then a "buffering effect" minimizing the CO exposure within the automobile occurs when the windows are kept closed during short trips (Clifford et al. 1997). Conversely, the mean concentration of CO during an evening commute was higher than during a morning commute; the authors attributed this to residual CO in a vehicle at the start of an evening commute (Clifford et al. 1997), although the difference was reduced as the average speed of the automobile increased (Flachsbart et al. 1987). During longer commutes the average VOC concentrations of two vehicles driven in tandem

along the same route, one with the windows opened and a second with the windows closed, were not significantly different (Lawryk and Weisel 1996).

In-vehicle CO concentrations varied temporally, dependent on the roadway air concentrations immediately around the vehicle at a given time, and increased while the vehicle was waiting at traffic lights (6.8 to 14.9 ppm) surrounded by the exhaust from other automobiles. Carbon monoxide spikes have been observed while driving on an open parkway when individual vehicles with apparently high emissions of CO drove past a vehicle with a monitor (Buckley and Ott 1996). Individual CO concentrations can be as high as 50 ppm for short (<1 min) time periods (Weisel, unpublished data).

68.3 EXPOSURES IN BUSES, TRAINS, MOTORCYCLES, PEDESTRIANS, AND BICYCLES

Sources of Pollutants

The proximity of a variety of transportation modes to roadways results in elevated concentrations to compounds emitted by automobiles and trucks compared to other microenvironments. The utilization of a particular transportation mode by the general population varies with location because of differences in mass-transit infrastructure, culture, and economics. Commuting to work by buses, trains, bicycles, motorcycles, and walking is more common within urban centers, where the infrastructure for these modes of commuting exists, and outside the United States, where the culture and economics can favor these transportation modes rather than an automobile. Automotive emissions originate in roadways and diffuse outward. Air concentration gradients existing in roadways depend on traffic density. Individuals riding motorcycles and bicycles in the street are in closer proximity to exhaust emissions from the surrounding vehicles than are individuals riding in an automobile and therefore have potentially higher exposures. Increased respiratory rates while walking and bicycling compared to driving increases inhalation exposures compared to driving for the same air composition. Drivers have breathing rates slightly higher than individuals who are sitting at rest (USEPA 1997).

The movement of pollutants away from a roadway is a function of wind speed, wind direction, and atmospheric stability. The air concentrations on sidewalks immediately adjacent to highly traveled roadways will mirror the air concentration pattern within the roadway and therefore be highly variable. Air concentrations decrease with distance from the roadway as roadway air is diluted by mixing with the surrounding air. Lower concentrations occur with increasing wind speed and upwind of the roadway. Temporal differences within and between days are also predicted, with highest concentrations during commuting times.

Comparison of Concentrations and Exposures among Different Modes of Transportation

Most studies of exposures in alternate transportation modes have measured carbon monoxide and volatile organic compound exposures (Table 68.2), although limited data on particulate and biological exposures also exist (Bevan et al. 1991; Chan et al. 1991a, 1991b, 1993; Fernandez-Bremauntz and Ashmore 1995; Flachsbart 1988; Flachsbart et al. 1987; Jo and Park 1998; Spengler et al. 1997; Tsai et al. 1997). Differences in reported air concentrations are likely to reflect different source strengths in the various countries where the measurements were made. In addition to the differences inherent among the various modes of transportation, variations could be due to the types of emissions controls, traffic

density, meteorological conditions, and mode of operation of the alternate transport. Trains operate both above and below ground. Buses make a varying number of stops to pick up and discharge passengers, often near busy intersections. Motorcycles are often driven in the same lanes as automobiles, while bicycles may not be.

Two studies have measured particles during nonautomotive travel. Individuals who commute by bicycle were exposed to higher levels of respirable suspended particles ($<3.5 \mu\text{m}$), $130 \mu\text{g}/\text{m}^3$, than they would encounter indoors (Bevan et al. 1991). Air concentrations of platinum, which come from the catalytic converters in cars, were higher on buses traveling on routes with the highest traffic density (Schierl and Fruhmman 1996).

Microbial measurements in the air and wipe samples from seats have been made on buses, subways, and trains for fungi, bacteria, and allergens, examining individual taxa (Spengler et al. 1997). Microbial concentrations were similar to or slightly lower within these vehicles than in Boston area living rooms measured during the same time period, and the taxa reflect human sources. None of the individual transportation modes was consistently higher for all types of microbes. No data on microbiological levels within cars have been identified, although it is expected to be a combination of the concentration in the surrounding air, which will vary with location, and whether the fabric in the car can be a source for growth of microbes.

68.4 AIRPLANES

Sources of Pollutants

Airplanes are enclosed environments that rely solely on recirculating air when airborne and are in close proximity to evaporative fuel emissions and exhaust from other aircraft and ground vehicles when at a terminal. Airplanes also transport people within close quarters along with daily or more frequent cleaning and disinfecting of the interior than other transportation vehicles. The temporal variability of carbon dioxide, carbon monoxide, and particle counts and average concentrations of nitrogen dioxide, VOCs, and ozone have been measured on a limited number of commercial flights (Spengler et al. 1997, Lee et al. 1999). Carbon dioxide comes from exhaust emissions while on the ground and from passengers while airborne, and averaged 1400 ppm (1200 to 1800 ppm) and 1700 ppm (1000 to 2300 ppm) during cruising and boarding, respectively. Carbon monoxide's average concentration was 0.7 ppm (0.8 to 1.3 ppm). The ranges of particulate mass concentrations for entire flight segments were 1 to $5 \mu\text{g}/\text{m}^3$ while cruising and 10 to $25 \mu\text{g}/\text{m}^3$ while boarding, with maximum 10-min average values varying from 3 to $10 \mu\text{g}/\text{m}^3$ while cruising and 11 to $90 \mu\text{g}/\text{m}^3$ while boarding. Temporal concentration profiles of these compounds had the highest concentrations when a plane was required to remain at the gate and the passengers entered and left the plane. All measurements reported above were made on domestic U.S. flights where smoking is prohibited (Spengler et al. 1997). Higher particulate matter concentrations were found on smoking flights, 81 to $264 \mu\text{g}/\text{m}^3$ (Lee et al. 1999). The mean nitrogen dioxide air concentration measured in airplanes was 36 ppb (23 to 60 ppb), while ozone concentrations were consistently below detection level (<10 ppb). Individual VOCs, associated with specific sources onboard the aircraft, were consistently detected in air samples. The VOCs identified included ethyl alcohol, from the alcoholic beverages served; acetone, a bioeffluent from people; isopropyl alcohol, a common cleaning agent; butanone, which is emitted from plastics; limonene, from air fresheners; 111-trichloroethane, a degreaser; toluene, used in cleaning and cosmetic products; and tetrachloroethene, a dry-cleaning agent.

Microbial agents on airplanes are at similar or lower levels than in typical indoor environments and on other modes of public transportation, buses, subways, and trains (Spengler

et al. 1997). On airplanes people occupy smaller volumes of space than in a typical office setting and are the likely source of bacteria which had an overall in-plane mean concentration across all segments of the travel of 201 cfu/m³. The fungal concentrations in the air of the plane and in the dust of the seats were lower than on other modes of public transportation, although no striking differences among the taxa were found across the different modes of transportation. Dustborne allergen concentrations on seats were somewhat higher on the airplane than in other modes of public transportation and in a living room in Boston, the city in which the investigators lived. The lower bacterial and fungi air concentrations on the planes may reflect the frequent cleaning and the filtering of the circulating air within airplanes. The greater the amount of upholstery in airplanes than in homes, offices, buses, or trains could serve as a reservoir for dustborne allergens. The bacterial counts during boarding a plane in Hong Kong were slightly higher (53 to 79 cfu/m³) than during midflight (40 to 76 cfu/m³) (Lee et al. 1999).

Similar concern for exhaust and evaporative emissions, and microbial and indoor generated air contaminants would also exist for ships that have interior cabins. Occupational exposures during loading and unloading of fuel during maritime operations are higher than for trucks because of the greater amount of fuel transferred and the longer exposure periods (Smith et al. 1993). No studies were identified that measured the air contaminant levels within the cabins of ships.

68.5 ANCILLARY FACILITIES AND IMPACT ON SURROUNDINGS

Refueling

Potential for high acute exposures to the volatile components from gasoline can occur during fueling and the delivery of fuel to neighborhood service stations. Service stations also have idling automobiles and trucks waiting to refuel, contributing to exposure to exhaust emissions. The greatest exposure concentrations occur to the individual who actually fills the gasoline tank (Johnson et al. 1993, NESCAUM 1989), with total hydrocarbon concentrations near the pump exceeding 200 ppm (Table 68.3). The introduction of vapor recovery systems on gasoline pumps, such as "Stage II systems," has reduced the evaporative emissions into the air and therefore potential exposures to VOCs even in the presence of spills during refueling (MacIntosh et al. 1994). The breathing zone concentrations are of concern to service station employees who work 8-h shifts and for single acute, 3- to 5-min exposures to the general population. On any given day 20 percent of the population has reported visiting a gasoline station for up to 10 min, with slightly more than half of those individuals pumping their own gasoline (Tsang and Klepeis 1996). In addition to the person pumping gas being exposed to elevated air concentrations of gasoline components, elevated levels have been measured within the automobile being fueled (Liroy et al. 1994, Vayghani and Weisel 1999). These elevations are due primarily to evaporative emissions associated with the fueling of the automobile. The highest in-vehicle concentrations were identified when the window was opened during fueling (Vayghani and Weisel 1999). The evaporative emission rate from the automobile being fueled was also a controlling factor, with the highest concentrations evident when the automobile was known to have a leak or malfunction in the fuel system (Liroy et al. 1994).

Fuel properties as well as ambient conditions affect the evaporative emission rates and composition. *Gasoline volatility*, as defined by the *Reid vapor pressure*, is adjusted seasonably to minimize evaporation during the summer while maintaining sufficient vapor pressure in the winter for the automobiles to start in cold weather. High air concentrations

during fueling are therefore likely to occur on warm days when the fuel volatility is high. This is one likely reason for the difference in the air concentrations observed in the 1993 and 1999 studies in New Jersey (Liroy et al. 1994, Vayghani and Weisel 1999). The 1993 study was done in April, when low vapor pressure fuel was in use, whereas the 1999 study included samples collected on several warm days in January and February with higher-vapor-pressure fuel. The addition of fuel additives alters the distribution of compounds emitted. Oxygenated additives such as MTBE and ethanol have resulted in concerns about exposure to these compounds and to increased aldehyde emissions during the combustion processes. Diesel fuel has lower overall volatility than gasoline because it contains a greater percentage of higher-molecular-weight alkanes. This difference in composition between gasoline and diesel fuel results in differences in the composition of their evaporative emissions, and diesel exhaust emissions produce more particulate matter than does gasoline combustion. The use of other alternate fuels, such as methanol or mixtures of methanol and gasoline, would also change the profile of compounds emitted and potential exposures from automotive emissions.

Fenceline Impacts on Surrounding Homes

The impact of emissions from service stations on surrounding communities is an environmental concern. Typically, the air concentrations at the fenceline or perimeter of the service

station downwind of the facility is considered to be the maximum exposure for the community. The Northeast States for Coordinated Air Use Management incorporated a number of studies into a modeling exercise to predict concentrations off site using the USEPA *industrial source complex long-term dispersion model*, a steady-state gaussian plume model (NESCAUM 1989). The predicted total hydrocarbon exposure levels in the residential area had mean and upper limit values of 5.4 and 28 ppb, respectively. The predicted mean (upper limit) values for benzene, toluene, and xylene residential area concentrations downwind of service stations were 0.04 (0.16) ppb, 0.08 (0.37) ppb, and 0.03 (0.15) ppb, respectively. These predictions are considerably lower than measurements made at the perimeter of service stations in New Jersey, New York, and Connecticut during 1993, median and maximum values for total hydrocarbons of 200 and 11,000 ppb and benzene median and maximum values of 1 and 8 ppb (Johnson et al. 1993). However, the model did not use parameters specific to the stations sampled, and the predictions were for residences in the community, not service station perimeter values, although the model was generated for the northeastern United States.

Residential and Commercial Parking Garages

Parking an automobile in a garage attached to a home results in evaporative emissions from the fuel tank entering the garage. During the summer, benzene air concentrations in the garage were tens to hundreds of $\mu\text{g}/\text{m}^3$ (Furtaw et al. 1993, Lansari et al. 1996, Thomas et al. 1993, Weisel and Mohan 1994). The volatile gasoline contaminants in the garage air can penetrate into the attached residence at a rate dependent on the air exchange rate between the garage and residence. The penetration of garage air can cause evaporative fuel emission to be the major source of VOCs in the home (Lansari et al. 1996, Thomas et al. 1993). Since people spend large portions of the day indoors at home, this source of contaminants to the indoor home can be an important exposure pathway for many volatile compounds in gasoline.

Elevated air concentrations of exhaust and evaporative emissions have been measured in commercial parking garages (Colome et al. 1992, Flachsbarth 1988, Weisel and Mohan 1994). The exhaust emissions arise from idling cars looking and waiting for parking spaces, and the evaporative releases are from hot-soak emissions. Air concentrations up to 150 $\mu\text{g}/\text{m}^3$ for benzene and 52 ppm for CO have been reported. For individuals who use these facilities daily, this microenvironment can be a significant contributor to the total exposure to automotive emissions even though the amount of time spent in a parking garage is relatively short; the median daily duration for those visiting parking facilities is 20 min (Tsang and Klepeis 1996). The air concentrations within a parking garage can be significantly reduced by not completely enclosing the parking garage (Weisel and Mohan 1994). The gasoline derived VOCs and CO in the air within the parking garage can penetrate into attached office buildings if the inlet for the building's HVAC system is near the garage.

68.6 RELATIVE IMPORTANCE OF EXPOSURE DURING TRANSPORTATION ACTIVITIES RELATED TO TOTAL EXPOSURE

Activities surrounding transportation result in elevated exposures to pollutants arising from automotive and diesel exhaust and evaporative emissions, including CO, CO₂, NO_x, particulate matter, and VOCs from fuels. The impacted microenvironments include automobiles, buses, trains, airplanes, service stations, sidewalks, roadways, parking garages, and homes with attached garages. In the United States, traveling in an automobile is the most common mode of transportation. While the amount of time that people spend in an automobile is a

small portion of a given day, daily average of 1.6 h or 6.6 percent of a day (Klepeis et al. 1996), the elevated mean concentration for many of these compounds in vehicles relative to ambient and indoor air results in ~13 percent of the daily exposure to these species occurring during traveling. The 90th-percentile exposures while driving are 5 to 10 times the median exposures, thereby contributing an even greater fraction of the total daily exposure to the fuel-derived pollutants (Lawryk et al. 1995). The elevated air concentrations of gasoline-derived compounds observed in other modes of transportation relative to ambient and indoor air concentrations result in most transportation microenvironments having the percentage of daily exposure exceeding the percentage of the day spent traveling. The contribution to exposure to compounds in exhaust and evaporative emissions of automobiles during traveling may be even more pronounced in countries where the controls on automotive and diesel emissions are less stringent than in the United States. Acute high exposures to volatile components from gasoline have been identified with fueling of automobiles and to volatile compounds and CO with time spent in parking garages. These acute exposures can contribute to acute health responses as well as contributing significantly to total exposure, even though the time spent fueling cars and being in parking garages is short. Exposures to microbial agents within public transportation are similar to those that occur indoors. The exposure concentrations and time spent in microenvironments associated with transportation are lognormally distributed, with the higher-end air concentrations often associated with malfunctioning vehicles. Almost 20 percent of the total benzene exposure among the general population who do not smoke occurs while driving a car (Wallace 1996). Benzene is an extensively studied hazardous air pollutant present in gasoline. Further, population distributions of benzene exposures also included driving as an important contributor across the entire range of the population exposure distribution (MacIntosh et al. 1995). As discussed previously, CO exposures while driving were a major component of total CO exposure (Ott et al. 1988). Thus, total population exposure assessments to compounds contained in evaporative and exhaust emissions of automotive and diesel engines need to factor in all transportation activities, particularly for the high-end exposure group, to fully assess exposures to the compounds emitted.

CHAPTER 69

DAY-CARE CENTERS AND HEALTH

Jouni J. K. Jaakkola*
*Environmental Health Program
The Nordic School of Public Health
Göteborg, Sweden*

69.1 CHILDREN'S HEALTH PROBLEMS AND FORM OF DAY CARE

Since 1980 an increasing number of mothers of young children are entering the workforce in the industrialized countries, and as a consequence a larger proportion of children attend day-care centers outside the home. The day-care arrangements vary from care in small groups in families outside the home to publicly or privately organized day-care centers where usually professionally trained staff take care of the children while parents are at work. In the United States the percentage of children aged 3 to 5 years enrolled in preprimary programs increased from 37 percent in 1970 to 59 percent in 1990 (Willer et al. 1991). In Norway 80 percent of the children and in Finland 50 percent attend day-care centers some time before school. The quality of day-care centers is therefore important, and there is need to monitor both the physical and social environmental factors. The importance is emphasized by the fact that exposure to day-care environment begins early in life during a period when the human, still developing, is more susceptible to the effects of environmental factors than later in life.

A British study reported in the 1940s that children in wartime nurseries experienced more frequent respiratory infections compared with children in home care (Allen-Williams 1945). Similar observations were made during the same time period in Sweden (Hessselvik 1949). Population-based studies from Finland (Louhiala et al. 1995), the United States (Fleming et al. 1987, Marbury et al. 1997), and Norway (Nafstad et al. 1999) have quantified the effects of care in day-care centers on different upper and lower respiratory tract infections. Table 69.1 shows the results of three comparable studies from different countries. The magnitude of effects are similar. Several studies have clearly shown that the effect of the type of day care on respiratory infections is strongest in the youngest children (Louhiala et al. 1995, Marbury et al. 1997). A cohort study carried out in Minnesota

*Formerly of School of Hygiene and Public Health, Johns Hopkins University, Baltimore, Maryland.

TABLE 69.1 Form of Day Care and Respiratory Infections

Authors (year), location	Study population	Study design	Infection	Home care incidence rate, episodes per person-year	DCC incidence rate, episodes per person-year	Adjusted incidence rate ratio

			Otitis media	0.31	0.44	1.48 (1.22–1.80)

*Not enough episodes.

children indicated a genetic susceptibility, showing a stronger effect of day-care center attendance on the lower respiratory tract among children whose parents have asthma than in children of nonasthmatic parents (Marbury et al. 1997). They also showed a higher incidence rate ratio of lower respiratory tract illness for girls than for boys. The inference is complicated by the fact that the base incidence rate among girls was lower than among boys. We showed in a study of Oslo children that care of an older sibling in a day-care center substantially increased infants' risk of both upper and lower respiratory tract infections (Nafstad et al. 1996), as well as otitis media (Kværner et al. 1996).

A traditional explanation for the increase in infections in day-care center children follows from the paradigm of infectious diseases; experience of a greater number of contacts with other children in day-care centers compared with home care increases probability of being exposed to infectious agents, the direct causes of infections. Presence of infectious agents is by definition a necessary cause of infections. A sufficient cause of infection may include individual characteristics ("host factors") as well as environmental factors in addition to the infectious agent. We observed a large variation in the occurrence of infections in different day-care centers in a Finnish population-based study of 30 randomly selected day-care centers (unpublished results) even after taking into account the number of children in the center, as well as the age distribution. This suggests that environmental factors play a role in the transmission of infections.

There is increasing evidence that exposure to physical, chemical, and microbiological indoor air pollutants also may cause various health problems other than infections (reference to other chapters). The possible health effects vary from respiratory symptoms caused by short-term exposure to volatile organic compounds (VOCs) in the air to lung cancer caused by long-term exposure to radon or environmental tobacco smoke. We do not know enough about day-care centers to estimate their contribution to children's total exposure to various environmental factors. Information about the environmental conditions in day-care centers would enable us to assess the possible health effects on the basis of studies carried out in the homes. Only a few studies have empirically assessed the relations between day-care environment and health of children and nursing workers.

This chapter reviews the current knowledge about environmental conditions in day-care centers, and considers possible health effects on the basis of exposure information. The limited number of studies of health effects carried out in an actual day-care environment are reviewed. This chapter also summarizes the main types of infectious diseases whose risk may be increased as a result of day-care center attendance, and the role of airborne transmission as part of the general topic of indoor air quality. The body of literature about spread of infections in day-care centers is large (Churchill and Pickering 1997) and belongs mainly to the domain of infectious disease epidemiology, and thus is not covered here.

69.2 THE DAY-CARE CENTER ENVIRONMENT

This section presents two different models for the health effects of indoor environment, and gives an overview of the determinants of indoor air quality, which are dealt with in more detail in Sec. 69.3.

Models of Health Effects

The impact of indoor air quality in day-care centers on health forms a complex causal web, which is not well understood. There are two different models for the health effects of indoor environment: the *infectious disease model* and a model commonly used in studies of physical, chemical, and biological exposures referred to here as the *environmental disease model*.

In the conventional infectious disease model, the spread of infections depends on the characteristics of the infectious agent, host, and the environment (Gordis 1996). The transmission of infectious agents can take place via air, water, physical objects, and direct contact of individuals. In this chapter, we are interested mainly in the role of indoor air in day-care centers in spreading infections. Indoor air quality may influence the spread of infections by an effect on the viability of the agent and an effect on the host's susceptibility to infections. Ventilation rate, air distribution, and recirculation of air are theoretically likely to influence the spread of infectious agents, although this topic has not yet been studied empirically in indoor environments. An important feature of this model is the dynamics of epidemics in groups after one individual has contracted an infection. Different organisms spread in different ways, and the potential of a given organism for spreading and producing outbreaks depends on the characteristics of the organism, such as rate of growth and the route(s) by which it is transmitted from one person to another.

In the environmental disease model, the concentrations of pollutants over time encountered by an individual are seen as the key. Short-term or long-term exposure to these concentrations may have direct health effects. But in contrast to infectious diseases, environmental diseases are not communicable. There are two types of links between infectious and environmental disease models: (1) environmental exposures influence an individual's susceptibility to contract an infection in the presence of infectious agents and increase the risk of outbreaks of infection in populations and (2) individuals suffering from an infectious disease may be more susceptible to the effects of environmental exposures.

Determinants of Indoor Air Quality

The determinants of indoor air quality can be divided into (1) outdoor sources, (2) building envelope, (3) occupants and their activities, (4) physical indoor sources, and (5) heating, ventilation, and air conditioning. Table 69.2 gives examples of different determinants of indoor air quality in buildings in general and with a special reference to day-care centers.

TABLE 69.2 Determinants of Indoor Air Quality in Day-Care Centers

Source	Pollutants/influence
Outdoor	
Air	NO _x , SO ₂ , particles
Water	Volatile trihalomethanes
Soil	Radon progeny
Building envelope	
Structure	Penetration and elimination
Openings	Penetration and elimination
Occupants	
Body	Metabolic products: CO ₂ , viruses, bacteria
Activities	VOCs, particles, cleaning residues, allergen resuspension
Smoking	VOCs, particles
Physical environment	
Building materials	VOCs, organic and inorganic particles
Surface materials	VOCs, organic and inorganic particles
Dampness	Molds
Use of pesticides	SVOCs
Use of cleaning materials	VOCs
HVAC	Organic and inorganic particles

Outdoor Sources. All the environmental elements surrounding the building, including air, water, and soil, have a potential impact on indoor air quality. The roles of air pollutants from industry, traffic, heating, and natural sources have received most interest, although only few studies of outdoor-indoor penetration have been conducted. Radon progeny from the soil are a well-described source of carcinogenic exposure in homes (Samet 1991). Although there are no major reported studies of the levels of radon progenies in day-care centers, the studies of dwellings suggest that exposure to radon occurs in a large proportion of day-care centers in the areas where radon levels in dwellings are high. In addition to ingestion, inhalation, and absorption through the skin are possible routes of exposure to pollutants in the tapwater during showers and baths. Volatile chlorination by-products (Maxwell et al. 1991) and radon progeny (Barnett et al. 1995) are examples of potentially carcinogenic compounds in the tapwater. Thus, geographic location of the day-care center is an important factor that determines the exposure to environmental factors both outdoors in the playground and indoors. For example, day-care centers in the vicinity of industrial plants or busy traffic routes may contribute substantially to children's total exposure to various environmental factors. Good location of the day-care centers has not received the attention it deserves among the decisionmakers, architects, or health officials.

Building Envelope. The type of building, the structures, openings, and the type of ventilation system influence the penetration of outdoor pollutants into buildings as well as elimination of air pollutants from indoor sources.

Occupants as Indoor Sources. Children and day-care personnel constitute a substantial source of indoor air pollution. The human body produces carbon dioxide, carbon monoxide, ammonia, acetone, alcohol, and various other odorous organic gases through respiration and perspiration, and skin releases particles into indoor air. Occupants also are sources of bacteria and viruses, which may cause infectious diseases. Clothing materials may release various types of particles, and clothes may carry particles and absorbed gas from one microenvironment to another. For example, individuals can bring animal dander in their clothes from homes to day-care centers.

Physical Indoor Sources. Building materials used in floors, walls, and ceiling are potential sources of indoor air pollution. Formaldehyde related to emissions from building materials was a typical large-scale health problem that emerged in the 1970s (Marbury and Krieger 1991). Also materials used in furniture, curtains, and carpets may emit substantial amounts of VOCs or particles and may serve as a reservoir for allergens. Dampness problems in buildings may be caused by structural deficiencies; the typical problems vary across different climates. Dampness promotes microbial growth and creates suitable conditions for house dust mites and cockroaches. Use of pesticides in day-care centers may cause high short-term exposures. Little is known about the frequency of pesticide use in the day-care centers, but studies in homes have indicated that exposures to toxic semivolatile pesticides, such as chlorpyrifos, can be high if pesticides are used (Fenske et al. 1990). Chlorpyrifos have a tendency to accumulate on floors and toys and be absorbed through the skin and ingestion (Gurunathan et al. 1998). Cleaning materials are an additional load that may increase children's chemical exposure substantially (Wolkoff et al. 1998).

Heating, Ventilating, and Air Conditioning. Heating, ventilation, and air conditioning (HVAC) may influence indoor air quality in various ways. Air change dilutes the concentrations from indoor sources given that outdoor concentrations are substantially lower than indoor concentrations. Ventilation systems may also increase indoor air pollution by carrying indoor pollutants from outdoor to indoor air. Air humidification may alleviate health problems related to the effects of too dry air, but air humidification equipment may also

serve as a source of microbial growth in indoor air pollution, leading to adverse health effects.

69.3 ENVIRONMENTAL CONDITIONS AND HEALTH

This section systematically presents the current knowledge about environmental conditions in day-care centers, and evaluates the possible health impact on the basis of exposure information, and studies of the health effects of environmental factors in day-care centers.

Air Change

The main purpose of a ventilation system is to maintain good indoor air quality in buildings by changing air by removal and dilution of pollutants and supply of fresh air. In naturally ventilated buildings, air moves into and out of the building through intentionally provided openings, such as windows and doors, or through nonpowered ventilators, or by infiltration. Day-care centers are sited in different types of buildings, either specially designed for the purpose or located in buildings originally planned for other purposes. Correspondingly, all main types of ventilation systems are represented.

Studies that have systematically assessed the ventilation rates of at least 10 day-care centers have been reported only from the Nordic countries (Olsen and Døssing 1982, Pejtersen et al. 1991, Sverdrup et al. 1990, Ruotsalainen et al. 1994). Table 69.3 summarizes the air change rates from these studies. Pejtersen and colleagues (1991) reported a mean air change rate of 2.4 h^{-1} [i.e., 2.4 ACH (air changes per hour) (range 0.3 to 4.1) in 10 Danish day-care centers, which corresponded to 6.9 L/s per person (range 3.6 to 11.8). In 71 Swedish day-care centers, the mean air change rate was 1.3 h^{-1} , no values were given for ventilation rates per person (Sverdrup et al. 1990). In a random sample of 30 day-care centers in the city of Espoo, southern Finland, the mean air change was 1.5 h^{-1} (range 0.1 to 4.0) and the ventilation rates were on average 3.8 L/s per person (range 0.2 to 8.8 h^{-1}).

The general observation was that air change is insufficient in a majority of day-care centers, although there were also some day-care centers with good air quality. Air change rates measured as airflow in volume units per hour were relatively low, but in particular airflows calculated per person were very low, and probably insufficient to dilute human emissions such as carbon dioxide. High carbon dioxide concentration has direct influence on alertness at levels above 1000 ppm, at concentrations above 1500 ppm respiration is affected and breathing becomes faster, and concentrations above 3000 ppm can cause headache, dizziness, and nausea. Carbon dioxide concentrations indicate also high concentrations of other human bioeffluents. In a study of 91 randomly selected day-care centers in Montreal, the average CO_2 concentration was 1500 ppm (range 900 to 2400), indicating lower than optimal ventilation rates in a majority of the facilities (Daneault et al. 1992). Similar findings were reported from two studies of Norwegian day-care centers, one carried out in the Trondheim region (THF 1987) and the other in Oslo (Skåret and Nordvik 1998) (Table 69.3).

Insufficient air change is a common problem in day-care centers, and theoretically low air change increases concentrations of any air pollutant from indoor sources, so it may modify the adverse effects of indoor pollution. In the Finnish day-center study, nurses working in day-care centers with low ventilation rate ($< 2.5 \text{ L/s}$ per person) did not report more symptoms of the eyes, respiratory tract, or general symptoms compared with those working in day-care centers with higher ventilation rate, although perceptions

TABLE 69.3 Summary of the Studies on Air Change in Day-Care Centers

Reference	Country	N	Air change rate (h ⁻¹) mean (range)	Airflows, L/s per person* mean (range)	CO ₂ , ppm mean (range)
Sverdrup et al. (1990)	Sweden	71	1.3	—	—
Pejtersen et al. (1991)	Denmark	10	2.4 (0.3–4.1)	6.9 (3.6–11.8)	1400 (900–2600)
Ruotsalainen et al. (1993)	Finland	30	1.5 (0.1–4.1)	3.8 (0.2–8.8)	810 (400–2500)
THF (1987)	Norway	50	—	—	1500 (400–3000)
Daneault et al. (1992)	Canada	91	—	—	1500 (900–2400)
Skåret and Nordvik (1998)	Norway	50	—	—	— (700–2740)

* 1 L/s = 2.2 ft³/min.

of metabolic odors were more common (Ruotsalainen et al. 1993). The ventilation rates varied from 0 to 11 (L·s)/p, but the windows were operable, which may explain the lack of association between symptom occurrence and ventilation rate. Studies in office workers have indicated that the risk of eye, respiratory, skin, and general symptoms related to the sick building syndrome are greater in ventilation rates below 10 (L·s)/p (Jaakkola and Miettinen 1995, Godish and Spengler 1996). However, office buildings are not directly comparable with day-care centers, because of differences in sources of indoor pollution as well as age of occupants. A matched case-control study of bronchial obstruction in Norwegian children provides evidence of possible adverse health effect due to low ventilation rates. Although there was no association between experiencing bronchial obstruction during the first 2 years of life and ventilation rate in homes in the total study population (Øie et al. 1999), the association between the risk of bronchial obstruction and several exposure indicators, including dampness problems, and the presence of PVC and textile surface materials, was stronger in homes with an air change rate below Norwegian standards (0.5 h^{-1}). The results suggest that low ventilation rates contribute to bronchial obstruction, an early sign of childhood asthma, in homes with strong sources of indoor air pollution. Moreover, the results suggest that adverse effects could be alleviated by increasing ventilation rates.

In summary, low ventilation rates, such as have been measured in day-care centers, are likely to increase the risk of adverse effects by failing to remove air pollutants emitted from indoor sources. Increase of air change may often be a cost-effective way to improve indoor air quality, although the control of sources should always be the priority.

Air Temperature and Relative Humidity

At a constant level of physical activity and clothing, air and radiant temperature, air velocity, and humidity are the three most important factors affecting human thermal comfort (Fanger 1967). The thermal environment affects mucous membranes and skin, causing direct effects via neural sensors of the tissues. There are indirect effects on the central nervous system caused by neurosensory stimuli and changes in blood circulation (Berglund et al. 1991).

Small children's thermal comfort has not been studied, probably because of difficulties in collecting information of a subjective nature. Some of the day-care center studies measured both air temperature and relative humidity. In the Finnish day-care center study, the temperature, relative humidity, and CO_2 concentration of indoor air were monitored for a period of 7 h in two rooms, one room occupied by infants 0 to 2 years old and one occupied by children 3 to 6 years old (Ruotsalainen et al. 1993). Controlling the temperature was found to be a problem. The air temperatures varied from 19 to 26°C, with an average of 22.2°C [standard deviation (SD) 0.9°C]. There was an average increase of 1.5°C (range 0.5 to 3.0) during the time the children were in the room, and the temperature was 1°C higher in the afternoon than in the morning. The relative humidity varied from RH 7 to 66 percent in the buildings, none of which had air conditioning. In buildings without air conditioning or humidifiers, the outdoor thermal conditions are the main factors influencing the relative humidity. Humans are an important source of humidity during cold periods when indoor air tends to be too dry (<15 percent). The air temperatures varied in a wide range (20 to 28°C) also in the Norwegian day-care centers with a tendency toward temperatures above adult comfort level (Skårset and Nordvik 1998). The relative humidities were between RH 18 and 41 percent.

Temperatures above 23°C have been shown to increase occurrence of skin, respiratory, and general symptoms, such as headache and lethargy, in adults (Jaakkola et al. 1989, Menzies et al. 1993). No studies of the health effects of temperature in the range of indoor environments on children have been reported.

Dryness is a common complaint about indoor air quality in workers in day-care centers (Ruotsalainen et al. 1993) and office buildings (Menzies et al. 1993, Stenberg et al. 1993, Jaakkola and Miettinen 1995) during heating season in cold climates. The relation between dry air, air humidification, and mucosal symptoms is complicated: (1) dryness and irritation of the eyes and respiratory tract may be caused by low relative humidity, as well as chemical and particulate air pollution (Mølhave et al. 1986); (2) level and changes in relative humidity and temperature may influence emission and adsorption of volatile organic gases and influence air particle concentrations to the extent that it may be difficult to separate the direct and indirect effects of relative humidity; and (3) nonhygienic air humidification equipment may serve as a source of microbial air pollution.

Humidification has been found to alleviate the sensation of dryness and symptoms of the eyes and respiratory tract in experimental studies carried out in office buildings (Reinikainen et al. 1992) and hospitals (Nordström et al. 1994). Some studies in the 1960s and 1970s assessed the possibility of preventing respiratory infections by humidification of air in day-care centers, schools, army barracks, and office buildings (Arundel et al. 1986). In a Swiss study of 230 children, a vaporizing humidifier was installed to one part of two-part day-care center buildings, and the numbers of absences due to upper respiratory infections were compared during a period of 9 weeks (Ritzel 1966). The average relative humidity was RH 49 percent in the humidified and 40 percent in the nonhumidified spaces. A total of 3 percent of the children in humidified facilities and 5.7 percent of the children in the nonhumidified facilities were absent because of upper respiratory infections. In a Canadian study, the occurrence of respiratory infections was studied in 515 preschool children, aged 2 years, and 5 to 6 years, in three schools (Sale 1972). Humidification equipment was installed in one of the buildings, and information on air humidification at home was collected. The mean weekly absenteeism due to respiratory infections was lowest in children with humidification both in school and at home (1.3 percent) and highest in those with no humidification either in school or at home (7.1 percent). Mean weekly absenteeism was 3.9 percent in children with humidification at school and 5.1 percent at home only. Termination of humidification at school increased the weekly absenteeism to 5 and 6.5 percent in children without and with humidification at home, respectively.

Concern about adverse effects of nonhygienic humidification in office buildings and dampness problems in homes and other buildings may be responsible for the lack of interest in humidification as a possible preventive factor for respiratory infections and mucosal symptoms during cold winter periods. The potential for prevention is clearly high because of the high occurrence of respiratory problems in day-care centers. Future research on potential benefits of hygienic air humidification is warranted.

Dampness and Mold Problems

In damp buildings moisture accumulates in building constructions, and may lead to microbial growth. The usual signs of dampness are color changes in and loosening of the surface materials, wet spots on the surfaces, visible molds, and mold odor. Air humidity influences the materials in areas where the climate is moist and warm throughout the year, but has little influence in cold climate, where outdoor air humidity is relatively low throughout the year. Other sources of moisture are rainwater, melted water, surface water, groundwater, damp materials from construction, domestic water, and occupants. Water leaks through the building envelope, from water or drainage pipes, and condensation are common causes of water damage.

Dampness creates favorable conditions for fungal growth. Fungi produce spores and metabolic products that may cause adverse health effects via allergic or nonallergic (toxic, inflammatory or irritative mechanisms) reactions. House dust mites, including *Dermatophagoides pteronyssinus*, and *D. farinae*, are also more common in damp buildings. Exposure to their

feces and skin can cause allergic sensitization. There is a large body of literature showing an association between dampness and mold problems and respiratory illnesses in children, including chronic respiratory symptoms (Brunekreef et al. 1989, Dales et al. 1991, Jaakkola et al. 1993, Spengler et al. 1994), bronchial obstruction (Nafstad et al. 1998), asthma (Brunekreef et al. 1989, Dales et al. 1991, Spengler et al. 1994), and respiratory infections (Koskinen et al. 1995).

The nature and causes of dampness problems vary in different climates. Reports of the frequency of dampness problems in dwellings provide indirect evidence that the problems are also prevalent in day-care facilities. There is some direct evidence of the extent of these problems in actual day-care centers from both cold and subtropical climates. In the Finnish day-care center study, the extent of dampness problems was assessed as part of the site visit that was carried out in all 30 day-care centers as well as in questionnaires directed at nurses (Ruotsalainen et al. 1995). Water damage had taken place in 70 percent of the day-care centers (95 percent CI of the estimate for the building stock, 53 to 85 percent). Mold odor was perceived by 6 percent (3 to 9 percent) of all day-care workers in 17 percent of the day-care centers. In a Taiwanese study of 56 randomly selected day-care centers in Taipei, the occurrence of dampness problems was assessed in a questionnaire directed at day-care workers (Li et al. 1997). There were dampness problems in 75 percent, water damage in 49 percent, and visible mold in 26 percent of the day-care centers.

The effect of dampness problems in day-care centers on children's and nursing workers' health was assessed in four studies. In a Finnish study, children in a day-care center with serious mold problems had significantly higher prevalence of respiratory symptoms and occurrence of respiratory infections compared with children in a day-care center without such problems (Koskinen et al. 1995). In the Finnish study of 30 randomly selected day-care centers, the workers in day-care centers with water damage and mold odor had a higher prevalence of eye and some respiratory symptoms, such as nasal dryness and congestion and cough and phlegm, compared with workers in the unexposed day-care centers (Ruotsalainen et al. 1995). However, only the difference in eye symptoms was statistically significant. In the Taiwanese study of 614 day-care workers, the occurrences of eye irritation, upper and lower respiratory symptoms, and skin symptoms, as well as general symptoms, such as headache, lethargy, and fatigue, were significantly associated with different indicators of dampness and mold problems (Li et al. 1997). Rylander (1997) studied 14 female nursing workers of a Swedish day-care center that had microbial growth problems. He identified an airborne cell wall component of molds called (1->3)- β -D-glucan, which he hypothesized to be a potential cause of increased airway responsiveness and respiratory symptoms observed in the workers. Two years after renovation of the day-care center, the concentration of (1->3)- β -D-glucan had decreased from 11.4 to 1.4 ng/m³, and airway responsiveness, measured as FEV_{1,0} change after methacholine challenge, had decreased in the workers, which is consistent with the hypothesis.

Dampness also creates favorable conditions for house dust mites. Several studies have shown an association between the presence of house dust mites in homes and risk of asthma (Korsgaard 1983), or early signs of asthma, such as bronchial obstructions in young children (Nafstad et al. 1998). Dust mites are present in a large proportion of homes in mild climates, and therefore it can be assumed that in the same geographic regions there are also house dust mites in day-care centers. Two studies have assessed the level of major dust mites (Der p I/Der f I) in day-care centers (Munir et al. 1995, Engelhart et al. 1996). In a Swedish study mite allergens were identified in 9 of 22 sections in 7 day-care centers, and the concentrations varied between <16 ng/g and 106 ng/g dust (median <16 ng/g). Low humidity reduces the occurrence of dust mites (Korsgaard 1983), and the levels of dust mites are in general lower in areas of cold climate (Tuross 1979, Stenius and Cunningham 1972, Dotterud et al. 1995). In a German study, mite allergen levels above 10 μ g/g dust were found in a large proportion of day-care centers (Engelhart et al. 1996).

Results of a small number of studies of day-care centers, and inference based on findings from a larger number of studies of homes, suggest that dampness and mold problems in day-care centers are likely to be common in countries in a wide range of climatic conditions. However, the causes of dampness problems vary substantially from a climatic region to another. Current knowledge indicates substantial health effects related to dampness problems, and therefore efforts should be made to prevent dampness problems in the new buildings and to detect and cure the problems in the existing building stock.

Allergens

Exposure to allergens in early life is an important determinant of development of sensitization and asthma later in life (Holt 1995). Traditionally relevant exposures to allergens have been thought to take place in homes. The most important sources of domestic allergens are dander and feces from cats, dogs, and other hairy and feathered pets, house dust mites and their excretions, insects, pollen, molds, foodstuff, and particles from clothes and other textiles. Reports from the United States have indicated that cockroaches are potent sources of allergens responsible for specific sensitization and symptoms of asthma (Rosenstreich et al. 1997).

Exposure in day-care centers may be more important than previously thought for two reasons:

1. Studies have shown that children in day-care centers are exposed to common domestic allergens (Munir et al. 1995), probably because of transportation of allergens via children's clothing. Munir and colleagues (1995) studied the level of cat (Fel d I) and dog (Can f I) allergens in dust collected in seven Swedish day-care centers (22 sections). Cat and dog allergens were detected in all day-care centers and sections. The concentrations of dog allergen (median 4.3 $\mu\text{g/g}$; range <60 ng/g to 21 $\mu\text{g/g}$) and cat allergen (median 1.6 $\mu\text{g/g}$; range <12 ng/g to 22.8 $\mu\text{g/g}$) were substantial. The allergen levels were associated with the number of children and staff with cats or dogs at home. Neither cleaning methods nor the frequency of cleaning influenced the allergen concentrations. The exposure levels were lower in day-care centers than in homes of children with pets at home, but higher than in homes of children without pets.

2. Other findings indicate that individual sensitization takes place at relatively low levels of exposure and is partly determined by individual susceptibility (Munir et al. 1997).

Exposure to indoor allergens causes IgE-mediated, type I immunologic reactions in airways of individuals who have a tendency to form IgE against environmental substances. These reactions represent underlying mechanisms in allergic diseases, such as rhinitis, conjunctivitis, and asthma. There is increasing evidence that allergic diseases and the tendency to form IgE are partly genetically determined (Daniels et al. 1996, CSGA 1997), but environmental exposures are also necessary determinants. The day-care environment is important, because small children seem to be more susceptible to becoming sensitized, and this sensitization will increase the risk of developing asthma later in life. Exposure to allergens can exacerbate the disease after sensitization. Children with asthma may suffer from asthma attacks when exposed to allergens or to nonspecific indoor air pollutants, such as irritating gases, environmental tobacco smoke, or inorganic particles. Therefore, even low levels of exposure to specific allergens or nonspecific indoor pollutants in day-care centers may cause symptoms and signs of asthma, such as wheezing, cough, or bronchial obstruction, in children with underlying disease.

Volatile Organic Compounds

Building materials, in particular surface materials used in the walls, floors, and ceilings as well as in furniture, are potential emitters of chemical compounds and particulates. Other sources include chemicals used in cleaning and handicraft, and pesticides. New and recently renovated buildings are more likely to contain emitting materials than are old buildings. Hundreds of volatile organic compounds (VOCs) can be identified in indoor air of a given building (Wallace 1991, Wolkoff et al. 1998). The main classes of chemicals commonly found in the buildings include aromatic hydrocarbons, aliphatic hydrocarbons, cycloalkanes, terpenes, alcohols, glycols, aldehydes, ketones, halocarbons, acids, and esters (Mølhave et al. 1997). Given the vast number of different chemicals commonly present in indoor air from different sources, it is often unfeasible to measure the concentrations of all the separate components. Total VOC (TVOC) concentration has been used as a general measure of chemical burden. There are several limitations in the use of TVOC, including the fact that it is an ambiguous concept, that individual VOCs making up the whole can be expected to have different adverse effects, and that researchers have used different definitions and interpretations of TVOC (Andersson et al. 1997).

Two studies have reported levels of TVOCs in day-care centers. In a Swedish study of 71 day-care centers, the TVOC concentrations ranged from 253 to 393 $\mu\text{g}/\text{m}^3$, and the average concentration was 270 $\mu\text{g}/\text{m}^3$. In the Finnish study of 30 randomly selected day-care centers, the range was from 50 to 630 $\mu\text{g}/\text{m}^3$, the average was 170 $\mu\text{g}/\text{m}^3$, and the median was 130 $\mu\text{g}/\text{m}^3$ (Ruotsalainen et al. 1993).

The potential health effects of exposure to VOCs in the levels appearing in nonindustrial environments range from sensory irritation at low and medium levels of exposure to neurotoxic, organotoxic, and carcinogenic effects at high exposure levels. Some of the chemicals such as benzene and vinyl chloride have been identified as potential human carcinogens in much higher levels of exposure than occurring in nonindustrial environments; others, such as chloroform, have been found carcinogenic in animals (Golden et al. 1997).

Little is known about the effects of long-term, low-level exposure to VOCs. Effects of short-term exposure to single compounds and common mixtures of VOCs have been studied in controlled chamber studies. Odor perceptions and sensory reactions are mediated by the olfactory and trigeminal nerve systems. Comparison of the odor interactions models shows that the odor intensity of binary mixtures has a systematic relation to the odor intensities of the components; usually hypoaddivitivity is observed (Berglund and Olsson 1993). In a series of experiments, humans were exposed to concentrations of a mixture of 22 VOCs typically occurring in indoor air (Mølhave et al. 1986). A 2-h exposure of previously symptomatic subjects to the mixture at a concentration of 5 mg/m^3 caused symptoms of eye, nose, and throat irritation, and led to decreased scores in the digit span test designed to measure short-term memory impairment (Mølhave et al. 1986). A 4-h exposure to 25 mg/m^3 of a similar mixture caused an inflammatory response of the upper respiratory tract (Koren et al. 1990). There is some epidemiologic evidence of a relation between levels of TVOC concentration and reported symptoms in the indoor environment, but the results are inconsistent (Andersson et al. 1997). These studies that have assessed the effects of long-term, low-level exposure to VOCs have been limited by a number of weaknesses related to the cross-sectional study design, and compromised assessment of the outcomes and exposure.

There are some reasons to believe that exposure to chemicals in levels of nonindustrial environments could increase the risk of asthma. Inflammation of the airways is an important part of the mechanism in asthma and bronchial reactivity (Laitinen et al. 1985). Besides inflammation mediated by specific IgE antibodies, there also appear to be chemical compounds with a capacity to trigger inflammation without involving IgE production (Frew 1996). Long-term occupational exposure to relatively high levels of chemicals, such as formaldehyde (Nordman et al. 1985), toluene diisocyanate (Patterson et al. 1987), and acid

anhydrides (Newman-Taylor et al. 1987), has been shown to increase the risk of asthma. Exposure to some of these chemical compounds, such as formaldehyde, may also lead to development of specific airways hypersensitivity (Nordman et al. 1985). Plasticized polyvinyl chloride (PVC) materials are presently among the most frequently used wall- and floorcovering materials in homes because they provide inexpensive, easy-to-clean surfaces which are practical, especially in the kitchen, bathroom, and children's playrooms and bedrooms. PVC materials are potential emission sources of chemicals used as plasticizers, viscosity modifiers, and stabilizers in the production, and these emissions usually last long. In a matched-pair case-control study of Norwegian children, risk of bronchial obstruction, an early sign of asthma, was related to the amount of PVC surface materials in the home (Jaakkola et al. 1999).

The adverse effects of exposure to VOCs in concentrations encountered in day-care centers are not well known. Short-term or long-term exposure to some chemicals may have substantial health effects in low levels, and continuous research is needed to identify these specific compounds and their sources. Measurement of TVOC is a crude way to describe possible hazardous exposure. It is based on the idea that high TVOC concentrations are more likely to contain concentrations of single compounds in levels that alone or jointly cause health effects than are low TVOC concentrations. It is clear that low TVOC does not totally exclude the possibility of adverse effects; it just makes it less likely. Recognizing some obvious limitations, a European Community Working Group still considered measurement of TVOC useful and suggested some general principles (Møhlave et al. 1997). If the concentration obtained with a simple integrating detector is above $300 \mu\text{g}/\text{m}^3$, detailed analysis should be made following a recommended procedure. There is a general need to improve source control in order to reduce exposure to VOCs in indoor environments, which can be justified by concerns of health, comfort, and energy consumption. This need is underlined in day-care centers and other indoor environments occupied by small children. The European Community Working Group suggested that the levels of TVOC should be kept as low as reasonably achievable (ALARA). ALARA is a relative concept, which depends on the levels of VOCs and ventilation rates in the existing building stock, alternative building materials, accumulative knowledge about adverse effects of exposure to VOCs, and economic means to influence TVOC concentrations.

Infectious Agents

Infections constitute the most common disease group in small children. The occurrence of most of the infectious diseases, such as respiratory tract infections (Louhiala et al. 1995, Marbury et al. 1997, Nafstad et al. 1999); gastroenteritis (Bartlett et al. 1985, Alexander et al. 1990, Reves et al. 1993, Louhiala et al. 1997); herpes virus infections, including chickenpox (Jones et al. 1995); and some invasive bacterial diseases, including *Haemophilus influenzae* type b (Istre et al. 1985, Cochi et al. 1986), has been reported to be greater in day-care center children than in children in home care (Pickering and Morrow 1996). The main routes of transmission are direct contact and transmission via air, water, or physical objects. A given pathogen may have more than one possible route of transmission. Respiratory tract infections, some of the invasive bacterial diseases such as *Haemophilus influenzae* b, and vaccine-preventable diseases such as measles, mumps, and rubella spread typically via indoor air (Churchill and Pickering 1997). Several environmental factors may influence the spread of infections, including the area and volume of the facility, air change, number of occupants per area (crowding), mixing of different age groups, and various physical characteristics of the facility (Churchill and Pickering 1997).

According to traditional infectious disease control, hand washing is considered as the most effective means of preventing respiratory infections (Churchill and Pickering 1997).

However, little is known about how effectively airborne transmissions could be prevented in day-care centers. The preventive effect of air humidification is controversial, as discussed earlier in the section on air temperature and relative humidity. There are no studies of the relation between air change and occurrence of respiratory or other infections. Theoretically, low ventilation rate could increase the air concentrations of viruses and bacteria as well as concentrations of indoor air pollutants, which would influence the susceptibility to catch infections.

Outdoor Pollutants and Their Penetration into Indoor Air

Day-care children are exposed to ambient air pollution in their outdoor activities. Ambient air pollution is also a potential source of indoor air pollution. The location of the day-care center is important for both types of exposure. The type of building envelope and the type and performance of the ventilation and air filtration systems influence the outdoor-indoor penetration.

Two Finnish studies assessed the penetration of outdoor air pollutants indoors (Marttila et al. 1994a, 1994b; Alm et al. 1998). Alm and colleagues (1998) studied NO₂ exposure of 246 children aged 3 to 6 years in four urban and four suburban day-care centers in Helsinki. Four of the buildings were fitted with balanced mechanical ventilation (3 suburban), 3 had natural ventilation (all downtown), and one building had partly mechanical and partly natural ventilation. The exposure assessment included personal monitoring of NO₂, and measurements of outdoor and indoor concentrations using Palmes tubes. The outdoor and indoor concentrations of NO₂ were very similar in both the urban and suburban day-care centers in both winter [urban geometric means—outdoor = 40 µg/m³ (GSD 1.3); indoor 36 (1.2), suburban—outdoor = 27 (1.5), indoor 29 (1.2) and spring (urban—outdoor = 49 (1.6); indoor = 46 (1.5), suburban outdoor = 25 (1.5); indoor = 25 (1.4)]. These buildings did not have any indoor sources of NO₂, and therefore results indicated practically a complete outdoor-indoor penetration. Exposure to CO was assessed in two of the day-care centers using personal monitoring (Alm et al. 1994). Use of a gas stove in one of the day-care centers as well as homes was a major determinant of exposure. Exposure in the traffic between home and day-care center was also an important determinant of total exposure. Indoor exposure without existing indoor sources was low, indicating that outdoor-indoor penetration of CO does not add substantially to the total exposure.

Marttila et al. (1994a, 1994b) studied the indoor penetration of malodorous sulfur compounds such as hydrogen sulfide and methyl mercaptan, released by a pulp mill. The filtering effect of three different materials, connected to a gaseous filter unit, was assessed during six study periods. The materials were Sorbixofil based on gypsum impregnated by KMnO₄, Purafil based on Al₂O₃, and carbonized tissue. Without filtering, the sulfur compounds penetrated indoors effectively, but after some delay, and the indoor concentration-time curve was lower and wider compared with outdoor concentration-time curve. Purafil was the most effective and practically eliminated the indoor concentrations. Sorbixofil and carbonized tissue lowered the indoor concentrations substantially. In a study of 134 children, long-term exposure to malodorous sulfur compounds was associated with occurrence of nasal symptoms, cough, and headache (Marttila et al. 1994a, 1994b). The study indicated that these compounds penetrate indoors through ventilation ducts, but penetration and exposure can be prevented by filtering.

Indoor concentrations of respirable particulates in day-care centers from both indoor and outdoor sources is an important question in the light of the accumulating evidence of the adverse effects of respirable particles on children's respiratory health. Literature search did not reveal any studies that had elaborated this important issue in day-care environment.

69.4 TOWARD A BETTER DAY-CARE CENTER ENVIRONMENT

There are only a few systematic studies of indoor air quality in day-care centers, although day-care centers constitute an important part of children's total environment in many countries. The occurrence of infectious diseases is clearly higher among children in day-care centers compared with children in home care. Part of this excess morbidity is due to close contacts between children, which enhances spread of communicable diseases. However, there is evidence that the physical environment and indoor air quality in day-care centers may influence the occurrence of infectious diseases in several ways. Environmental factors may also increase the risk of noncommunicable diseases. Several suggestions for improvement of day-care centers can be made on the basis of the limited knowledge presented above.

Location of the day-care center is an important determinant of environmental exposures; therefore, more attention should be paid to it. Environmental measurements at the site or assessment of contaminant sources by other means before establishment of a day-care center should be required. The land should be free of toxic waste and other hazardous materials, and the distance to traffic, industrial facilities, and other potential sources of air pollution should be sufficiently large. Some studies have raised concern that the risk of childhood cancer is related to electromagnetic fields from high-tension electrical wires [e.g., Feychting and Ahlbom (1993), Li et al. (1998)]. Although the issue remains controversial (Campion 1997), it is advisable to avoid the vicinity of high-tension electrical wires. In areas with known radon problems, prevention of infiltration should be taken into account in the design phase by including a vapor barrier beneath any slabs on grade, providing substantial ventilation if needed, and sealing cracks in the slab between the slab and wall (Passantino and Bavier 1994). Exposure during daily transportation of the children is another relevant issue related to the location of day-care centers, and therefore families' access to the day-care center should be considered when planning the location.

There is increasing awareness among architects and engineers that environmental and health issues should be considered explicitly in architecture and building engineering, and architects' viewpoints have been expressed in medical literature (Passantino and Bavier 1994). Functional design and location of toilets, changing rooms, kitchens, and other spaces influences hygienic behavior and reduces transmission of infections. Use of building materials with low emissions of chemicals is an important part of source control to diminish indoor air pollution. Several macroscale activities are likely to reduce the population exposure from material emissions. Producers of building materials should develop materials with lower emissions. Testing of new materials introduced to the market is an important but difficult part in prevention, because the amount of given material may vary substantially in different microenvironments, and emission rates depend on a number of factors such as the level and variation of temperature and relative humidity. Special attention should be paid to materials that are planned to cover large surfaces such as floors and walls. Consumers should be informed about the materials and emission rates in the products. There is a need to develop appropriate ways to routinely predict the overall emission rates and concentrations in a space in the design phase of new buildings. Classification of building materials would help the consumers and guide the producers. The possibility of cleaning the surface is another important criterion for a choice of appropriate materials. This criterion may be in conflict with requirements of low emission rates. At the same time, cleaning materials are a potential source of emissions.

Sufficient air change in relation to emissions from occupants and indoor sources is perhaps the most important criterion of a good day-care environment. Systematic studies of minimum ventilation rate needed in day-care centers to control the emissions effectively

are missing. The minimum ventilation rate for office buildings based on epidemiologic studies has been suggested to be 10 L/s/p, given the current emissions and activities (Jaakkola and Miettinen 1995, Godish and Spengler 1996). Ventilation rates below 5 L/s per child are likely to result in indoor air pollution problems in facilities with high emissions. Air change can be easily measured directly or indirectly, and thus it can be regulated and monitored. Although it should be a secondary solution for removal of emissions from strong indoor sources, increase of air change can often be the first aid for apparent indoor air quality problems. The findings of a few studies emphasize the need for a better control over air temperature in day-care centers. No suggestions can be made about the usefulness of air humidification, although some of the findings in office environments suggest preventive effects.

A general program for providing training about indoor environmental issues should be developed for building maintenance personnel as well as for nursing personnel. Understanding of the hygienic principles and importance of indoor air quality in combination with practical tools and advice is needed.

Day-care centers must fulfill the general requirements of good healthful buildings, and at the same time there are a number of special requirements related to the age range and activities of the occupants. Systematic research programs of the impact of environmental exposures, such as emissions from surface materials and other sources on the health and well-being of children and personnel, should be established to guide the planning of better day-care facilities.

RISK ASSESSMENT AND LITIGATION

CHAPTER 70

THE RISK ANALYSIS FRAMEWORK: RISK ASSESSMENT, RISK MANAGEMENT, AND RISK COMMUNICATION

Pamela R. D. Williams, Sc.D.¹

*Exponent
Menlo Park, California*

70.1 INTRODUCTION

Risks are ubiquitous in our daily lives. Nearly every activity we engage in, from participating in sports to driving a car, poses some probability of harm. The indoor environment hosts many of its own unique hazards and risks. Toxic volatile organic compounds (VOCs) may be emitted from a variety of household sources, including carpeting, furniture, and paint. Pesticides applied to lawns, plants, and pets can pose human health risks from multiple exposure pathways. Lifestyle behaviors, such as smoking or poor nutrition, can also exacerbate existing conditions or introduce new health hazards.

Although we have an intuitive sense about the relative risks of different hazards, decisions about whether these risks warrant greater attention often require a more formal analysis than instinctive judgments about risk. *Risk analysis*, which consists of risk assessment, risk management, and risk communication, refers to a systematic framework for understanding and managing diverse risks. *Risk assessment* entails quantifying and characterizing risks, while *risk management* involves decisions about what to do about these risks. *Risk communication* involves conveying information about a risk or risk management decision to different groups. The value of the risk analysis framework is not that it provides the “right” solution to a problem, but rather that it allows for decisions to be made under scientific uncertainty. Consequently, risk analysis deters the “paralysis of protective action”

¹ Formally of Harvard Center for Risk Analysis, Harvard School of Public Health, Boston, Massachusetts.

that might otherwise occur while waiting for definitive data to make a decision (Ruckelshaus 1985).

The purpose of this chapter is to provide professionals involved with indoor air quality issues an overview of the risk analysis framework (see Fig. 70.1). Although risks in the indoor environment are the focus of this handbook, the process of assessing and managing risks are discussed more broadly. This chapter is divided into three main sections that emphasize how regulatory agencies approach human health problems. In the first section, the major steps of the risk assessment process are described, from identifying a potential hazard to characterizing the risk of a hazard. In the second section, key factors that influence risk management decisions are presented. Criteria for acceptable risk determinations and a framework for guiding decisionmaking processes are also discussed in this section. The third section provides an overview of how the public perceives risks and offers several strategies for communicating risk information.

70.2 RISK ASSESSMENT

Risk assessment is the process of determining the nature and extent of risks in the environment. More specifically, risk assessment can be defined as “the use of the factual base to define the health effects of exposure of individuals or populations to hazardous materials and substances” (NRC 1983). In this context, *risk* refers to the probability that an adverse effect will occur and the magnitude of that effect over a specified time period. Although the risk assessment process is scientific in nature, it is not entirely “objective” in that policy and value judgments are required throughout the process (NRC 1996). For example, subjective decisions are made about which hazards to investigate and how to interpret and summarize scientific data. Risk assessments ultimately consist of a culmination of scientific evidence, expert judgment, and “default” assumptions to estimate risks (Graham 1995).

Our current approach to characterizing risks can be traced to the fields of occupational health, food safety, and radiation exposure (McClellan 1998). In the past, regulatory toxicologists attempted to set “safe” levels of exposure to toxic agents according to the premise that there were some exposure levels below which no adverse effects occurred. The introduction of the “no-threshold hypothesis” for carcinogenic substances resulted in increased demand for the field of risk assessment (Graham 1995). Today’s risk assessments examine both threshold and nonthreshold effects and are performed by many administrative and regulatory agencies, including the U.S. Environmental Protection Agency (USEPA), the Food and Drug Administration (FDA), the Occupational Safety and Health Administration (OSHA), the Department of Energy (DOE), and the Consumer Product Safety Commission (CPSC).

The risk assessment process can be divided into four steps that were outlined in a National Academy of Sciences (NAS) report on *Risk Assessment in the Federal Government: Managing the Process* (NRC 1983). These steps include:

- Hazard identification
- Exposure assessment
- Dose-response assessment
- Risk characterization

In the first step, hazardous situations or agents are identified. In the second and third steps (which can be performed in any order), likely human exposures to a hazard and the health effects arising from these exposures are quantified where possible. In the final step, exposure and toxicity assessments are integrated to characterize the overall risk of a hazard. The following subsections discuss each of these steps in greater detail.

FIGURE 70.1 The risk analysis framework.

TABLE 70.1 USEPA Classification Scheme* for Human Carcinogenicity

Human evidence	Animal evidence				
	Sufficient	Limited	Inadequate	No data	No evidence
Sufficient	A	A	A	A	A
Limited	B1	B1	B1	B1	B1
Inadequate	B2	C	D	D	D
No data	B2	C	D	D	E
No evidence	B2	C	D	D	E

*Group A—Human carcinogen; group B—probable human carcinogen (group B1—limited evidence of carcinogenicity from epidemiology studies; group B2—inadequate human evidence but positive animal evidence); group C—possible human carcinogen; group D—not classifiable as to human carcinogenicity; group E—evidence of noncarcinogenicity for humans.

Hazard Identification

The first step of the risk assessment process is to identify the chemical, physical, or biological agents in the environment that may be causally linked to an adverse health effect. Identifying hazards is a qualitative process, where *hazard* refers to the potential for harm to occur. An *adverse effect* is one that causes functional impairment or affects an organism's ability to survive. These effects are typically regarded in terms of cancer or noncancer effects. Carcinogenic effects cause an increased incidence of tumors in animals or humans, while noncarcinogenic effects include organ damage, nerve damage, birth defects, and developmental and reproductive toxicity (Williams and Burson 1985).

Data Sources. The primary basis for assessing an agent's hazard potential is a review of the existing scientific literature. Sources of hazard information include clinical and epidemiologic studies, animal (in vivo) studies, cell and tissue (in vitro) tests, and structure-activity relations (Masters 1998, NRC 1983). Clinical and epidemiologic studies, which assess the incidence and distribution of disease in human populations, are the most desirable and direct source of human hazard data. However, statistical limitations and ethical constraints often preclude their use in risk assessments (McClellan 1998). For example, small risks may be difficult to detect in a large population, and many risks require a long latency period before the effects from an exposure are observed. As a result, animal bioassays are the most common source of data for assessing human risks. The use of animal data raises controversial issues about how effects observed in high-dosed test animals can be used to predict likely health outcomes in humans at much lower exposure levels. In vitro studies can provide data on potential mutagens and endocrine disrupters, while structure-activity data can be used to evaluate substances with similar physical or chemical properties.

Classification Schemes. Classification schemes have been developed by national and international organizations to allow for the easy identification of many carcinogenic substances. For example, USEPA (1986a) uses a *weight-of-evidence* approach that weighs all available scientific evidence, including positive and negative studies, to classify carcinogens (see Table 70.1). Substances are classified as a human carcinogen (group A) only if there is sufficient evidence of human carcinogenicity. Substances that have limited evidence of human carcinogenicity or sufficient animal evidence are classified as a "probable" human carcinogen (group B). If there are limited or inadequate data concerning an agent's carcinogenic potential, it will either be classified as a "possible" human

carcinogen (group C) or not be classified at all (group D). If there are at least two adequate negative animal or human studies, substances may be classified as noncarcinogenic to humans (group E).

Guidelines proposed by the USEPA would replace the current alphanumeric classification scheme with a narrative and three descriptor categories: “known/likely,” “cannot be determined,” and “not likely” (USEPA 1996b). Similar classification systems have been developed by the U.S. National Toxicology Program (NTP) and the International Agency for Research on Cancer (IARC). These programs use an alternative *strength-of-evidence* approach, in which only positive studies are used as evidence of carcinogenicity (McClellan 1998).

Exposure Assessment

A toxic substance poses a human health risk only if people are exposed to the substance. *Exposure* is defined as the event during which a person comes into contact with an agent (Ott 1985). Exposure is therefore the joint occurrence (in space and time) of a person and an event. Exposure assessment is the process of determining the “intensity, frequency, and duration of human exposure to an agent” in a specified population (NRC 1983). Assessing human exposures consists of two primary steps: (1) identifying the ways in which people are exposed to an agent and (2) estimating the amount of human exposure (Masters 1998).

Exposure Pathways. Human contact with an environmental agent can occur from multiple routes of exposure (see Fig. 70.2). Exposures can occur from consumption of contaminated food or water or from inhalation of toxic substances that are airborne. Dermal (skin) contact with a contaminated source represents another route of possible human exposure. Humans can be exposed to one agent or several agents via a single exposure pathway or multiple routes of exposure. Understanding the fate and transport of environmental agents is important for assessing the concentration and toxicity of an agent, since various transformations can occur as agents travel from one place or medium to another (Masters 1998). Other important considerations include an agent’s ability to accumulate, degrade, or bio-concentrate in the environment (USEPA 1986b).

It is important to determine not only how people are exposed to an agent but also who in the population is exposed. Exposed populations can be identified by review of census data or other survey data (USEPA 1986b). It is particularly important to identify individuals or subgroups in the population that may be especially vulnerable or susceptible to an agent’s effects, such as children, the elderly, pregnant women, and persons with impaired health (NRC 1983).

Estimating Exposures. Estimating human exposures can be based on either direct or indirect methods. The direct approach uses monitoring data to directly measure an agent’s concentration in the environment. The indirect approach uses mathematical models to predict human exposures. While the former approach is useful for determining whether an exposure problem exists, the latter approach is better suited for characterizing the major sources of an exposure problem (Ott 1985).

In risk calculations, exposures are typically expressed as a lifetime average daily dose (LADD), or equivalently, a chronic daily intake (CDI). These exposure measures indicate the amount of a substance that an individual will be exposed to on a daily basis over a specified exposure period. The LADD (or CDI) is expressed on a milligram per kilogram per day basis (mg/kg/day) and requires quantitative estimates (measured or modeled) of an agent’s concentration in different media. Information about the exposed individual is also required, including body weight, intake rate (e.g., breathing

FIGURE 70.2 Exposure pathways for toxic-waste site. (From EPA Superfund Public Health Evaluation Manual, Office of Emergency and Remedial Response, Washington, DC, 1986.)

or ingestion), and number of days exposed over a lifetime. Default assumptions that correspond to a typical or “average” individual in the population are often used for these factors in exposure assessments (see Table 70.2). The USEPA *Exposure Factors Handbook* (1997) provides a more detailed account of different exposure factors by various age/sex groups. The percentage of substance that is actually absorbed in the body is also used, if available, in exposure calculations. In the absence of such information, the absorption factor is assumed to be one.

$$\text{LADD (mg/kg/day)} = \frac{(\text{concentration}) (\text{intake rate}) (\text{exposure duration}) (\text{absorption factor})}{(\text{averaging time}) (\text{body weight})}$$

where Concentration = ppm (food or water) , mg/kg (food) , mg/L (water) , or mg/m³ (air)

Intake rate = ppm (food or water) , mg/day (food) , L/day (water) , or m³/day (air)

Exposure duration = days

Absorption factor = no units

Averaging time = days (period over which exposure is averaged)

Body weight = kg

These are some of the typical units (see Table 70.2 for default values).

Dose-Response Assessment

While all substances are toxic at some dose level, the primary objective of toxicologists is to distinguish between safe and unsafe levels of exposure. A dose occurs only if an agent crosses the human envelope, such as the skin, lungs, or gastrointestinal (GI) tract (Ott 1985). Dose-response assessment is the process of characterizing “the relationship between the dose of an agent received and the incidence of the health effect” (NRC 1983). As mentioned, animal bioassays are the most common source of toxicity information. Characterizing the dose-response relationship for humans requires two major extrapolations: (1) effects observed under high exposure conditions are used to estimate likely effects (in the same population) at much lower exposure levels; and (2) effects observed in test animals are used to predict responses in humans (Patton 1993).

TABLE 70.2 Standard Exposure Assessment Assumptions

Parameter	Assumption
Lifetime	70–74* years
Inhalation rate	
Adult	20 m ³ /day
Body weight	
Adult	70 kg
Drinking-water consumption	
Adult	1.4–2.0 L/day
Child	1.0 L/day
Duration at residence	
Average	9 years
Maximum	30–70† years

*USEPA uses 70 years; OSHA uses 74 years.

†USEPA Superfund Program recommends 30 years; USEPA Clean Air Act uses 70 years.

Source: Hoppin et al. (1993).

Toxicity Testing. The dose-response relationship is used to evaluate both acute and chronic health effects. *Acute effects* are those that occur within a short period of time after a single exposure to an agent. A standard measure of acute toxicity is the dose level that is lethal to one-half of all species tested (LD_{50}). In general, the lower the LD_{50} , the more toxic the agent. *Chronic effects*, on the other hand, are those that occur after a long period of exposure and can be permanent or irreversible. A standard measure of chronic toxicity for assessing cancer effects is the *chronic carcinogenesis bioassay*. Minimum test requirements set by the NTP include two species of rodents, at least two dose groups and one (no-dose) control group, and at least 50 males and females of each species per group. The resulting analysis takes about 2 years to complete and costs between \$500,000 and \$1.5 million (Masters 1998).

In chronic toxicity testing, the highest dose is traditionally set at the maximum tolerated dose (MTD), which represents the highest dose level that can be administered to a test animal over its lifetime without causing impaired growth or a shortened lifespan. The second dose is usually set at one-half or one-fourth the MTD. Test animals are exposed to high dose levels in order to increase the likelihood of observing an adverse effect. However, even studies that consist of 600 animals are able to detect only relatively high risks (e.g., 5 to 10 percent). Even with significantly more test animals, the lowest risks that can be measured in a chronic carcinogenesis bioassay are usually a few percent (Masters 1998).

Threshold Effects (Noncarcinogens). The process of characterizing the dose-response relationship depends on whether an agent exhibits a threshold (noncarcinogen) or non-threshold (carcinogen) effect (see Fig. 70.3). For noncarcinogens, it is assumed that there is some dose level below which no adverse effects are likely to occur (see Fig. 70.4). A two-step process is used to identify and quantify these threshold values (USEPA 1989, Barnes 1988): (1) the highest dose administered that fails to elicit an adverse effect, called the *no-observable-adverse-effect level* (NOAEL), is determined; then (2) the NOAEL is divided by a number of uncertainty factors (UFs) to account for data gaps and uncertainty in the dose-response assessment. Uncertainty factors of 10 are typically used to account for (1) sensitivity in the human population and (2) animal to human (interspecies) extrapolations. Threefold or tenfold uncertainty factors may also be used when the database is incomplete, when extrapolating from subchronic to chronic studies, or when a NOAEL has not been determined [in this case the dose corresponding to the lowest-observable-adverse-effect level (LOAEL) is used]. The application of additional uncertainty or modifying factors (MF) is based on professional judgment.

The resulting *reference dose* (RfD) for oral exposures or reference concentration (RfC) for inhalation exposures, sometimes referred to as the *acceptable daily intake* (ADI), is designed to indicate “safe” levels of human exposure to an agent. Specifically, the RfD is defined as “an estimate (with uncertainty spanning perhaps an order of magnitude or greater) of a daily exposure level for the human population, including sensitive subpopulations, that is likely to be without appreciable risk of deleterious effects during a lifetime” (USEPA 1989).

$$\text{RfD (mg/kg/day)} = \frac{\text{NOAEL (mg / kg /day)}}{(\text{UF}_H) (\text{UF}_A) (\text{UF}_S) (\text{UF}_L) (\text{UF}_D) (\text{MF})}$$

where UF_H^1 = human to sensitive human (10)
 UF_A^1 = animal to human (10)
 UF_S = Subchronic to chronic (3 to 10)
 UF_L = LOAEL to NOAEL (3 to 10)
 UF_D = incomplete to complete database (3 to 10)
 MF = based on professional judgment (3 to 10)

¹Usually applied in all RfD estimates.

FIGURE 70.3 Dose-response curves for carcinogens and noncarcinogens. (From G. M. Masters. 1998. *Risk assessment. In Introduction to Environment Engineering and Science*, Chap. 4, Fig. 4.8, p. 137. Englewood Cliffs, NJ: Prentice-Hall.)

FIGURE 70.4 Threshold assessment for noncarcinogens. (From G. M. Masters. 1998. *Risk assessment. In Introduction to Environment Engineering and Science*, Chap. 4, Fig. 4.11, p. 145. Englewood Cliffs, NJ: Prentice-Hall.)

Nonthreshold Effects (Carcinogens). For carcinogens, it is assumed that exposure to any amount of an agent will result in some probability of harm. The primary step involved for assessing the magnitude of a carcinogenic effect is to determine an agent's potency factor. The *potency factor* is the slope of the dose-response curve at low doses and specifies the rate of increase in cancer risk as a function of increasing dose. Since animal bioassays provide information on an agent's dose-response relationship at high dose levels, mathematical models are used to extrapolate to the low-dose regions of interest.

Different models have been proposed (e.g., one-hit, multihit, multistage, Weibull) that yield similar fits to the data in the observable high-dose region. However, these models tend to give very different estimates of low dose risks (see Figs. 70.5 and 70.6). Since there

FIGURE 70.5 Effect of model selection on low-dose extrapolation: observable region. (From Jane Hoppin, P. Barry Ryan, and John D. Graham. 1993. *Risk Assessment in the Federal Government: Questions and Answers*, Fig. 1, p. 26, Harvard School of Public Health, Center for Risk Analysis.)

FIGURE 70.6 Effect of model selection on low-dose extrapolation: unobservable region. (From Jane Hoppin, P. Barry Ryan, and John D. Graham. 1993. *Risk Assessment in the Federal Government: Questions and Answers*, Fig. 1, p. 27, Harvard School of Public Health, Center for Risk Analysis.)

is no strong scientific basis for any particular model, model selection is a policy choice that varies across regulatory agencies. The USEPA currently uses a modified form of the multistage model (the *linearized multistage model*) that is linear at low doses and provides a conservative upper-bound estimate of cancer risk (USEPA 1986a, Anderson 1983).

Note that in the process of characterizing the dose-response relationship for threshold and nonthreshold effects, various adjustments are made to account for differences between animals and humans. For example, a scaling factor based on body weight or surface area is used to normalize equivalent doses in animals and humans (Masters 1998). Other factors that may differ between species include lifespan, genetic variability, population homogeneity, existence of concurrent disease, pharmacokinetic effects (e.g., metabolism and excretion), and the exposure regimen (USEPA 1986a).

Risk Characterization

The final step of the risk assessment process is to characterize the magnitude of the health problem. *Risk characterization* involves integrating the information developed in the exposure and dose-response assessments to provide qualitative and quantitative estimates of risk. The risk characterization process should include an analysis of the key sources of uncertainty (e.g., statistical or biological) in the risk estimate and explain the rationale for using certain dose-response and exposure assessments (NRC 1993). Different methods are used to characterize the risks of carcinogenic and noncarcinogenic substances, and risk estimates are expressed in a variety of ways.

Cancer and Noncancer Risks. In assessing the risk of noncarcinogens, human exposures are compared to an agent's safety level or threshold. The ratio of the LADD (or CDI) to the RfD (or ADI) is referred to as the *hazard quotient* (Masters 1998). Hazard quotients (HQs) greater than 1 suggest possible adverse health effects from exposure to an agent, while ratios less than 1 imply no significant risk. If individuals are exposed to multiple agents or via multiple routes, a *hazard index* (HI) can be constructed by summing the individual hazard quotients for each agent or route.

An alternative measure of noncancer risks is the *margin of error* (MOE), which is defined as the ratio between the NOAEL and the LADD (Barnes 1988). In general, MOEs greater than 100 are considered to be representative of small risks.

$$HQ = \frac{LADD \text{ (mg/kg/day)}}{RfD \text{ (mg/kg/day)}} \quad HI = \text{sum of HQs}$$

$$MOE = \frac{NOAEL \text{ (mg/kg) /day}}{LADD \text{ (mg/kg) /day}} \quad [(\text{mg} \cdot \text{kg/day})]$$

In assessing the risk of carcinogens, human exposures are combined with information on an agent's ability to increase the rate of cancer risk. The incremental risk of cancer caused by an agent (above the background rate) is calculated as the product of the average daily dose over a lifetime and the potency factor. Risks from multiple exposures, such as those often encountered indoors, are typically combined to provide an aggregate risk estimate. Note that aggregating across risks assumes that there are no interactions or synergies between different agents or chemicals. As mentioned, the USEPA approach to estimating risks is conservative and represents a plausible upper bound on cancer risk, rather than a "most likely" or "best" estimate of risk (USEPA 1986a). In reality, the "true" risk is not likely to be higher than this value and could be as low as zero (Anderson 1983).

$$\text{Risk} = LADD \text{ (mg/kg/day)} \times CSF \text{ (mg/kg/day)}^{-1}$$

Risk Expressions. An important component of the risk characterization process is summarizing and presenting risk information. Understanding the various ways in which risks are expressed is important because risk management decisions are often based on these final characterizations. Several ways in which risks are expressed are

- Annual versus lifetime risk
- Individual versus population risk
- Risks based on average versus maximally exposed
- Attributable versus relative risk
- Point estimate of risk versus risk distribution

Annual versus lifetime risks. *Annual risks* represent the estimated probability of harm each year from chronic exposure to an agent. *Lifetime risks* represent the likelihood of an adverse effect occurring over a lifetime, usually assumed to be 70 years, from chronic exposure to an agent. An annual risk can be converted to a lifetime risk by multiplying the risk estimate by the lifetime assumed.

Individual versus population risk. *Individual risks* refer to the probability that an individual in the population will experience an adverse health effect. *Population risks* represent the number of cases or events that will occur in a specified population. A population risk is the product of an individual risk and the population size.

Average versus maximally exposed. Risks to the *average* individual are based on “average” or most likely exposure conditions. Risks to the *maximally exposed* individual are based on upper-bound estimates that relate to the “most exposed” individual in a population.

Absolute versus relative risk. *Absolute risk* refers to the actual chance of a specific outcome occurring given a particular exposure. *Relative risks* indicate the ratio of risk among individuals who are exposed versus nonexposed to a particular hazard. For example, the absolute risk of dying from lung cancer for persons who smoke one pack of cigarettes each day is about 1200 in 1,000,000 (or 0.12 percent) each year. The relative risk of lung cancer in smokers, however, is about 10 (i.e., smokers are 10 times more likely to develop lung cancer than are nonsmokers). In practice, absolute risks are better suited for evaluating the actual impacts of a risk on a specified population, while relative risks are more useful for identifying the causes of various health outcomes.

Point estimates versus risk distributions. A *point estimate* of risk is when a single number is used for each model input to generate a single risk number. A *risk distribution* is generated when probability distributions are used to characterize the uncertainty and/or variability in some or all of the model inputs (Thompson and Graham 1996). In the past, risk characterizations provided only point estimates of risk. However, as the field of probabilistic risk assessment continues to evolve, the use of risk distributions will become increasingly more common in risk characterizations.

Summary

Risk assessment is a technical (although not value neutral) process designed to quantify and characterize human health risks. Risk assessments can also be used to characterize ecological risks (EPA 1996a). The risk assessment process consists of four major steps: hazard identification, exposure assessment, dose-response assessment, and risk characterization. Despite the widespread use of these methods by different regulatory agencies, there are currently no universally accepted guidelines for how risk assessments should be performed. It is therefore important to be aware of the assumptions and limitations of statistical models

used in risk assessments as well as the various ways risk information is presented. The goal of risk assessment is to provide quantitative and qualitative data that will inform and improve decisions about the safety, management, and prioritization of societal risks. How risk information is used by regulatory decisionmakers is the topic of the next section.

70.3 RISK MANAGEMENT

While risk assessors are responsible for characterizing risks, risk managers must decide what to do about these risks. Risk management involves complex decisions about the level, acceptability, and distribution of risks in society. The risk management process weighs scientific evidence, political judgment, and the health and economic interests of various stakeholders in deciding how to incorporate risk assessment results (Zimmerman 1990). More formally, risk management can be defined as a “decision-making process that entails consideration of political, social, economic, and engineering information with risk-related information to develop, analyze, and compare regulatory options and to select an appropriate regulatory response” (NRC 1983).

Managing human health risks has roots in the broader context of organizational management and safety hazard analysis. Management practices, which use available resources to achieve stated organizational goals, have long been perceived as essential to the functioning and survival of organizations (Zimmerman 1990). Management principles were adopted in the 1950s by the nuclear, chemical, and aerospace industries, and more recently, by administrative and regulatory agencies (Kolluru 1996). Today’s approach to risk management differs from past management efforts in that it is prescriptive rather than descriptive in nature. In other words, risk management focuses on how problems *should* be formulated and solved rather than on how organizations actually manage these problems (Zimmerman 1990).

Although no single approach exists for making risk management decisions, various methods have been proposed to guide the decisionmaking process. The following section provides an overview of some of these approaches. First, several criteria commonly used by regulatory agencies in making acceptable-risk determinations are described. Next, a comprehensive framework recently developed by a Presidential/Congressional Commission on Risk Assessment and Risk Management is summarized.

Acceptable Risk Criteria

The fundamental issue that risk managers must determine is “how safe is safe enough” (Fischhoff et. al 1981). While some risks are “obviously too large to be acceptable,” other risks are “too small to be worth discussing” (Crouch and Wilson 1982). The concept of *acceptable risk* implies that society is willing to tolerate some level of risk from a technology or activity in exchange for the benefits associated with that risk. It is the role of risk managers to weigh these potential risks and benefits and determine acceptable risk levels.

In the past, regulatory agencies have relied on different criteria or “bright lines” to distinguish between acceptable and unacceptable risks (Kolluru 1996) (see Figs. 70.7 and 70.8). These criteria are typically based on risk-based or economic principles and include

- Zero risk
- De minimis risk
- De manifestis risk
- Value of statistical life

FIGURE 70.7 Risk-based approaches for risk management I. [From R. V. Kolluru. 1996. *Risk assessment and risk management: a unified approach*. In R. V. Kolluru, S. M. Bartell, R. M. Pitblado, and R. S. Stricoff (Eds.), *Risk Assessment and Management Handbook*, Fig. 1.4, p. 1.21. New York: McGraw-Hill.]

FIGURE 70.8 Risk-based approaches for risk management II. [From R. V. Kolluru. 1996. *Risk assessment and risk management: a unified approach*. In R. V. Kolluru, S. M. Bartell, R. M. Pitblado, and R. S. Stricoff (Eds.), *Risk Assessment and Management Handbook*, Fig. 1.5, p. 1.21. New York: McGraw-Hill.]

Zero Risk. According to the *zero-risk* criterion, no risk is deemed acceptable regardless of its magnitude or societal benefits (Kolluru 1996). Although advocated by some environmental and public advocacy groups, the zero-risk criterion is generally viewed as impractical and unattainable. Achieving a risk-free society is also viewed as undesirable since it would eliminate many of the technological benefits we currently enjoy and could stifle future technological innovation (Fiksel 1987).

An example of the zero-risk principle is the Delaney clause mandated by Congress as part of the Federal Food, Drug, and Cosmetic Act (FFDCA). The Delaney clause prohibits the use of any food additive found to induce cancer in humans or animals. This requirement has been challenged in the courts by the FDA and EPA, particularly as advances in analytical technologies have allowed for the detection of chemicals in the ppb (parts per billion) and ppt (parts per trillion) ranges (Graham 1995). Applied in specific cases, however, zero risk may be a reasonable criterion, such as when selecting materials based on knowledge of their emissions or designing containment or isolation of potential sources.

De Minimis Risk. Another risk-based criterion is the *de minimis* principle, in which very small risks are considered too trivial to warrant further attention or resources (Kolluru 1996). This principle has been viewed as a *pragmatic decision rule* and represents a threshold approach in which certain problems or hazards can be ignored if they are below a set cutoff point (Menkes and Frey 1987). Risks may be considered negligible if the incremental risk produced is so small that there is no incentive to modify the activity (Fiksel 1987).

The USEPA and FDA often consider individual lifetime risks of one in a million (i.e., 1×10^{-6}) or less to be acceptable for the general public (Kolluru 1996). However, regulatory agencies have been reluctant to adopt a formal *de minimis* risk policy since it is difficult to establish a level that is acceptable to all members of society. Options that have been proposed include setting *de minimis* risk levels equivalent to natural background levels, equal to risk levels commonly encountered by individuals, or equal to risk levels that have been tolerated in the past (Menkes and Frey 1987).

De Manifestis Risk. Contrary to the *de minimis* principle, the *de manifestis* principle arises when risks are so large that they require immediate attention, regardless of the control costs involved (Kolluru 1996). Significant risks should not be viewed as the opposite of *de minimis* risks since a risk can fail to meet the *de minimis* criteria and still not be significant (Bryd III and Lave 1987). *Significant risks* are defined as those that are “compelling” or “measurable,” while *insignificant risks* are defined as “trivial” or “undetectable” (Bryd III and Lave 1987). *De minimis* risks are considered to be even lower than insignificant risks.

The *de manifestis* criterion may be used in response to major chemical accidents or technological disasters. While the definition of significant risk is more ambiguous than that of trivial risks, risks greater than one in a thousand (i.e., 1×10^{-3}) are likely to spur government action (Kolluru 1996).

Value of Statistical Life. Besides risk-based criteria, economic criteria are often used implicitly or explicitly in determining acceptable risk levels. One such criterion, the “value of a statistical life,” is based on the marginal cost of avoiding a human fatality (Kolluru 1996). Initial efforts to value life used a human capital approach in which value of statistical life (VSL) estimates were based on various measures of earning potential (Viscusi 1992). More recently, contingent valuation (CV) methods have been used to determine how much money individuals are willing to pay for specific risk reductions or changes in risk (ΔR). Value of statistical life estimates are calculated by dividing aggregate willingness-to-pay (WTP) values by the actual reduction in risk ($VSL = WTP/\Delta R$). Although risk-dollar tradeoffs differ considerably depending on the context, reasonable estimates range between \$3 to \$7 million (Viscusi 1992).

The VSL approach is currently used by the U.S. Office of Management and Budget (OMB) for all new major federal regulations. Note that valuation is not on survival or life itself, but rather on the incremental reduction in the probability of an adverse effect that might otherwise have affected some random member of the population (Viscusi 1992). This approach centers the analysis on *statistical* lives rather than on certain or *identified* lives.

Risk Management Framework

Although the use of “bright lines” can help identify very large or very small risks, acceptable-risk determinations ultimately depend on the particular situation. The precise role of risk management, and its relationship to risk assessment, is also evolving and has been widely debated. (Zimmerman 1990). In an effort to integrate the risk analysis processes and evaluate risks more holistically, a recent Presidential/Congressional Commission on Risk Assessment and Risk Management was formed. In its final report, the Commission (1997) put forth a comprehensive “risk management framework” for making good risk management decisions. This framework is designed to be used in a wide variety of situations and by all types of risk managers, including government officials, private businesses, and members of the public.

The risk management framework consists of the following six stages (see Fig. 70.9):

- Define the problem or context.
- Analyze risks.
- Examine options.
- Make a decision.
- Take actions.
- Evaluate actions.

This framework can be scaled to the importance of a problem, and all stages are designed to incorporate broader contexts, stakeholder involvement, and iterations. Each of these stages is summarized below.

Defining the Problem in Its Context. The first and most important stage of the risk management framework is to define the problem of interest. This stage consists of two steps:

FIGURE 70.9 Risk management framework. (From Presidential/Congressional Commission on Risk Assessment and Risk Management. 1997. *Framework for Environmental Health Risk Management. Final report, Vol. 1.* Washington, DC.)

(1) identify and characterize the problem and (2) put the problem into its proper context. First, potential problems can be identified via a range of indicators and data sources. These include emission inventories, environmental monitoring, toxicity testing, disease surveillance, permit violations, local odors, and news reports. Once identified, a problem can be characterized according to its primary causes and whom it affects in the population. How a problem is characterized is important because it can have a major impact on the focus and outcome of the risk management process.

Second, problems must be considered in their broader environmental context. Historically, regulatory agencies have evaluated risks in an “artificially narrow context” that considers only single chemicals, exposure pathways and risks (Commission 1997). In order to examine real-life problems, risk managers must evaluate risks in their *multisource*, *multimedia*, *multichemical*, and *multirisk* contexts. For example, risk managers should consider whether individuals are exposed to the same agent from multiple sources or via multiple environmental media. Additional considerations include whether individuals are exposed to different agents from the same source, or face similar risks from a variety of agents and sources. This multidimensional approach can highlight the true complexities of a problem and is essential for effective risk management.

In this first stage, appropriate risk managers and risk management goals should also be identified. Deciding who will be responsible for managing the problem will depend on the problem’s context, and may include regulators, businesses, industries, clinicians, and citizens. Note that the person or entity responsible for managing the risk is not necessarily the person or entity responsible for generating the risk. Risk management goals can be risk related, economic, based on public values, or dictated by statutory or regulatory requirements. These goals should ultimately reflect broad stakeholder interest and be used to guide the rest of the decisionmaking process. For most indoor-related risks there are no clear responsibilities defined for government, private owners, designers, and manufacturers. The courts will continue to define responsibilities for managing indoor risks, which does not mean a consistent, coherent, or cost-effective scheme.

Analyzing Risks. The second stage of the risk management framework involves analyzing the risks that a problem poses. As discussed in Sec. 70.1, risk assessments provide quantitative and qualitative data on potential risks. The final step of the risk assessment process—risk characterization—serves as the bridge between risk assessment and risk management. Risk characterizations should provide risk managers with information on the nature and likelihood of the health risk, which individuals or groups are at greatest risk, the severity of anticipated adverse effects, the strength of the scientific evidence, and the sources of scientific uncertainty. Risk managers can then combine information on the scientific and contextual aspects of risks to arrive at their own risk characterization. In general, the level of detail of the risk analysis should be commensurate with the nature or importance of the problem.

Examining Options. In the third stage of the risk management framework, which can occur anytime after a problem has been defined in its proper context, potential risk management options are examined. This stage consists of two steps: identifying and analyzing options:

- Regulatory and nonregulatory alternatives to reducing risks are identified. These include pollution prevention and abatement programs, taxation strategies, enforcement tactics, educational campaigns, and establishing markets (or other incentives) for voluntary behavior changes. Risk managers should focus on identifying alternatives to command-and-control strategies that can result in greater levels of protection.

- Potential risk management options are evaluated for their effectiveness, feasibility, costs, benefits, unintended consequences, and cultural and social impacts. For example, risk managers must assess whether an option achieves the risk management goals stated earlier or results in additional benefits, such as technological development and employment opportunities. Risk managers must also consider the monetary and non-monetary costs associated with an option, including the costs of technology development, cleanup, transportation, health care, and loss of environmental assets (e.g., parks and wetlands). In addition, risk managers must evaluate whether an option itself will result in adverse or other unintended consequences, such as increased environmental or health risks, economic impacts, or an inequitable distribution of costs and benefits. Finally, risk managers must ensure that an option is feasible and is not constrained by technological, legal, political or economic factors.

While the Commission (1997) acknowledges that economic analysis can play an important role in the risk management process, it warns against using this as the sole or overriding determinant of a decision. One concern is that too much emphasis will be placed on assigning monetary values to different health outcomes. Another concern is that equity considerations will be ignored, resulting in decisions being based strictly on whether estimated benefits outweigh estimated costs. A final concern is that key assumptions and uncertainties will be ignored when conveying risk management decisions. Formal analytic techniques that have been developed for assessing risk management options include *cost-effectiveness analysis* (CEA), *cost-benefit analysis*, (CBA) and *decision analysis* (DA). These are described briefly below.

Cost-effectiveness analysis. CEA involves finding the lowest cost means of achieving a predetermined objective (Gold et al. 1996, Titenberg 1996, Weinstein and Fineberg 1980). Costs are measured in monetary terms, while effectiveness (benefits) is expressed as some unit of output or outcome (e.g., number of cases detected or number of lives saved). The central measure used in CEA is the cost-effectiveness (CE) ratio, which is the difference in costs between two alternatives, divided by the difference in effectiveness. CE ratios represent the incremental price of obtaining a unit of health outcome from a given option when compared with an alternative. Options are ranked from the lowest to the highest CE ratio and then selected until available resources are exhausted. Note that this approach does not necessarily lead to an efficient outcome, since the stated objective itself may not be efficient.

Cost-benefit analysis. CBA involves enumerating all tangible and intangible societal costs and benefits associated with a particular option (Titenberg 1996, Weinstein and Fineberg 1980, Stokey and Zeckhauser 1978). Costs and benefits are valued in a common unit, which is typically monetary. Net benefits are calculated as the difference between total benefits and total costs. In situations involving a choice between alternatives, the option that produces the greatest net benefits is considered to be socially optimal. This approach leads to efficient policy choices and allows for comparisons to be made across diverse programs. However, this approach does not address distributional issues since it only considers aggregate cost and benefit measures.

Decision analysis. DA represents a systematic approach for making decisions under conditions of uncertainty (Weinstein and Fineberg 1980, Keeney and Raiffa 1976). Once a problem and viable actions are identified, a *decision tree* is drawn indicating various paths along which choices can be made and chance events occur. Probabilities are then assigned to each chance event, and utility values are assigned to the consequences associated with each path of the tree. The optimal strategy is defined as the one that maximizes expected utility. This approach highlights what choices to make (starting at the beginning of the decision tree) and allows decisions to be made that are consistent with one's underlying beliefs and preferences.

Making a Decision. The fourth stage of the risk management framework involves choosing among potential risk management options. This decision is usually made by the person responsible for managing the problem, such as a government official or regulator, but may also reflect negotiations with various stakeholders. In making a final decision, risk managers should review all relevant information gathered during the previous two stages. The “optimal” decision will depend on the particular situation and on stated risk management goals.

In general, risk management decisions should be based on the best scientific, economic, and other technical information available. Risk management decisions should also account for a problem’s broader multicontext, with expected benefits reasonably related to expected costs. As mentioned, an alternative to command-and-control regulations should be encouraged, whenever possible, and priority should be given to both preventing and controlling risks. Finally, risk managers should be sensitive to political, social, legal, and cultural considerations. Although there are no definitive or value-free methods for choosing among alternative options, it has been proposed that risk management decisions be comprehensive, logically sound, practical, open to evaluation, politically acceptable, compatible with institutions, and conducive to learning (Fischhoff et al. 1981). Although these are ideas that can serve indoor air quality investigations well, concern about job actions and lawsuits tend to work against such openness.

If there is limited information about a problem, risk managers must determine whether the potential risks of delaying a decision (in order to obtain additional information) outweigh the immediate risks posed by the problem. In this case, decisions may be based on conservative principles or more formal information valuation techniques. For example, the *precautionary principle* states that regulatory action or precautionary measures should be taken to prevent a hazard even when evidence of harm is uncertain (Cross 1996, Hickey and Walker 1995). This “better safe than sorry” approach arises from concerns about potentially damaging or irreversible effects and reflects a preference for pollution prevention rather than pollution control. Value-of-information (VOI) techniques represent a more analytic approach to assessing the value of reducing uncertainty prior to a risk management decision (Thompson and Graham 1996, Clemen 1991). This approach uses influence diagrams and decision trees to calculate the expected value of information by comparing risk management decisions with and without new information.

Taking Action. The fifth stage of the risk management framework entails taking action by implementing the risk management decision. Selected options should be implemented in an effective and timely manner and be flexible enough to incorporate new information as it becomes available. Appropriate action takers will depend on the situation and may include public health agencies, community groups, citizens, businesses, industries, unions and workers, and technical experts. To ensure continued support for the decision, special effort should be made to involve stakeholders in the implementation phase.

Although risk management actions can take many forms, the current framework is intended primarily for decisions related to setting standards, controlling pollution, protecting health, and cleaning up the environment. Examples of risk management actions include educating the public and workers about different risks, upgrading pollution control technologies, improving manufacturing processes and manufacturing facilities, instituting recycling programs, and providing technical assistance to various groups.

Evaluating Results. The final stage of the risk management framework is to evaluate the results of a risk management decision. Evaluation is an important and often overlooked component of risk management. This stage involves reviewing what actions were implemented and how effective they have been in achieving stated goals. Useful tools for evaluation include monitoring data, research, disease surveillance, analyses of costs and benefits, and discussions with stakeholders.

Evaluation should provide information on the success of a risk management plan and the effectiveness of the risk management process. Evaluation can also help identify important data gaps and indicate whether new information about the problem or potential options is available. Public comment and other information-gathering techniques can be used to clarify or redefine the problem or identify risks in a broader context. Ultimately, a good decision will have a significant impact on the risks of concern and will provide insight for guiding future risk management decisions.

Summary

Risk management is a policy-oriented process that guides good decisionmaking about risks. The risk management process involves weighing scientific evidence, in conjunction with social and economic factors, to determine acceptable-risk levels. Although there is no single approach for making risk management decisions, a variety of formal and informal methods are available to aid in the decisionmaking process. The primary goal of risk management is to reduce human health risks. However, risk managers are also responsible for establishing a decisionmaking process that involves stakeholders and fosters public trust and credibility. This includes communicating risks and risk management decisions to the public, which is the topic of the following section.

70.4 RISK COMMUNICATION

Risk communication is the process of conveying information about a risk or risk management decision. The risk communication process is defined as “any public or private communication that informs individuals about the existence, nature, severity, or acceptability of risks” (Plough and Krimsky 1987). The definition of risk communication consists of five components: intention, content, audience, source, and flow (Plough and Krimsky 1987). One of the primary goals of risk communication is to better inform decisionmakers, in the context of either public debate or personal action (NRC 1989). In the regulatory or legislative context, risk communication involves describing and summarizing scientific knowledge about risk issues and interpreting scientific evidence. Risk communication directed toward individuals entails providing information, advice, warnings, and recommendations regarding personal actions.

Risk communication has roots in the broader field of communications theory. According to the “source-receiver model,” information sources send out clusters of signals (which form messages) to a transmitter or receiver for decoding (Kasperson et al. 1988). Messages may be altered along the route of transmission, resulting in signals that are intensified or attenuated. While communicating risks is more complex and interactive than this model implies, risk communication involves three key elements: messengers, messages, and receivers (Fessenden-Raden et al. 1987). Current risk communication efforts emerged out of the need to address perceived public risk perceptions and gain acceptance for decisions grounded in risk assessment methods (Plough and Krimsky 1987). Today, risk communication is an essential component of risk management in both the public and private sectors (Plough and Krimsky 1987). This is especially true in response to concerned parents, teachers or occupants of buildings experiencing publicized complaints. Fears about personal health or the health of children in buildings experiencing unexplained symptoms is an understandable human reaction. Managing the problem often requires skillful communications.

Effective risk communication entails an understanding of how people think about risks and what factors influence public risk perceptions. Once these factors are understood, there

are a variety of strategies and tools that risk communicators can use to convey risk information. The following section provides an overview of the social and psychological dimensions of the risk analysis framework. First, cognitive processes that people rely on when evaluating risks and their potential biases are discussed. Then differences in perceived risks between various groups are presented. Finally, strategies and tools for effective risk communication are highlighted.

Cognitive Heuristics

People rely on various mental strategies or “cognitive heuristics” to simplify and evaluate complex risk information (Slovic 1987). These judgmental rules, which are typically based on past experience and intuition, are used by members of the scientific community (i.e., experts) as well as the general public (i.e., laypersons). Several common heuristics that people use are

- Availability
- Anchoring
- Overconfidence
- Representativeness

Although these simplifying inferences may prove beneficial in some instances, they often lead to persistent biases and cognitive errors. The following subsection provides an overview of these heuristics.

Availability. The availability heuristic is often used when individuals attempt to assess the frequency or probability of occurrence of an event (Tversky and Kahneman 1982a). In such instances, events are perceived as frequent or likely to occur if they are easy to imagine or recall (Slovic et al. 1979). Use of this heuristic will therefore lead to overestimates of events that are rare, dramatic, sensational or salient, and underestimates of events that are abstract, not encoded in memory or not recently experienced (Morgan and Henrion 1990). For example, people tend to overestimate the risk of dying from botulism and floods, while underestimating the risk of dying from diabetes and heart disease (see Fig. 70.10). Although a helpful aid in some situations, the availability heuristic can result in biases if certain events are much easier to recall or imagine than are other events (Tversky and Kahneman 1982a).

Anchoring. The anchoring heuristic is commonly used when an initial estimate is given and adjustments are made to this estimate based on subsequent information (Tversky and Kahneman 1982a). In such instances, the starting point value acts as an anchor, biasing adjustments and final results toward this value. For example, research shows that when asked to estimate the annual risk of dying from various causes, public mean risk responses are significantly higher when one is confronted with a baseline risk of 50,000 for motor vehicle accidents, than when confronted with an initial risk value of 1000 for accidental electrocutions (Slovic et al. 1979). This heuristic is often observed when people take cues from their surrounding environment (which may be irrelevant) and anchor on these cues when making future risk judgments.

Overconfidence. The overconfidence heuristic can take many forms. People tend to be very confident about their risk judgments and believe that they can estimate uncertain risks with much greater precision than they actually can (Slovic et al. 1979). People also prefer certain events to uncertain events, and may deny that uncertainty exists in order to reduce anxiety associated with this concept (Slovic et al. 1979). Indeed, people often exhibit an

FIGURE 70.10 Relationship between judged frequency and actual number of deaths per year. (From P. Slovic, B. Fischhoff, and S. Lichtenstein. 1979. *Rating the risks: The structure of expert and lay perceptions. Environment* 21(3): 14–20, 36–39.)

“optimistic bias” in that they tend to believe they are less likely than others to experience harm (Weinstein 1989). This latter phenomena occurs when people have little experience with a hazard, when a hazard is judged to be within personal control, and when hazards are rated as unlikely (Weinstein 1989). In all of the contexts mentioned, people tend to have very strong prior beliefs that are difficult to change. New information is filtered according to personal beliefs so that evidence is considered useful and reliable only if it is consistent with prior opinions (Slovic et al. 1979).

Representativeness. The representativeness heuristic occurs when people try to judge the likelihood that an object belongs to a particular class or an event is generated by a particular process (Tversky and Kahneman 1982b). In this case, individuals often expect the fine structure or details of the object or event to reflect the larger class or process. For example, people perceive coin tosses of HTHHTH to be more likely than HHHTTT or HTHHTT, even though all three outcomes are equally likely to occur (Tversky and Kahneman 1982a). A consequence of this heuristic is that people pay too much attention to irrelevant details and not enough attention to important background information, such as prior probabilities or base rates (Morgan and Henrion 1990). In making risk judgments, people also tend to be insensitive to statistical considerations such as sample size, the role of chance, and regression to the mean (Tversky and Kahneman 1982a). This is a particular problem in many building investigations. Prevalence rates for disease, and symptoms or cause of death are rarely adjusted for the demographics of building occupants. Internal comparisons or comparisons to a reference building are seldom reliable because of sample size and reporting biases.

In addition to cognitive heuristics, different ways of presenting or “framing” the same information can influence public risk perceptions and actions (Tversky and Kahneman

1986). For example, people were found to have different perceptions of the same incident rate information, depending on whether it was expressed as a probability (e.g., 0.006) or a frequency (e.g., 600 in 1,000,000) (Siegrist 1997). Framing effects are particularly problematic when people lack strong prior opinions about an issue (Slovic 1987).

Risk Perceptions

The debate over “real” versus “perceived” risks is a central issue in risk communication. People tend to respond according to their personal assessment of a situation, regardless of whether scientific evidence supports these assessments. Public misperceptions can therefore have serious consequences on risk management decisions and risk communication efforts. Risk perceptions are heterogeneous across different groups as well as within specific groups. This has led to substantial disagreements about the relative importance of different hazards and the appropriateness of public perceptions (Fischhoff 1989). A number of studies have attempted to investigate how and why risk perceptions differ in the population. Differences in risk judgments have been attributed to a number of factors, including

- Expert versus lay status
- Scientific field and institution
- Gender and race
- Culture and worldview

Each of these factors is discussed below.

Expert versus Lay Status. Experts and laypeople often have divergent viewpoints about the relative riskiness of different hazards. For example, when asked to rank the risk of 30 public health hazards, two lay groups rated nuclear power as the riskiest technology or activity, while experts rated motor vehicles as posing the greatest risk (Slovic et al. 1979) (see Table 70.3). Similarly, risk rankings of environmental hazards show that the public rates hazardous-waste sites and chemical leaks as high-risk items, while USEPA experts rate indoor air pollution and ozone-layer destruction as posing a high risk (see Table 70.4). Comparisons of specific hazards, such as chemical and nuclear waste issues, also reveal significant differences in perceived risks between expert and lay groups (Sjöberg and Drottz-Sjöberg 1994, Kraus et al. 1992).

Differences in risk judgments suggest that the concept of risk means “different things to different people” (Slovic 1987). Experts tend to characterize risk as a function of the probability of an event and the magnitude of specific consequences. As a result, expert judgments often parallel estimates of annual fatalities. Laypersons, on the other hand, have a much broader conceptualization of risk that is based on a variety of qualitative attributes (see Table 70.5). For example, risks that are involuntarily imposed (e.g., biological or chemical sources within a building) tend to be viewed as riskier and more objectionable than do risks that are voluntary (e.g., smoking or driving a car). Similarly, hazards that are unknown, unfamiliar, or perceived as outside the realm of personal control are judged to pose a greater threat than do hazards that are known, familiar, or perceived to be within the realm of personal control. Hazards that invoke feelings of dread (e.g., cancer) or that afflict many people at one time (e.g., airplane crash) are also viewed as riskier than hazards that are not dreaded or that affect one person at a time. A hazard may be perceived as risky if its benefits and risks are inequitably distributed in the population.

Scientific Field and Institution. Besides differing from lay perceptions, expert risk judgments often depend on the scientific field or research institution to which an expert belongs. Studies show that life scientists perceive nuclear-related risks as significantly greater than do physical scientists (Barke et al. 1995, Barke and Jenkins-Smith 1993).

TABLE 70.3 Perceived Risk for 30 Activities and Technologies

Activity or technology	League of Woman Voters	College students	Active club members	Experts
Nuclear power	1	1	8	20
Motor vehicles	2	5	3	1
Handguns	3	2	1	4
Smoking	4	3	4	2
Motorcycles	5	6	2	6

Scientists in universities or state and local governments have also been shown to have higher perceived risks on nuclear issues than do scientists who work as business consultants, for federal organizations, or for private research laboratories (Barke and Jenkins-Smith 1993). In addition, differences in expert risk judgments appear to be a function of familiarity with a hazard. For example, nuclear experts were found to perceive nuclear-related risks as significantly smaller than did the public and other technical groups (Sjöberg and Drottz-Sjöberg 1994). All of these groups, however, had similar perceived risks for non-nuclear hazards.

Gender and Race. Studies show that public risk perceptions differ between men and women and whites and nonwhites. For example, when asked to rate the riskiness of a variety of hazards, women had significantly higher risk ratings than did men for all hazards considered (Flynn et al. 1994). Women also tend to have greater confidence that various hazards exist than do men (Graham et al. 1999a). Gender differences have been found to persist regardless of scientific or technical expertise (Graham et al. 1999b). For example, female scientists were found

TABLE 70.4 Risk Ratings for Environmental Hazards

	Public	EPA Experts
1.	Hazardous-waste sites	Medium to low
2.	Exposure to worksite chemicals	High
3.	Industrial pollution of waterways	Low
4.	Nuclear accident radiation	Not ranked
5.	Radioactive waste	Not ranked
6.	Chemical leaks from underground storage tanks	Medium to low
7.	Pesticides	High
8.	Pollution from industrial sources	Medium to low
9.	Water pollution from farm runoff	Medium
10.	Tapwater contamination	High
11.	Industrial air pollution	High
12.	Ozone-layer destruction	High
13.	Coastal water contamination	Low
14.	Sewage-plant water pollution	Medium to low
15.	Vehicle exhaust	High
16.	Oil spills	Medium to low
17.	Acid rain	High
18.	Water pollution from urban runoff	Medium
19.	Damaged wetlands	Low
20.	Genetic alteration	Low
21.	Non-hazardous-waste sites	Medium to low
22.	Greenhouse effect	Low
23.	Indoor air pollution	High
24.	X-ray radiation	Not ranked
25.	Indoor radon	High
26.	Microwave oven radiation	Not ranked

to have substantially higher perceived risks than were male scientists in regard to nuclear technologies and materials (Barke et al. 1995). Although it is not clear why this gender gap exists, several hypotheses have been proposed (Flynn et al. 1994). One hypothesis is that women are more nurturing and are perhaps more vulnerable to certain risks than are men. Other hypotheses are that women may be less knowledgeable than men about scientific and technological issues, or that women may distrust what they perceive to be male-dominated technologies. Interestingly, gender differences do not appear to exist among nonwhite population groups or in “stressed” environments (Greenberg and Schneider 1995, Flynn et al. 1994).

Additional studies have found that nonwhites have higher perceived risks than do whites (Flynn et al. 1994). In particular, white men tend to have significantly lower perceived risks and confidence ratings than do white women, nonwhite men, and nonwhite women (Graham et al. 1999a, Flynn et al. 1994). This phenomenon, termed the “white male effect,” is characterized by individuals who are better educated, have higher household incomes, are politically conservative, trust institutions and authorities, and are opposed to citizens participating in risk management decisions (Flynn et al. 1994). It is unclear why these differences exist, but the role of power, status, alienation, and trust are thought to be critical factors (Flynn et al. 1994).

Culture and Worldview People’s attitude, beliefs, and values toward society may also play a significant role in public perceptions of risk. Cultural theory is based on the assumption that all forms of society produce their own selected view of the natural environment (Douglas and Wildavsky 1982). These “cultural biases” or “worldviews” are hypothesized to orient people to have certain types of societal concerns and risk perceptions (Dake 1991). For example, worldview A and worldview B have been characterized as “progrowth” and “antigrowth” orientations, respectively. People who embody the worldview B orientation have been shown to have higher perceived risks for various technological hazards than do people who embody the worldview A orientation (Buss and Craik 1983). Contemporary worldview measures have also been characterized as *hierarchical* (i.e., value authority/reject social deviance), *egalitarian* (i.e., value equality/reject hierarchy), and *individualistic* (i.e., value self-regulation/reject social deviance). Egalitarianism has been correlated with significantly higher societal concerns than are the worldview orientations of hierarchy or individualism (Peters and Slovic 1996).

Risk Communication Strategies

Risk communication involves deciding what risks to focus on and how to present risk information. While it is relatively easy to identify hazards that all members of society agree are a problem, this task becomes increasingly more difficult when risk perceptions vary between expert and lay groups. Risk communication decisions also depend on the perspective of the risk communicator. For example, if risk communicators perceive the public as misinformed or irrational, this will result in a different communication strategy than if expert judgments are regarded as too simplistic. As mentioned, one of the main goals of risk communication is to better inform public decisionmaking. Risk communication is also used to influence public opinion or choice (NRC 1989). For example, risk communicators may want to arouse (or alleviate) public concerns about a risk issue that they believe has received too little (or too much) attention (Sandman 1993).

The effectiveness of risk communication efforts will vary depending on the subject matter, decision alternatives, intended audience, and other factors (NRC 1989). Although there is no single method or framework for communicating risks, various principles have been proposed for increasing the effectiveness of risk communication efforts. Several of these strategies, which are discussed below, include

- Engage in dialog.
- Explain risk information.
- Simplify and personalize.
- Address public concerns.
- Put risks into context.

Engaging in Dialog. To be effective, risk communication efforts must engage the public in meaningful dialogue. This implies a two-way interaction where participants both listen to and are heard by risk communicators. Such efforts are important not only for increasing public understanding about a risk issue but also for enlightening risk communicators as to what issues need to be communicated. Risk communicators should find out what participants know and believe about a particular risk issue and control alternatives, and what qualitative and quantitative information they need to know to make an informed decision (NRC 1989). Public dialogue should begin early on in the risk management process, and risk information should be released to the public as soon as possible. These efforts will help foster public trust in the risk message and the risk communication process, and will provide communicators with greater control over the content and accuracy of the risk information (Hance et al. 1989).

Explaining Risk Information. Explaining complex and uncertain risk information is perhaps the most challenging aspect of the risk communication process. People are generally capable of understanding risk probabilities and risk-tradeoff information when they are carefully explained (Sandman 1987). To ensure informed public decision-making, risk communicators must present all relevant information to the public, including data on risks and benefits. A complete information base consists of quantitative and qualitative information on the nature of the risk, benefits that might be affected if the risk were reduced, available alternatives, uncertainty in knowledge about risks and benefits, and risk management issues (NRC 1989). Risk communicators should also highlight important data gaps and areas of expert disagreement when explaining risk information. In addition, risk communicators should provide an indication of the level of confidence in risk estimates and the significance of scientific uncertainty in the decisionmaking process (NRC 1989).

Simplifying and Personalizing. Risk messages should be to the point and easy to understand. Risk communicators should avoid using technical jargon and present risk information in simple terms that do not overwhelm the public (NRC 1989). Simplifying risk information will necessarily entail judgments about what information is essential and what information can be left out (Sandman 1987). In general, simplifying complicated language is preferable to simplifying the content of a message. Highlighting important facts can also make it more available to the public, and hence, easier to imagine or recall (NRC 1989). Care should be taken, however, not to oversimplify or gloss over complex and uncertain information. Risk messages should be personalized whenever possible to make it more salient and of interest to the target audience (Sandman 1987). For example, risk messages should include practical advice about what actions to take and what options are available to the public. Risk information should also be expressed in terms of risk to a representative individual, rather than as a general population risks estimate (NRC 1989). Abstract information should be made more concrete by using specific examples and vivid images and focusing on real people and decisions (Sandman 1987).

Addressing Public Concerns. Effective risk communication entails addressing public concerns. As mentioned, people consider many factors in addition to scientific data when

evaluating risks. Any attempt to characterize and explain hazard information must be sensitive to the public's broader conceptualization of risk (Slovic 1986). Most risk communicators agree that these factors are as real, as measurable, and as much a part of risk and risk communication as are technical assessments of risk (Sandman 1993). Risk communicators can help alleviate some of these concerns by making risks more voluntary and familiar, legitimizing dread, sharing control and benefits, and focusing on a risk's magnitude (Sandman 1993). Individuals' subjective reactions should not be considered irrelevant or inferior to expert assessments, and risk communicators should show compassion when dealing with issues of illness and death (NRC 1989).

Putting Risks Into Context. Various risk communication tools have been developed to help people understand risk magnitudes and put risks into perspective. These methods typically consist of comparing a particular risk to other risks that people are familiar with. Risk comparisons are considered to be more meaningful to people than probabilities alone, especially when risk values are small (Slovic 1986). Several frequently used risk communication tools and tactics include

- Direct comparisons
- Risk rankings
- Risk ladders
- Verbal analogies
- Other visual aids

Direct comparisons. Direct risk comparisons are used to compare one risk to another risk on the same or different dimensions. For example, the same risk can be compared at two different time periods, or two risks with the same outcome can be compared at the same time period (see Table 70.6). Comparisons between risks that are based on the same hazards or have similar consequences are generally preferred to comparisons between dissimilar risks (NRC 1989, Covello et al. 1988). Empirical research, however, does not support the notion that some types of risk comparisons are better than others (Roth et al. 1990). Note that the use of risk comparisons in certain contexts may result in increased public hostility toward the risk of concern (Freudenburg and Rursch 1994).

Risk rankings. Risk rankings are used to demonstrate the position of a risk in relation to other risks on a particular dimension. For example, risks can be ranked in descending order according to the number of expected fatalities in the United States each year (see Table 70.7). It is important to be aware that the use of different denominators can lead to different risk rankings. For example, the risk measure "risk of dying" can be expressed as deaths per million people in a population, deaths per unit of pollutant concentration, or deaths per ton of chemical produced (Slovic 1986).

Risk ladders. A more visual approach to ranking risks is the use of risk ladders. Risk ladders can be drawn on different scales (i.e., linear or logarithmic), with each rung of the ladder representing a particular hazard and risk level (see Figs. 70.11 and 70.12). Risk ladders presented on a logarithmic scale, however, may cause confusion if people do not understand that the same length between different points on a scale represent different magnitudes. The framing of risk information on a risk ladder may also influence individuals' perceived risks (Sandman et al. 1994).

Verbal analogies. Verbal analogies can be used in addition to probability estimates when presenting risk information. Risks can be compared to their equivalency in time, distance, population, and games of chance (see Table 70.8). The use of verbal analogies is thought to more dramatically convey risk differences than do risk probabilities

TABLE 70.6 Ranking Hierarchy of Risk Comparisons

First-rank risk comparisons
1. Comparisons of the same risk at two different times
2. Comparisons with a standard
3. Comparisons with different estimates of the same risk
Second-rank risk comparisons (second choice—less desirable)
4. Comparisons of the risk of doing and not doing something
5. Comparisons of alternative solutions to the same problem
6. Comparisons with the same risk as experienced in other places
Third-rank risk comparisons (third choice—even less desirable)
7. Comparisons of average risk with peak risk at a particular time or location
8. Comparisons of the risk from one source of a particular adverse effect with the risk from all sources of that same adverse effect
Fourth-rank risk comparisons (fourth choice—marginally acceptable)
9. Comparisons of risk with cost, or of cost/risk ratio with cost/risk ratio
10. Comparisons of risk with benefit
11. Comparisons of occupational with environmental risks
12. Comparisons with other risks from the same source, such as the same facility or the same risk agent
13. Comparisons with other specific causes of the same disease, illness, or injury
Fifth-rank risk comparisons (last choice—rarely acceptable use—with extreme caution!)
14. Comparisons of unrelated risks

TABLE 70.7 Risk Ranking by Annual Fatalities (per 100,000 Persons at Risk)

Risk	Rate
Motorcycling	2000
All ages	1000
Aerial acrobatics (planes)	500
Smoking (all causes)	300
Sport parachuting	200
Smoking (cancer)	120
Firefighting	80
Hang gliding	80
Coal mining	63
Farming	36
Motor vehicles	24
Police work (nonclerical)	22
Boating	5
Rodeo performer	3
Hunting	3
Fires	2.8
1 diet drink/day (saccharin)	1.0
4 tablespoons peanut butter/day (aflatoxin)	0.8
Floods	0.06
Lightning	0.05
Meteorite	0.000006

(Weinstein et al. 1996). However, since these analogies are generally unrelated to the concept of risk, they may not be especially relevant (Sandman 1987).

Other visual aids. Many other types of visual aids have been developed to help people put risks into context. Examples include pie charts, bar graphs, dots, and community scales (see Table 70.9).

Although the strategies presented above serve as useful risk communication tools, they have several important limitations. Risk comparisons can not (and should not) be used to establish the acceptability of a risk. For example, just because two risks have the same magnitude does not imply that they are equally acceptable. Risk comparisons are also typically given as point estimates, with little or no indication of the uncertainty involved in risk estimates. In addition, risk comparisons tend to focus on a single dimension (e.g., annual fatality rate) and do not include information on other important attributes (e.g., voluntariness). Finally, risk comparisons may lead to cognitive biases depending on how risk information is framed.

TABLE 70.8 Risk Comparison Verbal Analogies

20 chances in 100,000 is about equal to:
The likelihood of flipping a coin and getting 12 heads in 12 consecutive tries 13 in. in a mile
The chance of dying from smoking one cigarette each day for 20 years
The chance of dying from taking 2000 flights on regularly scheduled jet airliners
The likelihood of rolling a dice and getting five sixes in five consecutive rolls 100 min in a year
20 spectator seats at the Rose Bowl football game on New Year's Day

TABLE 70.9 Community Risk Scale

Risk	Risk magnitude	Risk description (unit in which one adverse event would be expected)	Examples (based on number of deaths in Britain each year)
1 in 1	10	Person	—
1 in 10	9	Family	—
1 in 100	8	Street	Any cause
1 in 1000	7	Village	Any cause: age 40
1 in 10,000	6	Small town	Road accident
1 in 100,000	5	Large town	Murder
1 in 1,000,000	4	City	Oral contraceptives
1 in 10,000,000	3	Province or country	Lightning
1 in 100,000,000	2	Large country	Measles
1 in 1,000,000,000	1	Continent	—
1 in 10,000,000,000	0	World	—

Summary

Risk communication is a dynamic process that involves interaction over time with senders and receivers of risk information (Fessenden-Raden et al. 1987). Communicating risks requires an understanding of how risks are measured, managed, and perceived by different groups. To be effective, risk communicators must recognize that the public's conceptualization of risk may differ from expert opinion and may reflect legitimate concerns. Establishing trust and credibility in risk messengers, as well as in the risk communication process itself, is also necessary for effective risk communication. Risk communicators should be aware that the usefulness of different strategies and risk communication tools will depend on the particular context and that a combination of approaches may be required. Although risk communication is a vital part of the risk analysis process, conveying risk information will not necessarily resolve conflict or alter public risk perceptions. Risk arguments may in fact be a surrogate for other social or ideological concerns, such as feelings of fear and powerlessness (Slovic 1986). Understanding the nature and causes of public concerns will ultimately help strengthen risk communication efforts and lead to more informed risk decisionmaking. Occupants of a "sick building" have heightened anxiety. What they need is information about hazards and risk and insight into how building systems operate and influence the quality of their indoor environment.

CHAPTER 71

IAQ AND THE LAW

Mark Diamond, Esq., M.A. J.D.

*The Law Firm of Mark Diamond
Stamford, Connecticut*

71.1 INTRODUCTION

Although ambient and industrial pollution has garnered vast private, public, and governmental attention since the 1960s, considerably less attention has been paid to pollution that occurs inside our homes and offices. This is unfortunate since the air we breathe while performing our jobs, playing with our children, and sleeping is often considerably more unhealthy, even dangerous, than the air we breathe outdoors.

Considerable evidence has been revealed about the health consequences of radon, environmental tobacco smoke, formaldehyde, asbestos, latex, and many natural and synthetic allergens. Efforts at the state and federal levels to enact laws and regulations to prevent indoor pollution (IP) through ventilation, product testing, and various code improvements have not, in general, been successful. Despite the absence of legislation, legal suits have been brought by individuals against companies and classes of people against manufacturers, employers, landlords, building management realtors, architects, and contractors. Plaintiffs contend in these cases that sources in the indoor environments have damaged their health and diminished the value of their property.

The two well-known pollutants of indoor environments are asbestos and lead paint. Asbestos, which can scar lung tissue and cause cancer, led to years of litigation and extensive regulation. Many millions of dollars have been spent removing it from buildings. Lead paint can cause permanent retardation in children who ingest or inhale it in the form of paint chips and dust. Legislation has been enacted to ban and remove or encapsulate lead paint while supporting extensive screening programs for at-risk children. Litigation in this area is beginning and promises to be ample.

Lead paint and asbestos are the tip of the iceberg. The possible causes of indoor pollution go far beyond these two pollutants and include

- Improperly designed, constructed, and maintained heating, ventilating, and air-conditioning (HVAC) systems that allow the growth, accumulation, and distribution throughout a building of bacteria, mold, and dust in filters, ductwork, machinery, and internal insulation

- The very materials used in construction, renovation, maintenance, and furnishing. Items such as paint; wall, ceiling, and floor coverings and the mastics used to secure them; plywood; pressboard furniture; and office equipment offgas volatile organic compounds (VOCs) such as formaldehyde, often for many months, even years
- Cigarette smoke
- Improper temperature and humidity levels
- Misapplied and overapplied insecticides and pesticides
- Water and vapor seepage that encourages the growth of mold in porous building materials such as insulation, wallboard, carpeting, wallpaper, and ceiling tiles

Indoor pollution is often exacerbated by poorly designed, badly built, and/or inadequately maintained or operated mechanical ventilation systems. In a desire to cut the costs of heating and cooling indoor environments or build cheaper buildings, sufficient ventilation to handle the pollutant load may not be provided. In some cases the pollutant source is outdoors but is drawn into the building. In any event, the phenomenon of “tight building” or “sick building syndrome” (SBS) appears to have become more prevalent since the late 1960s.

Sick or complaint buildings may be as prevalent as 20 to 30 percent of American office buildings, according to the Occupational Safety and Health Administration (OSHA) [29 CFR Parts 1910, 1915, 1926, and 1928, *Indoor Air Quality Proposed Rule* (OSHA 29 CFR 1910)]. Over 21 million people who work in the 4.5 million nonindustrial, nonresidential structures in America are estimated to be at risk for SBS. Unhealthy indoor environments cause office workers to suffer 75,000 severe headaches and 110,000 upper respiratory incidents a year. It is responsible for about \$15 billion a year in lost worker productivity.

71.2 INDOOR AIR LEGAL SUITS

Indoor air quality (IAQ) legal cases are often quite complex. The difficulty of identifying a single specific cause for injury usually results in plaintiffs filing against multiple defendants. Some cases have named over 100 defendants in the initial complaint. This can include architects; engineers; builders; contractors and subcontractors; product manufacturers, distributors, retailers, and installers; building owners and managing agents; maintenance organizations; property agents; tenants; and employers.

The issue of who is responsible for an indoor environment is generally the easiest matter to resolve. Arguably those who design, build, and maintain buildings, as well as owners and other parties who make affirmative representations to would-be plaintiffs, such as property brokers, could be held responsible for adverse conditions.

By comparison, the issue of proving that injuries were caused by a particular contaminant or condition of the indoor environment is often a more difficult issue for a plaintiff. The case is, of course, stronger if the illness in question is diagnosable with clear etiology to a contaminant found indoors at injurious levels. Many cases must rely on retrospective interpretation of conditions that allegedly occurred prior to symptoms. Exposures, pathways, and even specific chemical, biological, or physical agents are difficult to identify. Many times, several consultants or state agencies have been asked to investigate complaints. These reports vary greatly in quality, completeness, and competency. Thus, a case must be built on sources present, the condition of source, proximity of plaintiffs to sources, and an understanding of the air distribution system as it operated in the past. Modeling conditions have played an important role in many cases to simulate previous situations.

The questions to answer in determining whether a defendant owed a duty of care to a plaintiff are thorny. *Duty of care* can be imposed by implied or express promises (e.g., con-

tracts and warranties), negligence standards, as well as other common-law and statutory impositions. Conversely, certain statutes or interpretations of common law may absolve one who would ordinarily be considered a responsible party. Workers' compensation laws, for example, normally cut off an employee's right to sue his employer even though the employer may be responsible for causing an employee's illness. Other statutes, such as the Americans with Disabilities Act, statewide human rights laws, and the dual-doctrine theory (in which an employer is held responsible as the building's landlord rather than an employer) may make an otherwise protected employer an exposed party.

71.3 LEGAL THEORIES

There are a variety of legal theories, or causes of action, by which a plaintiff can sue a defendant, including those described in the following paragraphs.

Negligence

As with any negligence lawsuit, two prerequisites for an IP action are causation and damages. A plaintiff must be able to prove

1. That the plaintiff's injuries were caused by IP and not some other factor, such as a non-building-related disease or condition
2. That the defendant(s) being sued had a duty to provide the plaintiff with an indoor environment that would not cause the plaintiff to become sick
3. That the duty-bound defendant knew or should have known that the indoor environment in question was making or would make someone sick
4. That the plaintiff became ill as a result of the defendant's failure to fulfill his duty.

A plaintiff need not show that the defendant intended the injury. Likewise, it is of limited value to a defendant that he did not realize that an injury would occur. A successful plaintiff need merely prove that anyone in the defendant's position using reasonable intelligence could have foreseen that an injury would occur to someone at some time.

Strict Liability

This cause of action is often confused with negligence. They are different. To prove strict liability a plaintiff must show that a defendant (1) was engaged in an unusually dangerous activity, (2) designed or manufactured a product that was unsafe, and/or (3) failed to give an adequate warning of the dangers of a product and how to avoid its risks.

Strict liability is harsh. It imposes liability even though due care was exercised and the defendant had no knowledge that a condition was dangerous, or even that it existed.

Breach of Contract

A *breach of contract* occurs when one party to an agreement fails to perform as promised. An agreement need not be written to be enforceable. Nor must the contract be express; it can be implied by the actions of the parties.

Even when a contract is neither express nor implied, a court may find that a defendant owed a plaintiff some contractual-type duty under the theory of quasi-contract, or promissory estoppel. To succeed, a plaintiff must show that a promise was made by the defendant and that the plaintiff justifiably relied on that promise to her detriment. For example, a lessee discovers that the filters of the HVAC system supplying her office are filthy, and she asks the managing agent to clean the filters because her employees are getting ill, noting that she is relying on the agent to take rapid and appropriate action. The agent promises to clean the system but fails to do so. As a result of this failure to perform, the lessee loses money because half her staff becomes sick. The lessee's lost income constitutes damages that she can seek from both the managing agent and her principal, the building owner, even though there was no formal contract. The agent is *estopped* from denying lack of a contract because he promised to *perform*, and the lessee justifiably relied on that promise to her detriment.

Breach of Warranty

This cause of action is often confused with breach of contract. It occurs when a specific relied-on assurance or representation is violated. Warranties come in two categories: express and implied. An *express warranty* can be written or oral, but in either event must be specifically communicated between the parties by such means as a contract, sales literature, or marketing and promotion material.

Express warranties may be disclaimed. An engineer, for example, can state in a contract that he is making no assurances to the owner about the safety of an HVAC system unless she (the owner) engages in proper maintenance procedures. Such a disclaimer is generally valid if it is clear, conspicuous, and specific.

Implied warranties are often imposed by statute or caselaw. Implied warranties include that of *merchantability*, which says that a party who trades goods to another automatically represents that those goods are fit for the particular purpose for which they are sold or leased. There are also implied *warranties of habitability*, which may require a lessor to provide safe premises to its lessee and the intended occupants. Unlike express warranties, which may be freely disclaimed, many states do not permit warranties of merchantability and habitability to be disclaimed.

Fraud and Misrepresentation

Fraud and misrepresentation occur when a party is injured by another party's intentional, reckless, or negligent concealment of a material fact that is not readily observable, such as (perhaps) the presence of friable fiberglass inside ductwork. In some jurisdictions the giving of a bad opinion, not just a statement of fact, to someone who relies on that opinion and could not reasonably have discovered its falsity may be actionable.

Battery and Assault

Assault and/or battery take place when one party who has not consented is touched or otherwise contacted by another person or thing. Exposing someone to volatile organic compounds, such as carpet glues, might be construed to be assault or battery.

Trespass and Nuisance

The first cause of action involves an improper interference with one's person or property that causes injury to health or property. The second cause of action occurs when one's use or enjoyment of property is impinged.

Federal, State, and Local Statutes

In addition to the common-law causes of action, there are a variety of federal, state, and local statutes that can impose duty for IP. They include

Asbestos

- National Emission Standards for Hazardous Pollutants
- Asbestos Hazard Emergency Response Act
- National Emissions Standards for Hazardous Pollutants

Radon

- Superfund Amendments and Reauthorization Act
- Indoor Radon Abatement Act

State environmental tobacco smoke

Lead-based paint

- Residential Lead-Based Paint Hazard Abatement Act

Water

- Safe Drinking Water Act

Poisons

- Federal Insecticide, Fungicide and Rodenticide Act

Various standards and recommendations have been developed by government bodies as well as trade and professional organizations that pertain to indoor environments. The American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. Indoor Air Quality Standard 62-1999 addresses ventilation for buildings (ASHRAE 1999). These consensus standards developed by the industry impose state-of-the-art knowledge on architects, engineers, and contractors. The National Association of Realtors and the National Association of Duct Cleaners have codes of ethics that impose a duty of good faith on their members. The Carpet and Rug Institute requires that its members place informational labels on their carpeting to warn of the potential hazards of new floor coverings. The U.S. Environmental Protection Agency (USEPA), in cooperation with the National Institute of Occupational Safety and Health and the Centers for Disease Control and Prevention, publishes useful books that help set the standard of care, such as *Building Air Quality* (USEPA 1991) and *Tools for Schools* (USEPA 1995).

71.4 INDOOR ENVIRONMENTAL CASES

Cases involving indoor pollution include *Bahura v. SEW Investors, Inc.* (1993), in which several employees of, ironically, USEPA headquarters in Washington, DC sued the building

owners and managers. Plaintiffs claimed that exposure to airborne toxins released during several years of renovation work caused them to suffer multiple chemical sensitivity and other IP-related symptoms. The result was a million-dollar verdict for the plaintiffs.

In the Martin County Courthouse case in Stuart, Florida (*Martin County v. Frank J. Rooney Inc.* 1996), the county was awarded \$11.5 million against the designers, builders, and their insurers for a poorly built courthouse and office building. Suits against the architect, mechanical engineer, and contractors were settled before trial. What started as minor problems with the air conditioning and leaks through walls and windows worsened to the point where the building had to be abandoned. Employees suffered sinus and respiratory problems, skin rashes, and other symptoms as the buildings experienced mold growth on the walls and ceilings.

In Plano, Texas, five employees sued J. C. Penney, Johnson Control Systems, and Penney's insurance carrier for injuries allegedly caused by poor offgassing of carpets, paints, glues, stains, and pesticides. In *County of DuPage v. Hellmuth* (1995), 700 employees had to be evacuated from a building that was polluted. The county spent \$4 million to fix the problem. The county was held liable for failure to respond in a timely fashion to complaints that were within its control to cure.

In *Polk County v. Reliance Insurance Co.* (1995), the county won \$26 million against the insurer of the general contractor. A bad HVAC system caused 80 percent of the workers in the courthouse to fall ill. Damages were awarded for repairs, relocation costs, worker compensation insurance that was paid to employees, and legal costs.

One early IP lawsuit was *Buckley v. Kruger-Benson-Ziemer* (1983). A computer programmer sued 289 defendants, including the architects; contractors; and manufacturers, sellers, and installers of floor tiles and chemicals. The case reportedly settled for over \$620,000.

One widely publicized case was *Call v. Prudential Insurance Company of America* (1985) in which several tenants in an office building and their employees sued the building owner, as well as the architects, engineers, contractors, and 250 unknown defendants, to recover personal and business injuries caused by indoor pollution. The building was new and was promoted as "energy-efficient and safe to occupy." Within a month after the first tenants moved in, employees began experiencing a variety of symptoms. The plaintiff alleged that the defendant failed to (1) properly evaluate, test, and investigate for toxic fumes, chemicals, and other substances that produced indoor pollution; (2) balance the air-conditioning system to produce a sufficient outside air/recycled air ratio; and (3) use proper building materials that would not offgas noxious substances.

In *Shadduck v. Douglas, Emmett and Co.* (1989), the plaintiff sued the building owner, leasing agent, and others for respiratory infections and other symptoms caused by a poorly constructed and maintained HVAC system, high levels of CO₂, filthy air filters, and closed ventilation louvers.

In *Bloomquist v. Wapello County* (1990), a jury awarded \$1 million to three office workers and their spouses for injuries caused by pesticides absorbed by carpeting and worsened by an HVAC system that did not dilute the infected air with enough outdoor air.

71.5 HOW TO PREVENT AN INDOOR ENVIRONMENTAL LAWSUIT

More so than many other legal actions, indoor environmental (IE) litigation presents special concerns. It can be complicated and particularly time-consuming. It can involve many products and materials. Medical evidence and testimony are involved. There are often multiple plaintiffs and defendants. Insurers are drawn in. Perhaps most upsetting is that there are few statutes, codes, and regulations to which defendants can turn to show compliance as a means of limiting their damages.

There are many questions that judges and juries will want IE professionals to answer in deciding whether they fulfilled their duties to occupants. The courts will want to know

Were they familiar with the workings of the systems that affect the indoor environment, such as the HVAC system?

Did they maintain a proper maintenance schedule or tell their clients how to maintain a proper maintenance schedule?

Did they respond to problems that came to their attention in a timely and effective manner or advise their clients how to respond?

Did they recommend that specialists be called in when specialists were called for?

These are just some of the questions defendants must answer in litigation.

Chapters 60 to 64 in Part 6 address various aspects of preventing indoor environmental problems. What follows are “tips” from an indoor air litigator to building owners and employers to help them ensure the safety of the indoor air quality in their buildings and to avoid lawsuits.

Exploring

Conduct regular walkthroughs of your office or building with an eye toward existing or potential IP-related problems. Smells, water stains, dust, and complaints are often indicators of problems. For new buildings or renovations, perform walkthroughs with the architect, engineer, and/or contractor to tap their knowledge and establish their liability should an IP lawsuit arise. Make sure your facility staff is fully trained in all building systems. A camera is useful to memorialize walkthroughs and to demonstrate that due diligence is performed on a regular basis.

A walkthrough is useful only if you can see what is going on behind closed doors. Therefore, contractors must be instructed to provide enough space and access to the HVAC and other IE systems to provide adequate exploration.

Following the Rules

It is important to build, operate, and maintain HVAC and other IE systems according to manufacturer standards, unless those standards make no sense. Many lawsuits occur because a properly designed HVAC system was modified or improperly maintained. It is also true, however, that many lawsuits arise because systems are improperly designed in the first place.

Air and water filters need to be changed on schedule with the proper size and type of filters. Drip pans should remain clean and unclogged. Ductwork should have minimal air leakage. Leaks must be repaired immediately. Air vents must remain unblocked. Office partitions should not impede the designed flow of air. Thermostats should not be covered.

Safeguard the building system operating manuals. Comply with industry standards, product labeling, and directions. Insecticides, for example, are often misapplied. Make sure that managing agents and service firms are aware of the special IE concerns.

Ventilating Properly

Maintain proper temperature and humidity levels; many IE complaints stem from temperature and humidity levels that are too high or too low. High humidity is a particular problem in warmer climates, where outdoor humidity tends to be higher. The problem is often exacerbated by modern air-conditioning systems that are so efficient at cooling a space quickly that they do

not have time to dehumidify the air. Despite higher heating and cooling bills, proper ventilation can help keep occupant and tenant complaints down, improve employee productivity, and reduce sick days. Marketing a building's sound IE policies could lead to economic benefits.

Appointing a Pointperson

Appoint a trained IE contact person, and establish an IE response team. Conversely, if there is a large group of complaining occupants, encourage them to elect a representative or group of representatives.

A *pointperson* establishes a focal point to which all indoor air complaints can be directed. Contact people can conduct informal talks with tenants and workers to garner their perceptions of the indoor environment. If occupants do not have a problem, memorialize the fact in writing. If occupants have complaints, asking them about their complaints shows due diligence. It is cheaper to discover a problem early than to deal with one that is long-standing. Keep records of conversations with tenants and occupants and their responses.

Keeping Records

Perform regular maintenance, and retain written records of maintenance actions. Keep an owner's manual consisting of detailed records about the building as well as the building's mechanical and environmental systems, including how they were designed, constructed, renovated, and maintained.

Renovations

Evaluate the materials and products specified for construction, renovation, and maintenance of building and IE systems. Materials offgas, so give them time to bake out. Some problematic chemicals, such as pesticides and cleaning fluids, can be applied on Friday evening in spaces that keep ventilation active over the weekend. Green products that have been shown to be safer than their traditional kin should be considered.

Assigning Coresponsibility

Shift the responsibility to another party by contract or lease. A building owner or managing agent can place part of the job of providing a safe indoor environment on a prime tenant by specifying goals and having the tenant promise to do certain tasks, such as making sure that air vents are not blocked by furniture and reporting water leaks immediately. On the other hand, a prime tenant can require that the owner maintain the building's HVAC system in compliance with manufacturers' recommendations and agree to respond to IP complaints in a timely fashion.

Use indemnification and defense clauses that address IP-related situations or lawsuits. Such clauses can be worth their weight in gold.

Insurance

Insurance policies often contain clauses that permit insurers to disclaim coverage for pollution, unless the polluting event occurred "suddenly and unexpectedly." Some modern policies go further by attempting to exclude pollution altogether.

So far, most courts have viewed indoor pollution, as opposed to such occurrences as oil spills and other toxic releases, as an event that cannot be disclaimed by an insurer. But courts could change their interpretations, and, of course, interpretations vary from jurisdiction to jurisdiction. Therefore, review all insurance policies carefully and buy an indoor environmental policy or rider to existing policies if necessary.

Be sure to notify the insurance carrier at the first sign of trouble. The longer the time between discovery of an IE situation and notification to the insurer, the greater the chances that the insurer will deny coverage.

Obtaining Good Legal Advice

Contact an attorney once an IE problem is suspected. IE complaints have the potential to escalate into serious legal problems, so they should be treated accordingly.

An attorney can maintain copies of clients' IE records in preparation for potential litigation, affording them some protection as attorney work product and confidential communications. An attorney should review all leases, offerings, contracts, marketing, and promotional material, and other business documents, as well as employment policies and practices, with the specific goal of preventing IE-related lawsuits.

An attorney can join a client on a walkthrough of the building; at the cost of a few hours of the attorney's time, the client will probably learn many ways to avoid the cost and aggravation of an indoor pollution lawsuit.

71.6 CONCLUSION

The public's increased awareness of indoor pollution assures that more and more IE-related lawsuits will be brought in years to come. As a result, over time, legislation will be broadened to cover the many nooks and crannies of indoor environments. Considering the pervasiveness of IP and the many people it can affect, it is wise to review all IE policies and practices now with the goal of preventing indoor pollution and limiting damages should IP occur.

Recommended readings on this subject include a chapter on the legal aspects of indoor air pollution by Kirsch (1991) in *Indoor Air Pollution: A Health Perspective* by Samet and Spengler (1991). A book by O'Reilly and colleagues, *Keeping Buildings Healthy: How to Monitor and Prevent Indoor Environmental Problems* (O'Reilly et al. 1998), presents legal issues of indoor air pollution in more detail.
