The inherent increased cost of sophisticated technology is justified if it can reduce total disease management by eliminating unnecessary diagnostic procedures and ineffective treatment. However, billing and reimbursement issues as well as the costs of required licensure are major obstacles for implementation of the current technology in many hospital settings. In addition, any one assay is required for clinical care relatively infrequently and the expense of training and maintaining personnel and equipment in a small laboratory is prohibitive. For most institutions, selected cases that have specific indications for molecular testing will be referred to a reference laboratory.

MINIMAL RESIDUAL DISEASE (MRD)

Failure of primary surgical treatment of cancer is usually attributed to the presence of undetected metastatic disease (minimal residual disease). The goal of adjuvant chemotherapy or radiation therapy is the elimination of occult micrometastatic disease before it becomes clinically evident. For most oncology patients, the decision to add systemic therapy to surgical treatment is based on the staging parameters of the patient's tumours (tumour size, lymph node status and, to some extent, the histological type and grade of the tumour). A statistical analysis of accumulated data from similar patients with the same type and extent of disease is in most cases used to assess the likelihood that the disease will recur and whether additional therapy is given or withheld. However, conventional histological and clinical staging systems are limited. For example, with breast cancer patients who have small tumours and no lymph node metastasis, there is still a 15–25% chance of distant metastasis and no current histological or molecular marker identifies this population. This is far from ideal and there is a real need for markers that will unequivocally segregate patients into those whose tumours have already metastasized from those whose tumours have not metastasized. If a patient does not have metastatic disease, surgical removal is curative and cytotoxic therapy and all its negative side effects can then be reserved for those patients who may actually benefit.

Bone marrow is an accessible and frequent site for tumour metastasis and it is becoming increasingly common to examine bone marrow for the presence of metastatic tumour cells from patients with solid tumours. Immunohistochemical detection of micrometastasis is currently the standard method for the detection of the disseminated tumour cells. The identification of minimal residual disease depends on recognizing specific characteristics of the tumour cells that are not found in the surrounding tissue to which it has presumably metastasized. For example,

haematopoietic cells rarely express epithelial antigens such as keratins and occult epithelial tumour cells in the bone marrow can be assessed using immunohistochemistry for cytokeratins. As few as one or two tumour cells in 10^6 bone marrow cells can be detected by cytokeratin immunohistochemistry and enrichment techniques can increase that sensitivity by a factor of 10 (Osborne *et al.*, 1991).

Increasingly, molecular methods are used to assess the presence or absence of micrometastatic disease. PCR amplification of tumour-specific abnormalities present either in the DNA or mRNA of the tumour cells or, alternatively, amplification of tissue-specific mRNA can identify individual patients who have metastatic disease at the time of diagnosis and are most or least likely to benefit from the added therapy. In haematological malignancies, the identification of tumour-specific abnormalities at metastatic sites has been very useful for the detection of MRD. For example, primers can be made that span the t(14;18) translocation in the majority of follicular lymphomas, and amplification occurs only if DNA with the translocation is present in the sample. A few solid tumours, primarily sarcomas, have similar characteristic translocations, and similar methods have been used to identify MRD in patient with Ewing sarcoma or alveolar rhabdomyosarcoma.

Unfortunately, the genetic abnormalities are much more heterogeneous in the common malignancies of adults such as breast, prostate, lung and colon cancers. However, these malignant cells continue to express markers characteristic of their cell of origin and identification of a tissue-specific mRNA can be used to recognize MRD. For example, even very poorly differentiated metastatic prostate cancer to lymph nodes often express PSA mRNA, sometimes even when no protein is detectable by antigenic methods. Detection of micrometastasis by molecular methods is likely to have a profound impact on how cancer patients are treated and monitored in the future. For further information, the reader is referred to a recent review (Ghossein *et al.*, 1999).

The process of metastasis is poorly understood, but malignant tumour cells leave the primary site and gain access to the lymphatic or vascular system. After transportation to a new organ they adhere to the walls of the vessels, transverse them, implant and eventually grow. Even less understood is the observation that malignant cells can become dormant for months, years or even decades at a distant site only to wake up and renew growth with a vengeance. In this dormant or nondividing state, malignant cells are unlikely to be killed by cytotoxic chemotherapy directed against replicating cells. Understanding and developing strategies either to eliminate the dormant tumour cells by novel immunotherapies or to prevent their regrowth by inhibiting angiogenesis are just two means under intense investigation.

THE FUTURE

Most of us who have spent our professional lives diagnosing cancer recognize that we are at the beginning of a revolution that is not just going to have a technical impact but that is also fundamentally challenging our traditional concepts of tumour classification by histogenesis and morphology. It is likely that the H&E section will be the cornerstone of diagnosis for the near future, but it is being and increasingly will be challenged. There will be reevaluation and redefinition of many diagnostic entities as our knowledge and understanding of the underlying alterations in DNA and RNA expression becomes increasingly sophisticated. The transfer to clinical medicine of this new technology and the information it generates will not be quick, easy or painless and diagnostic anatomical pathology will be in a transition state for many years. It will take time to determine what information is therapeutically applicable and cost effective and how it should be obtained. Application of this knowledge to individual patients will still require physicians, whether traditional pathologists or specialists in the new molecular pathology, to exercise judgment and insight. However, in the end the hope is that the process will open up new areas of treatment options that can be individualized for each patient based on the inherent characteristics of the tumour.

NORMAL DEVELOPMENT AND STRUCTURE

The human integument is an extraordinarily versatile organ composed of tissue that is in a state of constant self-renewal and differentiation. In adults, the skin is the largest and most massive organ of the body, accounting for a 1.2–2.3 m^2 of surface, 16% of body weight and a plethora of protective functions. Human skin provides protection, sensation, thermoregulation, biochemical, metabolic, and immune functions. It is composed of tissue that grows, differentiates and renews itself constantly. The skin is a complex organ system and there are both benign and malignant tumours described for each and every component. The benign tumours usually present as isolated, relatively stable skin nodules; the malignant lesions, on the other hand, form a complete spectrum from slowly growing tumours, which tend to invade only locally, to aggressive, rapidly growing and metastasizing lesions.

In utero, the skin forms from ectoderm and mesoderm, giving rise to the most superficial epidermal layer and the underlying dermal layer, respectively. Appendages results from down growths of specialized epidermal cells, which differentiate to become hair follicles, eccrine sweat glands and apocrine sweat glands. The epidermis is composed primarily of a continuum of four layers which represent a maturation sequence which produces tough, flattened cells filled with the structural protein keratin at the skin surface (**Figure 1; see colour plate section**). The basal cell layer, a reservoir for proliferating cells, takes part in maintaining a rate of epidermal turnover that is sufficient to maintain an effective environmental interface. Basal cell carcinoma (BCC) is an example of a tumour composed of cells with morphological resemblance to basal keratinocytes and basaloid hair matrix epithelial cells. The spinous layer contains larger polyhedral cells and is a site for active synthesis of keratin proteins. Usually, squamous cell carcinoma (SCC) recapitulates the spinous layer. The uppermost granular and cornified layers, representing either nucleated cells with keratohyaline granules or anucleated cells, are sites of terminal differentiation of the epidermal cells. Therefore, tumours, like some squamous cell carcinomas, that form keratin in association with granular layer differentiation show primarily epidermal-type differentiation, e.g. invasive squamous cell carcinoma. In addition, the epidermis contains two minority populations of dendritic cells, one (melanocytes) producing brown photoprotective melanin pigment, and the other (Langerhans cells) partly responsible for immune surveillance against environmental pathogens and proteins perceived as foreign. The dermis contains nutrient blood vessels, sensory and afferent nerve fibres, immune cells, dermal dendritic cells and fibroblasts which produce a tough leathery enveloping matrix termed collagen and more resilient elastin fibres which impart stretch and recoil upon exposure to mechanical stress. Tumours of the dermis may arise from any one of its cellular components e.g. the blood vessels, nerve cells, fibriblasts or smooth muscle. Usually, such tumours tend to be nonspecific cutaneous nodules and histological examination determines their origin. Metastatic skin cancer is relatively rare, but again diagnosis depends on histological analysis.

Specific anatomical features of skin structure and related function are described in **Figure 1**. As will be described below, understanding of the basic oncology of the skin depends heavily on appreciation of normal

structure, since most tumours recapitulate to varying degrees their normal cellular counterparts.

TUMOUR PATHOLOGY

Tumour pathology of the skin involves literally hundreds of benign and malignant neoplasms derived from epidermal cells (true epithelial cells, termed keratinocytes, and melanocytes) and dermal cells (endothelial cells, nerve cells, immune cells and fibroblasts). The primary goals of diagnostic tumour pathology are to utilize gross and microscopic examination (1) to classify neoplasms according to histogenesis, (2) to make some prediction concerning anticipated biological behaviour and (3) to assess adequacy of surgical treatment. Classification generally depends on how closely given neoplasms recapitulate their 'cell of origin.' For example, the two most common forms of epidermal malignancy, the basal cell carcinoma and the squamous cell carcinoma, show differentiation features that most resemble cells of the normal stratum basalis and stratum spinosum, respectively. Tumours anticipated to behave in a benign manner possess a number of features, including slow growth, architectural symmetry and cellular uniformity. By contrast, aggressive tumours (i.e. those prone to produce damage to normal structures or to seed distant sites through metastasis) often grow in a rapid and destructive manner, demonstrate asymmetry of architecture and show considerable variability in cell size and shape. Exceptions exist, however, and in some instances the ability to predict biological behaviour based on tumour pathology is limited based on currently available methods of analysis.

AETIOLOGY

There are numerous environmental factors responsible for the genesis of skin cancer. Predisposing factors for squamous cell carcinoma include exposure to ultraviolet (UV) radiation, industrial carcinogens (tars and oils), chronic, draining ulcers potentially giving rise to free radical formation, old burn scars, arsenical ingestion, ionizing radiation, and tobacco and betel nut chewing in the case of perioral and intraoral cancers. Sun exposure, particularly UVB, is a primary cause of most basal cell cancers, and both UVB and UVA have been implicated in the cause of melanomas. Products that may activate the carcinogenic process may be generated as a consequence of UV radiation absorbed by epidermal melanin pigment. Because the relevant cellular targets of such carcinogens may reside in the basal cell layer, which is less accessible to their diffusion, the upper layers of the skin may actually be protective (Moan *et al*., 1999). Prolonged exposure to UV radiation in the UVB part of the spectrum, 280–320 m, is a clearly established carcinogenic factor. Eye and hair colour, skin type and constitutive skin pigmentation also have a major role in cutaneous malignancies. Fair-skinned, blue-eyed individuals and lightly pigmented populations show a significantly higher number of cutaneous malignancies than more darkly pigmented populations, underscoring the importance of melanin pigment in protecting against UV radiation induced carcinogens. Individuals with darkly pigmented skin also selectively exhibit an increase in natural killer activity in response to irradiation with low-dose UVB, which could underlie at least partly their resistance to the development of photo dependent skin cancer (Matsuoka *et al*., 1999). It has been postulated, however, that whereas melanin granules discharged by melanocytes into the uppermost epidermal layers may be photoprotective, those within the melanocytes, which normally reside in the basal cell layer, may actually be carcinogenic upon absorption of UV radiation. Evidence to support this includes the observation that certain albino Africans, as compared with normally pigmented Africans, appear to have a relatively smaller risk of developing melanoma as compared with nonmelanoma skin cancer (Moan *et al*., 1999).

A corollary to understanding the roles effects of various environmental carcinogens on skin is the realization that breakdown in specific host defences may facilitate these processes. For example, defective melanin pigmentation or inability to develop photoprotective tanning, resulting in frequent sunburns, is associated with increased risk of developing skin cancer. Genetically determined predisposition to environmental carcinogens includes individuals with inborn errors in DNA repair after UV-induced damage, a condition termed xeroderma pigmentosum. Affected individuals cannot repair UV damage to the skin after exposure to UV radiation, and this leads to early development of cutaneous neoplasms – basal cell carcinoma, squamous cell carcinoma and malignant melanoma. Others suffer from gene mutations, which result in a tendency for dysregulated skin proliferation, resulting in numerous basal cell cancers at an early age (basal cell nevus or Gorlin syndrome). Exposure to ionizing radiation is an environmental factor that predisposes to cutaneous malignancy (X-irradiation, etc.). Immune deficiency may predispose to local defects in the body's ability to fend off deleterious mutations, thus producing an environment permissive to the genesis of skin cancer. Indeed, immune-suppressed populations experience higher rates of cutaneous malignancy than immunologically normal individuals. Moreover, certain viruses may incite altered cell proliferation in the setting of immune deficiency, as is the case of oncogenic human papilloma virus in the setting of renal transplantation and human herpes virus 8 in the setting of Kaposi sarcoma associated with acquired immunodeficiency syndrome (AIDS). In HIV infection, the risk of these cancers increases gradually, while the same risk increases fairly quickly among transplant patients (Mueller, 1999).

SCREENING AND PREVENTION

Environmental factors are potentially conspiring to produce increasing numbers of skin cancers, such as the progressive depletion of the photoprotective ozone layer by anthropogenic pollutants. Ozone depletion increases the amount of biologically harmful solar UV radiation that reaches the surface of the Earth, leading to an increased incidence of cutaneous neoplasms. Indeed, the incidence of malignant melanoma is increasing at an alarming rate, with an estimate of a 1 in 75 lifetime risk of developing this potentially lethal tumour for individuals born in 2000 (Brown and Nelson, 1999). The Caucasian population in Auckland, New Zealand, has the highest incidence of malignant melanoma in the world (Jones *et al*., 1999); Kauai, Hawaii, on the other hand has one of the highest melanoma rates recorded in the United States (Chuang *et al.,* 1999). Accordingly, skin cancer prevention has become increasingly focused on public education regarding avoidance of sun exposure and the use of effective topical creams that significantly block the relevant portion of the UV spectrum. Such measures are particularly important in lightly pigmented individuals, or in those where genetic background or immune status could predispose to cancer formation. Health care professionals and patients alike also have been targeted for educational programmes that enhance early detection of both melanoma and nonmelanoma skin cancers. This approach is particularly important, since even malignant melanoma is 100% curable if it is surgically removed before the development of vertical growth within the dermal layers has occurred. Monitoring of patients with multiple pigmented spots representing potential precursors for or markers of malignant change has also been facilitated by the use of sensitive computerized image analysis approaches for digitized mapping of potentially changing lesions over time.

GROSS AND MICROSCOPIC PATHOLOGY

Precursors of Skin Cancer: Dysplastic Moles and Actinic (Solar) Keratoses

Although some skin cancers appear to develop '*de novo*' in normal skin, many others are preceded by proliferations termed atypical or dysplastic. These lesions have already begun to lose normal responsiveness to control mechanisms that determine the order and uniformity typical of normal skin and benign proliferations. ln terms of malignant melanoma, the association of pigmented 'moles' (naevocellular naevi) with malignant melanoma was made over 160 years ago. However, it was not until 1978 that a genuine precursor of melanoma was described in detail. In that year, Clark and colleagues detailed the characteristics of lesions they termed 'BK' mole (a name derived from the first letters of the last names of the initial two families studied) (Clark *et al*., 1978).

Clinically, BK moles (today more often referred to as dysplastic naevi) are larger than most acquired naevi (often greater than 5 mm across) and may occur as hundreds of lesions on the body surface (**Figure 2a**, inset). They are flat to slightly raised, often with a 'pebbly' surface. Frequently they form target-like lesions, with a darker, raised centre and an irregular, flat periphery. In contrast to most benign moles, dysplastic naevi usually show variability in pigmentation (variegation) and borders that are irregular in contour. Unlike ordinary acquired moles, they have a tendency to occur both on non-sun-exposed and on sun-exposed body surfaces. Dysplastic naevi may occur in multiple members of families prone to the development of malignant melanoma (a condition therefore referred to as the heritable melanoma syndrome) (Reimer *et al*., 1978). Dysplastic naevi also occur as isolated lesions not associated with the heritable melanoma syndrome. In this more common situation, the risk of malignant change appears to be low. Transitions from dysplastic naevi to early melanoma have been documented clinically and histologically within a period as short as several weeks, although the majority of such lesions are relatively stable.

Upon microscopic examination (**Figure 2a–c**), dysplastic naevi consist of compound naevi with both architectural and cytological evidence of abnormal growth. Unlike ordinary moles, where the neoplastic melanocytes tend to be arranged in orderly, small, discrete theques or nests (**Figure 2a**), dysplastic naevus cells form nests that tend to be enlarged and exhibit coalescence (**Figure 2b** and **c**). As part of this process, single naevus cells begin to replace the normal basal cell layer of the epidermis, producing so-called lentiginous hyperplasia. Cellular atypia, consisting of irregular, often angulated, nuclear contours and obliteration of nuclear detail by DNA-rich nuclear contents (hyperchromasia), is frequently observed. Associated alterations in the superficial dermis consist of a sparse inflammatory infiltrate, loss of melanin pigment from presumably destroyed naevus cells, with uptake of this pigment by dermal macrophages (melanin pigment incontinence), and a peculiar linear scarring surrounding the epidermal ridge-like downgrowths that are involved by the naevus (**Figure 2c**). All of these features are of assistance in the histological recognition of a dysplastic naevus.

Several lines of evidence support the belief that some dysplastic naevi are precursors of malignant melanoma. In one study (Greene *et al*., 1985) it was shown that in a large number of families prone to the development of melanoma, over 5% of family members developed melanoma over an 8-year follow-up period. In addition, new melanomas occurred only in individuals with dysplastic naevi. From these and related studies, it has been concluded that the actuarial probability of persons with the dysplastic naevus syndrome developing melanoma is 56% at age 59.

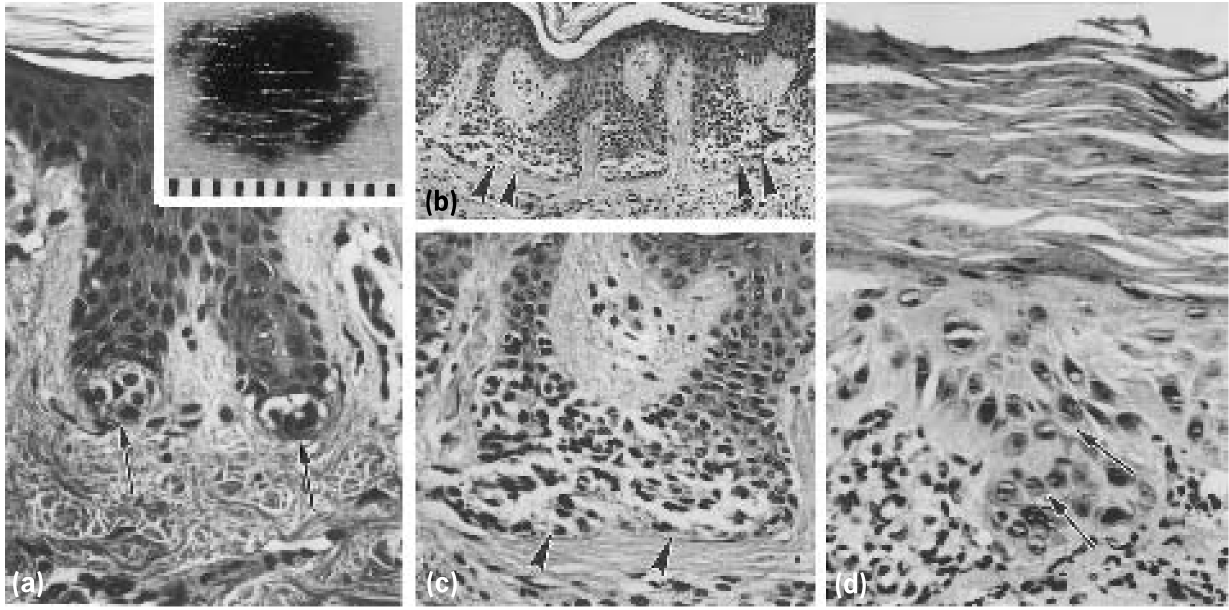

Figure 2 Premalignant dysplasia involving melanocytes and keratinocytes. (a) Unlike normal moles (also called melanocytic naevi) which grow as 'nests' of melanocytes at the tips of epidermal downgrowths called ridges (arrows), dysplastic naevi are characterized by abnormal patterns of growth, including readily recognized coalescence of adjacent melanocytic nests (b and c, arrowheads). The clinical result is a mole with irregular borders and non-uniform colouration (a, inset). Abnormal growth also is witnessed in a potentially premalignant dysplasia of epidermal keratinocytes termed an actinic keratosis (d). On comparison with **Figure 1a**, there is disordered growth of cells containing irregular nuclei within the basal and spinous cell layers (arrows), as well as abnormal formation of a thickened stratum corneum.

Further support of the relationship of melanoma to dysplastic naevi is the observation that the latter demonstrate expression of some abnormal cell surface antigens (Van Duinen *et al*., 1994), chromosomal abnormalities (Caporaso *et al*., 1987) and *in vitro* vulnerability to deleterious and mutagenic effects of UV radiation (Smith *et al*., 1987).

Specific steps have been proposed (Clark *et al*., 1985) whereby benign naevi may undergo aberrant differentiation to become dysplastic and eventually to evolve into melanoma. Parallels may be found in neoplasia involving other organ systems, such as uterine cervix, and thus dysplastic naevi are regarded by some as a paradigm for how certain malignant tumours develop from benign, albeit dysplastic proliferations of cells.

With regard to premalignant dysplasias of non-melanocytic epidermal cells, a series of progressively dysplastic changes typically occur in keratinocytes, a phenomenon analogous to the atypia that precedes carcinoma of the squamous mucosa of the uterine cervix. Excessive chronic exposure to sunlight can induce such premalignant lesions in the epidermis, causing histological changes in the normal keratinocyte maturation pattern and individual cell keratinization. Such a recognized condition is actinic keratosis, also termed solar keratosis. As would be expected, such lesions occur in particularly high incidence in lightly pigmented individuals. Exposure to ionizing radiation, hydrocarbons and arsenicals may induce lesions similar to or identical with actinic keratosis. Clinically, actinic keratoses are characterized by rough, scaling hyperpigmented plaques seen on the sun-exposed sites, especially the face, neck, upper trunk or extremities. Most lesions are usually less than 1 cm in diameter and may be tan–brown, red or skin-coloured. Some lesions may produce so much keratin that a 'cutaneous horn' develops, a phenomenon analogous to the formation of a true animal horn, which also originates from keratin-like protein. Because sites of predilection tend to be those prone to chronic UV damage, the lips may also develop similar lesions, and these are referred to as actinic cheilitis.

Cytologic atypia is seen in actinic keratosis in the lowermost layers of the epidermis and may be associated with increased numbers of basal cells (**Figure 2d**) or, alternatively, with thinning of the epidermis that results in a thin, semitransparent epidermal layer. The atypical basal cells usually contain enlarged, darkly stained nuclei. The superficial dermis contains thickened, blue–grey elastic fibres, a result of abnormal dermal elastic fibre synthesis by sun-damaged fibroblasts (Thielmann *et al*., 1987). The stratum corneum is thickened and, unlike in normal skin, nuclei in the cells in this layer are often retained, a pattern termed 'parakeratosis' (**Figure 2d**).

It appears that not all actinic keratoses (perhaps the majority) do not evolve into skin cancers, and some may actually remain stable or disappear due to immune responses. However, enough do become malignant to warrant conservative local eradication of these potential precursor lesions. This can usually be accomplished by gentle scraping, freezing or topical application of chemotherapeutic agents, which destroy the dysplastic cells. Radical or extensive surgery is not warranted.

Squamous Cell Carcinoma

Squamous cell carcinoma is the most common tumour arising on chronically sun-exposed sites. As such, it is typically detected on facial, extremity and trunk skin of older people. Except for lesions that develop on the lower legs, these tumours have a higher incidence in men than in women. Industrial carcinogens (tars and oils), chronic ulcers and draining osteomyelitis, old burn scars, ingestion of arsenicals, ionizing radiation and in the oral cavity tobacco and betel nut chewing, immunosuppression and genetic factors (xeroderma pigmentosum) are all implicated in the pathogenesis of squamous cell carcinoma, in addition to exposure to sunlight. In the case of tumours induced by sunlight exposure, endogenous melanin pigment is believed to provide an important photoprotective effect. UV radiation is believed to damage DNA by directly forming photoadducts, which contribute to cell mutation and altered proliferation. Normally, many such altered cells may be eliminated by immunosurveillance mechanisms before tumours become clinically apparent. Accordingly, albinos with defective melanin pigment production, patients with xeroderma pigmentosum, an inborn enzyme defect in DNA repair, and those with immunosuppression all tend to have a high incidence of this neoplasm.

Histological variants of SCCs include various well- and poorly differentiated tumours, which may mimic various nonsquamous neoplasms (Murphy and Elder, 1991c). Immunohistochemistry may assist in evaluating antigenic parameters, useful to determine the cell lineage of such tumours. This is important, because poorly differentiated squamous cell carcinomas may occasionally be confused with malignant melanomas, certain lymphomas or even mesenchymal neoplasms. For example, a panel of antibodies to determine the presence of keratin protein (carcinoma), leucocyte common antigen (LCA) (haematopoietic cells), S-100 protein (neural and melanocytic cells) and desmin/vimentin (dermal spindle cell tumours) may be helpful in diagnosing poorly differentiated variants of squamous cell carcinoma.

Squamous cell carcinomas that have not invaded through the basement membrane of the dermoepidermal junction (carcinoma *in situ*) clinically appear as sharply defined, red scaling plaques. More advanced, invasive lesions are nodular, show variable keratin production appreciated clinically as hyperkeratosis and may ulcerate (**Figure 3c**). Well-differentiated lesions may be indistinguishable from keratoacanthoma, a potential variant form with a tendency to regress spontaneously, possibly as a consequence of immune-mediated mechanisms. When the mucosa is involved by squamous cell carcinoma, a zone of white thickening is seen, an appearance caused by a variety of disorders and referred to clinically as leucoplakia.

Unlike the potentially premalignant dysplasia, actinic keratoses (see above), squamous cell carcinoma *in situ* is characterized by cells with atypical (enlarged, angulated, and darkly stained) nuclei completely replacing all layers of the epidermis (**Figure 3a and b**). When over time these cells acquire the ability to break through the basement membrane and enter into the underlying dermis, the process has become invasive. Invasive squamous cell carcinoma (**Figure 3d and e**) exhibits variable differentiation, ranging from tumours formed by polygonal squamous cells resembling those of the stratum spinosum arranged in orderly lobules and exhibiting numerous large zones of keratinization, to neoplasms formed by highly anaplastic, rounded cells with foci of necrosis and only abortive, single-cell keratinization (keratin ‘pearl’ formation).

Unlike some advanced melanomas (see below), invasive squamous cell carcinomas are usually discovered at stages where complete resection results in permanent disease eradication (North *et al.*, 1997; Rowe *et al.*, 1992). Up to 5%, however, may metastasize to regional nodes, particularly deeply invasive tumours that involve skin of the head and neck (Friedman *et al.*, 1985).

As indicated above, the most commonly accepted exogenous cause of squamous cell carcinoma is exposure to UV radiation light with subsequent DNA damage and associated mutagenicity. Individuals who are immunosuppressed as a result of chemotherapy or organ transplantation, or who have xeroderma pigmentosum, are at increased risk of developing malignant skin neoplasms (Penn, 1987). A considerable proportion of these tumours are squamous cell carcinomas, implicating aberrations in local immune networks in the skin in the production of an atmosphere permissive to neoplasia. Interestingly, sunlight, in addition to its effect on DNA, also seems to have a direct and at least a transient immunosuppressive effect on skin by influencing the normal surveillance function of antigen-presenting Langerhans cells in the epidermis (Cooper *et al*., 1985). For example, in experimental animals, it now appears that although Langerhans cells responsible for T lymphocyte activation are injured by UV radiation, similar cells responsible for the selective induction of suppressor lymphocyte pathways are resistant to UV damage (Granstein *et al*., 1987). Moreover, local exposure of the skin to UV radiation may also result in alterations in systemic immunity. Such phenomena could result in both systemic and local imbalances in T cell function that would favour tumour genesis and progression. DNA sequences of certain viruses

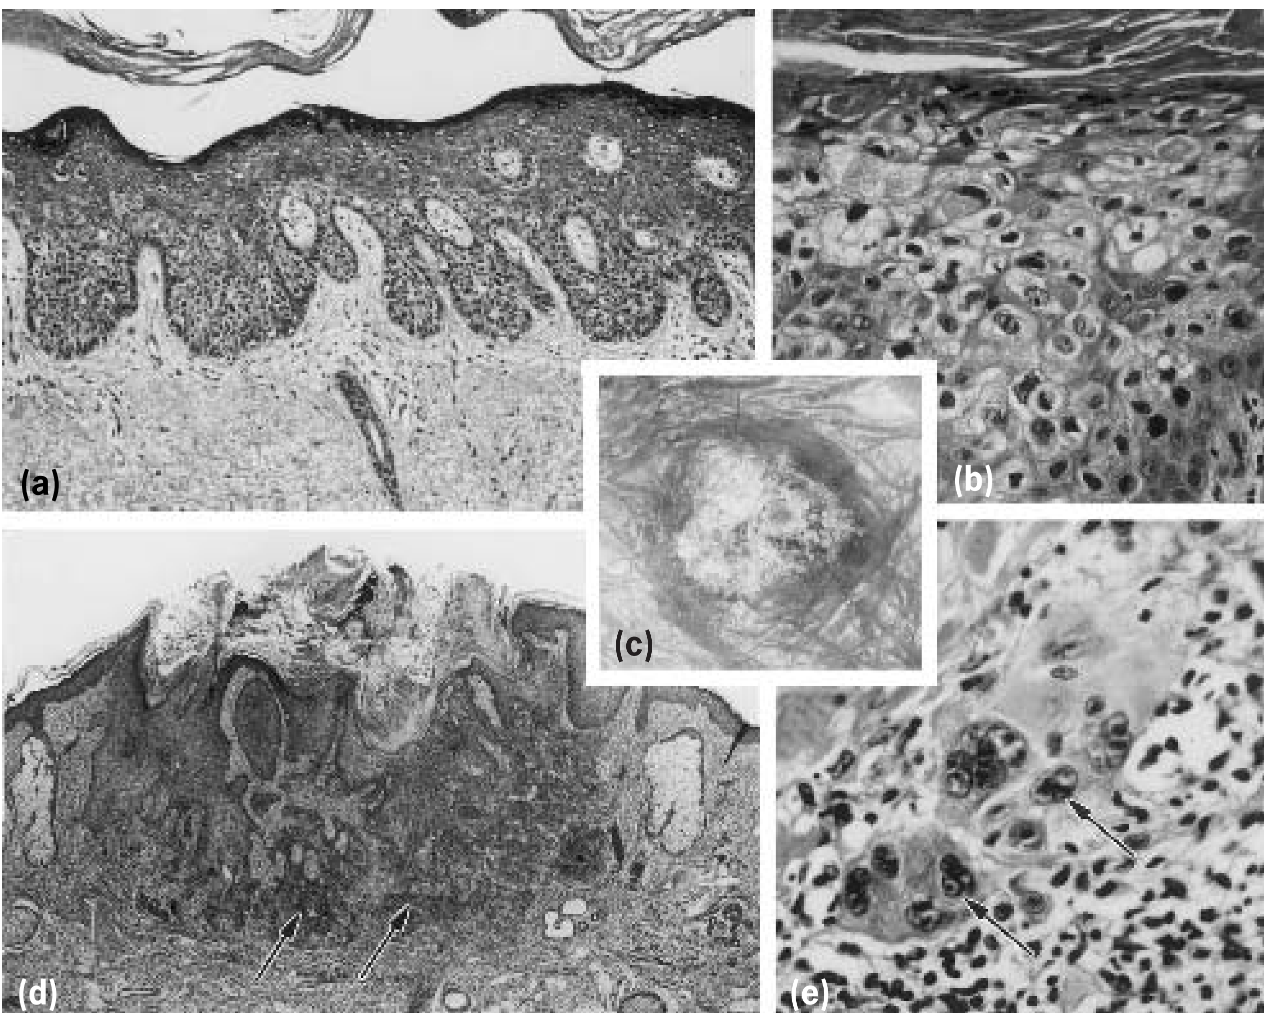

Figure 3 Squamous cell carcinoma. (a) and (b) malignant cells have not as yet invaded into the dermis, but have replaced most of the epidermal layer, a stage referred to as carcinoma *in situ*. (c) The clinical appearance of squamous cell carcinoma is characterized by a scaling, sometimes ulcerated nodule. (d) and (e) invasive squamous cell carcinoma differs from its earlier, *in situ* stage, by showing downward (invasive) growth of malignant cells into the dermis (arrows). These cells (e) have cytological features of malignancy, including enlarged, darkly staining, irregular nuclei (arrows).

(e.g. human papillomavirus HPV36) have been detected in DNA extracted from potential precursors of squamous cell carcinoma (Kawashima *et al*., 1986). This suggests a role for these agents in the causation of these cutaneous epithelial neoplasms. Finally, certain chemical agents appear to have direct mutagenic effects on epidermal keratinocytes by producing DNA adducts with subsequent oncogene activation (Hochwalt *et al*., 1988; Perez *et al*., 1997).

Basal Cell Carcinoma

Basal cell carcinoma by far is the most frequent of all cutaneous cancers. Like squamous cell carcinoma, basal cell carcinomas are slow-growing tumours that rarely metastasize. They also have a tendency to occur at sites subject to chronic sun exposure and in lightly pigmented people. Other predisposing factors include ionizing radiation, chronic scarring and arsenical exposure. As with squamous cell carcinoma, the incidence of basal cell carcinoma increases sharply with immunosuppression and in patients with inherited defects in DNA replication or repair (xeroderm pigmentosum). The rare, dominantly inherited basal cell naevus syndrome (Bale, 1997) is associated with the development of numerous basal cell carcinomas in early life, with abnormalities of bone, nervous system, eyes and reproductive organs, and with a specific gene mutation which now has been characterized.

Clinically, basal cell carcinomas present as smooth-surfaced, pearly papules often containing prominent, dilated subepidermal blood vessels termed telangiectasias

(**Figure 4b**). Some may contain melanin pigment and, as a consequence, may appear clinically similar to pigmented moles or melanomas. Chronic, large lesions may ulcerate (rodent ulcers), and extensive local invasion of bone, facial sinuses and deep subcutaneous nerves may occur after many years of neglect (Dixon *et al.*, 1989).

By light microscopy, tumour cells typically resemble those in the normal basal cell layer of the epidermis. Different histological variants of basal cell carcinoma can be distinguished according to the tumour growth pattern (e.g. nodular, sclerosing, cystic, pigmented). The earliest buds of basal cell carcinoma arise from the epidermis or follicular epithelium and do not characteristically occur on mucosal surfaces. Two patterns of growth include either multifocal origins from the basal cell layer of the epidermis and extending over several square centimeters or more of skin surface (**Figure 4a**), or nodular invasive lesions growing downward deeply into the dermis as cords and islands of darkly stained cells embedded in fibrotic matrix often with a pale blue hue as a consequence of associated mucin deposition (**Figure 4c–e**). Occasional tumours may appear cystic clinically and are found to contain large cystic spaces upon histological examination (**Figure 4d**). The cells at the periphery of the tumour cell cords and islands tend to be arranged radially with their long axes in approximately parallel alignment, a characteristic feature also seen in the bulb of hair follicles and referred to as 'palisading.' The stroma shrinks away from the epithelial tumour nests (**Figure 4d** and **e**), creating clefts or 'separation artifacts' that assist in differentiating basal cell carcinomas from certain follicular appendage tumours also characterized by proliferation of basaloid cells (e.g. trichoepithelioma).

Mutations in the tumour-suppressor gene termed '*PATCHED*' (*PTC*) have been detected in human patients with the basal cell naevus syndrome. In this condition, multiple basal cell carcinomas as well as other anomalies develop according to an inherited pattern. Moreover, mice genetically engineered to overexpress the attachment site or ligand for PTC molecule, which is termed 'sonic hedgehog' or SHH and which mimics the loss of PTC function, develop basal cell carcinomas (Oro *et al.*, 1997). Thus, both SHH and PTC may have important roles in human skin carcinogenesis in the basal cell naevus

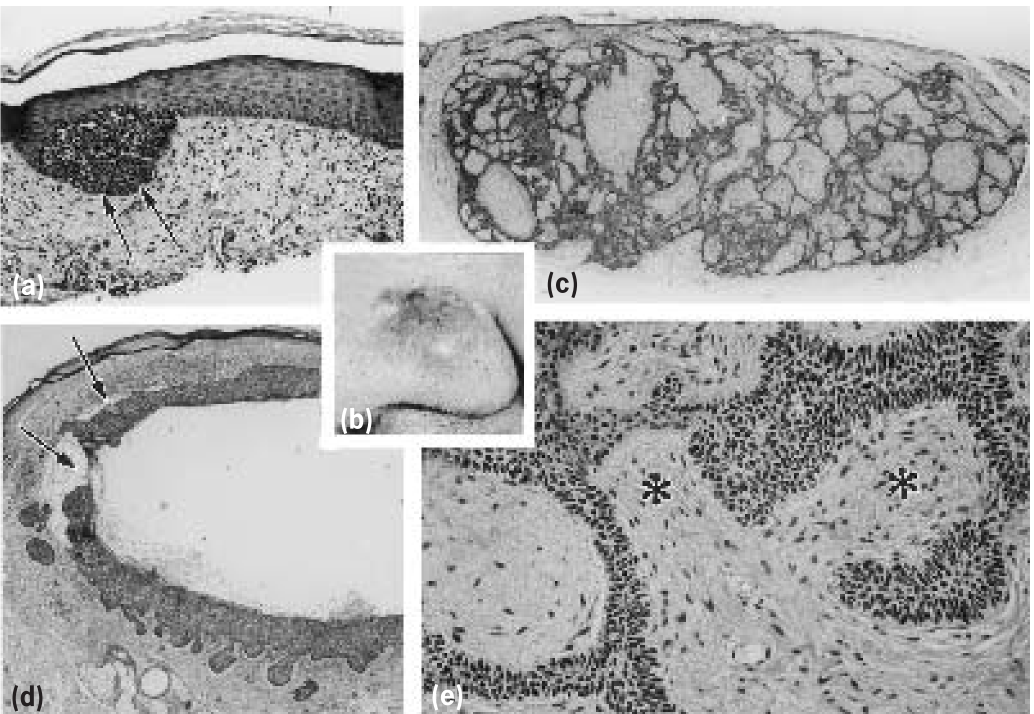

Figure 4 Basal cell carcinoma. (a) Tumours initially are formed by bud-like growth of darkly stained, 'basaloid' cells (arrows), here seemingly arising from the basal cell layer of the epidermis. (b) The clinical appearance of many basal cell carcinomas is that of a smooth-surfaced, 'pearly' nodule containing prominent superficial blood vessels. (c) Some nodular basal cell carcinomas may form an elaborate network of branching and anastomosing basaloid cells, while others (d) may have cystic spaces occupying their centres. (e) The cells forming these common tumours most resemble the epidermal basal cell layer and the basaloid cells that give rise to the hair follicle (matrix cells). The connective tissue that envelops the tumour cells (asterisks) resembles that of the bulb portion of the hair follicle, providing evidence that basal cell carcinoma is a tumour of follicular differentiation. Arrows in d indicate cleft-like spaces of artifactual stromal-epithelial separation.

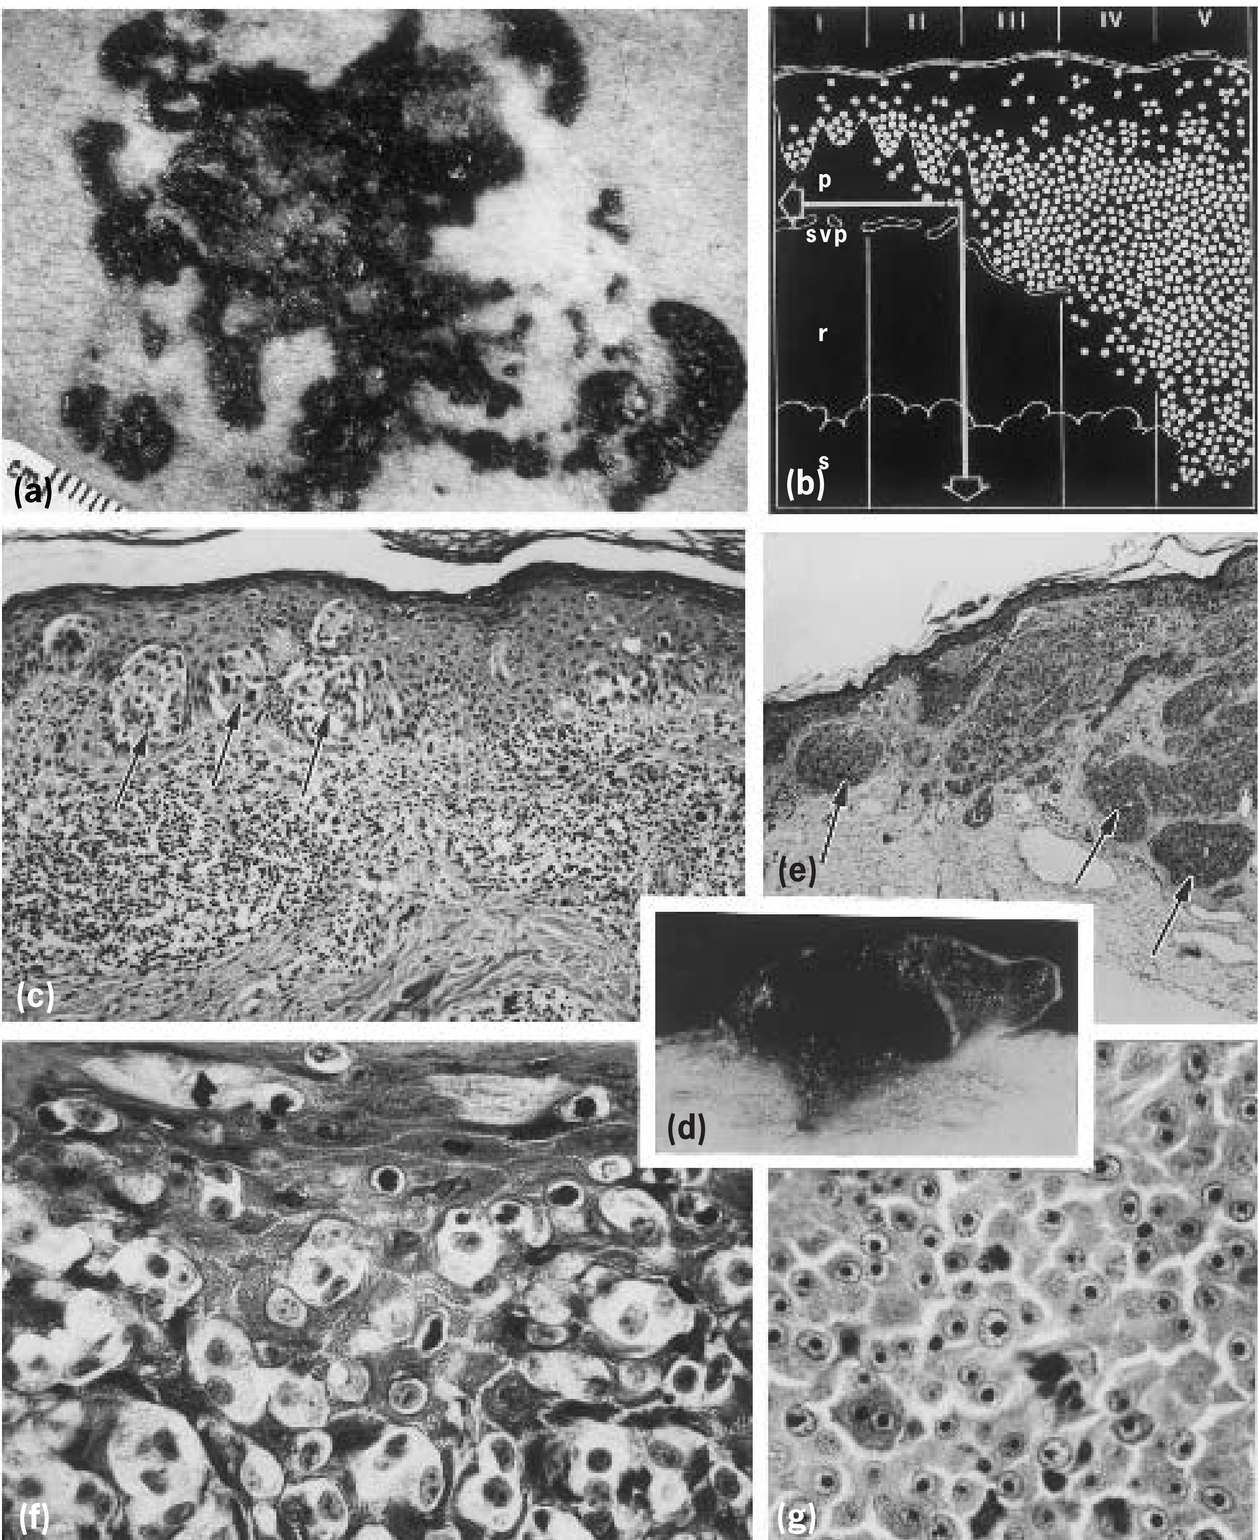

Figure 5 Malignant melanoma. (a) Clinically, melanoma is characterized by a diameter often greater than 1 cm, an irregular border and variation in colour. (b) Melanoma typically grows initially within the epidermal layer and as single cells within the superficial (papillary (p)) dermis, which is directly above an anatomic boundary called the superficial vascular plexus (svp). This early growth is generally curable with surgical excision and is termed the radial phase of growth (indicated by horizontal arrow). If untreated, the melanoma in time grows downward into the deeper (reticular (r)) dermal and subcutaneous (s) layers, an event termed vertical growth (signified by a vertical arrow). This stage carries with it the risk of metastatic spread which correlates with the depth and microanatomical levels of invasion, as

(*Continued*)

syndrome, although their precise roles in the majority of basal cell carcinomas unassociated with genetic patterns of inheritance remain to be elucidated.

Malignant Melanoma

Malignant melanoma is a relatively common neoplasm that as little as several decades ago was considered to be a potentially deadly form of skin cancer. The great preponderance of melanomas arise in the skin, although other sites of origin include the oral and anogenital mucosal surfaces, oesophagus, meninges and eye. All melanomas have the potential for metastasis if left untreated, and therefore the conventional modifier 'malignant' is really unnecessary. As a result of increased public awareness of the earliest signs of cutaneous melanomas, most are cured surgically in the early stages of their biological evolution (Mihm, 1971). Nevertheless, the incidence of malignant melanoma is on the rise, necessitating vigorous surveillance for its development.

As with epithelial malignancies of the skin (see above), sunlight appears to play an important role in the development of cutaneous melanoma. For example, men commonly develop this tumour on the upper back, whereas women tend have a relatively high incidence of melanoma on both the back and the legs. Lightly pigmented individuals are at higher risk for the development of melanoma than darkly pigmented individuals, an observation supported by epidemiological studies examining tumour incidence in equatorial regions versus those characterized by high latitudes. Sunlight, however, does not seem to be the sole predisposing factor for the development of melanoma, and the presence of a pre-existing naevus (e.g. a dysplastic naevus), hereditary factors or even exposure to certain carcinogens (as in the case of experimental melanomas in rodent models) may play a role in lesion development and evolution (Barnhill *et al*., 1993).

Clinically, malignant melanoma of the skin is usually asymptomatic, although itching and focal bleeding may be early manifestations. The most important clinical sign of possible dysplastic or malignant degeneration is change in colour in a pigmented lesion. Unlike benign (nondysplastic) naevi, melanomas usually exhibit striking variations in pigmentation, appearing in shades of black, brown, red, dark blue and grey. Occasionally, regions of white or flesh-coloured hypopigmentation are also present. The borders of melanomas are not smooth, round and uniform, as in naevocellular naevi; rather, they tend to be irregular and often 'notched' (**Figure 5a**). In conclusion, the clinical warning signs of melanoma are (1) enlargement of a pre-existing mole; (2) itching or pain in a pre-existing mole; (3) development of a new pigmented lesion during adult life; (4) irregularity of the borders of a pigmented lesion; and (5) variegation of colour within a pigmented lesion.

Crucial to understanding the complicated histology of malignant melanoma is the concept of radial and vertical growth. Simply described, radial growth indicates the tendency of a melanoma to grow horizontally within the epidermal and superficial dermal layers, often for a prolonged period of time (**Figure 5b**). During this stage of growth, melanoma cells do not have the capacity to metastasize and clinical cure is frequent. Specific types of radial growth phase melanoma are lentigo maligna, superficial spreading and acral/mucosal lentiginous. These can be defined on the basis of architectural and cytological features of growth within the epidermal layer as well as biological behaviour (e.g. lentigo maligna type of radial growth usually occurs on sun-damaged facial skin of the elderly and may continue for as long as several decades before the tumour develops the capacity to metastasize). With time, the pattern of growth assumes a vertical component. The melanoma now extends downward into the deeper dermal layers as an expansile growing mass lacking cellular maturation, without a tendency for the cells to become smaller as they descend into the reticular dermis (**Figures 5d, 5e**). Clinically, this event is heralded by the development of a nodule in the relatively flat radial growth phase, and correlates with the emergence of a clone of cells with true metastatic potential. The probability of metastasis in such as lesion may be predicted by simply measuring in millimeters the depth of invasion of this vertical growth phase nodule below the granular cell layer of the overlying epidermis (Breslow, 1970). Recently, prediction of clinical outcome has been improved further by taking into account factors such as number of mitoses and degree of infiltrative lymphocytic response within the tumour nodule (Clark *et al*., 1989).

Individual melanoma cells generally are considerably larger than naevus cells. They contain large nuclei with irregular contours and have chromatin characteristically clumped at the periphery of the nuclear membrane with prominent red (eosinophilic) nucleoli (**Figures 5f, 5g**).

(**Figure 5** *caption continued*)
indicated by convention as levels I–V. (c) Histological presentation of an early radial growth melanoma, where most of the malignant cells are present as irregular nests within the epidermal layer (arrows). (d) and (e) gross pathological (cross-section) and low-magnification histological representations of a heavily pigmented melanoma that has progressed to the vertical stage of growth. Note in (e) the numerous large nests of darkly stained cells that have found their way into the deeper dermal layers (arrows). Melanoma cells, whether within the epidermis as part of early radial growth (f) or within the dermis as part of vertical growth (g), are distinguished from most naevus cells by their enlarged nuclei which generally contain conspicuous central nucleoli.

These tumour cells proliferate as poorly formed nests or as individual cells at all levels of the epidermis (**Figure 5b**) in the radial phase of growth and, in the dermis, as expansile, balloon-like nodules in the vertical phase of growth (**Figure 5e**). The nature and extent of the vertical growth phase determine the biological behaviour of malignant melanoma, therefore it is important to observe and record vertical growth phase parameters in a pathology report. (See the chapter on *Models for Melanoma and Sarcomas*.)

Mycosis Fungoides (Cutaneous T Cell Lymphoma)

Cutaneous T cell lymphoma (CTCL) represents a spectrum of lymphoproliferative disorders that affect the skin (Murphy and Mihm, 1999). Two types of malignant T cell disorders were originally recognized: mycosis fungoides (MF), which is a chronic proliferative process, and a nodular eruptive variant, mycosis fungoides d'emblée. It is now known that a whole variety of presentations of T cell lymphoma occur, including MF, the eruptive nodular type, and an adult T cell leukaemia or lymphoma type. The latter disorder may present with a rapid progressive downhill course.

Mycosis fungoides is a T cell lymphoproliferative disorder, arises primarily in the skin and may evolve into generalized lymphoma (Murphy, 1988). Most afflicted individuals have disease that remains localized to the skin for many years; a minority has rapid systemic dissemination. This condition may occur at any age, but most it affects persons over 40 years of age.

Clinically, lesions of the MF type of CTCL represent scaly, red–brown patches, raised, scaling plaques that may even be confused with psoriasis, and fungating nodules. Eczema-like lesions describe early stages of disease when obvious visceral or typical nodal spread has not occurred. Raised, indurated and irregularly outlined, erythaematous plaques may then supervene. Systemic spreading correlates with development of multiple, large (up to 10 cm or more in diameter), red–brown nodules. Sometimes plaques and nodules may ulcerate, as depicted in **Figure 6a**. Lesions may affect numerous body surfaces, such as the trunk, extremities, face and scalp. In some individuals, systemic spread and seeding of the blood by malignant T cells is accompanied by diffuse erythema and scaling of the entire body surface (erythroderma), a condition known as Sèzary syndrome.

Histologically, the identification of the Sèzary–Lutzner cells is the hallmark of CTCL of the mycosis fungoides type. These are T helper cells (CD4 antigen-positive), they form characteristically band-like aggregates within the superficial dermis (see **Figure 6b**) and invade the epidermis as single cells and small clusters (Pautrier microabscesses). The tumour cells have markedly infolded nuclear membranes, imparting a 'hyperconvoluted' or 'cerebriform' contour (see **Figures 6c, 6d**). Patches and plaques show pronounced epidermal infiltration by Sèzary–Lutzner cells (epidermotropism), but in more advanced nodular lesions the malignant T cells often lose this epidermotropic tendency, grow deeply into the dermis and eventually seed lymphatics and the peripheral circulation.

The aetiology of CTCL is under active investigation. The discovery that a highly aggressive form of T cell lymphoma or leukaemia in adults is caused by infection of helper T cells by a specific retrovirus (human T cell leukaemia virus, or HTLV-I) (Murphy, 1988) promotes the possibility that conventional CTCL may also have an infectious causation. The proliferating cells in CTCL are clonal populations of lymphocytes of the CD4 subset; they often express aberrant cell surface antigens as well as clonal T cell receptor gene rearrangements, and detection of these features may be of diagnostic assistance in difficult cases (Bakels *et al.*, 1997).

Topical therapy with steroids or UV radiation is often delegated for early lesions of CTCL, while more aggressive systemic chemotherapy is indicated for advanced disease. In patients with circulating malignant cells, exposure of removed from the body blood cells to photosensitizing agents and UVA irradiation, followed by reinfusion into the patient (extracorporeal photopheresis; Rook *et al.*, 1991), has shown promise as a novel therapeutic approach to disseminated CTCL. (See also chapter *Lymph Nodes*.)

Angiosarcoma

Angiosarcoma is a rare malignant tumour showing variable degrees of vascular differentiation. It occurs primarily on the face and scalp, frequently in elderly people. The lesion presents as single or multiple plaques, may progress to become nodules, infiltrate the adjacent soft tissues and ulcerate. Histological examination shows diffuse dermal hypercellularity and irregular vascular spaces formed by malignant endothelial cells. These atypical neoplastic cells have hyperchromatic nuclei with irregular contours. The malignant cells of better differentiated tumours recapitulate vascular spaces, bulging into the vessel lumens and forming intraluminal tufts. Poorly differentiated tumours, on the other hand, often provide sheets composed of solid aggregates of tumour cells (Murphy and Elder, 1991a). Angiosarcoma can develop as a result of previous irradiation and in lymphedematous extremities, such as those produced after surgery for breast cancer or as a result of previous radiation therapy.

An angioproliferative disorder, which may show findings similar to angiosarcoma, is Kaposi's sarcoma. This vascular proliferative disorder occurs as two variant forms: an indolent cutaneous variety, seen in elderly individuals and common in Ashkenazi Jews and Southern Europeans, and a second form, characterized by an aggressive tumour that presents as a component of immunodeficiency states,

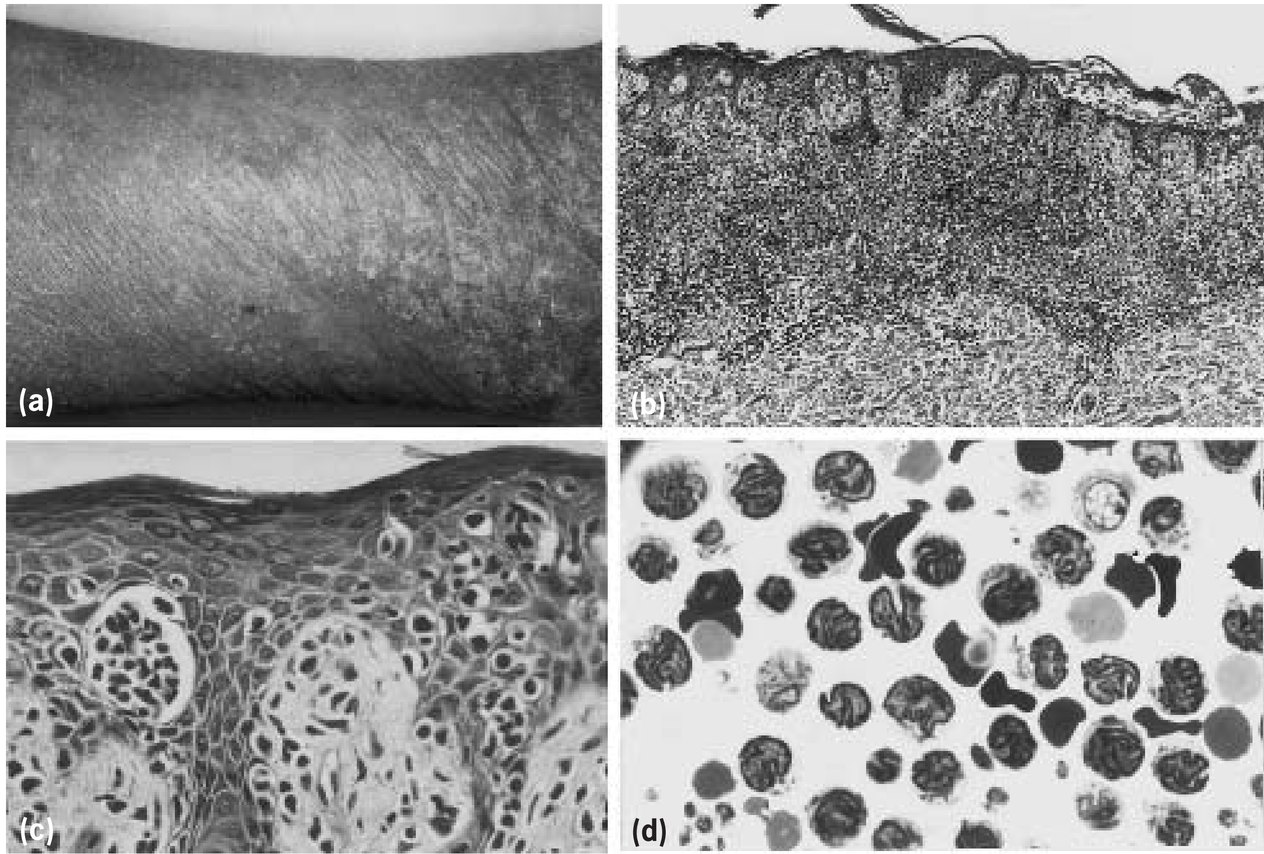

Figure 6 Mycosis fungoides (cutaneous T cell lymphoma). (a) Early lesions may present as pink–red, eczema- or psoriasis-like patches and plaques covered by adherent scales. (b) The biopsy at this stage may show a horizontal band of lymphocytes (many representing malignant T cells) within the upper dermis directly beneath the epidermal layer. (c) Inspection at higher magnification will often reveal large, darkly stained malignant lymphocytes abnormally collecting within the epidermis, where they tend to be found in association with Langerhans cells (see **Figure 1**). (d) Cytologically, the malignant T lymphocytes contain a nucleus with a characteristically infolded contour sometimes likened to the profile of a brain, and therefore referred to as 'cerebriform.'

especially in acquired immunodeficiency syndrome (AIDS). In this setting, its occurrence is associated with a new herpesvirus, human herpesvirus 8 (Murphy and Elder, 1991). Kaposi's sarcoma may begin as small solitary (isolated) purpuric papules, characterized by small zones of intracutaneous haemorrhage and comparable to bruises or petechiae (patch stage). Progression of Kaposi's sarcoma results in raised plaques and nodules, which are often large and destructive clinically. Advanced stage tumours frequently ulcerate. Histological examination during early phases demonstrates a multifocal angioproliferative process characterized by an increase in the number of spindle cells and thin-walled, poorly formed vessels within superficial vascular plexus, lymphoplasmocytic inflammatory infiltrates, and dilated lymphatics. Advanced lesions show expansive nodular growth of atypical spindle cells, containing hyperchromatic nuclei (Murphy and Elder, 1991). Such lesions may be confused with other malignancies of mesenchymal cells.

MOLECULAR GENETIC FINDINGS

In the case of the hereditary form of dysplastic naevi, genetic analyses have demonstrated the trait to be inherited as an autosomal dominant, possibly involving a susceptibility gene located on the short arm of chromosome 1, near the *Rh* locus (1p36) (Greene *et al.*, 1983). Other melanoma-susceptibility genes have been mapped to chromosomes 9p21 and 12q14 (Greene, 1997).

PROGNOSTIC FACTORS

The most common forms of skin cancer, namely squamous cell and basal cell carcinoma, are slowly growing, locally invasive, and tend not to exhibit metastatic behaviour. As mentioned earlier, some squamous cell carcinomas, particularly those that involve facial skin, may metastasize to

local lymph nodes. Basal cell carcinomas rarely metastasize, but when they do, large tumour size tends to be a constant feature. Locally aggressive basal cell carcinomas often will show a sclerosing or diffusely infiltrative pattern of dermal invasion.

Malignant melanoma, in contrast, shows a well-defined ability to metastasize once it has entered the vertical phase of growth. Numerous parameters have been defined which correlate with prognosis for such lesions. Negative attributes are represented by axial (versus acral) site of occurrence, male gender, progressive depth of dermal invasion, high mitotic count, absence of tumour infiltrating lymphocytes at the base of the tumour nodule, presence of regression and documentation of vascular invasion and microscopic satellite formation (Elder and Murphy, 1991). In lesions diagnosed unequivocally as vertical growth phase melanomas, such prognostic variables may be charted on multivariate databases, permitting prediction of 8-year survival with confidence intervals that demonstrate considerable accuracy.

A major drawback in predicting prognosis of melanocytic tumours is represented by a recently recognized, relatively rare but genuine group of neoplasms that possess hybrid or intermediate characteristics between melanocytic naevi and fully evolved malignant melanoma. These tumours have been variously termed borderline melanomas, minimal deviation melanomas, naevoid melanomas, severely atypical melanocytic naevi, severely atypical dermal and epidermal melanocytic proliferations and melanocytic tumours of uncertain malignant potential (MELTUPs) (Elder and Murphy, 1991). Depending on the designation, such problematic, grey-zone tumours may possess some or all of either the architectural or cytological features of melanoma, but do not qualify as fully evolved malignant lesions, leaving the prediction of their biological behaviour an open question. Diagnostic classification of such tumours, even among experts in dermatopathology (Farmer *et al*., 1996), has proven to be extremely problematic. Accordingly, a pathologist has been astute to have identified such a lesion as at least representing significant melanocytic atypia. Often the best that one can do at this juncture is to relate concern regarding the hybrid nature of the histological features and to recommend complete excision, in addition to close clinical follow-up. Hopefully, as more of these problematic lesions are characterized, reproducible diagnostic criteria and prognostic attributes will be identified that will permit more accurate determination of the likelihood of eventual metastasis.

OVERVIEW OF CLINICAL MANAGEMENT

Most squamous and basal cell carcinomas may be adequately treated by complete eradication either by excision or by destructive means, such as curretage, freezing or electrodesiccation. Excision has the advantage of providing for histological analysis to ensure negative margins, although the alternative modalities of local destruction have proven to be highly effective (Fitzpatrick *et al*., 1999), especially when lesions are small and biologically nonaggressive. In situations where tumours are present in close proximity to vital structures, particularly involving facial skin, a modified Mohs technique may be desirable (Leslie and Greenway, 1991). In this setting, multiple frozen sections of marginal tissue are examined at the time of the excision. Lymph node dissection in the case of invasive squamous cell carcinoma may be indicated when there exists suspicious clinical enlargement of draining lymph node chains.

The role of wide excision and lymph node dissection in the setting of vertical growth phase melanoma is potentially problematic. Primary lesions are generally recommended to be excised with a margin that will minimize the likelihood of local recurrence. However, this recommendation is controversial, with some experts arguing that although wider excisions may decrease the incidence of local metastases, they fail to improve survival. This assumption is based on the contention that local metastases of melanoma generally correlate with contemporaneous seeding of distant sites (Ackerman and Scheiner, 1983). In recent years, sentinel lymph node sampling has gained acceptance in the treatment of many vertical growth phase melanomas. In this procedure, a radiographically detectable dye is injected at the site of the primary tumour. This dye is taken up by draining lymphatic vessels and delivered physiologically to regional lymph nodes. The first nodes to be detected by this method are presumed to be candidates for early metastases, and therefore they are surgically removed and studied extensively by histological and sometimes by immunohistochemical analysis for the presence of occult melanoma metastases. Occasionally, entire lymph node chains will be removed as part of a procedure termed prophylactic elective regional lymph node dissection. The clinical rationale for such procedures is to eradicate surgically early metastases while they are theoretically confined to draining lymph nodes. This approach remains to be validated by prospective data. Moreover, it is complicated by the theoretical possibility that latent systemic metastases may occur synchronously with nodal ones, and by the notion that nodal deposits of tumour cells may in some instances eventuate in positive effects in terms of sensitizing the immune system against specific tumour-associated antigens.

In this regard, adjuvant therapy for melanoma has recently focused on immunoenhancing therapies, such as melanoma vaccines and treatment with proinflammatory mediators, such as interferon-α. Although these approaches have provided encouraging preliminary data in the treatment of clinically advanced melanoma metastases (Murphy *et al*., 1993), their role as adjuvants to ameliorate the potential for eventual metastatic spread is not as yet fully defined and awaits further experimental validation.

CONTENTS

- Normal Development and Structure
- Tumour Pathology: Squamous Cell Carcinoma
- Screening and Prevention: Gross/Histopathology/Preinvasive
- Tumour Pathology: Salivary Gland Carcinomas

NORMAL DEVELOPMENT AND STRUCTURE

During the third week of development of the human embryo, a deep groove develops below the forebrain that represents the future oral cavity. This groove is known as the primary oral fossa, or stomadeum, and it is lined by ectoderm that forms an additional ectodermal pouch, Rathke's pouch, that gives rise to the anterior lobe of the pituitary gland and to the dental organs that will form the enamel of the deciduous and permanent teeth. The stomadeum is separated from the endodermally lined foregut by the buccopharyngeal membrane that ruptures in the fourth week of development. In an adult the oral mucosa is covered by stratified squamous epithelium that is keratinized in areas exposed to masticatory forces, and is supported by fibrous tissue containing salivary glands, adipose tissue, skeletal muscle and bone. The red portion of the lips (vermilion) represents a transition zone from skin to mucosa but does not contain eccrine or sebaceous glands or hair follicles.

The salivary gland primordia develop as buds of primitive stomadeal epithelium that proliferate as strands into the underlying oral ectomesenchyme. This results in the formation of three pairs of major salivary glands the parotid, submandibular and sublingual glands and between 500 and 1000 lobules of minor salivary glands. Although the parotid is a single contiguous structure, the facial nerve courses through its centre, essentially dividing the gland into superficial (lateral) and deep (medial) lobes. The parotid gland is rich in lymphoid tissue, and normally contains from 3–24 lymph nodes, most in the superficial lobe (Ellis and Auclair, 1996). The minor glands are usually numerous in all oral mucosal sites except for the anterior hard palate and gingiva. The glands consist of secretory acini composed of mucous or serous acinar cells. Saliva then flows to the intercalated portion of the branching ductal system, lined by low cuboidal epithelium, then to the larger striated duct portion formed by columnar cells that have large numbers of mitochondria, and finally to the excretory ducts that are lined by stratified squamous epithelium where they merge with the oral epithelium. The acini are surrounded by myoepithelial cells that have ultrastructural features of both epithelium and smooth muscle.

TUMOUR PATHOLOGY: SQUAMOUS CELL CARCINOMA

Epidemiology

More than 90% of all cancers of the oral mucosa and lip vermilion are squamous cell carcinomas (epidermoid carcinoma). Although other forms of cancer, including sarcomas, melanomas and lymphomas, also affect the oral mucosa and jaws, only squamous cell carcinoma will be discussed in this section; adenocarcinomas that arise from the major and minor salivary glands will be discussed in the following section.

In the United States, squamous cell carcinomas of the oral mucosa and lip vermilion account for about 3% of all cancers of all sites, representing about 22 000 new cases each year. As shown in **Figure 1**, the incidence rates are strongly age-related. The death rate per 100 000 population

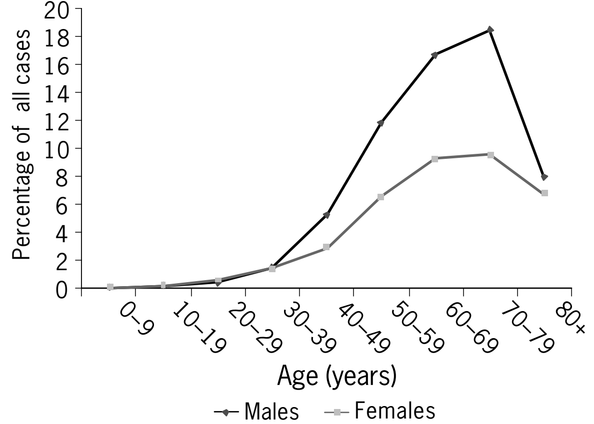

Figure 1 Age- and gender-specific incidence rates of oral and pharyngeal cancer. While the incidence rate for oral squamous cell carcinoma is greater in men than women, the rates in both increase dramatically with advancing age.

Table 1 Oral cancer death rates: selected countries[a]

Country	Male	Rank	Country	Female	Rank
Hong Kong	14.8	1	Singapore	4.8	1
France	14.3	2	Hong Kong	4.8	2
Singapore	12.8	3	Kuwait	2.4	3
Hungary	12.5	4	Cuba	1.8	4
Puerto Rico	9.0	5	Malta	1.7	5
Italy	6.4	11	Puerto Rico	1.4	11
Germany	6.0	13	United States	1.4	13
Spain	5.7	16	Canada	1.3	16
Canada	4.5	22	Luxembourg	1.2	22
Denmark	3.8	28	Belgium	1.0	28
United States	3.8	30	Germany	1.0	30
England and Wales	2.8	37	Netherlands	0.8	37
Venezuela	2.2	42	Finland	0.7	42
Mexico	1.7	45	Chile	0.7	45
Greece	1.6	46	Japan	0.6	46
Ecuador	0.9	50	Korean Republic	0.3	50

[a]*Source*: World Health Organisation data as adapted by the American Cancer Society, 1992.

for oral cancer (see **Table 1**) ranges in men from 0.9 in Ecuador to 14.8 in Hong Kong and in women from 0.3 in the Korean Republic to 4.8 in Singapore. In the United States the mortality rate ranges from 1.4 in Utah to 7.0 in the District of Columbia. In most populations males have an incidence rate about three times that of females and the incidence and mortality rates in the United States are greater among blacks than whites.

The tongue and floor of the mouth are the most commonly affected intraoral sites. There are exceptions, such as occurs in some Indian and South American cultures where carcinoma of the hard palate is endemic because of the custom of 'reverse' smoking (chutta). Women in particular hold the lit end of a slowly burning, hand-made cigarette inside the mouth in close proximity to the palatal mucosa, a site that rarely gives rise to carcinoma in most parts of the world.

Aetiology

It is estimated that about 90% and 60% of all deaths in males and females, respectively, caused by oral cancer can be attributed to cigarette smoking. Like cancers at other sites caused by smoking, the risk of developing cancer is dose related and is related to carcinogenic aromatic hydrocarbons. The relative risks are estimated to be at least five and as high as 10–24 for patients who smoke 40 cigarettes per day and this risk increases the longer one smokes. Pipe and cigar smoking appear to result in at least as great a risk. The association of the use of smokeless ('spit') tobacco with oral carcinoma is less clear. The prevalence of oral carcinoma is low in some countries where the use of smokeless tobacco far exceeds that of cigarette smoking (La Vecchia *et al.*, 1992; Vigneswaran *et al.*, 1995). On the other hand, some studies have shown that smokeless tobacco users are at increased risk and that about one-half of such cancers occur at the site where the tobacco is placed (Winn *et al.*, 1981). Another variation of topical use is seen in India and Southeast Asia where areca nut, tobacco and slaked lime are wrapped with betel leaf and chewed for long periods each day. This results in a precancerous scarring condition known as oral submucous fibrosis.

The fact that only a fraction of individuals with heavy exposure to tobacco and alcohol develop cancers of the upper aerodigestive tract suggests that there may be genetic differences between individuals that influence their susceptibility to these environmental agents. Heritable differences in head and neck cancer susceptibility have been found for nearly every step of tumorigenesis including carcinogen metabolism, DNA repair and progression as influenced by oncogenes and tumour-suppressor genes (Spitz, 1994; Khuri *et al.*, 1997; de Andrade *et al.*, 1998; Jahnke *et al.*, 1999). There is also increasing evidence to suggest that some of the population variance in response to therapy is due to interindividual genetic differences (Khuri *et al.*, 1997).

Because many heavy smokers are also heavy drinkers, it has been difficult to link alcohol use directly with oral cancer, but some investigators have estimated the relative risk at 2–6-fold. Alcohol acts synergistically with tobacco and together they increase a person's risk to 40-fold. Alcoholic beverages contain nitrosamines and hydrocarbons and, additionally, it has been proposed that contaminants or metabolites may promote malignant transformation (Blot, 1992). Malnutrition and vitamin deficiency may have a contributory role in oral cancers.

Vitamins A, B and C, are independently related to a reduced incidence of oral carcinoma and the risk of oral cancer in vitamin E users is half that of others according to one study (Gridley *et al*., 1992).

Cancer of the lower lip is strongly related to excessive exposure to ultraviolet light with a wavelength range of 2900–3200 Å, especially in fair-skinned individuals. Actinic cheilitis, similar in name and biology to actinic keratosis of the skin, represents the premalignant clinical condition. Just as in the skin, extensive damage is done to the collagen in the lamina propria (solar elastosis), but whether or not this event has any influence on epithelial transformation is unknown. Exposure to therapeutic X-irradiation is associated with an increased risk for the development of both carcinomas and sarcomas. Evidence of infection with human papillomavirus (HPV) has been found in clinically normal oral mucosa, benign and malignant neoplasms that arise from it, and some of the metastatic tumours. About 35% of oral cavity tumours have been found to contain HPV, usually the 'high-risk' types of the virus. HPV positivity correlates with age (< 60 years) and gender (male), but not with tobacco or alcohol use (McKaig *et al*., 1998). Nevertheless, its exact role remains elusive.

In summary, it appears that the pathogenesis of oral carcinomas is multifactorial with suppressor genes acting in association with growth factors, viruses, chemical carcinogens and oncogenes (Scully, 1993).

SCREENING AND PREVENTION: GROSS/HISTOPATHOLOGY/PREINVASIVE

Lesions/Ultrastructure/Immunohistochemistry

Squamous cell carcinoma (SCC) of the oral mucosa has numerous clinical appearances and is often preceded by premalignant lesions showing epithelial dysplasia or carcinoma *in situ*. The most common early form of premalignant or malignant disease, known as erythroplakia, is an asymptomatic, well-defined, erythematous macule or plaque that may have a finely granular surface texture. About 90% of erythroplakias show either dysplasia or carcinoma. SCC may also appear as a white patch but only between 5 and 25% of clinical white patches will show epithelial dysplasia or carcinoma, the remaining representing hyperkeratosis or other benign conditions. However, in sites designated 'high-risk,' including the ventral surface and lateral border of the tongue (**Figure 2; see colour plate section**), anterior floor of the mouth and soft palatal complex, the risk is much greater. Importantly, it is usually impossible to distinguish clinically between benign, premalignant and malignant disease. Often mucosal lesions show both red and white components (**Figure 3; see colour plate section**); the presence of an erythematous area in a lesion for which an obvious source of irritation is not evident should be biopsied and reviewed microscopically.

Advanced tumours may present as exophytic masses that often have a papillary surface (**Figure 4; see colour plate section**) and as nonhealing ulcers that reveal an endophytic, indurated nodule on palpation. Carcinomas that involve the gingiva, alveolar mucosa and tooth extraction sockets may first be discovered as irregular radiolucencies; those of the vermilion of the lower lip typically present as crusted ulcers (**Figure 5; see colour plate section**).

The most important morphological alterations that indicate a premalignant condition of the oral mucosa involve the squamous cell nuclei. They are enlarged, more darkly stained then normal, have irregular shapes and large, dark nucleoli and reveal increased and abnormal mitotic figures (**Figure 6; see colour plate section**). Cells showing these features extend above the parabasal cell layer in a haphazard arrangement, are crowded and often form bulbous rete ridges. The term carcinoma *in situ* signifies that the entire thickness of the spinous cell layer demonstrate these changes, but invasion has not yet occurred.

Grossly, squamous cell carcinoma is firm, has a glistening, heterogeneous grey–white cut surface and is often poorly delineated. Microscopically, individual epithelial cells or cords or islands of cells showing dysplastic changes infiltrate the underlying connective tissue (**Figure 7; see colour plate section**). When the tumour cells show a striking resemblance to normal squamous cells and show prominent keratinization, the tumour is considered 'well differentiated.' 'Moderately differentiated' carcinomas show a greater degree of cellular variability, less resemblance to normal squamous cells and much less keratinization. 'Poorly differentiated' tumours show very limited, focal resemblance to their cell of origin. Two benign oral lesions that often show an epithelial proliferation known as pseudocarcinomatous hyperplasia that histologically mimics well differentiated squamous cell carcinoma are granular cell tumour and necrotizing sialometaplasia.

The tendency of a patient to develop more than one oral mucosal primary carcinoma is know as 'field cancerization.' In a study of over 21 000 patients the rate of development of second tumours was 3.7% per year and the risk of a second was 2.8 times greater than expected (Day and Blot, 1992). The risks are highest in patients who continue to smoke and persist for more than 5 years after diagnosis of the initial cancer. Frequent periodic follow-up oral examinations for this possibility are essential.

Field cancerization is believed to be the result of multiple related lesions that arise from a field defect. This situation is similar to that seen in bladder cancer (Sidransky, 1997) and diffuse gastric cancer, where a single transformed cell clonally propagates and then spreads throughout a region. Subsequently, independent additional mutations occur in the

dispersed cells, giving rise to multiple malignancies over time, all of which share the original transforming mutations in common (Sidransky *et al.*, 1992; Sidransky, 1997). In head and neck squamous cell carcinoma (HNSCC), shared specific mutations in chromosomes 9p and 3p, as well as shared patterns of X-chromosome inactivation have been identified in synchronous and metachronous lesions along with independent mutations in each lesion (Nees *et al.*, 1993; Worsham *et al.*, 1995; Gauri *et al.*, 1996; Partridge *et al.*, 1997; Lydiatt *et al.*, 1998; Califano *et al.*, 1999). These findings indicate that multiple head and neck neoplasms may arise from a single clone which spreads, producing separate lesions that acquire additional mutations and progress individually.

There are several forms of squamous cell carcinoma that have important clinicopathological features different from the 'conventional' form previously described. Verrucous carcinoma is a low grade form that represents less than 10% of all oral squamous cell carcinomas. It most often occurs in patients who have used chewing tobacco for many years and appears as a white, papillary lesion that spreads slowly but progressively along the mucosal surface over one to several years (**Figure 8; see colour plate section**). Unlike conventional SCCs that may have a papillary configuration, the nuclear morphology is bland; characteristic architectural features, including broad, elongated, rounded rete ridges and papillary surface projections filled with parakeratin, facilitate the diagnosis. Invasive carcinomas develop in about 20% of cases mandating extensive tissue sampling. Proliferative verrucous leukoplakia is a term used to describe the white oral plaques that occur in some patients that, as they spread, change from having a smooth to fissured to granular to papillary surface texture (Hansen *et al.*, 1985). Some develop into verrucous carcinoma (**Figure 9; see colour plate section**) or conventional invasive SCC.

An aggressive variant is basaloid squamous carcinoma that most often occurs in the hypopharynx and base of the tongue. Histologically, the tumour is characterized by having well delineated nests of basaloid cells, some with hyaline cores and pseudoglandular structures, often resembling the solid variant of adenoid cystic carcinoma or small cell undifferentiated carcinoma. Weak immunoreactivity for neuron-specific enolase is seen in 75% of cases (Banks *et al.*, 1992) and ultrastructurally the basaloid cells reveal rare tonofilaments and varying numbers of desmosomes (Wain *et al.*, 1986). There is a poor prognosis; 40% of patients die within 17 months. Another variant is spindle cell carcinoma, a name chosen for the tumour's characteristic histopathological feature. The prominent spindle element resembles sarcomas but the focal presence of typical squamous cell carcinoma, dysplastic surface epithelium and immunoreactivity of the spindle cells for cytokeratin are all helpful in the distinction. These tumours are often clinically pedunculated, grow rapidly and about one-third are associated with prior therapeutic radiation.

Molecular Genetic Findings

Oral cavity and salivary gland neoplasms, like other solid tumours, arise from normal tissue that has undergone a series of genetic alterations. These changes include activating mutations of proto-oncogenes in addition to inactivation of tumour-suppressor genes, apoptotic genes and sometimes cell adhesion genes. For at least some cancers, tumour development also involves abnormalities in the cell's DNA repair system such that somatic mutations accumulate leading to malignancy (Sherbet and Lakshmi, 1997).

Investigations into the genetic-basis HNSCCs have resulted in a general molecular progression model for these neoplasms (**Figure 10**) (Califano *et al.*, 1996; Sidransky, 1997). This model resembles those developed by similar means for bladder cancer and non-small cell lung cancer (Sidransky *et al.*, 1992; Minna *et al.*, 1997) more than it corresponds to the colorectal cancer mutation paradigm (Fearon and Vogelstein, 1990). Whether this general progression model will hold true for all squamous cell

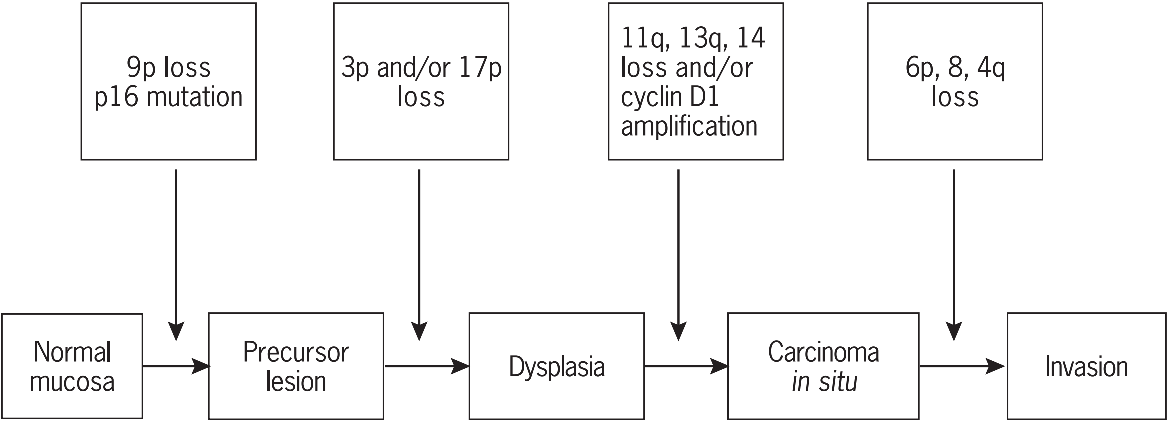

Figure 10 Preliminary molecular progression model for head and neck squamous cell carcinoma.

carcinomas of the head and neck remains to be seen. Some recent genetic evidence suggests that primary head and neck cancers arising in different locations are, in fact, separate clinical entities with independent genetic aetiologies and should be treated as such (Takes *et al*., 1998; Gleich *et al*., 1999).

Part of the rationale for grouping all head and neck cancers together, or at least all HNSCCs, has to do with shared aspects of disease management, their natural history (e.g. field cancerization and tendency for synchronous and metachronous lesions) and the common role of carcinogens in their origin, particularly the role of tobacco and alcohol exposure (Sidransky, 1997; Spitz, 1994). In molecular genetic studies, this tendency to group various head and neck cancers together makes it difficult to interpret the literature with regard to any particular subset, such as oral cavity lesions. Some research aimed at identifying specific genes involved in tumorigenesis and progression for head and neck cancers in general did not include oral cavity tumours in the study sample. A relatively small number of investigations focused on oral cavity lesions specifically. Therefore, it is unclear whether a conserved set of gene abnormalities is responsible for all head and neck cancers (or at least all HNSCCs) with minor variations on the theme, or whether each neoplasm has a distinct aetiology as has been suggested recently (Takes *et al*., 1998; Gleich *et al*., 1999)

Chromosomal changes detectable by cytogenetic methods provided the first clue to the identification of specific genes involved in tumorigenesis and progression. The chromosomal regions involved in rearrangement, deletion, amplification, etc., in tumour cells indicate sites where oncogenes, tumour-suppressor genes or other genes contributing to tumour development reside. The chromosomal changes most frequently reported for HNSCC include deletions of 3p, 5q, 8p, 9p, 18q and 21q (Sidransky, 1997), amplifications of 11q (Callander *et al*., 1994; Sidransky, 1997) and breakpoints at 1p22, 3p21, 8p11 and 14q (Sidransky, 1997). These common abnormalities identify potential tumour-suppressor genes and oncogenes contributing to HNSCC progression. Their correlation with certain stages of tumour progression allowed for their relative placement, chronologically, in a preliminary genetic progression model (**Figure 10**) (Jares *et al*., 1994; Sidransky, 1997). Multiple regions of deletion on chromosome arm 13q indicate the presence of a tumour-suppressor gene implicated specifically in oral cavity and supraglottal SCC (Gupta *et al*., 1999).

Further refinement of the location of putative tumour-suppressor genes contributing to head and neck cancers is provided by loss of heterozygosity (LOH) analysis to define the minimal regions of loss within the larger common areas of chromosomal deletion. Correlation of these regions defined by molecular markers, with the known map position of various tumour-suppressor genes, reveals likely candidates for gene mutation (followed by loss of the corresponding normal allele on the deleted chromosome). Evidence from LOH analysis and direct mutational screening indicates that a number of tumour-suppressor genes play a role in HNSCCs, including *TP53*, *VHL*, *CDKN2/INK4/p16*, *p21/WAF/CIP* and *TGFβR* (Brachman, 1994; Sidransky, 1997). Molecular genetic studies on oral cavity lesions specifically have implicated *TP53*, cell cycle inhibitors *p16* and *p27* and a tumour-suppressor gene other than *RB* or *BRCA1* located on the long arm of chromosome 13 (Gupta *et al*., 1999; Kanekawa *et al*., 1999; Riese *et al*., 1999; Venkatesan *et al*., 1999).

Despite the abundance of characterized oncogenes believed to play a role in tumorigenesis in humans, relatively few have been convincingly linked to the progression of any primary tumour. In head and neck cancer, there are a few cases of direct alteration of an oncogene or its overexpression and stage-specific progression. Well documented examples of oncogene activation in HNSCCs and corresponding tumour-progression include *cyclin D1* and *EGFR* (Brachman, 1994; Sidransky, 1997). There is strong evidence that overexpression of *cyclin D1* and the ligand–receptor pair HGF–c-Met play a role in progression of oral cavity neoplasms (Marshall and Kornberg, 1998; Matthias *et al*., 1998).

A variety of other genes have been identified that, when mutant, are involved in uncontrolled cell proliferation or the mechanisms by which benign lesions becomes invasive and metastatic. Some examples of additional genes that appear to promote development of various head and neck cancers including oral cavity tumours are *bcl-2*, *E-cadherin*, *EMS-1*, *telomerase*, *Ki-67*, *retinoic acid receptor*, *e1F4E*, *K19*, *GADD 153*, and *Cat D*, *B* and *L*. These genes encode apoptosis factors, cell adhesion molecules, translation initiation factors, cysteine proteases and other proteins for which the function of the altered gene product is unclear (Brachman, 1994; Kos *et al*., 1996; Drachenberg, *et al*., 1997; Friedman *et al*., 1997; Takes *et al*., 1998; Vo and Crowe, 1998; Crowe *et al*., 1999; Los *et al*., 1999; Nathan *et al*., 1999).

Numerous investigators have attempted to determine the clinical relevance of specific gene mutations in terms of their value as diagnostic markers or their reliability in predicting outcome and likelihood of recurrence. Some genes believed to play a role in the development of oral cavity tumours show potential as prognostic indicators or molecular markers of response to therapy, most notably low levels of p27 protein and poor response to treatment (Venkatesan *et al*., 1999), *GADD153* (growth arrest and DNA damage gene) mRNA levels as a predictor of response to cisplatin (Los *et al*., 1999), overexpression of *bcl-2* and poor prognosis, and *cyclin D1* polymorphism as a predictor of clinical outcome (Friedman *et al*., 1997). In addition, flow cytometric DNA content measurements (indicative of aneuploidy) can provide significant prognostic information, such as serving as an independent predictor of metastatic potential and clinical outcome

(Ensley and Maciorowski, 1994; Hemmer *et al*., 1999). Abnormal chromosome copy numbers measured by FISH in exfoliated epithelial cells of tumours and clinically normal margins can detect subclinical tumorigenesis (i.e. chromosome imbalances indicative of preneoplastic cells in the 'field') (Barrera *et al*., 1998).

Prognostic Factors

It has been shown that 14% of epithelial dysplastic lesions that were not excised progressed to invasive carcinoma within a follow-up period of 20 years, but 50% remained unchanged and 15% regressed (Lumerman *et al*., 1995). Nonetheless, the potential progression of any dysplastic lesion to carcinoma must be presumed and, when possible, should be excised with microscopically uninvolved surgical margins. Only 6.2% of 65 patients who had excision developed SCC compared with 15.4% of 91 patients who received no treatment (Lumerman *et al*., 1995).

Prognosis of oral squamous cell carcinoma is most directly related to the clinical stage of the tumour. The TNM staging system and Stage Grouping are shown in **Table 2**. Prior to 1992, 'fixation' of a node was considered in determining the N category, but now only the size of the node is evaluated, and bilateral nodal involvement is N2 rather than N3.

Most staging protocols do not include microscopic features. Nonetheless, some investigators have suggested that tumour thickness or depth of invasion independently correlates with patient outcome (Spiro *et al*., 1986). One study, for instance, found that tumours that invaded less than 4 mm, 4–8 mm and more than 8 mm showed metastatic rates of 8.3, 35 and 83%, respectively (Shingaki *et al*., 1988). Others have shown that tumour thickness correlates best with lesions of the vermilion border.

Overview of Present Clinical Management

Treatment failure most often is associated with uncontrolled regional disease. For most tumours, surgery with or without adjunctive postoperative radiotherapy is considered standard therapy, but patients with detectable distant metastases are usually treated palliatively. Radiation includes both external beam and interstitial brachytherapy. Local recurrence is more likely to follow excision of tumours with positive surgical margins so the goal is to establish tumour-free margins of 1–2 cm. The risks of occult cervical metastases in clinically negative necks is significant so elective neck dissections are often performed. Identification of positive lymph nodes in elective neck dissections has been reported to be 19, 40–50 and 25–54%, respectively, for tumours of the gingiva, floor of the mouth and oral tongue (de Braud *et al*., 1989). Elective radiation to the regional lymph nodes of the neck is often performed instead.

Systemic and regional chemotherapy is used mainly for palliation of patients with tumours that can not be treated effectively with surgery or radiation, and to help improve regional control of aggressive tumours. The drugs used most often singly or in combination with others are methotrexate, bleomycin, *cis*-platinum and 5-fluorouracil.

Survival benefits with chemotherapy have not been demonstrated. Research and early clinical trials using monoclonal antibodies, such as antiepidermal growth factor antibody C225, are under way and, it is hoped, will offer effective additional treatment options in the future (Huang *et al*., 1999).

It has only recently become possible to integrate information about an individual's genetic susceptibility and/or knowledge of specific genetic abnormalities in an individual's tumour with overall risk and response to particular therapies. Retinoid chemoprevention in head and neck cancers represents one of the most promising attempts at this sort of 'rational' intervention, in which levels of *RAR-B* expression in oral lesions predict response to intervention with retinoids (Khuri *et al*., 1997). The mechanism of action of retinoids and role of *RAR-B* in tumorigenesis are becoming clear (Grandis *et al*., 1996; Lotan, 1996; Cheng and Lotan, 1998; Vo and Crowe, 1998).

Gene therapy is also under exploration as a possible intervention for oral cavity and salivary gland cancers. This strategy provides a less invasive means of therapy compared with traditional management, and may prove particularly effective in combating aspects of recurrence associated with field cancerization. Adenovirus-mediated *p53* gene therapy has reached phase II clinical trials (Clayman *et al*., 1999), and combination chemo- and gene therapy is under initial investigation in mice as a means of treating salivary gland tumours (O'Malley and Li, 1998).

TUMOUR PATHOLOGY: SALIVARY GLAND CARCINOMAS

Epidemiology

The annual incidence of both benign and malignant salivary gland tumours reported in most studies varies from 0.4 to 6.5 cases per 100 000 population. They account for about 2% of all neoplasms of the head and neck. Primary epithelial tumours comprise approximately 90% of the tumours seen, with most of the remaining cases being soft tissue tumours, lymphomas and metastatic tumours. Adenocarcinomas, on which this discussion is focused, represent between 21 and 45% of the primary tumours. Current classifications of salivary gland tumours include 23 different types of carcinomas, and all but one, primary squamous cell carcinoma, represent adenocarcinomas.

The average age of patients with salivary carcinomas is 47 years, but two of the most common types, mucoepidermoid carcinoma and acinic cell adenocarcinoma, have

Table 2 TNM staging system for oral squamous cell carcinoma[a]

T	*Primary tumour*
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
TIS	Carcinoma *in situ*
T1	2 cm or less in greatest dimension
T2	More than 2 cm, but not more than 4 cm, in greatest dimension
T3	More than 4 cm in greatest dimension
T4 (lip)	Tumour invades adjacent structures such as cortical bone, inferior alveolar nerve, floor of mouth, skin of face
T4 (oral cavity)	Tumour invades adjacent structures such as cortical bone, muscle of tongue, maxillary sinus, skin. Superficial erosion alone of bone/tooth socket by gingival primary is not sufficient to classify as T4
N	*Regional lymph nodes*
NX	Regional lymph node cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral cervical lymph node(s) less than 3 cm
N2	Metastasis in a single ipsilateral node more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral nodes, none more than 6 cm; or in bilateral or contralateral lymph nodes, none more than 6 cm
N2a	Metastasis in single ipsilateral lymph node 3–6 cm
N2b	Metastasis in multiple ipsilateral nodes, none more than 6 cm
N2C	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
N3a	Clinically palpable ipsilateral node(s), at least one more than 6 cm
N3b	Bilateral clinically palpable bilateral nodes
N3c	Clinically palpable contralateral nodes
M	*Distant metastasis*

a peak incidence in the third and fourth decades, unlike most of the other types. Females are more often affected than males but there is variation according to the tumour type. About 55, 10, 0.3 and 34% of the carcinomas occur in the parotid, submandibular, sublingual and minor glands, respectively. However, the proportion of all salivary gland tumours at a particular site that are malignant varies significantly. For instance, while less than 25% of parotid tumours are malignant, 45% of submandibular tumours, 50% of minor gland tumours and nearly 90% of sublingual gland tumours are carcinomas. Furthermore, in some minor gland sites, including the tongue, floor of the mouth

and retromolar area, 80–90% are malignant. Most parotid gland tumours arise in the lateral (superficial) lobe and present as preauricular swellings. Those that develop in the deep lobe often expand into the parapharyngeal space and manifest as pharyngeal swellings.

Aetiology

Little is known about the cause of most salivary gland carcinomas, but there is a strong relationship with exposure to ionizing radiation. Studies of the survivors of the atomic bombings of Hiroshima and Nagasaki demonstrated an 11-fold increased risk for development of salivary carcinoma. The risk was greatest in patients closest to the hypocentre and during a period 12–16 years after exposure. Patients exposed to therapeutic radiation also appear to be at increased risk.

Although there is a strong association of cigarette smoking with the development of Warthin tumour, a benign neoplasm, no such association has been shown for salivary carcinomas. Occupations associated with increased risk of development of salivary gland carcinomas in a small number of cases include asbestos mining, industries with significant use of rubber products and plumbing (Auclair *et al*., 1991). A strong association of lymphoepithelial carcinoma, a rare salivary gland malignancy, with Epstein–Barr virus has been shown. Hamilton-Dutoit *et al*. (1991) found EBV genomes in all 18 such tumours removed from Greenlandic and Alaskan Eskimos that they studied.

Gross/Histopathology/Preinvasive Lesions/Ultrastructure/ Immunohistochemistry

Most patients with a salivary gland tumour, whether benign or malignant, present with an asymptomatic mass and both pain and rapid growth occur in both benign and malignant tumours (**Figures 11 and 12; see colour plate section**). However, facial paralysis occurs in about 12% of carcinomas but rarely in benign tumours and, when present, tumour fixation or ulceration suggest malignancy.

Most salivary gland carcinomas arise *de novo* rather than from morphologically recognizable premalignant disease. The most notable exception is carcinoma that arises from mixed tumours (carcinoma ex mixed tumour). The incidence of malignant transformation in mixed tumours, which is the most common of all benign salivary gland tumours, increases with duration. The incidence in tumours present for 5 years or less is 1.6% compared with 9.6% for those present more than 15 years (Eneroth and Zetterberg, 1974). Microspectrophotometric analysis has shown a similar tetraploid fraction in benign mixed tumours of long duration and in carcinomas.

Salivary gland carcinomas demonstrate extremely diverse cellular and architectural features (**Figure 13; see colour plate section**). Unlike carcinomas at many sites, most do not demonstrate a significant degree of nuclear pleomorphism and, therefore, their recognition as malignant is based on their characteristic growth patterns. Histological grading is based on one of four methods. For most salivary gland carcinomas there is a single grade determined by classification. For instance, acinic cell adenocarcinoma or basal cell adenocarcinoma are low grade whereas salivary duct carcinoma or undifferentiated carcinoma are high grade. The other three methods are uniquely applied to individual tumours: adenocarcinoma, not otherwise specified, is graded on its cytomorphological features, adenoid cystic carcinoma on the predominant growth either as cribriform-tubular (intermediate grade) or solid (high grade), and mucoepidermoid carcinoma on specific criteria that include the presence or absence of growth characteristics and cytomorphological features (Auclair *et al*., 1992).

Immunohistochemical staining shows that in normal gland, intercalated, striated and excretory ductal epithelium react strongly with antibodies for keratin intermediate filaments, but acinar and myoepithelial cells react weakly or not at all. Myoepithelial cells are reactive with smooth muscle actin antibodies and variably with antiglial fibrillary acidic protein antibodies. Immunoreactivity for S-100 protein is seen in intercalated duct and myoepithelial cells in glandular tissue that is next to tumour or severe inflammation but otherwise variable. The usefulness of immunohistochemical studies in diagnostic surgical pathology of salivary gland tumours is very limited. It is helpful in demonstrating neuroendocrine differentiation in small cell undifferentiated carcinoma. It is also invaluable in the identification of benign and malignant mesenchymal tumours and metastatic tumours such as malignant melanoma that involve the parotid glands.

Molecular Genetic Findings

Far fewer cytogenetic and molecular genetic studies have been carried out on salivary gland tumours than on SCCs of the oral cavity and, of those, most have investigated genetic alterations in pleomorphic adenoma and adenocarcinoma. For various salivary gland tumours, the most common chromosomal abnormalities reported are 11q;19p translocations (Martins *et al*., 1997), rearrangement at 6p23, amplifications and other abnormalities of 8q12 (Voz *et al*., 1998) and LOH at 3p, 6q, 8p, 8q and 12q (Gillenwater *et al*., 1997). The genetic lesions at 8q12 are associated with overexpression of *PLAG1*, the pleomorphic adenoma proto-oncogene which appears to be an early event in tumorigenesis (Voz *et al*., 1998). Tumour-suppressor genes involved in salivary gland tumorigenesis include *TP53*, *CDKN2*/*INK4*/*p16*, and an unidentified locus on 6q (Pignataro *et al*., 1998; Quemao *et al*., 1998; Suzuki *et al*.,

1998). Other genes that appear to play a role in development of salivary gland neoplasms include *TNF-α*, *bcl-2*, *MDM2* and the oncogenes *MYC* and *CDK4* which reside at 8q and 12 q (Rao *et al*., 1998; Soini *et al*., 1998). At present there is no genetic progression model for any salivary gland neoplasm or for salivary gland tumours in general.

Prognostic Factors

Clinical stage of disease correlates well with patient outcome for major gland disease. Staging largely depends on the size of the primary tumour and presence or absence of local neoplastic extension (**Table 3**). Local extension is the

Table 3 Staging system for major salivary glands[a]

Primary Tumour (T)	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1*	Tumour 2 cm or less in greatest diameter without extraparenchymal extension
T2*	Tumour more than 2 cm but not more than 4 cm in greatest dimension without extraparenchymal extension
T3*	Tumour having extraparenchymal extension without seventh nerve involvement and/or more than 4 cm but not more than 6 cm in greatest dimension
T4	Tumour invades base of skull, seventh nerve, and/or exceeds 6 cm in greatest dimension
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
Distant metastasis (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

clinical or macroscopic evidence of invasion of skin, soft tissues, bone or nerve. Regional nodes are those within or immediately adjacent to the salivary gland and the deep cervical lymph nodes. There are no comparable staging criteria for intraoral minor gland tumours, but it has been shown that the criteria for intraoral squamous cell carcinoma can be applied successfully (Spiro *et al*., 1991).

The grade of the tumour also influences the prognosis. For instance, in two recent studies, 3.3% of patients with low-grade mucoepidermoid carcinomas died of disease compared with 46.3% of those with high-grade tumours (Auclair *et al*., 1991; Goode *et al*., 1998). Tumour site also appears to affect biological behaviour with tumours of the submandibular gland of the same type and grade having the worst prognosis.

Overview of Present Clinical Management

The principal therapy for salivary gland carcinomas is surgical and the best results correlate with complete initial tumour resection. Partial parotidectomy, usually removal of the lateral lobe, with preservation of the facial nerve, if possible, is indicated for low-grade carcinomas whereas total parotidectomy is performed for high-grade carcinomas and recurrent low-grade tumours. Total removal of the submandibular or sublingual gland is indicated for carcinomas in those sites. Low-grade carcinomas of the minor glands are removed by wide local excision whereas high-grade tumours are more radically excised. For tumours of the hard palate, bone is not removed for low-grade carcinomas except for those exceptional cases that erode or infiltrate the palatal bone. For tumours of all sites, prophylactic neck dissection is indicated for high-grade carcinomas and in any patient in whom clinically suspicious lymph nodes are discovered. Radiotherapy is used postoperatively for some high-grade tumours and for treating residual tumour when positive surgical margins are found. Neutron beam therapy has shown promise in controlling locoregional disease but needs further study (Spiro, 1998). Chemotherapy is often used for palliation of patients with recurrent, unresectable disease.

Chapter 36

Respiratory System

Phillip S. Hasleton
Wythenshawe Hospital, Manchester, UK

CONTENTS

- Normal Upper Respiratory Tract
- Upper Respiratory Tract Tumours
- Lung
- Lung Tumours

The upper and lower respiratory tracts are the site of many common primary and secondary tumours. This area is exposed to many noxious influences, some environmental and others occupational.

NORMAL UPPER RESPIRATORY TRACT

The nose warms, humidifies and filters air via hairs and conchae (turbinates) (**Figure 1**). These cause alterations in airflow, trapping particles larger than 6 μm in diameter in nasal mucus.

The nasal sinuses are collections of air cells called the frontal, sphenoidal, maxillary and ethmoid sinuses. The inner nasal cavity and sinuses, with their ostia in the lateral nasal walls, are lined by ciliated, pseudostratified columnar epithelium. A type of mucus cell called the goblet cell appears in the sinuses. Beneath the epithelium are seromucinous glands, which produce additional mucus, IgA and other immunoglobulins as defence mechanisms.

The epiglottis prevents aspiration of food and other materials into the respiratory tract. Because of the antigen load, in the nasopharynx there are large masses of lymphoid tissue – the adenoids, the palatine, tubal and lingual tonsils and aggregates of lymphoid tissue, which circle the pharyngeal wall (Waldeyer's ring). This forms part of a mucosa-associated lymphoid tissue (MALT), part of the immunological defence of the lung and gastrointestinal tract (**Figure 1**). With antigenic stimulation, especially in childhood, these areas enlarge. Any marked enlargement of the nasopharyngeal tonsil causes mouth breathing. This affects the efficiency of nasal function, impairing pulmonary function.

The larynx is divided into the supraglottis, glottis and subglottis (**Figure 2**). The larynx acts as a vibrator, via the vocal cords for speech. During normal breathing the cords are held wide open to allow air passage. With speech the folds close, so air causes vibrations. The intrinsic laryngeal muscles are innervated by the recurrent laryngeal branch of the vagus nerve. Lung cancer metastases may entrap the vagus, causing hoarseness.

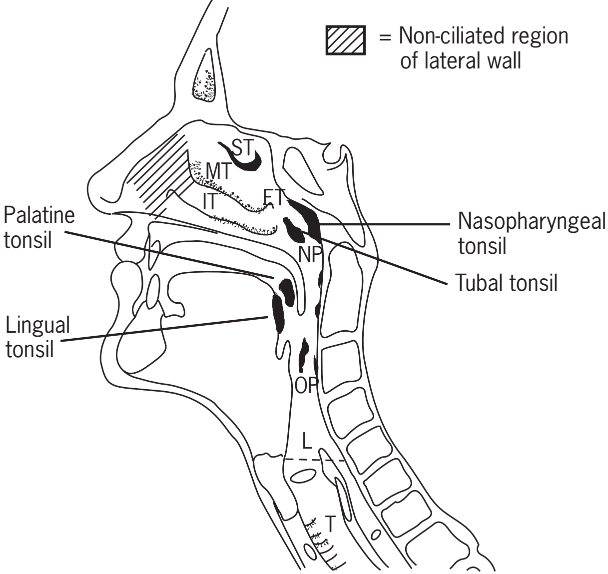

Figure 1 Diagram of nose, turbinates and larynx, showing relationships of the nasal cavity, nasopharynx (NP), oropharynx (OP), larynx (L) and distribution of lymphoid tissue (Waldeyer's ring). ST, MT and IT = superior, middle and inferior turbinates. ET = eustachian tube opening. Dotted line marks lower limit of the upper respiratory tract; below are the larynx (L), trachea (T) anteriorly and oesophagus (O) posteriorly. (Adapted from Jones, 1994.)

The epiglottis is lined by stratified squamous epithelium but in the lower half it gives way to a ciliated pseudostratified columnar type, characteristic of most of the larynx. The false cords enclose fibroadipose tissue, admixed with striated muscle and many seromucinous glands. The true cords are lined by stratified squamous epithelium and may contain some melanocytes along with elastic

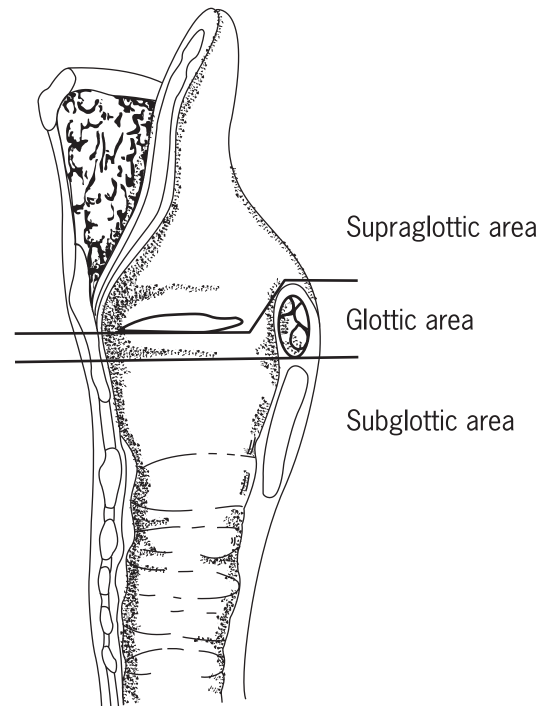

Figure 2 Division of the larynx into supraglottic, glottic and subglottic areas. [From Gregor, 1998, Jones, Phillips and Hilgers (eds.) *Diseases of the Head and Neck, Nose and Throat* (Arnold, London).]

tissue. The larynx is supported by a cartilaginous framework, connected by ligaments.

The trachea has a series of C-shaped cartilages extending into the bronchi, joined by fibroelastic membranes forming a hollow tube. Posteriorly lies the trachealis muscle. The midline cervical trachea lies anterior to the oesophagus. Subglottic tracheal lesions may cause oesophageal problems and vice versa. The isthmus of the thyroid is anterior to the second to fourth rings.

The trachea divides into the main bronchi. The right follows the general direction of the trachea, the left diverges at a greater angle. Thus aspiration is commoner in the right lung. The trachea and main bronchi are conducting airways. Bronchial cartilage is progressively decreased with distance from the trachea. The airways continue dividing into respiratory bronchioles, alveolar ducts and finally alveoli (**Figure 3; see colour plate section**). The terminal bronchiole is the smallest airway lined by bronchial epithelial cells.

The trachea and main bronchi have an inner lining of immunoglobulin and mucus for protection. Beneath is a lining ciliated, pseudostratified epithelium with a variable number of goblet cells attached to a basement membrane.

The cilia maintain the mucociliary escalator, causing upward passage of mucus and entrapped organisms or particulate matter to be expectorated. The ciliary shaft or cilium is a cytoplasmic extension from the surface of the cell. Just above the basement membrane are Feyrter cells [neuroendocrine (NE) cells], whose role in adults is unknown. They have clear cytoplasm and may occur as clusters, termed neuroepithelial bodies. NE cells contain dense core neurosecretory granules and secrete hormones. In the first 3 months of life, where there is relative hypoxia, they may act as chemoreceptors. These cells are the precursors of neuroendocrine tumours.

There is a surface, non-ciliated, bronchiolar secretory cell termed a Clara cell. These contain electron-dense membrane-bound inclusions and a few osmiophilic myelin bodies and produce surfactant apoprotein A.

In the subepithelial tissue there is collagen, elastin, nerves, lymphatics and small blood vessels. In addition there are serous and mucous glands (**Figure 4; see colour plate section**). The former produce lysozyme and if there is chronic cough they are converted to the mucous glands. The epithelium is regenerated by small pyramidal basal cells attached to the basement membrane.

Bronchus-associated lymphoid tissue (BALT) consists of subepithelial, mucosal, lymphoid follicles, containing both B and T lymphocytes. It develops at points of particle deposition, suggesting that it is stimulated as a response to inhaled particles. It is absent at birth and commoner in smokers.

The respiratory zone of the lung begins at the respiratory bronchiole and continues into alveolar ducts and alveoli. The alveolus is cup-shaped and thin-walled. Its cells can only be identified by electron microscopy. Up to 96% of the alveolar wall is covered by type I pneumocytes (**Figure 5; see colour plate section**). These are specialized cells, which cannot regenerate if damaged. The cytoplasm is thin to facilitate gas transfer between the alveolus and the pulmonary capillary. The edges of adjacent cells are bound by tight junctions, which restrict the movement of ions and water. These save the alveoli from flooding with water, as in pulmonary oedema.

Some 7% of the alveolar surface is covered with type II pneumocytes, which lie in the corners of alveolar walls. These cells form surfactant from their intracytoplasmic osmiophilic lamellar bodies. Surfactant is a phospholipid [dipalmitoylphosphatidylcholine (DPPC)]. This lowers the surface tension in the alveoli at the air/water interface. It acts similarly to a patch of oil on a road surface, repelling water. Any oedema can therefore be converted into droplets and they are removed by the pulmonary lymphatics.

The interstitial space is the part of the septal wall, which lies between the alveolar epithelial and capillary endothelial basement membrane. Normally it is inconspicuous but is distended in any form of alveolar damage. It contains macrophages, myofibroblasts, mast cells and occasional collagen and elastic fibres. Any thickening of this space causes alveolar diffusion problems. The interstitial connective tissue forms a continuous sheet with that surrounding blood vessels and bronchioles. This is efficient for removing fluid from alveoli into pulmonary lymphatics.

Pulmonary lymphatics aid the spread of infection and tumours. These are present around pulmonary blood

vessels at an alveolar level and in the pleura. These drain directly into the mediastinal nodes, in the upper lobes especially. The lymphatics can be traced to the respiratory bronchioles and continue around small bronchi and bronchioles forming a plexus outside muscle. If the lymphatics are distended, Kerley B lines are formed on chest radiographs.

UPPER RESPIRATORY TRACT TUMOURS

These tumours are well documented in the book *Tumours of the Upper Aerodigestive Tract* (Mills *et al*., 2000).

Tumours of the Nasopharynx

Clinical Features

Most nasal tumours cause nasal obstruction, occasionally epistaxis and facial pain, irrespective of their histology.

Squamous Papillomas

These are benign exophytic tumours with no association with human papillomavirus (HPV) and are seen in the oropharynx, larynx and trachea. They are covered by a bland, stratified, keratinizing squamous epithelium lining a fibrovascular core.

Schneiderian Papillomas

The ciliated columnar epithelium lining most of the nasal and paranasal cavity is called the Schneiderian membrane. The commonest tumour arising from this epithelium is the inverted Schneiderian papilloma, seen most commonly on the lateral nasal wall in the paranasal sinuses. They present as nasal polyps growing through the lateral wall within the maxillary or ethmoid sinuses. The nests of epithelium grow down into the underlying stroma with dilated ductal structures lined by multiple layers of epithelium. The epithelium may be squamous, ciliated, columnar or transitional and is often thick, being sometimes over 20 layers or more (**Figure 6; see colour plate section**). Mitoses are usually confined to the lower epithelial levels but nuclear pleomorphism may be identified. They may co-exist with a squamous cell carcinoma and any papillomas should be thoroughly sampled for evidence of carcinoma. These tumours have a recurrence rate of up to 75% when treated by local excision.

Fungiform Schneiderian papillomas are not associated with malignancy and arise predominantly from the nasal septum as polypoid tumours. The epithelium is similar to that of the inverted tumour but there are admixed mucous cells and little nuclear pleomorphism. Unlike papillary squamous cell carcinoma, there is no mitotic activity or dyskeratosis. They have a low recurrence rate.

Squamous Cell Carcinoma

These are relatively rare in the nasopharyngeal region. The distribution is maxillary antrum 58%, nasal cavity 30%, ethmoid sinuses 10% and frontal and ethmoid sinuses 1% each (Lewis and Castro, 1972). They are commonest on the lateral nasal wall. Tumours in the maxillary antrum may be misdiagnosed as chronic sinusitis, delaying treatment. Sinonasal squamous carcinomas occur predominantly in males, often in their 60s.

There is an association with cigarette smoking, nickel mining and refining and chromium exposure and, more recently, formaldehyde has been suggested as a carcinogen. HPV types 16 and 18 DNA have been found in 14% of sinonasal squamous cell carcinomas but the high sensitivity of polymerase chain reaction (PCR) suggests that contamination cannot be totally excluded (Furuta *et al*., 1992).

The tumours are typically papillary, polypoid and are usually moderately or well differentiated squamous cell carcinomas. Nasal lesions spread to the submental and submandibular nodes and they enter the facial and superficial parotid deep cervical nodes. Spread of paranasal sinus carcinoma to regional nodes is uncommon when the tumour is confined to the sinus cavity.

Sinonasal Carcinoma

This is strongly associated with hardwood dust exposure but additional 'risk' occupations are logging, milling, exposure to leather dust and softwood dusts (Cecchi *et al*., 1980). Most of these tumours occur in men, with origins in descending order of frequency in the ethmoid sinuses, nasal cavity, maxillary antrum and indeterminate. They present with the usual symptoms, as well as rhinorrhea or a mass in the cheek. The tumours mimic ulcerated or haemorrhagic inflammatory nasal polyps.

There is malignant, small and large intestinal type mucosa along with Paneth, goblet and argentaffin cells. These tumours do not usually express carcinoembryonic antigen (CEA), unlike metastatic small or large bowel carcinomas. Sinonasal adenocarcinomas are usually chromogranin-positive, which is less common in colonic carcinomas.

The optimum treatment is surgical resection with radiation therapy to the region of the tumour. Grade and subtype correlate with survival. The better prognosis is with the papillary subtype as opposed to sessile or alveolar mucoid variants (Batsakis *et al*., 1963). Woodworkers also appear to have a better survival than patients who present without this risk factor.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma arises near the fossa of Rosenmuller (the internal opening of the middle ear canal) causes middle ear obstruction and involves the cervical nodes. These tumours are classified into keratinizing squamous cell

carcinoma, nonkeratinizing carcinoma and undifferentiated carcinoma. These tumours affect a broad age range, including children. There is a distinct bimodal age distribution with peaks in the second and sixth decades of life.

Cigarette smoking may play a part in lymphoepithelial carcinoma but this cell type is especially predominant in Chinese patients, even when they emigrate to other countries. It is associated with Epstein–Barr virus (EBV). In Hong Kong it accounts for 18% of all malignancies compared with 2% in the United States (Digby *et al.*, 1941). Chinese patients in Singapore with lymphoepithelial carcinoma have an increased frequency of histocompatibility antigens HLA-A2 and HLA-BW46 (Simons *et al.*, 1976).

Clinically the nasopharynx may be normal, full or show surface granularity. An obvious carcinoma is uncommon. It is usually a poorly differentiated squamous cell carcinoma often with a marked inflammatory component, including lymphocytes, plasma cells and eosinophils (lymphoepithelioma) (**Figure 7; see colour plate section**). They may be confused with a lymphoma because of the prominent inflammation. Mitoses are typically numerous, ranging from 5 to 10 per 10 high power fields. The tumour cells have a syncytial growth pattern or form cohesive nests and cords. They tend to metastasize to regional nodes, where they may be first detected. Distant metastases to lung, brain, liver and bone are common. Lymphoepitheliomas are usually treated by radiation.

Other variants of squamous carcinoma are adenoid, angiosarcoma-like, papillary, spindle cell, basaloid and adenosquamous.

Squamous carcinoma also occurs in the oropharynx and hypopharynx. In both of these sites surgery is the mainstay of treatment followed by radiation.

Neural Tumours

Nasal glioma is a heterotopia due to failure of the developing frontal lobe to retract completely via the foramen caecum. They are therefore encephaloceles, not true tumours. Ectopic pituitary tissue may be seen in the same area and present as a pituitary adenoma.

Nasopharyngeal neurofibromas, neuromas and neurilemmomas are similar to those seen in other areas of the body.

Melanotic neuroectodermal tumour of infancy (MNTI) occurs in infants under the age of 1 year; 70% are seen in the anterior maxillary area. These are lobular, well-circumscribed, unencapsulated tumours, measuring up to 13 cm in diameter. They are grey/white to dark brown with nests of small neuroblastic cells, often surrounded by larger melanin-containing cells with an alveolar or tubular pattern. Nuclear pleomorphism, mitoses and necrosis are uncommon.

Paraganglioma (carotid body tumour) can be seen in the nasal cavity, paranasal sinuses, nasopharynx and larynx. They are no different from extra-adrenal paraganglial tumours of the autonomic nervous system in other parts of the body.

Olfactory Neuroblastoma

There are no known risk factors for this tumour, which has a bimodal distribution, at the ages of 15 and 55 years. In addition to the usual symptoms, headaches, visual disturbances and anosmia may also occur. The ethmoid sinus is often involved. Radiologically the tumour has a 'dumbbell' appearance extending across the cribriform plate (**Figure 8; see colour plate section**).

They are polypoid, vascular, red/tan masses set high in the nasal cavity. The tumour may have circumscribed nests of cells, which are small with round nuclei and little cytoplasm or grow as diffuse sheets of neoplastic cells set in a background of capillaries and little intervening stroma. There is a fibrillary cytoplasmic background in haematoxylin and eosin-stained sections. Necrosis is a poor prognostic indicator.

Most of these tumours stain positively for synaptophysin. Treatment is by surgical excision with adjuvant radiotherapy or chemotherapy.

Undifferentiated Sinonasal Carcinoma

This is rare but is seen in both young adults and the elderly. Typically it presents as a large fungating mass obstructing the nasal cavity and invading surrounding structures. There are nests, sheets, ribbons and trabeculae of polygonal cells, often with an organoid appearance. Mitoses are prominent and there is extensive vascular permeation. This tumour must be differentiated from a lymphoepithelioma.

Primary Small Cell Carcinoma

This is similar to that seen in the lung and may arise rarely in the sinonasal region. Malignant melanoma is rarely seen as a primary tumour developing in the nasal cavity or the paranasal sinuses.

Lymphoid Tumours

Non-Hodgkin Lymphoma (NHL)

Up to 10% of NHL may involve Waldeyer's ring (adenoids, oropharynx, tonsilar and lymphoid tissue at the base of the tongue). After gastrointestinal lymphomas, it is the commonest extranodal lymphoid tumour. Most involve the tonsil but 35% involve the nasopharynx. It is often difficult to determine if a lymphoma is strictly confined to the nose or paranasal sinuses. There is often involvement of multiple sinuses. They are usually localized, affecting a wide age span from the first to the tenth decades.

The tumours are greyish/white, firm and up to 10 cm in diameter. Under the REAL classification 85% are B cell lymphomas, half of which are diffuse large cell

lymphomas (**Figure 9; see colour plate section**). There is a diffuse proliferation of large cells with immunoblastic features or diffuse mixed and large cells. Mantle cell and low-grade lymphomas also occur in Waldeyer's ring. A subset of nasopharyngeal lymphomas are of T/NK phenotype, especially in the Far East. These are probably human T cell leukaemia/lymphoma-virus induced, while others are more closely related to sinonasal T/NK cell lymphoma (Tomita *et al.*, 1996).

Radiation is the treatment of choice and chemotherapy is added for locally advanced or disseminated tumours. (See also chapter *RNA Viruses*.)

Sinonasal T/NK Cell Lymphoma

Virtually no B cells are seen in normal nasal epithelium but there are T cells. T helper cells outnumber the T cytotoxic/suppressor cells. T/NK cell lymphoma used to be termed midline malignant reticulosis, lethal midline granuloma and midfacial destructive lesion, amongst others. These terms are now no longer used. T/NK lymphoma is an angiocentric, immunoproliferative lesion. It is commoner in Asians. The disease can occur at any age with a median of 47 years with a male predominance (Aozasa *et al*., 1995).

The patients present with mid-facial destruction, involving the nasal cavity, paranasal sinuses and in some cases the palate and other mid-facial structures. It may extend to involve the larynx. There is sometimes collapse of the nasal bridge, ulceration, necrosis, septal perforation, fever and weight loss. The tumour often spreads to other extranodal sites, such as skin, subcutaneous tissue, gastrointestinal tract and testis.

Histologically there is extensive necrosis, which may involve the cartilage and bone. Small lymphocytes, plasma cells, immunoblasts and some cytologically atypical lymphocytes, as well as polymorphs, eosinophils and histiocytes are seen. There is much angioinvasion, causing thrombosis. Mitoses are frequent. T/NK lymphoma is typically reactive for CD2, a T cell marker, and CD 56, a marker of NK cells. However, clonal T cell receptor gene rearrangements are absent in this lymphoma.

Other Lymphomas of the Sinonasal Tract

These include extramedullary plasmacytoma, post-transplant lymphoproliferative disorder (PTLD) and rare cases of Hodgkin's disease. The histology of these tumours does not differ from those elsewhere in the body.

Vascular Tumours

Haemangioma is a hamartoma. They are common in the nose.

Nasopharyngeal Angiofibroma

This usually arises in the posterior nasal cavity and nasopharyngeal wall. It is seen almost exclusively in male adolescents. The tumours have testosterone receptors (Gown *et al*., 1993). Their vascularity can be reduced by oestrogen therapy. The mean age of the patients is 15 years and the presenting symptoms are those of any other nasal lesion. They are firm, sessile or polypoid tumours with a fleshy appearance. There is a fibrous stroma containing many vessels of varying sizes. Some are thick-walled with an obvious media (**Figure 10; see colour plate section**). The stroma consists of characteristic spindled and stellate shaped mesenchymal cells and haphazardly arranged collagen. Mitoses are rare. The deeper portions of an angiofibroma away from the central feeding vessels may be hypovascular. Angiofibromas lack the lobular arrangement of a capillary haemangioma. Treatment is by surgical excision but recurrence is common.

Glomus tumours, although rare, may occur in the nose.

Other Tumours

These include fibroma, solitary fibrous tumour, aggresive fibromatosis, osteoma, osteosarcoma, often involving the maxilla, teratoma involving the nasopharynx and metastatic tumours especially from breast, kidney and lung.

Other soft tissue tumours to involve the nasopharyngeal area are leiomyoma, chondroma, chondrosarcoma, rhabdomyosarcoma (nose) and leiomyosarcoma (nose).

Larynx

Squamous papillomas may arise from the true cords, at other sites in the larynx, the oropharynx and the trachea. They may be part of juvenile laryngeal papillomatosis, which may be single or multiple. 'Juvenile' is arbitrarily classified as presenting before the age of 20 years. Multiple is usually defined as more than three lesions.

Most laryngeal papillomas are probably caused by HPV, types 6 and 11 (Travis *et al.*, 1999). These tumours are glistening, nodular, exophytic masses and, depending on their site and size, cause hoarseness, stridor or respiratory distress. A rare complication is squamous cell carcinoma, which may develop in the larynx or lung.

Histologically there are multiple layers of orderly squamous epithelium with no atypia, covering a fibrovascular core. A few cases may show varying degrees of dysplasia. Prominent surface keratin or intraepithelial dyskeratosis suggests verucca vulgaris or veruccous carcinoma. Squamous carcinomas usually arise in the juvenile lesions. Treatment is by surgery but recurrence is frequent. Solitary adult and juvenile papillomas are often cured by surgery.

Keratosis and Dysplasia

Keratosis is an epithelial area with a marked degree of orthokeratosis or parakeratosis unassociated with underlying epithelial proliferation (AFIP). Typically keratosis is due to long-term tobacco abuse and affects the vocal cords. The mucosa is thickened and white. 'Leucoplakia' is a

clinical term meaning 'white plaque' and not a pathological description. Keratotic epithelium usually separates from the vocal cords. This is helpful diagnostically since an intact basal layer helps exclude invasive carcinoma.

Non-dysplastic keratosis shows a normal or increased thickness of squamous epithelium with a prominent granular layer and overlying layers of orthokeratin admixed with parakeratosis. Maturation is orderly and mitoses are basal. If there is no dysplasia there appears to be only a minimal risk of developing a subsequent carcinoma.

Dysplasia is graded into mild, moderate and severe and has similarities to the system used in the cervix except that keratinization is more common in the larynx. Mild dysplasia involves the basal layer, moderate extends upwards to involve usually two-thirds but does not involve the superficial epithelium. Severe dysplasia shows increased mitoses and involves the full thickness of the epithelium. The more severe the dysplasia, the greater is the chance of an invasive carcinoma co-existing or developing in the larynx. Involvement of the underlying seromucinous glands by dysplastic epithelium is not considered to be evidence of invasion.

Invasive Squamous Cell Carcinoma

Squamous carcinoma of the larynx is associated with cigarette smoking and excess alcohol intake. 'Social' use of alcohol does not appear to cause an increased risk. There is no association between asbestos exposure and carcinoma of this site. Carcinoma of the larynx is divided into supraglottic, glottic and subglottic types. This division has relevance for surgical management. Transglottic carcinoma is a term applied to carcinomas bridging the laryngeal ventricle and involving both the vocal cord and supraglottic regions. Most are glottic carcinomas extending into the supraglottis.

Most carcinomas of the larynx are glottic, arising anteriorly on the mobile part of the cord. They cause hoarseness. The majority of the remaining laryngeal carcinomas are supraglottic and arise from the epiglottis, ventricles, false cords and aryepiglottic folds. These give rise to changes in voice quality and may cause difficulty in swallowing or the feeling of a mass in the throat. Subglottic carcinomas account for 5% or less of all laryngeal carcinomas.

The tumours are usually ulcerated and vary in size from small lesions to large masses, which may almost obstruct the laryngeal lumen (**Figure 11; see colour plate section**). There are varieties of squamous cell carcinoma, including spindle cell. Since the true cords have a limited lymphatic supply, tumours at this site have a good prognosis. Thus they are often cured by radiation or limited surgical resection. With an increase in size the cords become fixed and the tumour may extend outside the larynx, involving nodes. Subglottic carcinomas are often circumferential and extend beyond the larynx, penetrating the cricothyroid membrane. These cases are likely to involve cervical nodes.

Early carcinomas are usually cured with limited surgery or radiation but laryngectomy is one of the treatments for larger tumours. Recently chemotherapy has been shown to play a role. The size of the tumour and degree of differentiation are important factors in determining prognosis. Patients with laryngeal carcinoma have an increased risk of developing another tumour, especially in the lung or elsewhere in the head or neck.

Genetic Changes in Laryngeal Carcinoma

P53 status over-expression does not result in cell cycle arrest in some studies, although a correlation with this oncogene and early stage glottic cancer as well as those tumours recurring locally has been described (Narayana *et al*., 1998). It may also relate to decreased survival (Bradford *et al*., 1997). C-erbB-2 plays no part in prognosis in this tumour (Krecicki *et al*., 1999). Retinoblastoma protein, however, does relate to survival (Dokiya *et al*., 1998). Cyclin D1 overexpression identified patients with poor grade laryngeal carcinoma, tumour extension, lymph node involvement and poor histological differentiation (Bellacosa *et al*., 1996).

Adenosquamous Carcinoma

This may affect the larynx. These are usually high-grade tumours, similar to adenosquamous carcinoma in the lung. Adenocarcinoma is very rare in the larynx and the possibility of a secondary tumour should be considered.

Neural Laryngeal Tumours

Neurilemmomas, neurofibromas, granular cell tumour, paraganglioma, malignant melanoma and carcinoid tumour [this includes all neuroendocrine carcinomas (see the section on the lung) can all be identified in the larynx. These tumours are histologically identical with the pulmonary lesions described below.

Lymphoma

Localized laryngeal non-Hodgkin lymphoma is rare. Extramedullary plasmacytoma has been well described in the larynx, where it causes a subepithelial tumour.

Haemangiomas may arise in the larynx. In infants they present with respiratory distress and affect the subglottic region. Adult haemangiomas are commoner and usually affect the supraglottic and glottic areas. They may cause cough and haemoptysis, as well as hoarseness. Inflammatory myofibroblastic tumour may involve the larynx and in some cases it is caused by *Mycobacterium avium intracellulari*, often in HIV-positive or immunosuppressed patients. The commonest site is on the vocal cords, where they cause hoarseness and stridor.

Carcinomas may metastasize to the larynx, the commonest tumour is melanoma followed by breast, kidney, lung, prostate and gastrointestinal tract carcinomas. Soft tissue laryngeal tumours include liposarcoma, chondrosarcoma and rarely rhabdomyosarcoma, leiomyosarcoma and malignant fibrous histiocytoma.

Trachea

The trachea is rarely involved by tumours, the commonest being polyposis and adenoid cystic carcinoma but any of the neoplasms mentioned below may affect this area.

LUNG

Cigarette Smoking

This is one of the major causes of mortality and morbidity in the Western world. As some of the tobacco sales decline in this area, the producers are ensuring that Third-world countries are targetted.

Cigarette smoke yields more than 4000 constituents. These include carbon monoxide, hydrogen cyanide, aldehydes, cadmium, ammonia, nicotine and benz[*a*]anthracene, a potent carcinogen. In addition, there are aromatic hydrocarbons and other toxic substances, which may be tumour initiators, such as benzanthracenes and benzopyrenes. There are suspended water droplets, which vary in size and have central resinous cores. These smoke droplets are absorbed on bronchial walls and propelled on the mucociliary escalator back to the mouth; 98% of smoke particles landing in the bronchi are removed by cilia within 24 h. Smaller particles enter alveoli and, if undissolved, are ingested by macrophages and removed to lymphatics.

Nicotine makes cigarettes addictive. The faster a cigarette is smoked, the more nicotine is present in the mainstream smoke; 85% is absorbed in the lungs and it causes an increase in heart rate, blood pressure and cardiac output.

Cigarette smoking may be active or passive. The latter occurs in smokers and nonsmokers, in the same environment as a smoker. Passive smoking increases the risk of lung cancer by 26% and of ischaemic heart disease by 23%. In addition, passive smoking is linked with an increased incidence of asthma and chest infections in children.

This habit affects virtually every organ system, ranging from adenolymphoma of the parotid to peripheral vascular disease. (See the chapter *Tobacco Use and Cancer*.)

LUNG TUMOURS

These may be primary or secondary, benign or malignant. Because the lung receives the entire cardiac output, tumour metastases are common.

Classification of Lung Tumours

There has been an increase in new pulmonary lesions described in the last 18 years (Travis *et al*., 1999). In addition to bronchial squamous dysplasia, the concept of atypical alveolar hyperplasia, as a precursor for adenocarcinoma of lung, is becoming well established. It is impossible in a chapter such as this to give a comprehensive description of all lung tumours and the reader is referred to specialist texts (Hasleton, 1996).

Benign Lung Tumours

These may be central or peripheral. Central indicates they involve main bronchi and peripheral, the lung parenchyma. The site of the neoplasm determines signs and symptoms. Central tumours cause collapse of a lobe or lung, with recurrent infections leading to bronchiectasis. All central lung tumours present with similar symptoms, i.e. cough, recurrent chest infections and haemoptysis, due to ulceration of the surface of the tumour.

Peripheral lung tumours are often detected as a chance radiological finding, known as 'a solitary pulmonary nodule.' As a rough guide, 40% of solitary nodules are malignant and 60% are benign. The benign lesions may well be inflammatory or non-neoplastic rather than benign tumours. For any individual patient these figures are meaningless and do not help with diagnosis. By convention a nodule is 4–6 cm in diameter; a larger lesion is termed a mass, often suggesting malignancy. The treatment options for a solitary nodule are outside the scope of this book but with computed tomography (CT) scans and fine-needle biopsy, some of the diagnostic responsibility rests with the histopathologist.

Radiologically benign lesions tend to have a smooth circumscribed periphery; malignant ones are larger with irregular margins. A calcified nodule can be followed up and is considered benign. If a nodule has been radiologically stable in size for 2 years and the patient is below 35 years of age, it is malignant in only 1–5% of cases. The widespread policy in remaining solitary nodules of unknown aetiology is resection.

It is unnecessary for anyone to memorize every benign lung tumour. If one remembers the normal bronchial wall components, i.e. epithelium, neuroendocrine cells, connective tissue, muscle, cartilage, fat and nerves, and the fact that the mucous and serous glands of the bronchial wall act as a minor salivary gland, the nature of the majority of benign tumours can be predicted. Only the important or commoner ones will be considered here.

Hamartoma

These tumours develop in adults and have an abnormal karyotype. The most characteristic aberration is a 6p21 rearrangement but a 12q14–15 rearrangement has also been identified. These molecular abnormalities indicate these 'hamartomas' are true neoplasms and a better term is 'mesenchymoma.' This tumour is twice as common in smokers and is associated with bronchial carcinoma. They are often peripheral and range from 1 to 4 cm in diameter. The cut surface is grey (**Figure 12; see colour**

plate section) but if fat is prominent it is yellow. If the tumour is central, there is distal bronchiectasis. They consist of cartilage, bone, fat, loose myxoid tissue and islands of ciliated or columnar epithelium.

Papilloma of the Bronchus

Papillomas are classified into solitary or multiple. The solitary lesions are rare, presenting in middle-aged smokers as a central tumour. It grows as a wart-like lesion into the bronchial lumen and consists of nonkeratinizing squamous epithelium. Papillomatosis is seen in children. HPV (human papillomavirus) types 6 and 11 can be identified in both solitary and multiple tumours. One-third show carcinoma *in situ* or invasive carcinoma and thus papillomas require at a minimum close follow-up.

Glandular and mixed squamous and glandular papillomas are solitary, benign central tumours.

Neuroendocrine Tumours

There are no real premalignant neuroendocrine lesions. DIPNECH (diffuse idiopathic pulmonary neuroendocrine hyperplasia) has been placed in the preinvasive section of the new WHO classification. The author has seen very rare cases, associated with tumourlets and typical carcinoids. However, DIPNECH is a nonspecific reaction to airway inflammation and/or fibrosis. There is neuroendocrine (NE) cell hyperplasia in association with peripheral carcinoid tumours. However, adjacent to central typical carcinoids there is a decrease in NE cells. No *in situ* lesion has been found in association with small cell carcinoma, although dysplastic squamous epithelium may lie over the tumour.

A tumourlet is defined by the WHO as 'a microscopic, peribronchiolar, nodular aggregate of uniform, round to oval or spindle-shaped cells with moderate amounts of cytoplasm and morphology similar to the cells of carcinoid tumours.' An arbitrary size of 0.5 cm or less is given for these lesions; larger tumours are termed bronchial carcinoids. Tumourlets usually occur with focal pulmonary fibrosis and bronchiectasis but not diffuse interstitial pulmonary fibrosis. They are found incidentally. They may be mistaken for small-cell carcinoma but lack this tumour's cytological features and have no mitoses.

Bronchopulmonary Carcinoid Tumours

As shown in **Figure 13** there is a spectrum of biological behaviour in these tumours, ranging from the 'benign' bronchopulmonary carcinoid to small-cell lung carcinoma (SCLC). The latter neoplasm accounts for 15–25% of all lung malignancies. This figure does not imply there is any transition from one tumour type to another. Typical carcinoid (TC), atypical carcinoid (AC) tumours and large-cell neuroendocrine carcinomas (LCNEC) are rare, together accounting for 2–3% of lung tumours. Nearly all patients with AC, SCLC and LCNEC are cigarette smokers. While TC and AC are morpologically similar to neuroendocrine tumours elsewhere in the body they do not always behave in a similar fashion. For example, the carcinoid syndrome is relatively rare in bronchial carcinoids but commoner with hepatic metastases from ileal tumours. Bone production is rare in gastrointestinal carcinoids but commoner in bronchial tumours.

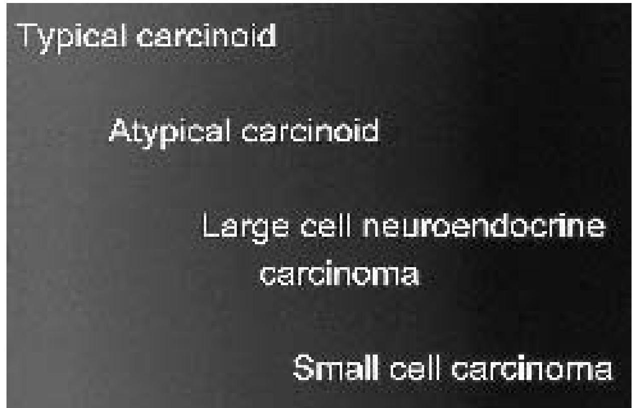

Figure 13 Diagram of neuroendocrine tumours of the lung, excluding non-small cell carcinomas with neuroendocrine features. This diagram does not imply that there is any biological transition from typical carcinoid into atypical carcinoid, etc. It merely depicts the increasing malignancy of these tumours with large-cell neuroendocrine tumours and small cell neuroendocrine carcinoma being the most malignant of the neoplasms.

TC may be central or peripheral. Central tumours give the signs and symptoms mentioned above but nearly 20% of cases may be asymptomatic. Endocrine manifestations are rare but hormones and peptides, including calcitonin, bombesin and cytokines are easily detectable immunohistochemically. This paradox may be due to the small tumour volume and the efficiency of endothelial cells in detoxicating such products. The tumours cause haemorrhage, due to the presence of many small blood vessels. These vessels are caused by TGF (transforming growth factor)-α formation by the tumour. Macroscopically they are yellow/white (**Figure 14; see colour plate section**) with foci of haemorrhage. Up to 30% of tumours contain bone, due to elaboration of osteogenic cytokines, including TGF-β and IGF-1.

TC has trabecular, insular or acinar growth patterns (**Figure 15; see colour plate section**). Other histological patterns have been documented. There should be fewer than two mitoses/2 mm^2/10 high-power fields (hpf) and no necrosis. These tumours may show cytological atypia, especially on frozen section (Sheppard, 1997), increased cellularity and lymphatic invasion. If there are tumour deposits in lymph nodes, the lesion may still be

classed as typical if the histology is as described above. Special stains are not always necessary to confirm the diagnosis, since the histological pattern may be distinctive. Ultrastructurally they contain dense core neurosecretory granules, typical of NE cells.

AC may be central or peripheral, have the NE architecture as described above, and a mitotic rate of 2–10/ 2 mm^2/10 hpf and/or punctate necrosis.

LCNEC are usually peripheral, tan tumours with focal necrosis and haemorrhage. Histologically there is a neuroendocrine appearance, with large cells, irregular pleomorphic nuclei and low nuclear/cytoplasmic ratios. The cytoplasm is abundant, granular and eosinophilic. Necrosis is usually geographic and mitoses are frequent, with a mean of 75 per 2 mm^2 per 10 hpf. Prognosis is poor.

SCLC ('oat cell carcinoma') is described with malignant tumours.

Bax, *bcl-2* and *p53* in Neuroendocrine Tumours

The *bax* gene is one of the main effectors of apoptosis and can be considered a tumour suppressor gene. *Bcl-2* is an oncogene and can block both p53-mediated and p53-independent apoptosis. There is an inverse correlation between the scores of *Bax* and *bcl-2* expression in NE tumours. A predominant *Bax* expression is seen in low-grade NE tumours (TC or AC) and mainly *bcl-2* expression in small-cell and large-cell lung cancers. The p16-retinoblastoma pathway is normal in typical carcinoids but abnormal in the higher-grade NE tumours. (Dosaka-Akita *et al*., 2000) P53 mutation or stabilization is absent in TC. AC may show focal (less than 10%) or patchy P53 positivity, are more aggressive and have significantly shorter survival times than those without P53 staining (Brambilla and Brambilla, 1999).

Carcinoma of Lung

Epidemiology

The lung is the commonest site of cancer worldwide and is in first place in all areas of Europe and North America. Lung cancer appears to be rising in incidence by 70% in women and 30% in men (Travis *et al*., 1995). In the USA the largest percentage increases in age-adjusted rates are for small-cell carcinoma and adenocarcinoma (60% each) with a smaller change for the latter tumour (14%). In the EEC, lung cancer accounts for 21% of all cancer deaths in men and the corresponding figure for women is 4%. This latter figure is increasing and worldwide lung cancer is the fifth most frequent cancer in women. This is due to the social acceptability of smoking, the targetting of women in tobacco advertisements and appetite suppression caused by cigarettes. A decline in incidence in all cell types is predicted soon in the USA. The rate in the West will probably continue to decrease balanced by an increase the Third-world countries, now targetted by tobacco companies. This proposed decrease does not take into account any drug habits of teenagers.

Tobacco is associated with most of the major histological types of lung cancer. The increase in lung cancer risk according to the number of cigarettes smoked appears stronger for squamous and small cell carcinomas than for adenocarcinoma. The increase in this latter cell type has yet to be explained. In the USA there has been a decline in tar and nicotine levels due to filter-tipped cigarettes. There has been a progressive introduction of specially processed tobacco and perforated cigarette paper. These changes may have altered the types of carcinogens in the cigarette smoke, affecting the histological type.

Aetiology

Cigarette Smoking

Cigarette smoking (see earlier) is the most important cause of lung cancer. With an increase in sales of cigarettes at the beginning of the 1900s, changes were made in the types of tobacco used. The smoke was milder and thus easier to inhale. pH was adjusted so that absorption did not occur across the oral mucosa. Subjects had to inhale smoke into the lung to absorb substantial amounts of nicotine. This deep inhalation and absorption of the tobacco's toxic and carcinogenic substances enhanced the lung cancer risk. The evidence linking cigarette smoking with lung cancer started to accumulate in the 1930s. Four retrospective studies showing the relationship between lung cancer and smoking were published in the 1950s, each showing a consistent statistically significant association. Relative risk increases in a stepwise fashion with the increased number of cigarettes smoked. The age at which the subject begins to smoke is also critical.

Other types of tobacco inhalation, ranging from pipes and cigars in the West to bidis in Asia, also correlate with a significant risk for lung cancer.

Involuntary (Passive) Smoking

This is a combination of sidestream smoke, emitted into the air from a burning cigarette between puffs and some of the mainstream smoke, exhaled by the smoker. The potential carcinogenicity of passive smoking was highlighted by the increased risk of lung cancer in nonsmoking women married to smokers. It is now estimated that in the USA at about 2000 deaths per year are due to passive smoking.

Genetic Predisposition

Some 85–90% of smokers who are consuming 20 or more cigarettes a day will not develop lung cancer. Therefore, host factors must be important in altering the risk/predisposition to the development of this disease. There is

mounting evidence that some of the genetic changes predisposing to lung cancer are inherited in a mendelian character. First-degree relatives of lung cancer relatives have a 2.4-fold increased risk of lung cancer or other nonsmoking-related cancers. Patients treated for lung/laryngeal cancer have an increased risk of developing second lung tumours. More tangible evidence of linkage between hereditary and lung cancer has been shown in relatives of patients with retinoblastoma, with a 15-fold risk of lung cancer developing in carriers. Lung cancer is seen in some families with Li–Fraumeni syndrome. This is an inherited cancer-prone condition, due to mutation of the *p53* tumour-suppressor gene. Both the *RB* and the *p53* gene are mutated or inactivated in most small-cell and non-small-cell lung cancers.

Occupation

This is a complex subject since employees may be exposed to more than one potentially carcinogenic substance. The proportion of lung cancer attributable to a given occupational exposure has been estimated at 10–15%. Tobacco smoke acts as a strong confounder in the association.

A prime example of industrially induced cancer is asbestos. Cigarette smoke and asbestos have a multiplicative effect in increasing the incidence of lung cancer.

Metals and Gases

Arsenic and its compounds, chromates, nickel, beryllium and cadmium are associated with an excess of lung cancer deaths.

Hydrocarbons, derived from coal or petroleum and polycyclic aromatic hydrocarbons, such as dibenzanthracene and benzo[*a*]pyrene, are known carcinogens. Exposure to hydrocarbons with increased lung cancer risk is seen in coke oven workers, gas-house workers and aluminum workers, exposed to pitch volatiles (tar). Car and bus exhausts also contain hydrocarbons and truck and bus drivers have an increased risk of lung carcinoma.

Radiation

The increased risk of lung cancer in radiation was first shown in Schneeberg due to radon gas in the mines. Radon is a decay product of naturally occurring uranium. An increased risk of lung cancer is seen in uranium miners in Colorado and fluorspar miners in Newfoundland.

Pulmonary Fibrosis

An increased incidence of lung cancer complicates interstitial pulmonary fibrosis or other significant causes of pulmonary fibrosis and COPD. However, the earlier concept of pulmonary scar cancer is no longer regarded as valid since it has been shown that the fibrosis is a reaction to the tumour and not the cause. The increase in type III collagen in lung cancer is a host response (Madri and Carter, 1984).

Viruses and Cancer

The role of Herpes virus in the causation of papillomatosis has already been mentioned. Human immunodeficiency virus (HIV) infection is only seen as a cause of lung cancer in young individuals with a history of heavy tobacco smoking as well as a moderately advanced immunodeficiency status (Tirelli *et al*., 2000). These patients were considerably younger than most patients with carcinoma at this location. Lymphoepithelioma-like carcinoma of lung is EBV-related in Asian patients, but not usually in Caucasians. This tumour is not usually related to cigarette smoking.

Chromosomal Changes in Lung Cancer

SCLC shows deletions on the short arm of chromosome 3, but this loss has also been observed in non-small-cell lung cancer.

Oncogenes regulate normal growth and development, but when activated promote tumour formation. Dominant oncogene mutations are seen in the *myc* family in SCLC and in the *ras* family in NSCLC (non-small-cell lung cancer). The *myc* family encode nuclear phosphoproteins, which bind to DNA and probably have transcriptional regulatory functions. Amplification of c-, N- and L-*myc* has been detected in SCLC.

The *ras* family of proto-oncogenes consists of H-*ras*, K-*ras* and N-*ras*. These encode related 21-kDa membrane-associated proteins, which probably have a role in transduction of growth signals. *Ras* gene mutations are found in 20–40% of NSCLC, especially adenocarcinomas. They are not seen in SCLC. K-*ras* mutations in NSCLC tumours is associated with shortened survival. K-*ras* mutations correlate with smoking in lung adenocarcinoma. This suggests that exposure to the carcinogens in tobacco smoke activate K-*ras* mutations.

The C-*ErbB-2* proto-oncogene encodes a transmembrane tyrosine-specific protein kinase, p185 neu, which acts as a putative growth factor receptor. Overexpression of p185 neu is common in NSCLC and adenocarcinoma and is associated with shortened survival.

p53 and the retinoblastoma (*RB*) gene are tumour suppressor genes. *RB* gene is always mutated in SCLC but in only 20% of NSCLC. p53 acts as a suppressor of cell division. p53 mutations are seen in 75% of SCLC and 50% of NSCLC. The commonest mutation is a guanine to thymine transversion.

Premalignant Lesions

Three types of the preinvasive epithelial lesions are documented in the new WHO classification. These are

1. squamous dysplasia and carcinoma *in situ*;
2. atypical adenomatous hyperplasia (AAH);
3. diffuse idiopathic pulmonary neuroendocrine hyperplasia (DIPNECH).

Preinvasive Squamous Lesions of the Bronchi

There is a great impetus in the United States and Japan, and beginning in Europe, to detect early bronchial carcinomas, so they may be resected early, hopefully producing a cure. LIFE (laser imaging fluorescence endoscopy) uses the different characteristics of malignant and premalignant tissues to enhance the bronchoscopist's ability to detect small neoplastic bronchial lesions. In high-risk groups, such as smokers, it is six times more sensitive than white light bronchoscopy in detecting preneoplasia (Lam *et al*., 1998). One study spawned from this technique showed deletions of 8p21–23 commenced early during the multistage development of lung cancer, at the hyperplasia/metaplasia stage in smokers without cancer. Allelic deletions persisted for up to 48 years after smoking cessation (Witsuba *et al*., 1999).

Auerbach *et al*. (1957) demonstrated a range of changes in smokers and patients with carcinoma of the lung, explaining the above molecular studies. These changes ranged from loss of normal ciliated lining cells with basal cell hyperplasia, low columnar nonciliated epithelium or squamous metaplasia and increasing degrees of dysplasia (**Figure 16; see colour plate section**) through to carcinoma *in situ* and invasive carcinoma. They meticulously blocked out entire bronchial trees and showed all these changes co-existed in any one cancerous lung.

Basal (reserve cell) hyperplasia, immature squamous hyperplasia and squamous metaplasia may be misdiagnosed as dysplasia by the unwary. As with any other dysplastic lesion elsewhere in the body, the diagnosis of preneoplasia should be made with great caution in the presence of active chronic inflammation, as well as adult respiratory distress syndrome (ARDS) (Hasleton and Roberts, 1999). Previous radiotherapy and/or chemotherapy may cause misdiagnosis. These two latter treatment modalities should be suspected if there are large, bizarre nuclei and plentiful cytoplasm.

Atypical Adenomatous Hyperplasia (AAH)

AAH is defined by the WHO as a focal lesion, often 5 mm or less in diameter, in which the involved alveoli and respiratory bronchioles are lined by monotonous, slightly atypical cuboidal to low columnar epithelial cells with dense nuclear chromatin, inconspicuous nucleoli and scant cytoplasm (**Figure 17; see colour plate section**). The size of the lesion, which is arbitrary, distinguishes it from bronchioloalveolar carcinoma (BAC). Other features delineating AAH from BAC are given below in the differential diagnosis.

Geographical Differences in Incidence of AAH and BAC

There appears to be a geographical difference in the incidence of AAH and BAC between Japan and the UK. Many papers relating to these two lesions originate from the East, suggesting there are biological variations in the incidence of lung cancer between different continents. However, AAH has been described in the UK (Kerr *et al*., 1994). There appears to be an increase in adenocarcinomas, both in the East and the USA (Travis *et al*., 1995). This is not mirrored in the UK, where squamous cell carcinoma remains the predominant cell type in lung cancer.

Clinical and Pathological Considerations

AAH is asymptomatic and is an incidental pathological finding at lobectomy or pneumonectomy (Miller, 1990). It is found incidentally in up to 10% of surgically resected lungs for carcinoma (Kitamura *et al*., 1996). AAH may co-exist with squamous carcinoma of the lung and metastatic colonic and renal cell carcinomas, but is seen most commonly with primary pulmonary adenocarcinoma.

The lesions are minute (smaller than 5 mm) white lesions, where the airways may still be identified, after magnification. Histologically there is a uniform proliferation of atypical cuboidal or low columnar epithelial cells with no mitoses growing along the alveolar septa. There are no admixed ciliated or mucus-secreting cells. There is variation in the cell density, with larger nuclei having increased variation in size, shape and nuclear hyperchromatism. Eosinophilic intranuclear inclusions may be seen. These are not specific for neoplastic cells, being present in reactive alveolar epithelium at times. The cells are ultrastructurally Type II pneumocytes or Clara cells. The alveolar septa may be thickened and infiltrated by lymphocytes.

Immunohistochemistry

Urine protein 1, which is identical with Clara specific 10-kDa protein, may be expressed in 70% of overt BAC but not in AAH lesions (Kitamura *et al*., 1999). Ki-67, a marker of cell proliferation, has demonstrated AAH has a proliferative activity intermediate between normal cells and adenocarcinoma (Kitaguchi *et al*., 1998). A useful marker may be cyclin D1. The frequency of lesions with this cell cycle control protein showing overexpression is high in AAH cycle (47–89%) but decreased in 'early' adenocarcinoma (28%) and overt adenocarcinoma (35%) (Kurasono *et al*., 1998).

Molecular Studies

Both 3p and 9p deletions may be found in certain populations of AAH cells. In another study, 3p, 9p and 17p showed loss of heterozygosity (LOH) in 18, 13 and 66% of AAH cases, respectively. The corresponding carcinomatous lesions showed LOH in 67, 50 and 17%, respectively. This suggests that AAH lesions with moderate or severe atypia are a preneoplastic stage of lung adenocarcinoma.

There is allelic loss of tumour suppressor gene loci in the tuberous sclerosis complex-1 (TSC-1)-associated regions on the long arm of chromosome 9 (9q) and on the short arm of chromosome 16 (16p) in human lung carcinoma; 24% of adenocarcinomas show LOH on 9q and partial LOH on 9q.

The incidence of associated AAH is significantly higher in adenocarcinomas harbouring a partial LOH in the TSC-1-associated regions. These results suggest that TSC-1-associated regions are new candidate loci for tumour-suppressor genes in lung adenocarcinoma, especially when accompanied by multiple AAH lesions (Suzuki *et al*., 1998).

Differential Diagnosis

In a small biopsy AAH or BAC may be part of an invasive adenocarcinoma or an intrapulmonary metastasis. The distinction of AAH from BAC has been considered above. AAH and multiple synchronous lung cancers may be part of the Li–Fraumeni syndrome, due to a constitutional mutation of the *p53* gene (Nadav *et al*., 1998).

Alveolar or papillary adenomas may be misdiagnosed as AAH on small biopsy specimens. These two entities are solitary tumours.

Honeycomb lung (end-stage interstitial fibrosis) may show bronchiolar epithelial proliferation but the distribution of the epithelium is irregular. The epithelium does not grow along slightly thickened uniform alveoli with an intact architecture, as in BAC, but is part of an extensive fibroblastic process.

Organizing pneumonia is associated with Type II cell hyperplasia but there is intra-alveolar fibrosis.

Atypical type II proliferations suggest radiotherapy or chemotherapy-induced change, as with Busulphan or adult respiratory distress syndrome. In cytology specimens ARDS shows bizarre type II or bronchiolar cells. Typically the sheets or balls of cells in BAC are composed of monotonous cells, uniform in size and shape. They have round to oval nuclei and a finely granular chromatin. In ARDS there is group to group variability of cells, often with marked variation in the nuclear/cytoplasmic ratio.

Alveolar hyperplasia can be seen in lymphangioleiomyomatosis (Lantuejoul *et al*., 1997).

Prognosis

There was no difference in the age, follow-up interval or survival rate in one study of 13 patients with no detectable nodules preoperatively compared with cases showing nodules on CT scan.

Some cases of BAC have a good prognosis (Logan *et al*., 1996). The 5-year survival rate in stage 1 disease was 72.9% and stage 2 60.6%, falling to 27.1% in stage 3a and 0% in stages 3b and 4. The 5-year survival rate was higher (64.6%) in AAH associated with well-differentiated adenocarcinoma, as opposed to the presence of this lesion in adenocarcinoma with pulmonary metastases.

Tumourlets

Tumourlets are micronodular, neuroendocrine cell proliferations extending beyond the bronchial/bronchiolar walls, forming aggregates with organoid and nested patterns and measuring less than 0.5 cm in diameter. This measurement, like that of AAH, is purely arbitrary. Any lesion larger than 0.5 cm is diagnosed as a pulmonary carcinoid. Tumourlets are often associated with fibrosis in the walls of bronchiectatic cavities but are uncommon in interstitial pulmonary fibrosis, for some unknown reason. A possible explanation is the prominent inflammation seen in bronchiectasis, whereas in interstitial pulmonary fibrosis inflammation is an early event and is usually less prominent than the fibrosis at the time of biopsy. The differential diagnosis is considered under DIPNECH below but the unwary on a biopsy may suggest small cell lung carcinoma. It does not have the mitotic activity or the lack of cytoplasm of this tumour.

Diffuse Idiopathic Neuroendocrine Hyperplasia (DIPNECH)

DIPNECH is a proliferation of neuroendocrine cells limited to the bronchiolar epithelium (**Figure 18; see colour plate section**). There are increased numbers of scattered single cells, small nodules (neuroendocrine bodies) or linear proliferations of neuroendocrine cells within the bronchiolar epithelium. It is typically associated with obliterative bronchiolar fibrosis and co-existing interstitial or airway fibrosis or inflammation should be absent. This is because, especially with inflammation, there is a proliferation of NE cells.

DIPNECH is a rare condition and may be part of a diffuse neuroendocrine proliferation or identified adjacent to a peripheral carcinoid (Miller and Muller, 1995). DIPNECH may present as an interstitial disease (Armas *et al*., 1995). Rare cases may show the full gamut with DIPNECH, tumourlets and peripheral typical carcinoid tumours (Miller *et al*., 1978).

Differential Diagnosis

Minute meningiothelioid nodules are perivenular, interstitial aggregates of small regular cells with no airway contact. The cells often have a lobular, whorled arrangement, reminiscent of chemodectomas. Meningiothelioid nodules co-express vimentin and epithelial membrane antigen (EMA). DIPNECH is positive with neuroendocrine markers, such as NCAM (neural cell adhesion molecule), chromogranin and synaptophysin.

Carcinoma of Lung

All lung carcinomas show histological heterogeneity. If one accepts that there is a common stem cell, consequently there are mixtures of squamous and adeno or small cell carcinoma. However, major heterogeneity is found in only 5% of cases. The heterogeneity explains why after chemotherapy for SCLC a squamous or adenocarcinoma may develop at the site of the original tumour.

Synchronous tumours arise at the same time as a primary, while a metachronous one consists of a second

tumour occurring after resection of the initial neoplasm. The incidence of synchronous and metachronous tumours is difficult to elucidate from the literature but approximately 1% of common lung neoplasms are multiple.

Classification of Lung Tumours

The WHO has now produced a new lung and pleural tumour classification (1999). The main tumour variants are given in **Table 1**.

Clinical Presentation Due to Local Disease

Central tumours cause obstructive symptoms, including cough, haemoptysis, wheezing and stridor, similar features to benign neoplasms. The haemoptysis is caused by bronchial ulceration but in a few cases there may be infiltration into a large pulmonary artery, causing life-threatening haemorrhage. In addition, there may be bone pain, dyspnea, clubbing and dysphagia. More than 90% of patients with lung cancer are symptomatic at presentation, reflecting advanced disease. This is especially the case with SCLC, which is assumed to be a systemic disease at presentation by most oncologists. However, some patients have stage I disease and in some centres have been offered surgery and chemotherapy, although the role of surgery has yet to be established in patients with more extensive nodal disease (Lucchi *et al*., 1997). Patients with general systemic symptoms or metastases in both small cell and non-small-cell lung cancer have a poor prognosis.

Pancoast tumours (superior sulcus tumours) are localized, arising posteriorly at the apex of the upper lobe near the brachial plexus. They infiltrate C8, T1 and T2 nerve roots, causing pain, temperature changes and muscle atrophy in the shoulder and arm innervated by these nerve roots. Horner's syndrome is caused by involvement of the sympathetic chain and stellate ganglion, giving unilateral enophthalmos, ptosis and miosis. Superior vena caval obstruction presents as oedema and plethora of the face, as well as dilated neck and upper torso veins. Hoarseness is due to recurrent laryngeal nerve entrapment, seen more frequently in left upper lobe tumours, as the left recurrent laryngeal nerve loops around the aortic arch. Tumour can involve the phrenic nerve, paralysing a hemi-diaphragm. The oesophagus may be infiltrated causing dysphagia and, if the pleura is involved, an effusion occurs.

Metastases are common in SCLC, with 20% of cases metastatic at presentation. Squamous cell carcinoma tends to remain intrathoracic whereas adeno- and large-cell carcinoma show metastases to regional nodes, liver, gut, adrenals, central nervous system and bone.

Table 1 Classification of lung tumours

Epithelial tumours
- Benign
  - Papilloma
  - Adenoma
- – alveolar and papillary
    - – salivary gland type
    - – mucous gland
    - – pleomorphic
    - – mucinous
- Preinvasive lesions
  - Squamous
  - Atypical adenomatous hyperplasia
  - Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia
- Malignant
  - Squamous cell carcinoma (and variants, including basaloid))
  - Small-cell carcinoma (and variants)
  - Adenocarcinoma (and variants)
  - Large-cell carcinoma (and variants, including large-cell neuroendocrine carcinoma and lymphoepithelial carcinoma)
  - Adenosquamous carcinoma
  - Carcinomas with pleomorphic, sarcomatoid or sarcomatous elements (including carcinosarcoma and pulmonary blastoma)
  - Carcinoid tumour – typical
    – atypical
  - Carcinomas of salivary gland type (including mucoepidermoid and adenoid cystic carcinomas)
  - Unclassified
  - Soft tissue tumours

Mesothelial tumours
Miscellaneous tumours (including hamartoma and sclerosing haemangioma)
Lymphoproliferative disorders
Secondary tumours

Paraneoplastic Syndromes

This term identifies symptoms and signs secondary to cancer, occurring at a site distant from the tumour or its metastases. They are caused by the production of products, such as polypeptide hormones, hormone-like peptides, antibodies, immune complexes, etc., by the tumour. Nonmetastatic hypercalcaemia is commonest in squamous cell carcinoma. The squamous carcinoma cells secrete a parathormone-related protein (PTH-rP), which shows a limited sequence homology with parathyroid hormone. Cushing's syndrome, the commonest, is due to ectopic ACTH production, usually seen in SCLC. The syndrome of inappropriate antidiuretic hormone secretion (SIDDH) is seen mainly with SCLC. In half the cases there is ectopic vasopressin secretion from the tumour. In the remainder there is abnormal release of this peptide from the posterior pituitary because of altered or defective chemoreceptor control. Gynaecomastia develops because of increased levels of β-hCG (human chorionic gonadotrophin) produced by the tumour. This hormone is most commonly seen in germ cell tumours of the mediastinum and gonads and very rarely as a primary pulmonary tumour.

Neurological Syndromes

These are most often associated with an autoimmune reaction, in which the tumour shares antigens with normal nervous tissue. In recent years, antibodies reactive with nuclear and cytoplasmic antigens and neurons throughout the CNS and peripheral ganglia have been identified in patients with these syndromes. The Lambert–Eaton myasthenic syndrome is uncommon and is associated with SCLC. There is muscle weakness and fatigue and it is most pronounced in the pelvic girdle and thighs. There may be dysarthria, dysphagia and blurred vision. Hypertrophic osteoarthropathy is characterized by finger clubbing, periosteal bone formation (see below) and arthritis. Other neurological syndromes include autonomic neuropathy and subacute sensory peripheral neuropathy.

The enlargement of the distal phalanx of the digits due to an increase in the connective tissue in the nail bed is termed clubbing and is almost always a feature of hypertrophic osteoarthropathy. It is seen especially in squamous and adenocarcinomas but has also been documented in other diseases, including congenital cyanotic heart disease and cystic fibrosis. It may be neurogenic (vagally mediated), hormonal owing to a high oestrogen or growth hormone or vascular owing to arterio-venous shunts.

For treatment purposes lung carcinomas are divided into SCLC and NSCLC, the former only rarely having surgery. The commonest non-small-cell carcinomas are squamous, adeno- and large cell.

Squamous Cell Carcinoma

These are often central, in main or segmental bronchi, or peripheral. They may show an endobronchial growth pattern or infiltrate between the cartilaginous rings initially, in time destroying them to invade surrounding tissue. The tumour is solid, grey/white but may show cavitation (**Figure 19; see colour plate section**). Such cavity formation may cause clinical misdiagnosis as apical cavitating tuberculosis. Very rarely both diseases may co-exist. There is often related bronchiectasis and obstructive pneumonitis, due to bronchial obstruction. The pneumonitis causes both radiological and macroscopic problems in definition of the true extent of the tumour. This problem may be accentuated if there is a prominent inflammatory component to the tumour.

Adjacent to the tumour there may be carcinoma *in situ* as well as chronic bronchitic changes. In addition, there is squamous metaplasia and reserve cell hyperplasia. The tumour shows varying degrees of squamous differentiation, lying in a fibrous stroma with a varying amount of acute and chronic inflammation. Foci of recent and old haemorrhage are seen. Well-differentiated tumours show keratin pearls and keratinization (**Figure 20; see colour plate section**). Intercellular bridges should be sought and paradoxically can be best identified with a mucin stain. Rarely mucin can be seen in the malignant cells but more than 10% of the tumour should show a distinctive glandular component before an adenosquamous carcinoma is diagnosed. Tumour giant cells imply a poor prognosis. Clear cell change, due to glycogen accumulation, is also a feature of some tumours but has no prognostic connotation. The nuclei are hyperchromatic and may show prominent nucleoli. The tumour may encircle the bronchus and a fibre-optic biopsy may only reveal fibrosis.

Squamous cell carcinomas manifest earlier than other types of pulmonary malignancy because of obstructive symptoms. They may involve lymph nodes by direct spread. There may be lymphatic and vascular invasion, but the prognostic significance of vascular invasion in non-small-cell carcinoma is uncertain. Some studies suggest that vascular invasion indicates a poor prognosis, others show it has no effect on survival, since the tumour-associated desmoplasia causes occlusive intimal fibrosis in thin walled pulmonary arteries and veins.

A small subgroup of squamous carcinomas is termed basaloid carcinoma. This tumour grows exophytically in proximal bronchi. Mediastinal pleura or adipose tissue are often invaded. There is a solid lobular or anastamotic trabecular pattern with small, moderately pleomorphic, cuboidal or fusiform cells. There is peripheral pallisading and a high mitotic rate. Other subtypes of squamous carcinomas are clear cell, not to be confused with adenocarcinoma, papillary, pleomorphic and spindle cell and small cell variant of squamous.

Differential Diagnosis

Conditions to be considered in the differential diagnosis are florid squamous metaplasia in the bronchus or states associated with an inflammatory process, dysplasia, which if high grade can be very difficult to distinguish on a small biopsy, any benign lung tumour with squamous metaplasia on the surface, especially granular cell myoblastoma, benign squamous cell papilloma, tumours with a squamous component, such as carcinosarcoma, spindle cell sarcomas, metastatic tumours with a squamous appearance, including sarcomas, which can be primary or secondary, and mesothelioma. Special stains, including mucins and cytokeratins, are often helpful in determining the cell of origin and in some cases the site.

It may be difficult with poorly differentiated tumours to differentiate squamous from adenocarcinoma. In such cases if mucin stains are diffusely negative the term 'non-small cell carcinoma' is used. This enables medical oncologists to give appropriate treatment, as they need to distinguish this tumour from small-cell lung carcinoma.

Treatment and Prognosis

Treatment depends on the stage of the disease. Cases with stage IIIA disease or less are treated by surgery though the role of surgery has yet to be established in N2 and N3 disease. Other options for more advanced disease are radiotherapy, either direct beam or intraluminal, brachytherapy and chemotherapy.

Prognosis depends on the stage. Five-year survival rates are stage I, 50%, stage II, 30% and stage IIIA, approximately 10% (Mountain, 1988).

Adenocarcinoma

It is often impossible to distinguish a bronchial primary from secondary pulmonary tumour. If an adenocarcinoma is thought to be secondary, a primary should be sought in the stomach, colon, pancreas, breast, ovary, prostate or kidney. Special stains, such as cytokeratins 7 and 20, TTF-1 (thyroid transcription factor 1, but commonly expressed in lung cancer), PSA (prostate-specific antigen), ER (oestrogen receptor) and PR (progesterone receptor) may help in identifying the site of the primary tumour.

Adenocarcinomas are usually peripheral, well-circumscribed masses (**Figure 21; see colour plate section**). If the pleura is involved there is fibrosis and puckering. These tumours may be central, arising from bronchial mucous glands. The peripheral tumours usually occur in females while the bronchial gland type tends to have a male predominance. There is no significant survival difference between the two variants. Adenocarcinomas vary in size and may occupy an entire lobe. They sometimes contain carbon pigment and may show marked scarring. The term 'scar carcinoma' is no longer used, since the stroma is a desmoplastic response to tumour rather than arising in a pulmonary scar (pulmonary fibrosis). Adenocarcinomas may be single or multiple and this may create confusion with metastases. Pleural seeding is common and may mimic a mesothelioma.

Histologically there are different growth patterns with tubular, papillary, acinar, signet ring and solid variants (**Figure 22; see colour plate section**). It is common to have a mixture of the above patterns in any one tumour. The cells are large, polygonal and tend to be discohesive with a high nuclear/cytoplasmic ratio. Some cases have mucin vacuoles. However, 30% of adenocarcinomas show no mucin on special stains. Spindle cell and giant cell foci may be identified. The tumour spreads aerogenously and may show a peripheral bronchioloalveolar pattern. This should not be diagnosed as bronchioloalveolar carcinoma. It rapidly invades lymphatics, blood vessels and the pleura and spreads to distal sites.

Differential Diagnosis

This includes any secondary adenocarcinoma, as detailed above, adenosquamous carcinoma, muoepidermoid tumour of the bronchus, germ cell tumours, carcinoid tumours with glandular foci, pulmonary blastoma and in the case of a pleural biopsy, mesothelioma. The stains mentioned above will help to differentiate *some* primary pulmonary tumours from secondary ones.

Trainee pathologists may misdiagnose benign lesions, such as radio or chemotherapy-induced change, type II cell hyperplasia associated with interstitial pulmonary fibrosis and resolving ARDS, alveolar adenoma, sclerosing haemangioma and atypical adenomatous hyperplasia.

Treatment and Prognosis

Surgery is the most appropriate treatment option. Survival is related to stage, stage I has a 50% 5-year survival rate, stage II approximately 25%, and stages IIIA and B, less than 10% (Mountain, 1988). These figures are pre-CT scans and the Japanese literature suggests they are detecting earlier tumours with this modality.

Bronchioloalveolar Carcinoma (BAC) (Alveolar Carcinoma)

This is a subtype of adenocarcinoma. It is the commonest tumour in North American women. There are greyish/white nodules with a central scar in some cases. If close to the pleura there is puckering and fibrosis, as in adenocarcinoma, but the tumour does not usually infiltrate this layer. Mucinous tumours have a glistening appearance. The tumour may involve an entire lobe (**Figure 23; see colour plate section**) or lung, often giving bronchorrhoea.

There are two main subtypes, mucinous and nonmucinous. Nonmucinous consist of Clara or type II cells and mucinous have goblet or mucin-producing cells. Both grow along intact alveolar walls as a single layer or occasionally forming papillae. If stromal invasion is identified, the tumour is classified as adenocarcinoma. In nonmucinous BAC, the cells are cuboidal with an eosinophilic, ciliated cytoplasm and prominent nuclei. In mucinous BAC there are tall columnar, mucinous cells that are well differentiated and lack cilia. The nuclei are uniform and show varying degrees of hyperchromasia. The cells produce much mucin. Discrete satellite nodules are seen in either type.

The differential diagnosis is similar to adenocarcinoma as detailed above. It is impossible on a small biopsy to differentiate invasive adenocarcinoma from BAC or AAH.

Treatment and Prognosis

The optimum treatment is resection and the 5-year survival rate is 42.1%, with a higher survival rate for stage I disease.

Small-cell Lung Carcinoma (SCLC)

This tumour grows rapidly and may occasionally present as metastases without any visible primary tumour. A primary tumour in the upper respiratory tract, oesophagus or cervix may metastasize to the lung. This tumour is responsive to chemotherapy. It presents as hilar masses with extension into lymph nodes (**Figure 24; see colour plate section**). The tumour is soft, white and shows extensive necrosis. In advanced cases the bronchial lumen is obstructed by extrinsic compression. There are two main histological variants.

The first is 'classical' small cell carcinoma (**Figure 25; see colour plate section**) and the second a combined

small cell carcinoma. In classical SCLC there are sheets of small, hyperchromatic nuclei with nuclear moulding and little cytoplasm. There is a high mitotic rate. Because of the high cell turnover and necrosis, DNA leaches out and is taken up by blood vessels ('Azzopardi effect'). A combined SCLC has the above pattern and adeno-, large-cell or squamous carcinomatous components.

This tumour stains positively with NCAM (neural cell adhesion molecule), synaptophysin and chromogranin. Lymphovascular invasion occurs early and distant metastases are common. These are seen in bone marrow, liver, kidney, adrenals, cerebrum, cerebellum, meninges, regional and cervical lymph nodes. After chemotherapy, recurrent tumour may be predominantly squamous or adenocarcinoma.

Differential Diagnosis

Benign lesions may be confused with SCLC, especially if there is crush artifact. In the presence of this, a diagnosis of SCLC should never be made, since any chronic inflammatory condition, such as tuberculosis, may have crush artifact. Tumours that may be confused with SCLC are tumourlets, other neuroendocrine tumours, on a small biopsy, squamous, large-cell and adenocarcinomas, which may have an SCLC component, metastatic carcinomas and lymphomas.

Treatment and Prognosis

This is neoplasm is usually treated with chemotherapy, since cases with stage I disease are rare. There is an approximately 10% 5-year survival after treatment.

Large-cell Carcinoma

Large-cell carcinomas are large necrotic masses, which frequently invade the overlying pleura and grow into adjacent structures. This is a diagnosis of exclusion since no acinar or squamous differentation or mucin production are seen. Large-cell carcinomas have sheets and nests of large cells with prominent vesicular nuclei and nucleoli (**Figure 26; see colour plate section**). The cell borders are easily visualized. Necrosis and haemorrhage are frequent and there may be acute and/or chronic inflammation.

There are several variants. These include clear cell carcinoma, composed entirely of clear cells, basaloid carcinoma and lymphoepithelioma (lymphoepithelial-like carcinoma). Lymphoepithelial-like carcinoma has a marked lymphoplasmacytic infiltrate admidst large cell carcinoma. Epstein–Barr virus genome may be identified in this tumour. It is commoner in the Far East.

The differential diagnosis is similar to pleomorphic carcinoma, described below. It includes all the carcinomas, primary or secondary, described above, as well as large cell neuroendocrine carcinoma, primary or metastatic sarcoma, anaplastic large cell lymphoma and melanoma. The prognosis is grim, with an approximately 1% 5-year survival.

Adenosquamous Carcinoma

These are usually peripheral tumours. There must be definite squamous and adenocarcinomatous components, one of which must comprise more than 10% of the tumour.

Pleomorphic Carcinoma of Lung

This entity was first described by Fishback *et al*. (1994), who studied 78 cases of this entity, with a male to female ratio of 2.7 : 1. About 80% of the patients had thoracic pain, cough and haemoptysis but 18% were asymptomatic. Foci of squamous cell carcinoma were present in 8%, large cell in 25% and adenocarcinoma in 45%. The remaining 22% of tumours were completely spindle and/or giant-cell carcinomas. Spindle and giant-cell carcinomas were found together in 38% of patients. Nodal metastases were the most significant single prognostic factor. Only 1% of cases had SCLC foci; such cases are classified as combined small-cell carcinoma.

The malignant spindle cell component consists of fusiform cells with eosinophilic cytoplasm (**Figure 27; see colour plate section**). The spindle cells vary from an epithelioid appearance to a slender banal morphology. The chromatin is frequently vesicular or coarse and hyperchromatic. Giant-cell carcinoma, with multiple tumour giant cells, covered by neutrophil polymorphs (emperopolesis), is a variant of pleomorphic carcinoma. However, tumour giant cells are an integral component of pleomorphic carcinoma. There is a mild to moderate inflammatory component, predominantly lymphocytes. As in mesothelioma, separation of spindle cell carcinoma from a desmoplastic stroma is often difficult.

Molecular techniques have shown that K-*ras*-2 showed mutations in fewer pleomorphic carcinomas than adenocarcinomas. Pleomorphic carcinomas also showed fewer *p53* point mutations than adenocarcinoma or squamous carcinoma. The *p53* point mutations in pleomorphic carcinoma were commoner exon 7 than those of squamous and adenocarcinoma, which were exon 8 (Pryzygodzki *et al*., 1996).

The differential diagnosis is largely described above under Large-cell Carcinoma. In addition, any spindle cell lesion has to be considered. The WHO recommends epithelial markers, such as keratin or epithelial membrane antigen, as useful in confirmation of the carcinomatous differentiation in the spindle cell component. However, if these markers are negative the tumours are classified as pleomorphic carcinomas, assuming the neoplasm does not have the immunoprofile of one of the tumours noted in the differential diagnosis, especially a soft tissue sarcoma. Heterologous elements are necessary for the diagnosis of carcinosarcoma.

Keratin may be positive in synovial sarcoma, mesothelioma, epithelioid haemangioendothelioma, rarely in leiomyosarcoma, anaplastic large cell lymphomas and occasionally in malignant peripheral nerve sheath tumours. Therefore, reliance on a single cytokeratin will cause problems. In such problematic pulmonary tumours a battery of immunostains may be useful.

Pulmonary Lymphomas

Pulmonary lymphoid proliferations may occur in rheumatoid disease and in Sjogren's syndrome. Lymphomas in the lung are classified as lymphoid interstitial pneumonia, non-Hodgkin lymphomas, primary pulmonary Hodgkin disease, plasma cell neoplasms and leukaemic infiltration.

Lymphoid interstitial pneumonia (LIP) consists of a diffuse infiltrate with small lymphocytes and plasma cells affecting large areas of the lung. There may be reactive lymphoid follicles and it may be associated with autoimmune disease and poly- or monoclonal gammopathy. Cases with monoclonal light-chain restriction probably represent 'MALT' lymphomas. Some cases have polytypic light-chain expression and have been classed as non-neoplastic.

Primary Pulmonary Non-Hodgkin Lymphoma

These are similar to non-Hodgkin lymphomas elsewhere, most being B cell in origin. Patients are middle-aged with respiratory and systemic symptoms. There may be lobar consolidation as well as skin, renal and central nervous system involvement. About 50% of patients are asymptomatic, the rest having a variety of respiratory and constitutional symptoms. In the T cell lymphomas there is often a vasculitic (**Figure 28; see colour plate section**) and granulomatous pattern, with necrosis.

Sarcomas

Primary pulmonary sarcomas are rare. Epithelioid haemangioendothelioma is a low-grade vascular sarcoma, occurring more commonly in young women. There is chest pain, dyspnea, mild cough and multiple bilateral nodules. It can also affect liver, bones and soft tissues. The tumour may resemble a mesothelioma. Kaposi sarcoma may be seen in HIV-positive patients and is described elsewhere.

Carcinosarcomas have a mixture of sarcomatous and carcinomatous elements.

Secondary Tumours

The lung is frequently the site of secondary adenocarcinomas and sarcomas, especially osteogenic and chondrosarcoma. Because of advances in chemotherapy it may be beneficial to treat these patients with localized resection. In the case of secondary adenocarcinomas, as mentioned above, TTF-1 and cytokeratins can be useful in determining whether a tumour is primary or secondary.

Websites

The websites given are those of predominantly pulmonary journals, since there is no purely pulmonary pathology journal. These pulmonary journals feature good review articles, especially the *European Respiratory Journal* and the *American Review of Critical Care and Respiratory Care Medicine*. Pathology journals also carry original pulmonary articles. The recommended ones are *Modern Pathology*, *American Journal of Pathology*, *Laboratory Investigation*, *American Journal of Clinical Pathology*, *Histopathology* and *Journal of Pathology*. The *New England Journal of Medicine* has an excellent weekly clinicopathological conference with many pulmonary topics. Most of these journals require subscriptions/passwords, etc., to obtain full text but most libraries will be able to provide access.

- Conclusion

INTRODUCTION

Worldwide, oesophageal and gastric cancers are very common tumours, accounting for 6–34% of cancer-related deaths (Aoki *et al*., 1992). Variations in carcinogen exposures account for striking geographical differences in the frequency of both tumours. Oesophageal and gastric cancers have decreased in both incidence and mortality rates in economically prosperous populations but their incidence remains high in less prosperous countries. This chapter will summarize the current status of our knowledge of the origin, pathology, molecular biology and behaviour of upper gastrointestinal tumours. We will also describe methods used to prevent and treat these malignancies.

NORMAL DEVELOPMENT AND STRUCTURE

General Organisation

The gastrointestinal tract is divided into several major anatomical regions, each with its own unique physiological functions and structure. The various regions share a basic structure. The inside has a mucosal lining beneath which is a thin muscular layer known as the muscularis mucosae. The mucosa serves many of the digestive and absorptive functions of the gastrointestinal tract. Beneath the muscularis mucosae is the submucosa. The next layer is the muscularis propria, which is responsible for propelling gastrointestinal contents forward throughout the gut.

Oesophagus

The oesophagus develops from the cranial portion of the primitive foregut, becoming recognizable at the 2.5-mm stage of development (approximately the third gestational week) as an annular constriction located between the stomach and pharynx (Fenoglio-Preiser *et al*., 1999). The oesophagus elongates, growing in a cephalad direction and becoming increasingly tubular. Early in development, the cephalad portions of both the oesophagus and trachea lie within a common tube. When the oesophagus and trachea divide, the oesophagus comes to lie dorsal to the trachea. The oesophageal mucosal lining progresses through a series of epithelial changes before attaining the appearance of the glycogenated, nonkeratinized, stratified squamous epithelium present in the adult.

The mucosal lining of the oesophagus consists of stratified layers of squamous cells resembling those found in the skin (**Figure 1**). These stratified cells show an orderly progression of differentiation from the bottom of the epithelium to its surface. This squamous cell lining regularly renews itself. New cells form from progenitor cells at its base just above the basement membrane. The basement membrane is a linear structure lying under the epithelium; it serves as a boundary between the epithelium and its underlying tissues. Old, nonfunctional cells are shed from the mucosal surface. Newly formed epithelial cells pass upward in the mucosa, becoming increasingly more mature as they do so. At the surface they are held tightly together by intercellular junctions. This mucosal layer protects underlying tissues from damage by abrasion from food passing over it and from damage induced by the chemical contents of material in the oesophageal lumen.

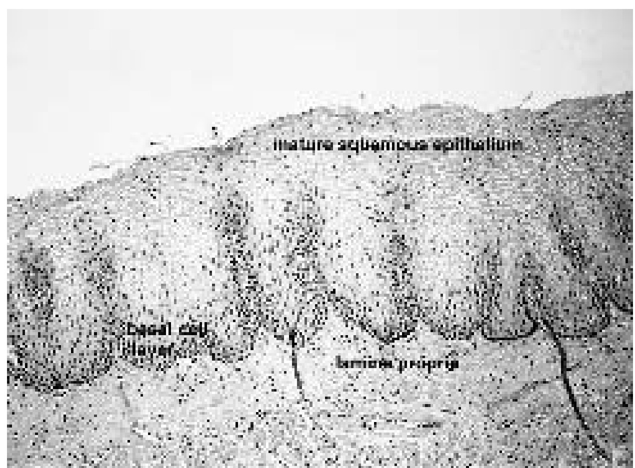

Figure 1 The normal histology of the oesophagus. The oesophagus consists of squamous epithelium arranged in stratified layers. The cells at the bottom (basal layer) are small and these cells represent the proliferative compartment. They give rise to daughter cells which pass upward into the overlying epithelium, becoming increasingly mature as they do so. As a result, the amount of cytoplasm relative to the nucleus, the nuclear : cytoplasmic ratio decreases. The basement membrane separates the basal cell layer from the underlying lamina propria.

The oesophageal lining is lubricated by mucus derived from the salivary glands and from oesophageal submucosal mucus glands. Passage of food and liquid through the oesophagus into the stomach is accomplished by contraction of its thick muscular coat. A muscular sphincter, known as the lower oesophageal sphincter, acts as the gateway to the stomach, controlling the passage of food forward and preventing reflux of gastric acid and digestive enzymes back into the oesophagus.

Stomach

The stomach is a bag-like structure lying between the oesophagus and the intestines. It develops from a fusiform swelling of the foregut at approximately 4 weeks gestation. During the sixth to seventh fetal week the gastric curvature develops. In the ninth week, a diverticulum appears in the upper stomach, which subsequently merges with, and lengthens, the greater curvature. The stomach is initially lined by stratified or pseudostratified epithelium. Later, it is replaced by cuboidal cells. As secretions accumulate, droplets and vacuoles coalesce to form the gastric lumen. The first differentiated cell types to appear are mucous neck cells that act as progenitors for other cell types. Gastric glands grow by progressively branching, a process that continues until birth.

Food reaching the stomach is mixed with acid and digestive enzymes to accelerate the digestive process. The muscles of the stomach wall help mix and churn the gastric contents increasing the contact between food and the digestive mixture and grinding the food into smaller particles.

The stomach has three functionally and anatomically distinct parts: the cardia, the corpus and the pyloric antrum (**Figure 2**) (Fenoglio-Preiser *et al.*, 1999). These three areas are covered by a mucosa that contains a lining epithelium composed of gastric pits and gastric glands. The histological features of the lining epithelium of the gastric pits (**Figure 3**) is similar in all three areas, although the lengths of the pits differ in different gastric regions. In contrast, gastric glands differ in their histological features in the three anatomical regions. The cardia, a 1-cm segment of the stomach lying at its junction with the oesophagus, consists of mucus-producing glands resembling oesophageal mucus glands. The corpus normally constitutes approximately two-thirds of the gastric surface area. Its glands are lined by two major cell types. Chief cells produce pepsin, a digestive enzyme, from its precursor, pepsinogen. Parietal cells have several functions. They act as proton pumps that secrete hydrochloric acid into the stomach lumen, lowering the pH of gastric juice to 1.5. They also serve as the source of intrinsic factor which modulates small intestinal absorption of vitamin B_{12}. Autodigestion of the stomach by pepsin and hydrochloric acid is prevented by a thick mucus coat elaborated by mucosal surface cells. The pyloric antrum constitutes the distal third of the stomach. As in the corpus, its surface cells produce a thick layer of protective mucus. Antral glands contain chief cells that, like those in the corpus, secrete pepsin. Pepsinogen occurs in two forms. Pepsinogen group I (PGI) occurs only in the corpus, while pepsinogen group II (PGII) is made in all three parts of the stomach. The gastric epithelium in all three regions of the stomach maintains a dynamic equilibrium between cell production and cell loss. Cell proliferation increases any time that there is an excessive loss of gastric cells due to any mucosal injury (**Figure 4**).

The gastric mucosa also contains a diverse endocrine cell population. The predominant antral endocrine cell is the gastrin-producing G cell. The G cell is part of a physiological negative feedback loop. When acid secretion is low, gastrin stimulates acid secretion by parietal calls, followed by inhibition of gastrin release. Acid secretion also follows neural stimulation. Prolonged acid suppression induced by drugs, vagus nerve denervation or atrophy of the corpus mucosa leads to an increase in the G cell population and hypergastrinaemia (**Figure 5**). Hypergastrinaemia stimulates the growth of corpus ECL cells which may develop into small localized growths. Gastrin also functions as a general mucosal growth factor. Other gastric endocrine cells produce substances such as serotonin and somatostatin. Hormones produced by all gastric endocrine cells integrate physiological communications between the

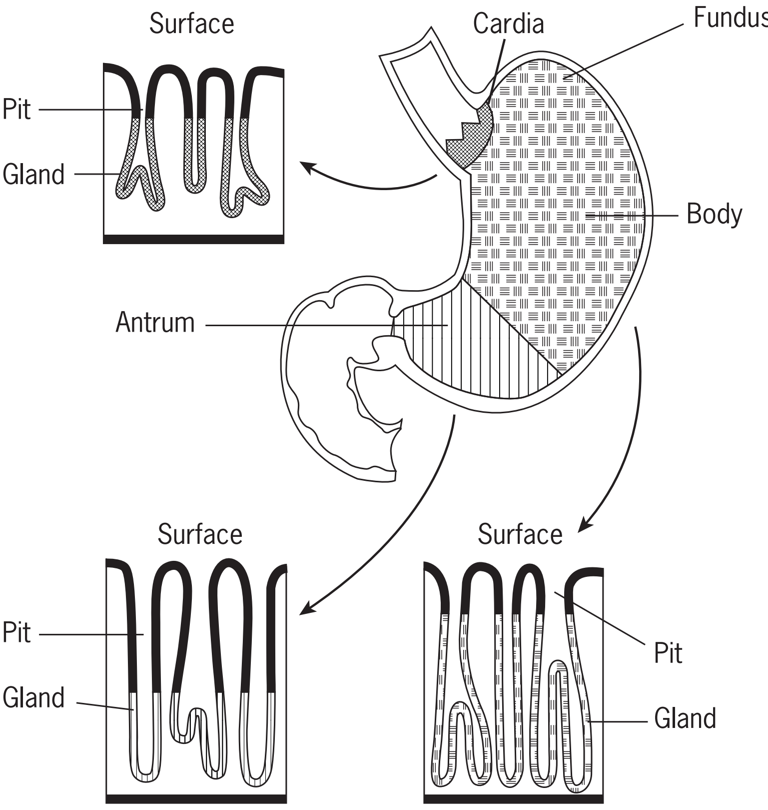

Figure 2 Diagrammatic representation of the stomach. The stomach is divided into four areas: the cardia, fundus, body and antrum. In each of these areas, the stomach is lined by surface epithelium which extends down into the gastric pits. Underlying the gastric pits are the gastric glands. The gastric glands of the fundus and body resemble one another and are sometimes referred to as oxyntic glands. These glands differ from those seen in the cardia and the antrum.

central and peripheral nervous system and the cells in the gastric mucosa and the muscle layers.

EPIDEMIOLOGY

Oesophageal Cancer

There are two major types of oesophageal cancer, squamous cell carcinoma (SCC) and adenocarcinoma, each with different risk factors and epidemiologies. SCC arises from the squamous cells lining the oesophagus. Adenocarcinomas arise in areas of metaplasia known as Barrett oesophagus.

Squamous Cell Carcinoma

The geographical distribution of oesophageal cancer shows wide variations within and between countries, in both mortality and incidence (Munoz and Day, 1996). As much as a 500-fold incidence difference can exist between the most and least affected areas of the same country and between different countries. SCC is virtually nonexistent in western and northern Africa. It also remains relatively rare in most of North America and Western Europe. In contrast, a high-risk zone extends from eastern Turkey through the southern former Soviet Union, Iraq, and Iran to northern China. High-risk areas also include Chile, the Transkei region of South Africa, Japan and regions of France and Brazil. Even in China, where 60% of oesophageal cancers develop, widespread differences in incidence and mortality exist. These high-risk foci have been explained on the basis of local food preservation practices that favour the generation of carcinogenic nitroso compounds from mould growing in pickled vegetables. Familial clusters of SCC of the oesophagus have been observed in Chinese high-risk areas. This can be attributed to shared environmental hazards, or to a common genetic influence.

Adenocarcinoma

Adenocarcinomas, cancers that form glands, constitute a relatively small proportion of oesophageal cancers worldwide, but among white males in the United States

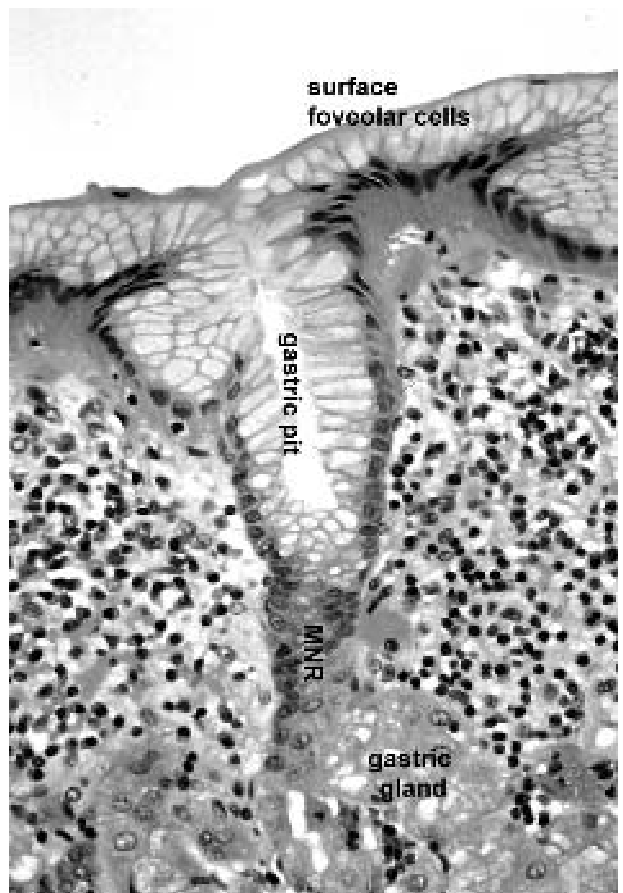

Figure 3 Photograph of the superficial portion of the gastric mucosa showing the surface foveolar epithelium extending into the gastric pit. Cell replication occurs in the mucous neck region (MNR), which is the area of junction betweem the pit and the underlying glands.

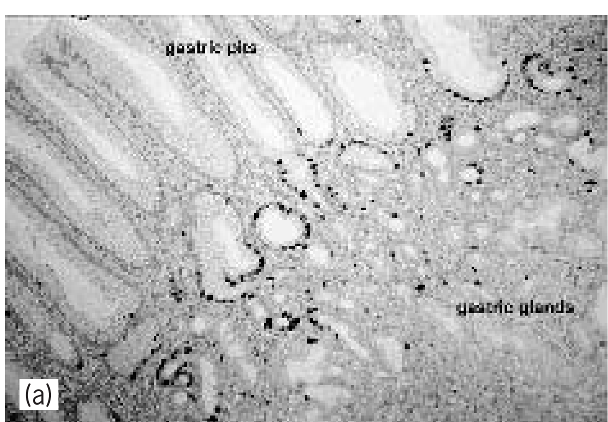
they are now more frequent than SCC (Zheng *et al*., 1993). Indeed, most affected patients are white males. Oesophageal carcinomas share many clinical features with cancers of the gastric cardia, and it may be difficult to determine whether a cancer involving the gastro-oesophageal junction originates from the oesophagus or the stomach. Thus, it is likely that epidemiological studies of oesophageal adenocarcinomas include some cancers of the cardia, and vice versa. This may explain why both cancers share similar time trends and a predisposition to affect white men. Both tumours have increased in incidence between 1975 and 1995, but the increased incidence of oesophageal adenocarcinoma in white males is especially strong, rising from 0.7 to 3.2 per 100 000, an increase of more than 350%. A diet characterized by a high intake of meat, fat and calories, but a low intake of fruits and vegetables, has also been identified as a risk factor for this tumour.

Stomach Cancer

As in the oesophagus, there is more than one form of gastric cancer and the epidemiology of the various forms differs.

Intestinal-type Gastric Cancer

The most common form of stomach cancer in high-risk populations is a gland-forming tumour that arises in the pyloric antrum and is preceded by the appearance of mucosal glands that resemble those in the intestine – a condition called intestinal metaplasia. The tumours that develop in the intestinalized mucosa are termed intestinal-type gastric cancers. Intestinal-type tumours account for almost two-thirds of the gastric cancers in the high-risk areas of northeast Asia, central America and eastern Europe. They arise after long-term infection with



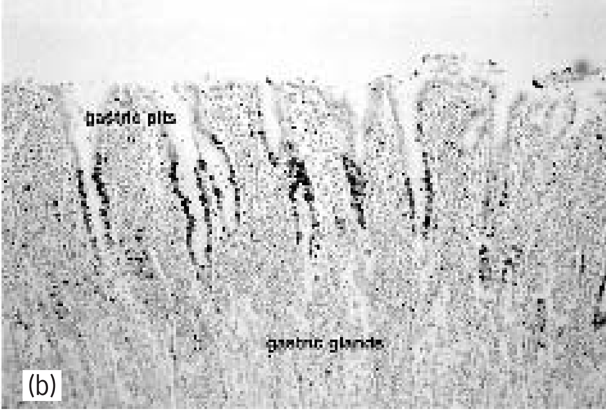


Figure 4 The area of the gastric pits which lies between the surface cells and the underlying gastric glands represents the proliferative zone of the stomach. (a) Under normal circumstances, isolated replicating cells are present, as indicated by the darkly stained cells. (b) When the mucosa becomes damaged, the number of brown staining cells increases and the gastric pits shorten. These changes indicate increased proliferation in response to mucosal injury.

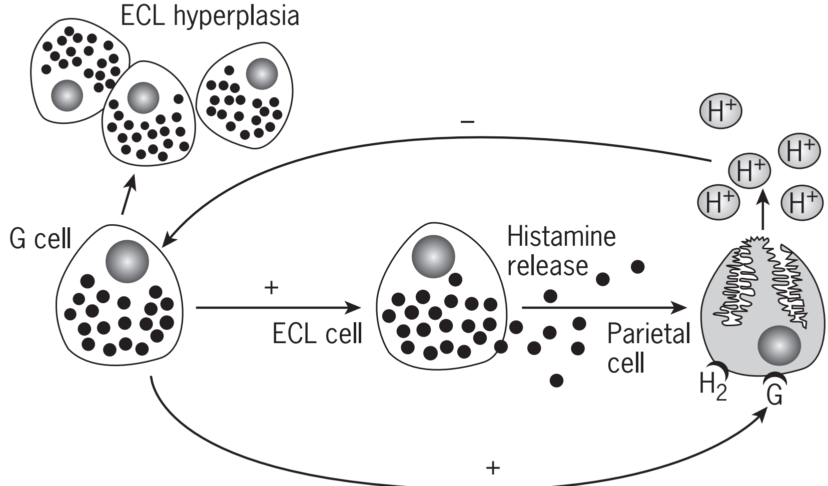

Figure 5 A feedback loop exists between parietal cells and G cells that secrete gastrin. When acid is secreted, the acid suppresses G cell function. In situations of hypochlorhydria, G cells increase their gastrin output. This serves directly to stimulate gastrin receptors on the surfaces of parietal cells. Gastrin also acts indirectly by stimulating ECL cells to release histamine. The histamine then binds to histamine receptors on the parietal cells. The binding of both gastrin and histamine to their respective receptors on parietal cells causes the acid secretion. In situations of prolonged G cell secretion, ECL hyperplasia develops.

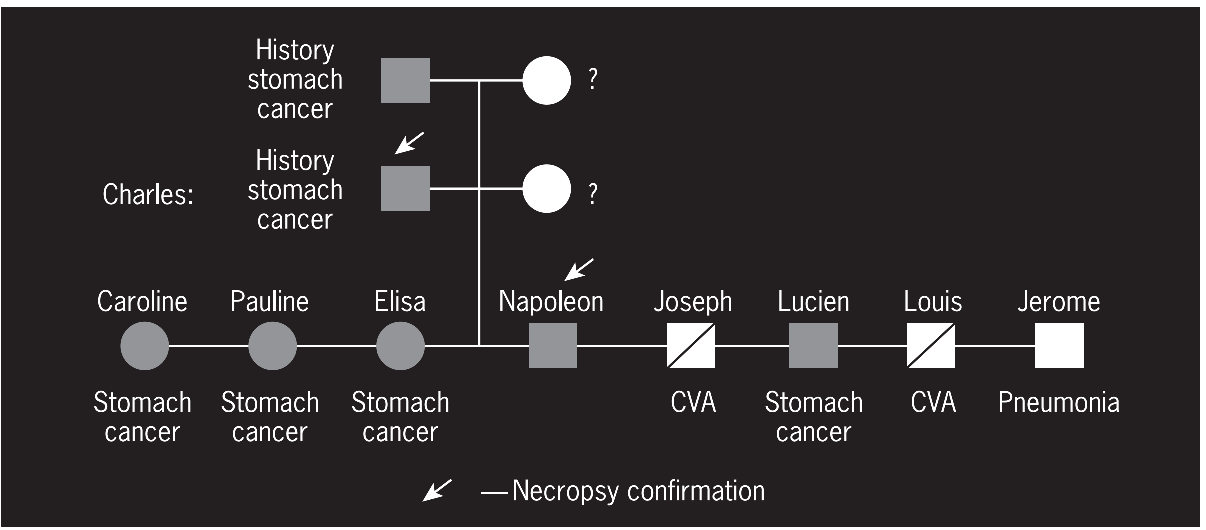

Figure 6 Diagram of the Bonaparte family tree indicating the presence of gastric cancer in several generations of the family.

Helicobacter pylori in persons whose diet is deficient in antioxidant vitamins (Correa, 1988; Nomura, 1996). Intestinal-type gastric cancer has shown a dramatic decrease in frequency in Western Europe and North America since 1940. This rapid decline in tumour incidence in westernized countries, and the persistence of high incidence rates in developing countries, suggest that gastric cancer risk is closely tied to socioeconomic status.

It is well recognized that the first-degree relatives of stomach cancer patients are at increased risk of developing gastric cancer, perhaps because the patients share common risk factors such as diet and *H. pylori* infections or because they share genetic factors that increase their risk of developing gastric cancer, or both. The Bonaparte family is a good example of a familial gastric cancer cluster (**Figure 6**) (Sokoloff, 1939). Napoleon and his father had autopsy-confirmed antral cancers. Four of his seven siblings were diagnosed with gastric cancer. Subsequently, there were 30 offspring from Napoleon's generation, and none developed gastric cancer. This and other similar familial kindreds suggest a pattern of weak genetic penetrance modulated by environmental factors. Napoleon's

brothers and sisters were raised in rural Corsica under less than ideal living conditions imposed by the hand to mouth existence of parents who, for many years, were active participants in a guerilla war against the French. The small size of the Bonaparte families after the move to the European mainland is typical of migrants who improved their economic status. The children were now housed in palaces and probably escaped *H. pylori* infection. They would have had an improved diet as well, that could have accounted for the absence of stomach cancer in subsequent generations.

Diffuse Gastric Cancer

Diffuse tumours preferentially arise in the corpus of patients <50 years of age who have severe superficial gastritis due to *H. pylori* infection (Nomura and Stemmerman, 1993). The appearance of these cancers in younger individuals without atrophic gastritis suggests the presence of a genetically driven increase in vulnerability to environmental carcinogens. Two observations support this concept. The first is the fact that patients with diffuse gastric cancers are more likely than the general population to have blood type A (Correa *et al*., 1973). Second, families with clusters of stomach cancer usually have diffuse-type carcinomas (Lehtola, 1978).

AETIOLOGY

Oesophagus

Squamous Cell Carcinoma

Oesophageal SCCs can be divided into two major risk groups: those tumours associated with tobacco and alcohol consumption and those occurring in populations consuming a poor, generally monotonous diet that lacks green, leafy vegetables, citrus fruits, micronutrients such as zinc, riboflavin and vitamin A and other unknown factors. These circumstances render the oesophageal mucosa more susceptible to injury by various carcinogens, including mycotoxins in the Transkei, substituted hydroxyphenanthrenes (a strongly mutagenic form of opium) in Iran, and *N*-nitroso compounds in China.

Heavy alcohol and cigarette consumption are recognized risk factors for oesophageal SCC, especially in Western populations. The increased risk with increasing alcohol consumption is exponential while the increase in risk from tobacco is linear (Tyuns *et al*., 1977). The strong association of oesophageal cancer with alcohol helps explain the especially high rates of oesophageal cancer in calvados-producing regions of northern France. Alcohol may contribute to an increased oesophageal cancer risk by reducing nutrient intake and by displacing protective dietary micronutrients (Ziegler, 1986). In addition, alcoholic beverages may contain carcinogens, or facilitate the transport of tobacco-associated carcinogens across the oesophageal lining. It may also impair the ability of the liver to detoxify carcinogens. In contrast, there appears to be a strong protective effect between the consumption of antioxidant vitamins and fresh fruits in areas at high risk for SCC.

Human papillomavirus (HPV) associates with the development of squamous cell carcinomas at many sites, including the oesophagus. There are approximately 70 distinct HPV strains, two of which, types 16 and 18, have been identified in oesophageal SCC. The frequency of HPV in oesophageal cancer varies from country to country, and appears to be most common in South Africa (Lewin and Appleman, 1996). HPV is probably not involved in the evolution in all oesophageal SCCs since it is absent from the majority of oesophageal cancers in Asia and Europe. When present, viral genetic sequences are present in nonneoplastic, dysplastic, invasive and metastatic lesions.

Motility disorders that delay oesophageal emptying increase the exposure of oesophageal squamous cells to ingested carcinogens. One such disorder, achalasia, results from impaired relaxation of the lower oesophageal sphincter and absent motility in the oesophageal wall. It is usually diagnosed after age 60 years. A population-based study showed that during the 24 years of follow-up, the risk increased more than 16-fold (Sandler *et al*., 1995). Fortunately, achalasia is uncommon.

Adenocarcinoma

The lining of the lower oesophagus can be injured if it is exposed to prolonged reflux of gastric acid and digestive enzymes. As a result, the normal squamous epithelium may change into a glandular lining resembling that of the stomach or intestines, producing the lesion known as Barrett metaplasia or Barrett oesophagus (Jankowski *et al*., 2000). Barrett oesophagus is a precursor to the development of oesophageal adenocarcinoma. Barrett oesophagus associates with decreased oesophageal sphincter resistance and increased gastric acid production, both of which lead to severe reflux oesophagitis. Obesity is also a risk factor, since it too predisposes to reflux disease.

Stomach Cancer

Intestinal-type Cancers

Intestinal metaplasia first appears in foci of atrophic mucosa at the antral–corpus junction (**Figure 7**). These foci ultimately fuse as the process progresses along the lesser curvature (Stemmerman, 1994). Further progression may result in the replacement of the entire antral mucosa by intestinal type glands and by proximal extension into the corpus. In late stages of the process all but a small portion of the corpus mucosa may be replaced by intestinal-type glands. In high-risk populations intestinalization of the stomach begins in adolescence, initiating a

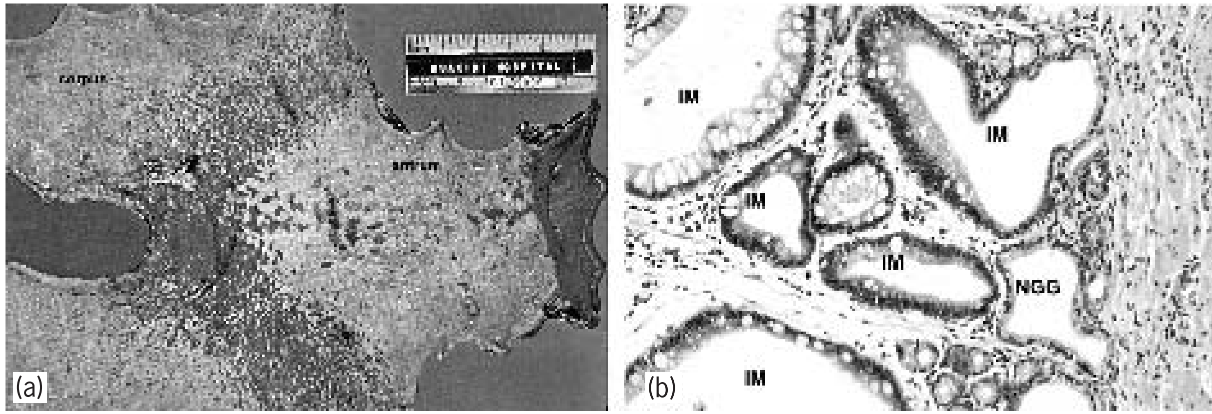

Figure 7 Intestinal metaplasia in the stomach. (a) This gross photograph of the stomach shows areas of dark staining. The stomach was immersed in a solution of alkaline phosphatase. This preferentially stains areas of intestinal metaplasia, resulting in the dark, inverted V-shaped pattern at the junction of the corpus and antrum. The duodenum located at the right hand edge of the photograph also intensely stains with the enzyme. (b) Histological features of intestinal metaplasia (IM) showing replacement of the normal gastric glands (NGG) with intestinalized glands.

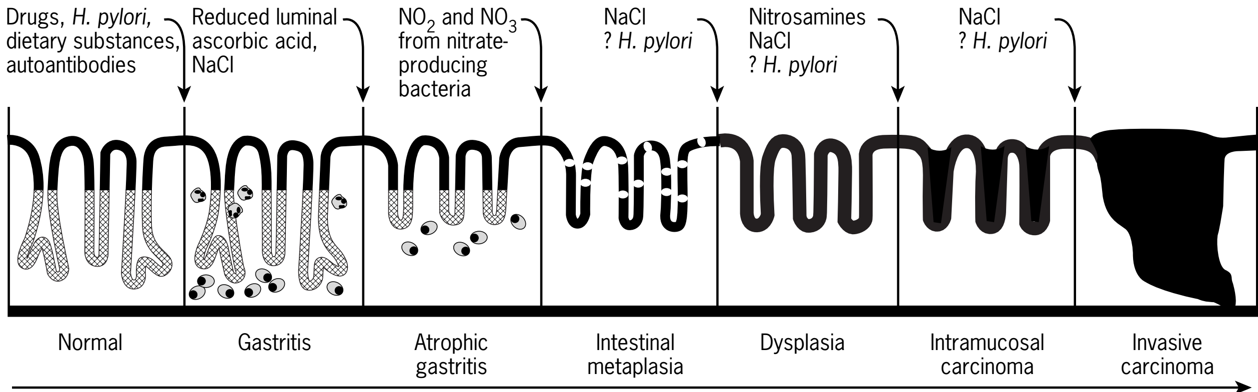

Figure 8 Diagram of the sequential abnormalities occurring in the development of intestinal-type cancers in the stomach. The individual steps are listed along the arrow at the bottom of the photograph. Substances thought to play a role in the progression of these steps are indicated above the diagram. This process is multifactorial and involves the presence of *H. pylori*, dietary substances and autoantibodies which produce gastritis and atrophy of the gastric glands that then lead to intestinal metaplasia. As a result of the atrophic gastritis and the replacement of gastric mucosa by mucosa resembling the intestine, the parietal cells decrease in number and as a result hydrochloric acid production decreases or ceases, allowing bacterial growth. These bacteria then serve to metabolize gastric contents into additional carcinogens. Additionally, the bacteria elicit an inflammatory response that generates genotoxic damage, further contributing to the molecular alterations occurring within the stomach and the genesis of a progressively abnormal gastric mucosa.

progressive expansion of the metaplasia. By the seventh decade, the metaplastic process may reduce the parietal cell volume to a level insufficient for maintaining gastric acid production. Loss of corpus chief cells results in low serum levels of PG I. As a result, tests that measure gastric acid production and serum PG I levels can identify persons who are at an increased risk for developing stomach cancer. Unfortunately, these tests do not identify individuals destined to develop stomach cancer before the intestinal metaplasia is sufficiently advanced to affect gastric function.

The sequential, multifactorial steps in the development of intestinal-type cancers seen in high-risk populations are shown in **Figure 8**. The gastritis results from the combined effects of *H. pylori* infection (**Figure 9**), high salt and nitrate intake, smoking and a diet deficient in fresh vegetables and protective antioxidant vitamins. Prospective studies have shown that 95% of persons who

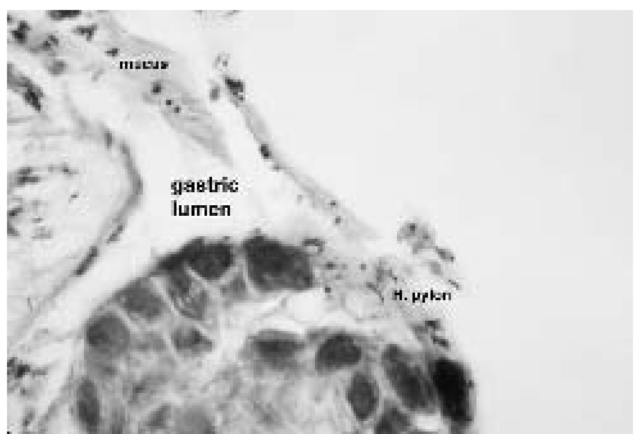

Figure 9 *H. pylori* infection of the stomach showing the presence of numerous *Helicobacter* attached to the surface epithelium. Alcian yellow stain of *H. pylori* infection showing the presence of numerous corkscrew-shaped organisms in the mucus overlying the gastric epithelial cells.

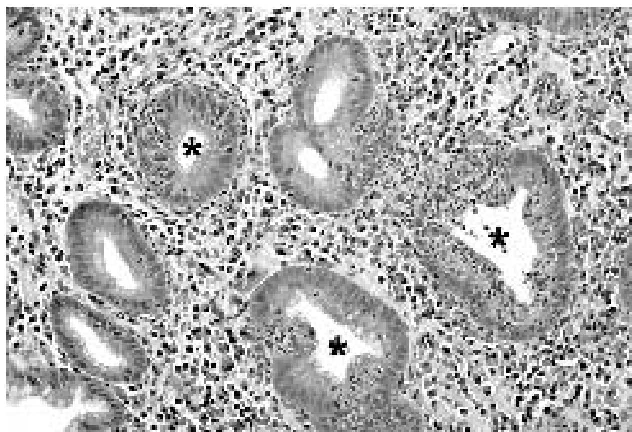

Figure 10 (a) Active chronic gastritis due to *H. pylori* infection. (b) Note the presence of large numbers of acute inflammatory cells in the starred glands.

develop cancer were infected with *H. pylori.* However, although at least 75% of persons in high-risk areas are infected with *H. pylori*, only 5% actually develop stomach cancer (Nomura and Stemmerman, 1993). Whether or not an infected person develops cancer probably depends upon their genetic predisposition to develop cancer, their level of exposure to other risk factors and possibly to the strain of *H. pylori* infecting them.

H. pylori Infection

H. pylori infection is most frequent in large families occupying crowded living quarters and lacking hot water. The infection is usually acquired during childhood, is related to birth order; the highest incidence affects the youngest children of large families (Goodman and Correa, 1995). *H. pylori* infection is most common among those with the shortest duration of schooling. The smaller families and improved housing that typify a prosperous economy in developed countries may explain, at least in part, the decrease in their gastric cancer rates.

H. pylori infection increases gastric cancer risk via several pathways. The infection causes epithelial cell damage and the rate of cell proliferation increases in response to the cell loss. As the cells proliferate, the DNA unwinds, increasing the number of gastric cells vulnerable to genotoxic damage and subsequent genetic instability. Additionally, *H. pylori* infections generate a brisk inflammatory response with invasion of the replicating epithelium by white blood cells (**Figure 10**). Two types of inflammatory cells, neutrophils and monocytes, generate the toxic molecule, nitric oxide (NO) (**Figure 11**). In addition, other toxic molecules can be generated from NO including nitrosamines. Nitrosamines induce mutations in bacteria and are gastric carcinogens in many animal models. The local production of these compounds near the replicating gastric epithelium exposes them to an increased risk of DNA damage. The inflammatory cells also induce free radical damage due to the formation of NO and its oxidative byproducts. Vitamin C (ascorbic acid), an antioxidant, protects the gastric mucosa against oxidative stress. However, *H. pylori* infections decrease ascorbic acid concentrations in the gastric juice. Not all *H. pylori* are equally efficient in inducing the changes noted above. The most virulent of the bacteria contain a gene known as *cag* (Blaser *et al*., 1995).

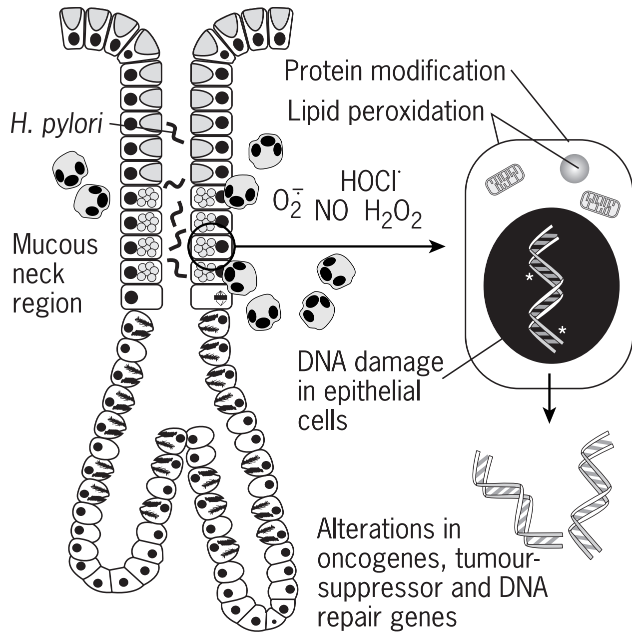

Figure 11 Diagram of the injury induced by neutrophils in the mucous neck region.

Diet and Stomach Cancer

Dietary patterns were once thought to be *the* most important basis of gastric cancer induction, and although diet has recently conceded the pride of place to *H. pylori* infection, diet still retains a major role in the cause and prevention of this tumour. Strong experimental and epidemiological evidence links salt intake to gastritis, intestinal metaplasia and gastric cancer. Evidence that dietary nitrite and nitrate play a direct role in gastric carcinogenesis is inconclusive, but these substances do induce intestinal metaplasia. Foods with high salt and nitrate concentrations, such as dried and salted fish or pickled vegetables, predispose to stomach cancer in many studies. Such foods constituted a major portion of the diet prior to the almost universal ownership of household refrigeration in Western countries and the availability of fresh or frozen fruits, vegetables, fish and meat. The decrease in gastric cancer rates in Western countries since 1945 is attributable to altered dietary habits with decreased consumption of the potential carcinogens in smoked, salted and pickled foods.

Autoimmune Gastritis

Autoimmune gastritis is a precursor to both benign and malignant stomach tumours. It is less common than multifocal gastritis and it develops when patients generate antibodies against their own parietal and chief cells. Cell proliferation in the corpus increases in response to the antibody-mediated cell loss. However, because cell destruction proceeds faster than cellular replacement, the mucosa of the corpus becomes atrophic. Loss of parietal cells results in a reduction in gastric acid production and a compensatory increase in antral gastrin secretion. The increased gastric cancer risk in this condition results from several synchronous events: (1) a bacterial flora emerges in the stomach which can generate potential carcinogens from dietary amines; (2) endogenous production of mutagens may follow NO production by reacting white cells in the stomach lining; (3) the increased cell turnover puts more cells at risk of accumulating genetic damage; and (4) gastrin functions as a growth promoter of gastric lining cells.

The diagnosis of autoimmune gastritis is confirmed by demonstrating low or no stomach acid and very low serum levels of pepsinogen group I (Samloff *et al*., 1975). As in multifocal gastritis, the gastric mucosa of patients with autoimmune gastritis may develop intestinal metaplasia. The increased gastrin production stimulates gastric mucosal growth, sometimes contributing to the development of gastric polyps and gastric carcinoma (**Figure 12**). The risk of developing carcinoma with autoimmune gastritis varies from 2.1 to 5.6 times that of persons without the condition. The cancers arise in the antrum as well as in the corpus.

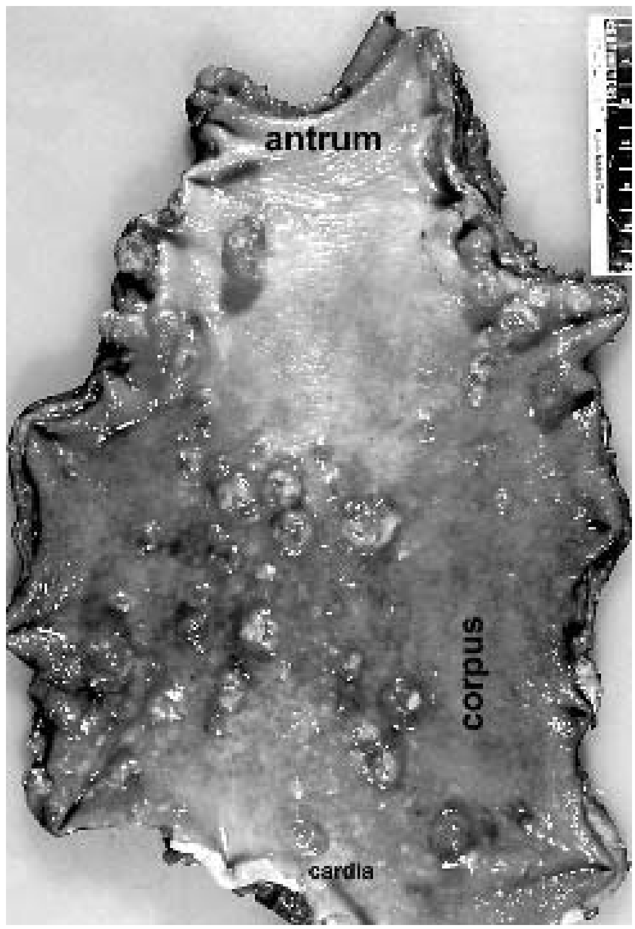

Figure 12 Gross photograph of a stomach from a patient with autoimmune gastritis showing the presence of numerous gastric polyps, as well as a gastric carcinoma. They mainly arise in the corpus. The surrounding mucosa is atrophic.

Previous Surgery

The risk of developing stomach cancer complicates previous ulcer surgery (Fisher *et al*., 1993). Bleeding from antral or duodenal peptic ulcers historically required the removal of these segments of the gastrointestinal tract, and also the nerves that stimulate acid secretion. The gastric remnant was often joined to a small intestinal loop, resulting in reflux of intestinal and pancreatic juices into the gastric remnant. This reflux of digestive enzymes into the denervated gastric remnant causes a gastritis resembling multifocal or autoimmune gastritis, increasing the gastric cancer risk. The elevation of risk becomes apparent 20 years after the resection and increases thereafter. The younger the patient at the time of surgery, the greater the risk of ultimately acquiring a carcinoma.

Radiation

The stomach is sometimes in the radiation field in patients with abdominal tumours, especially certain forms of lymphoma occurring in young people. A small number of these patients have an increased risk of developing stomach cancer. The tumours derive from X-ray-induced mutations in the gastric mucosa. Japanese victims of the

Hiroshima/Nagasaki atomic bomb explosions also had an increased incidence of gastric cancer.

Diffuse Cancer

The aetiology of diffuse gastric cancer is poorly understood, although *H. pylori* infections appear to play a role in their genesis.

SCREENING AND PREVENTION

Oesophagus

Squamous Cell Carcinoma

Patients with SCC present with dysphagia (difficulty swallowing) or with odynophagia (pain). Initially, symptoms only occur with the consumption of solid foods, but as the tumour progresses even liquids are swallowed with difficulty. Severe weight loss results from decreased food intake. Many cancers ulcerate, resulting in upper gastrointestinal bleeding. The bleeding is usually inconspicuous and is not noticed by the patient. Fatal internal bleeding may occur if a deeply invasive cancer erodes a major blood vessel. The only way to avoid these dire consequences is to screen populations at risk for the disease. The intent of screening programmes is to detect tumours while they are still curable. This is possible because cancers develop over a period of time, usually evolving over a decade or more.

The study of oesophageal lining cells that are dislodged by the passage of a brush or a balloon (cytological examination) allows the discovery of cancerous cells in early phases of tumour progression (**Figure 13**). Cytology screening programmes form the basis of community screening programmes in the high-risk areas of central China where up to 50% of the resected oesophageal cancers are noninvasive or early invasive tumours (Qui and Yang, 1988). In contrast, SCC is too uncommon in Western populations to justify community screening programmes. Rather, diagnostic procedures in most Western, low-risk countries are designed to explain the symptoms of late-stage disease and to estimate the extent of the cancer that caused them. The diagnosis is usually made on tissue obtained from an endoscopic biopsy.

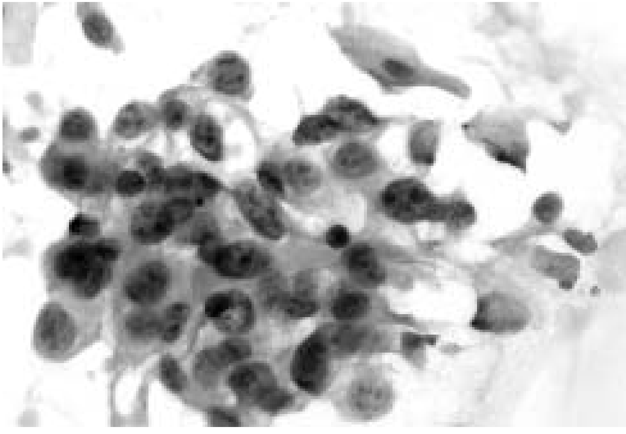

Figure 13 Cytological preparation of a carcinoma of the oesophagus. These cells were brushed off the surface of the oesophagus. They preferentially dislodge because of their malignant qualities. They have enlarged nuclei and small amounts of cytoplasm. There is cytologic atypia.

Suggested guidelines for endoscopic surveillance of the oesophageal mucosa in patient populations with a high risk of developing squamous cell cancer areas are as follows: biopsy specimens should be obtained from all plaque-like, nodular, erosive and friable areas; normal areas, including mildly wrinkled mucosa and isolated small white patches, need not be sampled; and biopsy specimens should be obtained from diffusely irregular (prominently wrinkled) mucosa and distinct areas of focal reddening at the endoscopist's discretion.

It remains unclear as to whether these recommendations should be applied to patients in non-high-risk areas, although they may be a desirable addition to the examination of patients entering an alcohol abuse treatment programme.

Adenocarcinoma

The symptoms associated with progression of oesophageal adenocarcinomas are essentially similar to those associated with SCC – difficulty swallowing, obstruction of the passage of solid foods, weight loss and dissemination to other sites. As is the case of SCC, long-term survival requires diagnosis at a preinvasive or early invasive stage. This is most likely to occur if patients known to have Barrett change are screened on a regular basis in order to detect progression of the process to the level of high-grade dysplasia.

The following management approach is that recommended by the 1990 Barrett's Esophagus Working Party of the World Congress of Gastroenterology (Dent, 1989):

- A programme of regular endoscopic surveillance for dysplasia and early carcinoma is recommended for patients with Barrett oesophagus unless contraindicated by comorbidity. For patients who have no dysplasia or cancer, endoscopy (with procurement of biopsy and brush cytology specimen(s) from the Barrett's epithelium) is performed every other year.
- If dysplasia is detected, the finding should be confirmed by at least one other expert pathologist. If any doubt remains, the endoscopic examination is repeated immediately to obtain more biopsy and cytology specimens for analysis.
- For patients confirmed to have multiple foci of high-grade dysplasia, surgery is advised to resect all of the oesophagus lined by columnar epithelium.

- For patients confirmed to have low-grade dysplasia, intensive medical antireflux therapy (including omeprazole) should be given for 8–12 weeks, at which time endoscopic examination is repeated to obtain multiple oesophageal biopsy and cytology specimens.
- For patients whose specimens show histological improvement, intensive surveillance (e.g. endoscopic examination every 6 months) is recommended until at least two consecutive examinations reveal no dysplastic epithelium.
- For patients with persistent low-grade dysplasia, continued intensive treatment and surveillance are recommended.

Stomach

The nature of the symptoms depends upon the site and growth pattern of the tumour. Bulky tumours may erode and cause bleeding, while diffuse tumours may restrict the expansion of the stomach, causing early satiety and severe weight loss due to decreased food intake. It is not unusual for the first symptoms to be caused by metastases in sites remote from the stomach. In young women, the spread of gastric cancer to the ovaries produces so-called Krukenberg tumours that may reach the size of a grapefruit. Other symptoms caused by metastases include spread of the cancer to the lymph nodes of the lower neck and to the accumulation of excess fluid in the abdominal cavity. The configuration and mode of progression of stomach cancer depend upon the age and sex of the patient, the subsite of its origin within the stomach and its histological type.

The Japanese, in response to the high incidence of gastric cancer in their country, have introduced community screening to detect cancers early in their development. As a result, 50–60% of stomach cancers are discovered while still limited to the stomach lining or to the tissues immediately beneath it. Recent Japanese studies have also assessed the effectiveness of radioimmunoassays to determine the serum pepsinogen group I level (PG I), and the ratio between PG I and PG II in predicting the presence of stomach cancer in participants in an endoscopic screening programme (Kitahara *et al*., 1999). However, the sensitivity of this approach is not sufficient to detect all tumour cases. Additional variables must be identified before a focused screening programme can be used to identify high-risk subjects in low-risk Western settings. These might include two or more of the following: (1) first-generation migrants from countries with high rates of gastric cancer; (2) a high *H. pylori* antibody level; (3) persons with a strong history of stomach cancer among close family relatives; (4) smokers with a history of stomach ulcer; (5) persons who have had a partial resection of the stomach 17 or more years previously; and (6) persons who have received radiation treatment to the upper abdomen prior to age 30. Japanese studies of patients with untreated early cancer suggest that re-examination need not be performed more frequently than every 5 years.

PATHOLOGY

Oesophageal Carcinoma

Squamous Cell Carcinoma

As the oesophageal lining passes through a series of sequential steps that eventually result in the development of invasive SCC, it becomes progressively abnormal, a change that can be seen both by gross examination and by examination under the microscope. These steps include the presence of varying degrees of intraepithelial (non-invasive) neoplasia, termed dysplasia, finally ending in an invasive carcinoma that has the ability to spread and kill the patient (**Figure 14**).

Gross Appearance

The gross appearance of oesophageal neoplasia varies with the stage of neoplasia present. The earliest lesions may

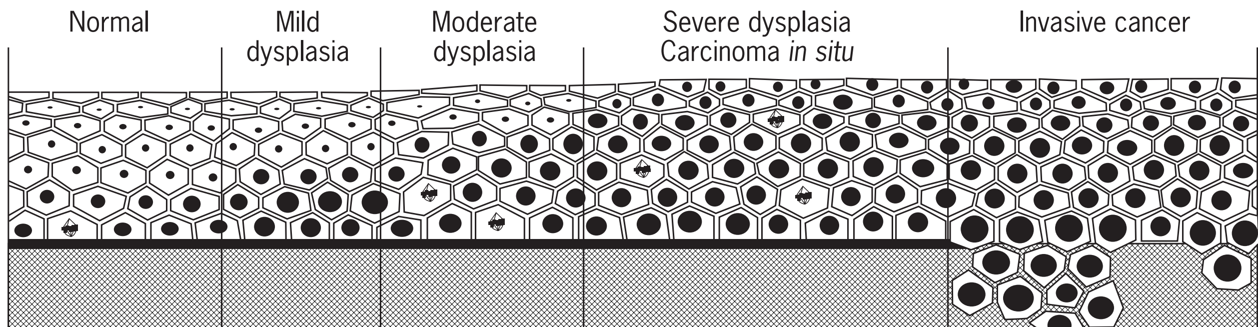

Figure 14 Diagrammatic summary of the progression of squamous cell neoplasia. As the disease progresses, more and more of the thickness of the oesophageal mucosa becomes replaced by neoplastic cells. These eventually invade through the area of the basement membrane into the underlying lamina propria and then into the submucosa. From here they can metastasize to sites distant from the oesophagus.

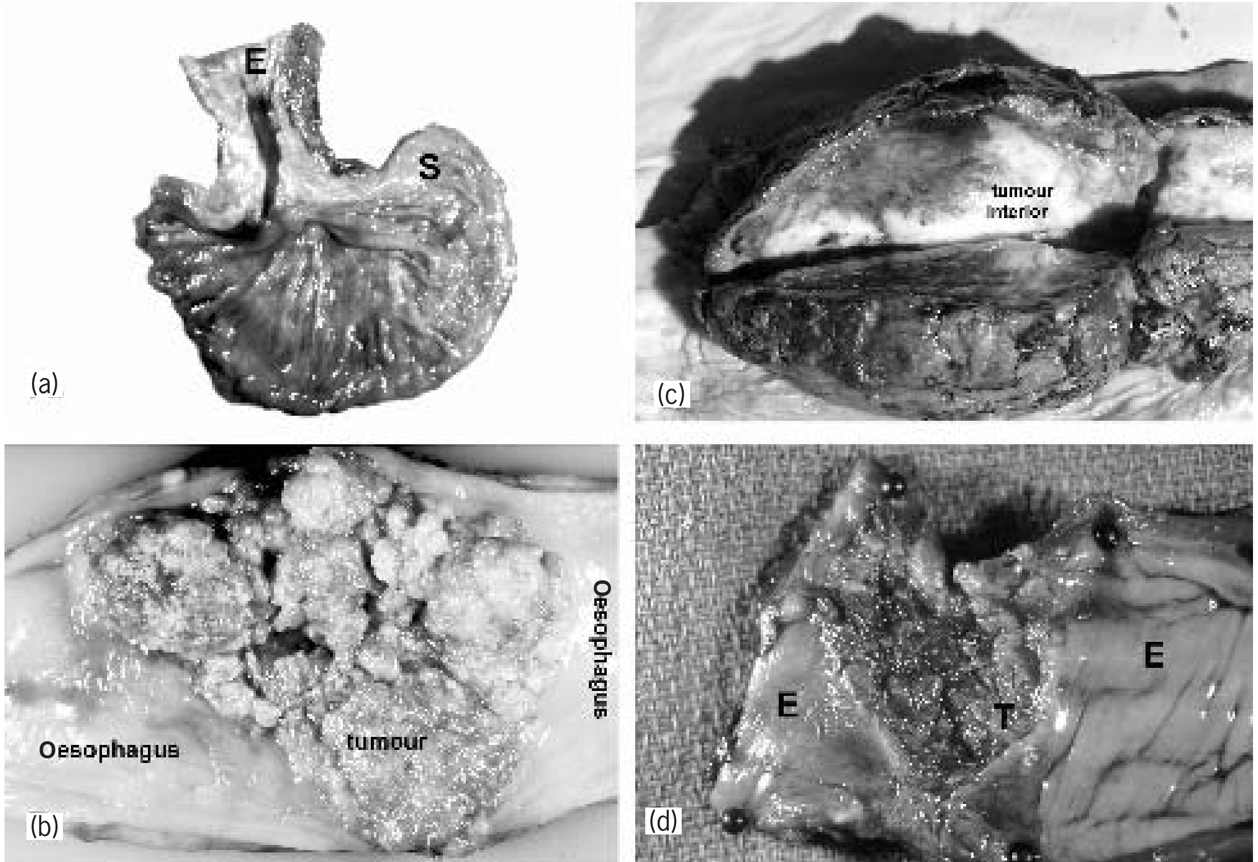

Figure 15 Gross appearances of oesophageal cancers. Oesophageal squamous cell cancers may assume a variety of gross appearances. (a) Diffuse infiltration of the oesophageal wall causes thickening of the distal end of the oesophagus (E). The line shows the area of the tumour. The stomach (S) is also present. (b) An exophytic papillary tumour rises above the surrounding oesophageal mucosa. (c) A large, bulky, polypoid growth. The tumour has been cut in half. (d) An ulcerating oesophageal cancer (T) is surrounded by normal oesophagus (E).

appear completely normal to the naked eye or to the endoscopist. (The endoscopist is the clinician who examines the oesophageal mucosa with a magnifying camera inserted into the oesophageal lumen). Alternatively, the oesophageal mucosa may appear reddened owing to inflammation and vascular congestion induced by the presence of neoplastic cells. Early lesions (intraepithelial or minimally invasive lesions) may also appear as areas of superficial erosion and/or as whitish plaques. Such lesions may be single or multiple. Invasive carcinomas usually arise from these erosive or plaque-like lesions. Invasive SCC usually arise in the distal half of the oesophagus, although they can occur anywhere. Grossly, invasive oesophageal squamous cell cancers assume various growth patterns (**Figure 15**). They may be large bulky polypoid lesions growing into and obstructing the oesophageal lumen. Other tumours grow as flat lesions or they grow into the oesophageal wall, creating oesophageal ulcers. Still other tumours diffusely infiltrate the oesophageal wall, causing oesophageal strictures. These growth patterns can occur alone, or they can associate with one another. The extent and configuration of an invasive tumour partly determines how a patient presents. Patients with bulky polypoid lesions, or with areas of stenosis, are more likely to experience difficulty in swallowing than those with ulcerating or flat tumours.

Microscopic Appearance

As indicated in an earlier section, the oesophageal mucosal lining consists of an orderly arrangement of squamous epithelial cells that regularly renew themselves. Progenitor cells lying in the basal zone give rise to new cells that become increasingly mature as they pass upward in the mucosa. As part of their maturation, the cells progressively enlarge acquiring a smaller nuclear–cytoplasmic ratio as they do so. When the cells become neoplastic, they lose this orderly pattern of growth and maturation and proliferation no longer remains restricted to the basal cell layer. The cells appear disorganized and jumbled, and depending on the degree of change that is present, mitotic activity appears at various levels in the epithelial layer. This earliest form of neoplasia is called dysplasia and

implies the presence of an unequivocally neoplastic epithelium.

Historically, dysplasia came in several grades, ranging from mild to moderate to severe (**Figure 16**). When the entire epithelial thickness is replaced by neoplastic cells, the process may be termed carcinoma *in situ* (CIS). Today there is a tendency to place intraepithelial neoplasias into two grades, high- and low-grade dysplasias. Using such a two-tier system, CIS falls into the category of severe dysplasia. Progression of squamous cell neoplasia beyond CIS is recognized by the presence of disruption of the basement membrane and penetration of the tumour into the underlying tissues. The term microinvasive carcinoma can be used if the invasive tumour tongues are minute, penetrating only a few millimetres into the underlying tissues. Once invasion has occurred, the tumour may spread horizontally beneath the intact squamous cell lining adjacent to the cancer, or it may variably penetrate through the oesophageal wall, eventually reaching its external surface and potentially entering contiguous structures. If that structure is the trachea, ingested food can be aspirated into the lungs via the fistula created by the tumour. If the adjacent structure is the aorta or pulmonary artery, massive and fatal internal haemorrhage will result. If the patient is spared either of these devastating events, the tumour may find its way into the lymph channels that drain the wall of the oesophagus. Tumour cells in these lymphatics may then spread to regional lymph nodes and then disseminate to more distant sites causing metastases in other organs.

Invasive squamous cell carcinomas exhibit varying degrees of cellular differentiation. If they closely resemble the squamous cells from which they arose, they are termed well-differentiated squamous cell carcinomas. Tumours composed of cells difficult to recognize as being squamous in nature are termed poorly differentiated. Tumour cells whose degree of differentiation is intermediate between these two extremes are said to be moderately differentiated.

Adenocarcinoma of the Oesophagus

As indicated above, oesophageal adenocarcinomas do not arise from the native squamous epithelium. Rather, they arise from areas of Barrett oesophagus which is a metaplastic epithelium consisting of glandular cells. As with squamous cell carcinomas, the epithelial lining of Barrett oesophagus becomes progressively abnormal as it passes through a series of sequential steps that eventually result in the development of invasive adenocarcinoma (**Figure 17**). These steps include the development of glandular dysplasia followed by the appearance of an invasive malignancy.

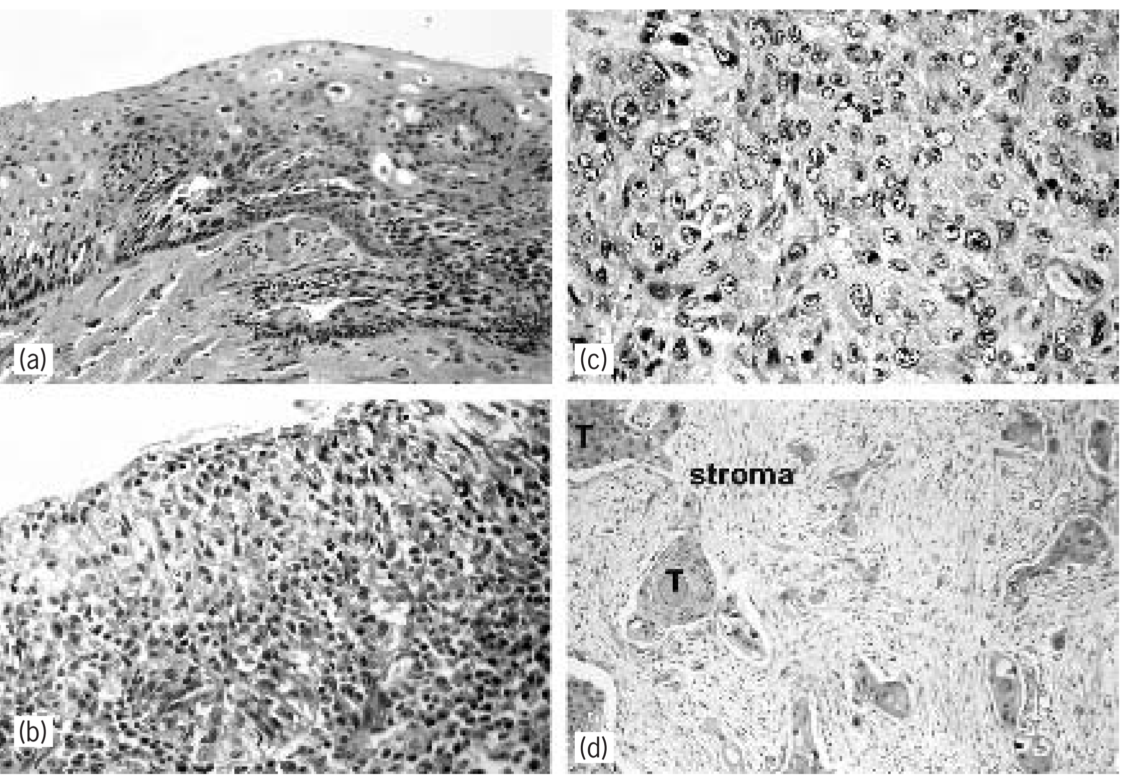

Figure 16 Histological features of the progression of oesophageal squamous cell neoplasia. (a) Low-grade dysplasia. (b) High-grade dysplasia. (c) Carcinoma *in situ*. (d) Invasive cancer. The tumour nests (T) are surrounded by a desmoplastic stroma.

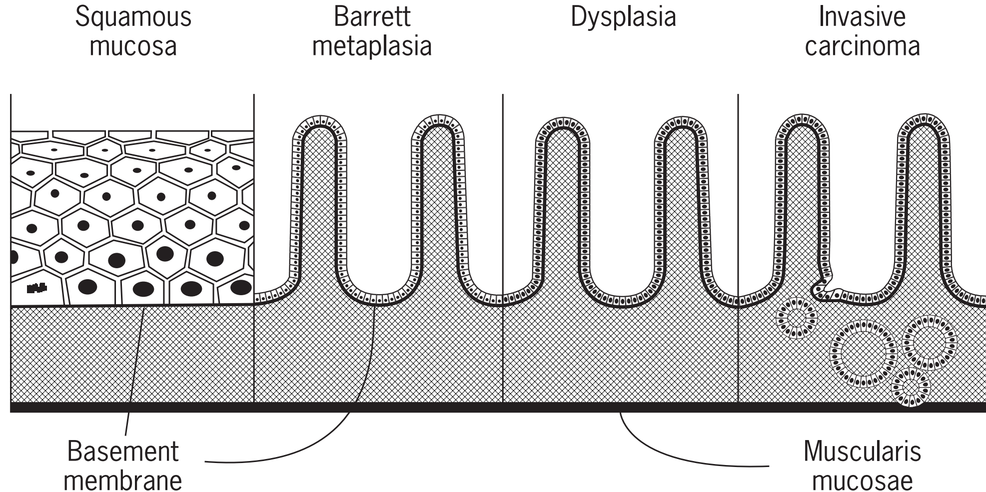

Figure 17 Diagrammatic representation of the progression of the normal oesophagus to an adenocarcinoma arising in the background of Barrett oesophagus.

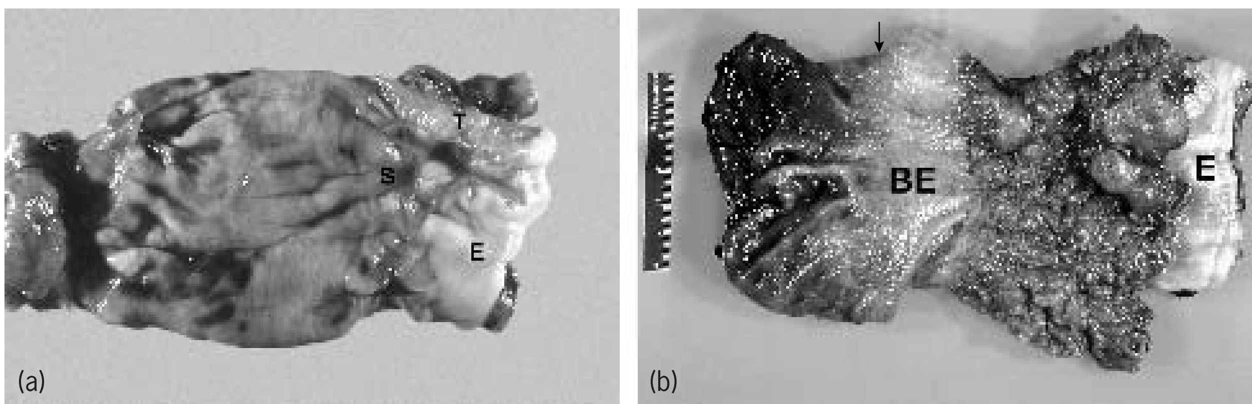

Figure 18 Gross appearance of adenocarcinoma arising in Barrett oesophagus. (a) Note the irregularity of the squamocolumnar junction. Normally, there should be a sharp demarcation with the distal stomach. The stomach (S) ends near the S. The smooth, lighter coloured mucosa represents the normal colour of the oesophagus (E). A small tumour is present beneath the T. (b) This photograph shows a large, fungating neoplasm arising in an area of Barrett oesophagus. The gastric folds terminate at the area of the arrow. The area above this is replaced by Barrett oesophagus (BE). Above that is the tumour, and the smooth, lighter coloured area of the mucosa represents normal oesophagus (E). The oesophagus has been extensively replaced by glandular epithelium and by the neoplasm.

Gross Appearance

The gross appearance of oesophageal glandular neoplasia varies, depending on the stage in the process at which it is examined (**Figure 18**). The lower end of the oesophagus loses its normal pinkish tan smooth appearance, typical of the native squamous mucosa, and instead it becomes reddened and less smooth. This is the earliest change and it is seen in patients with Barrett oesophagus. The mucosal alterations may make it difficult to determine where the original gastro-oesophageal junction lay before the Barrett oesophagus developed. The best way of determining the proximal extent of the stomach is to identify the termination of the gastric folds. The dysplasias that develop in the areas of Barrett oesophagus may be flat or polypoid. Those that are flat may be completely invisible to the naked eye and to the endoscopist. Some areas of dysplasia may appear slightly depressed or ulcerated. As invasive cancers develop, they tend to invade both laterally and into the oesophageal wall. Such lesions may be more visible when the cut surface of the oesophagus is examined or if the tissues are palpated for areas of firmness. It is very common for adenocarcinomas to extend underneath adjacent normal tissues. When the tumours become large, bulky polypoid or ulcerating lesions, it may be impossible

to tell whether they arose in the distal oesophagus or in the cardia of the stomach. These are sometimes referred to as tumours of the oesophageal–gastric junction The majority of these cancers are flat or ulcerated, although in a third of the cases they may form elevated masses – polypoid cancers.

Microscopic Appearance

Disordered cell growth, called dysplasia, constitutes the first step in the progression of Barrett change into cancer. Dysplasia is recognized by the appearance of an increased nuclear–cytoplasmic ratio and loss of nuclear polarity. Initially, the metaplastic glands are lined by cells that become pseudostratified, somewhat resembling colonic adenomas. As the degree of dysplasia progresses, the cells become increasingly disorganized and the nuclei lose their pseudostratified appearance. Invasive cancer becomes recognizable once the tumour cells extend through the muscularis mucosae into the underlying submucosa. The evolution from low-grade dysplasia through moderate- to high-grade dysplasia and invasive cancer is shown in **Figures 17 and 19**. Overall, many invasive tumours appear to be very well differentiated because they make clearly identified glands. Other tumours are poorly differentiated and it is difficult to identify glandular structures. Even well-differentiated tumours have the tendency to undermine adjacent non-neoplastic tissues and to invade the lymphatics of the oesophageal wall at an early stage. As a result, most cancers arising at the cardio-oesophageal junction are late-stage tumours, with dissemination to lymph nodes on both sides of the diaphragm at the time of diagnosis. Spread of these tumours to the liver is also fairly common. Oesophageal cancers that have progressed to the point of causing symptoms carry an extremely poor prognosis. The majority of symptomatic oesophageal cancers are unresectable, and the average life expectancy of untreated patients is less than 10 months.

Stomach Cancer

Gross Appearance

The gross appearance of early gastric cancers tumours is shown in **Figure 20**. Protruded, type 1, early cancers are most likely to occur in the antrum of older male patients with diffuse intestinal metaplasia of the stomach. Flat or ulcerated type 2 and 3 early tumours are more likely to occur in younger patients and may arise in the mucosa at the junction of the antrum and corpus of a stomach showing minimal or no intestinal metaplasia.

The appearance of advanced tumours is shown in **Figures 21 and 22**. Cancers that arise in the corpus are usually type IV tumours, as are most cancers that occur in women <50 years old. All other growth patterns preferentially affect antral tumours, and they are most frequent in older men from high-risk populations.

Microscopic Appearance

Gastric cancer presents a complex variety of growth patterns, and one cancer may assume several forms. Lauren, a Finnish pathologist, devised a simplified classification of these tumours (Lauren, 1965), which subsequently proved helpful to epidemiologists studying the origins of stomach cancer. This system is based on the observation that many stomach cancers form rudimentary glands that superficially resemble intestinal glands; these are termed intestinal in type (**Figure 23**). Others consist of discohesive cells that form no distinct structures and stimulate an overgrowth of the supporting connective tissues (**Figure 24**). These are termed diffuse tumours and their cells may be so widely separated from one another that that they are difficult to identify. The antral tumours in older men with extensive multifocal gastritis generally are intestinal in type, whereas the cancers that arise in the corpus of younger men and women are usually diffuse in type. In addition, most stomach cancers arising in high-risk areas are intestinal in type. It is not unusual for gastric cancers to show both patterns of growth and these can be called mixed tumours. A committee of World Health Organisation pathologists devised another classification scheme, that identifies the many variants of stomach cancer (**Table 1**). Classifying gastric cancer is difficult by either system, and interobserver differences lessen their value as prognostic markers for individual cases.

TREATMENT

Oesophagus

Squamous Cell Carcinoma

Surgical treatment of SCC is most likely to be successful when the tumour is confined to the lining of the oesophagus or when the invasive tumour is limited to the most superficial portion of the oesophageal wall. The extent of the tumour may be estimated through the use of endoscopic sonography, which uses echoes of ultrasonic pulses at the time of endoscopy to measure the depth of tumour penetration into the oesophageal wall and to identify metastases into the regional lymph nodes. This procedure allows the physician to assign a stage to the tumour and to plan patient treatment. The standard staging method employed is termed the TNM system, where T indicates the extent of tumour penetration, N indicates the presence or absence of lymph node metastases and M indicates the presence or absence of distant metastases. The TNM staging criteria for oesophageal cancer are shown in **Table 2**.

The treatment of the late-stage oesophageal cancer that typically confronts the physician in most Western countries is more likely to be palliative than curable. Surgery may resect or bypass the tumour, ionizing radiation may be used to shrink or destroy it and chemotherapy may be used

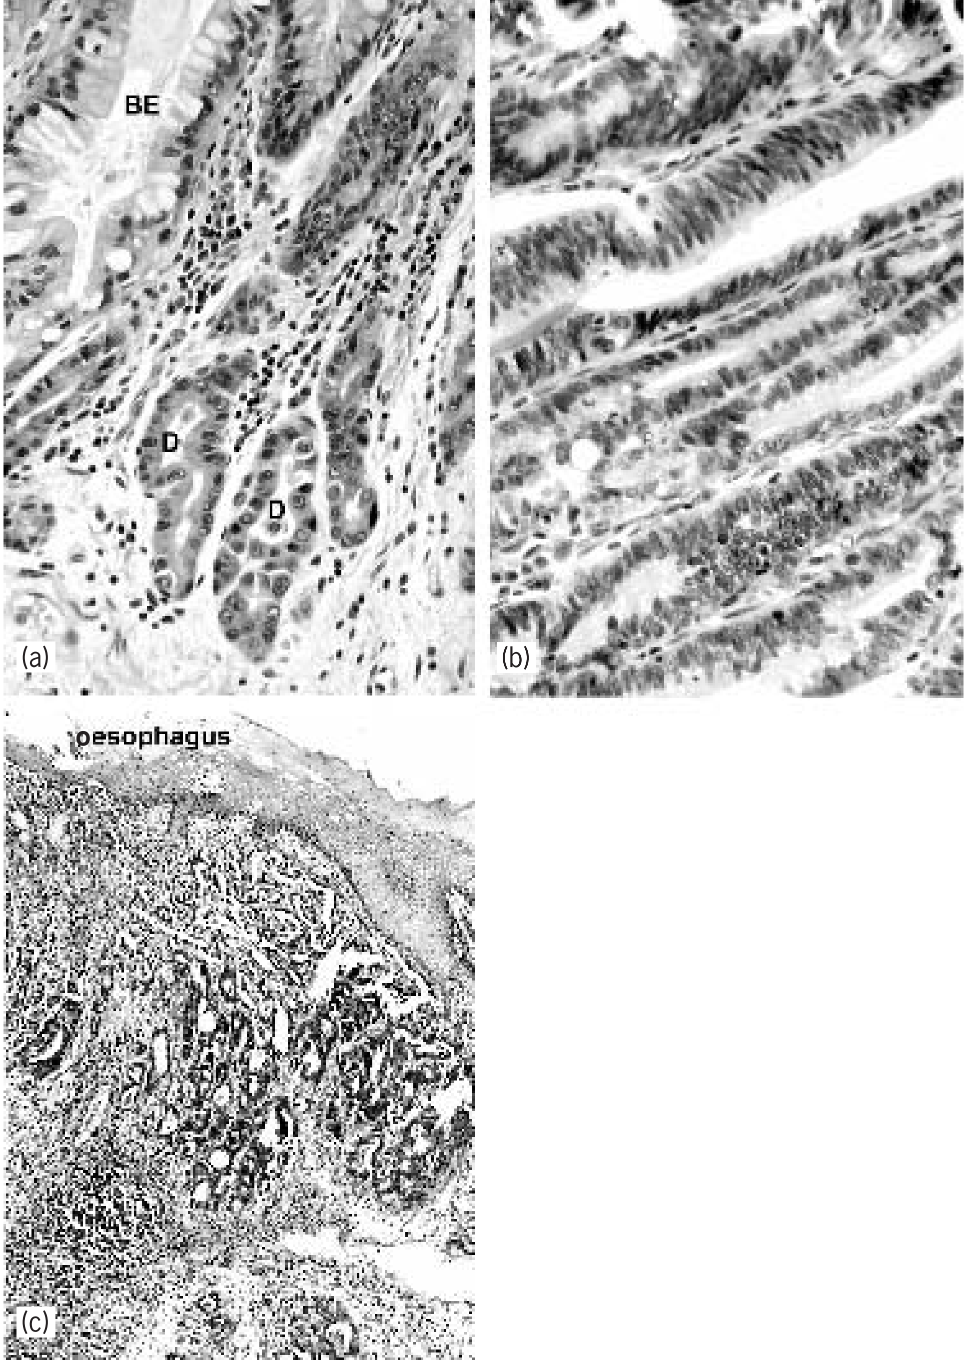

Figure 19 Evolution of the neoplastic changes in Barrett oesophagus. (a) The squamous epithelium has been replaced by glandular epithelium. One gland is a non-neoplastic gland representing Barrett oesophagus (BE). The majority of the glands that are present show evidence of low-grade dysplasia (D). (b) Further progression of the dysplasia with the presence of large numbers of cells showing nuclear palisading. (c) An invasive adenocarcinoma undermining the normal squamous mucosa of the oesophagus.

to control its growth. These approaches may be used alone or in combination with one another, depending upon the stage of the tumour and the physical condition of the patient. For example, the presence of cirrhosis of the liver, a not uncommon condition among heavy alcohol users with advanced oesophageal cancer, may preclude the use of many chemotherapeutic agents. In contrast, an early cancer in an otherwise healthy patient may be treated by surgical resection alone. Radiation or chemotherapy may be used prior to surgery (so-called neoadjuvant therapy) in

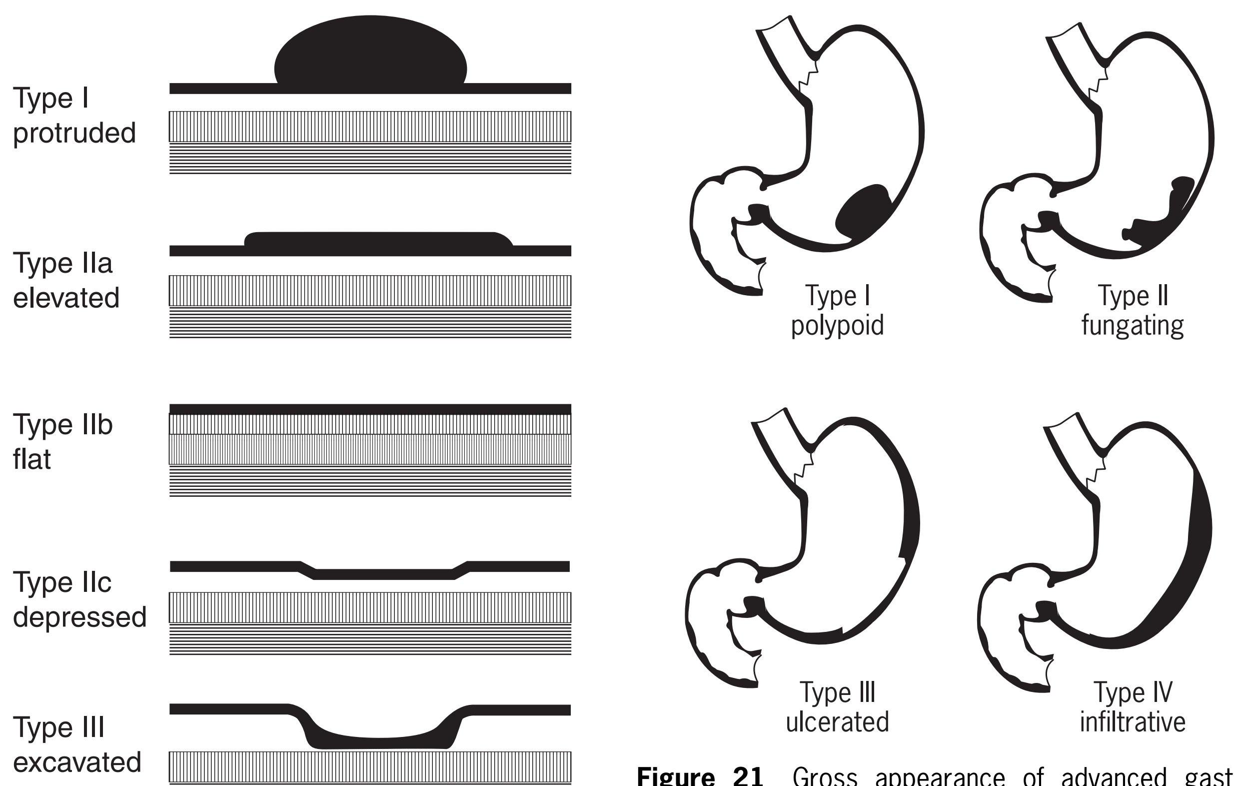

Figure 21 Gross appearance of advanced gastric cancer.

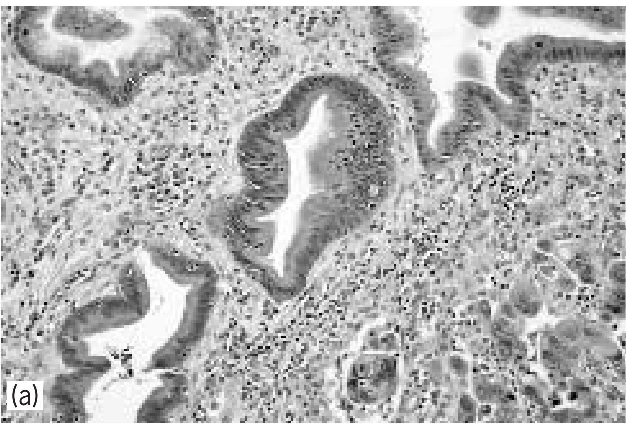
(b) A Borman type III lesion shows a heaped-up, ulcerated lesion. (c) A Borman type II gastric carcinoma shows a fungating tumour. (d) Linitis plastica with diffuse thickening of the gastric wall.



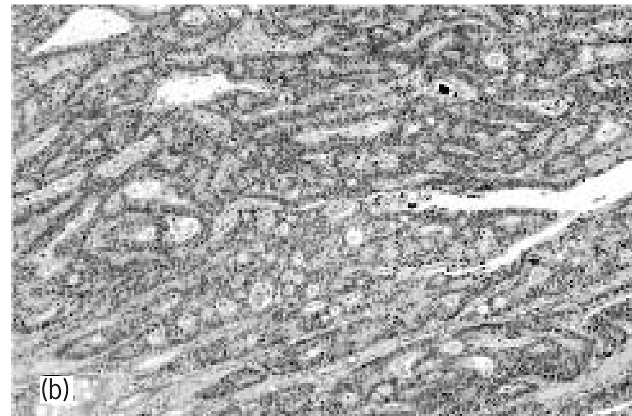


Figure 23 Gastric cancer of the intestinal type. (a) A combination of well- and poorly-differentiated carcinoma. The tumour forms reasonably intact glands everywhere except in the lower right-hand corner where they are discohesive. (b) Back-to-back glands in a moderately differentiated intestinal-type carcinoma.

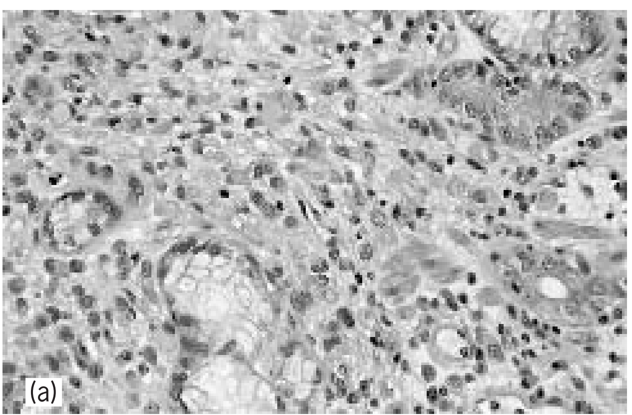

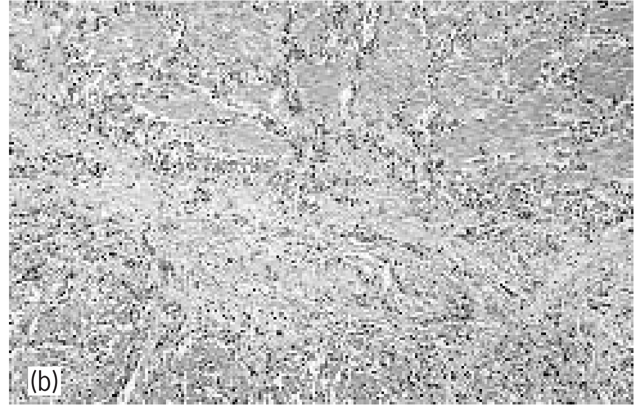

Figure 24 Diffuse gastric carcinoma. In contrast to the cancers illustrated in Figure 23, glandular formations are not present. (a) The tumour cells diffusely infiltrate the intestinal wall. (b) Infiltration of these same cells through the deeper layer of the stomach.

Table 1 World Health Organization classification of histological types of epithelial tumours of the stomach

Adenocarcinoma	Adenosquamous carcinoma
Papillary	Squamous cell carcinoma
Tubular	Undifferentiated carcinoma
Mucinous	Unclassified carcinoma
Signet ring cell carcinoma	

order to reduce the tumour to manageable proportions or may be used to supplement a surgical procedure so as to diminish the risk of early recurrence, so-called adjuvant therapy. Radiation may also be used alone to palliate symptoms in treating patients with inoperable disease.

The relative 5-year survival with oesophageal cancer in the United States for the year ending 1988 was only 8.1%. This is a measure of the grim prognosis that accompanies the late-stage cancers that prevail in that country. Fewer than 3% of patients with late-stage tumours survive for 5 years after diagnosis.

Table 2 TNM classification of oesophageal tumours

Primary tumour (T)	
T1	No obstruction or circumferential involvement
T2	Obstruction and/or circumferential involvement
T3	Extraesophageal spread
Nodal involvement (N) (surgical evaluation)	
N0	No involvement
N1	Positive nodes
Distant metastases (M)	
M0	None
M1	Present
Stage I	T1, N0, M0
Stage II	T1, N1, M0T2, N0, M0
Stage III	Any T3
	Any M1

Adenocarcinoma

Adenocarcinomas extensively infiltrate the oesophageal wall and often show lymphatic and vascular involvement,

as well as direct extension through the oesophageal wall. Both regional and distant metastases develop. Primary oesophageal adenocarcinomas rarely spread distally into the stomach, whereas proximal spread commonly occurs.

About 33% of intramucosal tumours, 67% of intramural and 89% of transmural oesophageal adenocarcinomas metastasize to the regional lymph nodes; 60% of patients with nodal recurrence have recurrence at sites outside the resection margins. Patients with lymphatic metastases can be cured, particularly if fewer than four nodes are involved.

Stomach

The microscopic measurement of the depth of tumour penetration of the stomach wall and quantification of the number of regional lymph nodes involved by cancer are the most consistent methods for predicting the subsequent course of gastric cancer. This method is called the TNM system, as in the oesophagus, and is used to identify the stage of the tumour at the time of diagnosis. This staging system is summarized in **Table 3**. A British study of 31 716 gastric cancers showed that as stomach cancers advance from stage I to IV, the 5-year survival drops from 80% to less than 3%. These data reflect the experience of gastric cancer patients in most Western countries prior to the development of modern diagnostic and therapeutic methods (Craven, 1993). The cancers in this series were so far advanced that only 20% were considered suitable for curative resections. More recent Japanese experience reflects the advantage of making a diagnosis in early stage disease, of more extensive surgery and of adjuvant chemotherapy for advanced disease. A report of 2824 patients treated between 1979 and 1990 noted that 95% were considered suitable for surgical resection, that half of the patients were at Stage 1 and that their overall 5-year survival was 72% (Kinoshita *et al*., 1993).

Surgery remains the principal treatment for gastric cancer; the extent of surgery depends upon tumour stage. Japanese surgeons who have had the opportunity to treat many early cancers have used sonographic techniques to assess the depth of tumour invasion and have excised the tumour from the stomach lining endoscopically, leaving the stomach intact. Unfortunately, this procedure is not applicable to the late-stage tumours typically found in Western patients. Resection of all, or part, of the stomach is required for all advanced, operable tumours. As in the oesophagus, surgery may be supplemented by neoadjuvant or adjuvant radiation and chemotherapy. The relative 5-year survival of stomach cancer patients in the United States, treated in the years 1983–1989 was only 16.9%, reflecting the late stage of the great majority of these cancers at the time of presentation.

Table 3 TNM classification of gastric cancers

1. Primary tumour (T)

The principal factor is the degree of penetration of the stomach wall by carcinoma.

TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma *in situ*: intraepithelial tumour without invasion of the lamina propria
T1	Tumour invades lamina propria or submucosa
T2	Tumour invades the muscularis propria or subserosa
T3	Tumour penetrates the serosa (visceral peritoneum) without invasion of adjacent structures
T4	Tumour invades adjacent structures (spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine and retroperitoneum)

2. Nodal involvement (N)

The regional nodes include the perigastric nodes along the lesser and greater curvatures and the nodes along the left gastric, common hepatic, splenic and coeliac arteries. Involvement of other intraabdominal nodes represents distant metastasis.

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in perigastric lymph nodes within 3 cm of the edge of the primary tumour
N2	Metastasis in perigastric lymph nodes greater than 3 cm from the edge of the primary tumour, or metastasis in lymph nodes along the left gastric, common hepatic, splenic and coeliac arteries

3. Distant metastasis (M)

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

MOLECULAR GENETIC FINDINGS

Oesophageal Cancer

Squamous Cell Carcinoma

A condition known as tylosis accounts for some forms of familial SCC. This autosomal dominant genetic disorder associates with oesophageal cancer in 90% of affected persons. The cancers usually appear during middle age, but are presaged in early life by marked thickening and fissuring of the palms of the hands and soles of the feet. Tylosis results from a mutation in the *TOC* (tylosis oesophageal cancer) gene on chromosome 17.

Molecular alterations are more commonly investigated in patients with sporadic oesophageal SCC and a number of abnormalities have been detected. These include the accumulation of p53 protein in aggressive cancers. The p53 protein is overexpressed in more than 75% of oesophageal SCC and it may associate with dietary factors. It may also

predict responsiveness to chemotherapy. (The *p53* gene is important in regulating the cell cycle and it plays a critical role in protecting the cell from acquiring genetic damage that can be passed on to daughter cells. When the gene is overexpressed it is usually due to the presence of a mutation that potentially makes the protein nonfunctional and therefore predisposes the altered cells to genetic instability.) Another gene that is commonly abnormal in oesophageal SCCs is the *Cyclin D1* gene (another cell-cycle regulator) which is frequently amplified and overexpressed. Allelic loss on chromosome 13q12–13 may associate with lymph node metastasis in these patients.

Adenocarcinoma

Oesophageal adenocarcinomas associate with a number of molecular abnormalities, some of which resemble those seen in other gastrointestinal adenocarcinomas. Abnormalities in the expression of growth factors and their receptors, especially epidermal growth factor receptor, epidermal growth factor and transforming growth factor alpha, occur commonly and may contribute to nonregulated cell growth. These three substances are overexpressed in Barrett oesophagus and in oesophageal adenocarcinomas and may play a role in the progression of Barrett oesophagus to carcinoma, perhaps by providing a proliferative advantage to metaplastic cells overexpressing the proteins. Another protein related to cell proliferation that becomes abnormal in Barrett oesophagus and the cancers associated with it is p27, which is a cyclin-dependent kinase inhibitor and a negative regulator of cell cycle division. It is found that p27 is inactivated in many Barrett oesophagus-associated cancers and its loss associates with an aggressive tumour behaviour and unfavourable outcome. Other genes that may also be abnormal in patients with oesophageal adenocarcinomas are those which are often altered in colon cancer. These include the *p53* gene mentioned above for oesophageal SCC, the *APC* gene (a gene that predisposes to colon cancer) and the *DCC* (deleted in colon cancer) gene.

Gastric Cancer

There are several forms of hereditary gastric cancer in which the genetic makeup of the patient and the patient's family strongly favour the development of gastric cancer.

Germ-line mutations account for a small proportion of familial gastric cancer clusters, some of which may also be influenced by environmental factors. The hereditary nonpolyposis colon cancer (HNPCC) syndrome is an autosomal dominant disease that carries an increased risk of stomach and colon cancer. It results from a germ-line mutation in one of a number of DNA mismatch repair genes. Affected cells are susceptible to an accelerated accumulation of mutations.

Familial adenomatous polyposis (FAP) resulting from germ-line mutations in the *APC* gene on the long arm of chromosome 5 predispose patients to intestinal polyposis and cancer. In addition, the stomach develops adenomas that may evolve into carcinomas. An environmental influence on the underlying genetic alteration is suggested by the observation that Japanese patients with FAP more frequently have gastric adenomas and carcinomas than Westerners with this trait, reflecting the higher risk of gastric cancer experienced by all Japanese (Utsonomiya *et al*., 1994).

A newly recognized autosomal dominant mutation in the E-cadherin gene was first found in a familial cluster of poorly differentiated gastric cancers in a Maori, New Zealand family. This observation was quickly followed by the observation of other gastric cancer families with germ-line E-cadherin mutations in Europe, Korea and Japan (Gayther *et al*., 1998). The gastric cancer resulting from this defect develops in early life and is diffuse in type. E-cadherin is an adhesion molecule, and loss of its function might explain the discohesive growth pattern of these diffuse tumours.

Genetic polymorphisms may also contribute to gastric cancer risk. Inherited differences in the ability to detoxify potential carcinogens, and inherited variations in the ability to induce transcription or programmed cell death might explain some familial clusters of gastric cancer. The glutathione *S*-transferase enzyme system represents an example of a polymorphism that may favour the development of gastric cancer. These enzymes catalyse the conjugation of numerous carcinogens. Persons lacking the mu form of this enzyme (GSTM1) constitute 40% of the Japanese population and absence of this form of the enzyme increases the risk of developing gastric cancer (Katoh *et al*., 1996). A similar finding has been noted in an English study. Smoking increases the risk of both gastric cancer and its precursor lesion, intestinal metaplasia of the stomach lining. The null variant of this enzyme may contribute to the increased gastric cancer risk associated with smoking due to alterations in the production of potential gastric carcinogens present in tobacco smoke. These interactions may be further modulated by dietary influences.

Polymorphisms present at codon 72 of the *p53* gene may also be important in the development of gastric cancer. Ethnic differences occur in the frequencies of different forms of this codon. The majority of people of European origin are *p53* argenine homozygotes, as are patients with cancer of the cardia of the stomach. Whether the predilection for cardia cancers to occur among white males is due to excess vulnerability derived from *p53* argenine homozygosity, or only reflects parallel, unrelated traits, remains to be determined. The same observation applies to the association of blacks with the presence of a proline allele at codon 72 and antral GC.

CONCLUSION

It is apparent that environmental hazards account for most oesophageal and stomach cancers worldwide. Both tumours are closely related to a poor economic status. Prevention of these cancers is a socioeconomic rather than a medical problem, and should include improved housing, raised living standards, better education and a food distribution system that makes fresh fruit and vegetables available on a year-round basis to all levels of society. Medical intervention is necessary when these ideals are not achieved, but this will only produce a major reduction in mortality rates if the proportion of patients who are treated in the early stages of tumour progression is greatly increased. The Japanese and Chinese community screening programmes for stomach and oesophageal cancer have achieved this result and they are clearly adaptable to other high-risk societies, and the development of focused, tumour-specific, screening programmes is necessary where these cancers are less common. These should be given high priority since the late stages of these tumours have not proved amenable to currently available therapeutic strategies.

NORMAL DEVELOPMENT AND STRUCTURE

Development

The foregut, midgut and hindgut are derived from the embryonic yolk sac, which is of endodermal origin. During embryogenesis, the midgut communicates with the remains of the yolk sac via the vitello-intestinal duct. The midgut is supplied by the superior mesenteric artery and from it develop the third and fourth parts of the duodenum, jejunum, ileum, caecum, appendix, ascending colon and transverse colon. As the midgut lengthens, it becomes coiled and this promotes the development of its dorsal mesentery containing the superior mesenteric artery. Eventually, the midgut can no longer be accommodated in the abdominal cavity and it is extruded into the umbilical cord as a physiological hernia. A process of rotation occurs before the gut is restored to the abdominal cavity and takes up its normal anatomical position.

The hindgut is suspended by a shorter mesentery through which passes the inferior mesenteric artery to supply the descending colon, sigmoid colon and upper rectum. The superior, middle and inferior rectal arteries are derived from the inferior mesenteric, internal iliac and internal pudendal arteries, respectively. At 5 weeks, the distal hindgut, allantois and urogenital tract end in a common cloaca. Downward growth by the urorectal septum occurs until it fuses with the cloacal membrane. Two anal tubercles arise from adjacent ectoderm to fuse with the urorectal septum, forming the proctodeum where ectoderm and endoderm are in direct contact. The proctodeum then fuses with the rectum and canalizes during the third month to become the anus.

Gross Appearance

The small intestine is approximately 500 cm in length (shorter in life owing to tone in the longitudinal muscle coat) and lacking obvious features on external examination apart from its mesentery (the duodenum is retroperitoneal). The large intestine (colon and rectum) is 150 cm in length and variably covered by peritoneum in its different regions. The longitudinal muscle is arranged in three continuous bands (taeniae coli) which fuse into a continuous sheet at the junction of sigmoid colon and rectum. The taeniae coli shorten the colon and produce the characteristic sacculations or haustra. The colon is also distinguished from the small intestine on external inspection by the rows of fat tags called epiploic appendages. The superior and inferior mesenteric arteries anastomose via a continuous marginal artery along the mesenteric border of the colon (**Figure 1**).

Histology

The layers of the intestinal wall from within outwards comprise mucosa, submucosa, muscle coat and serosa or peritoneum (**Figure 2**). The mucosa consists of columnar

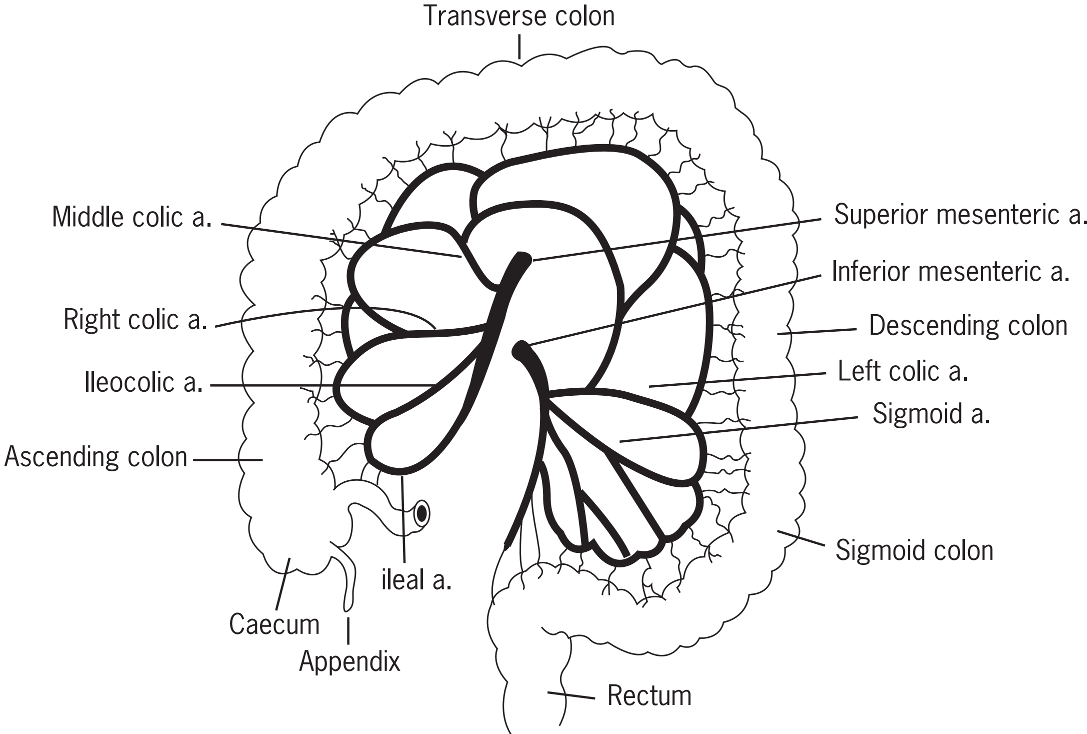

Figure 1 Transverse colon lifted to show arterial blood supply to the large intestine. (a. = artery)

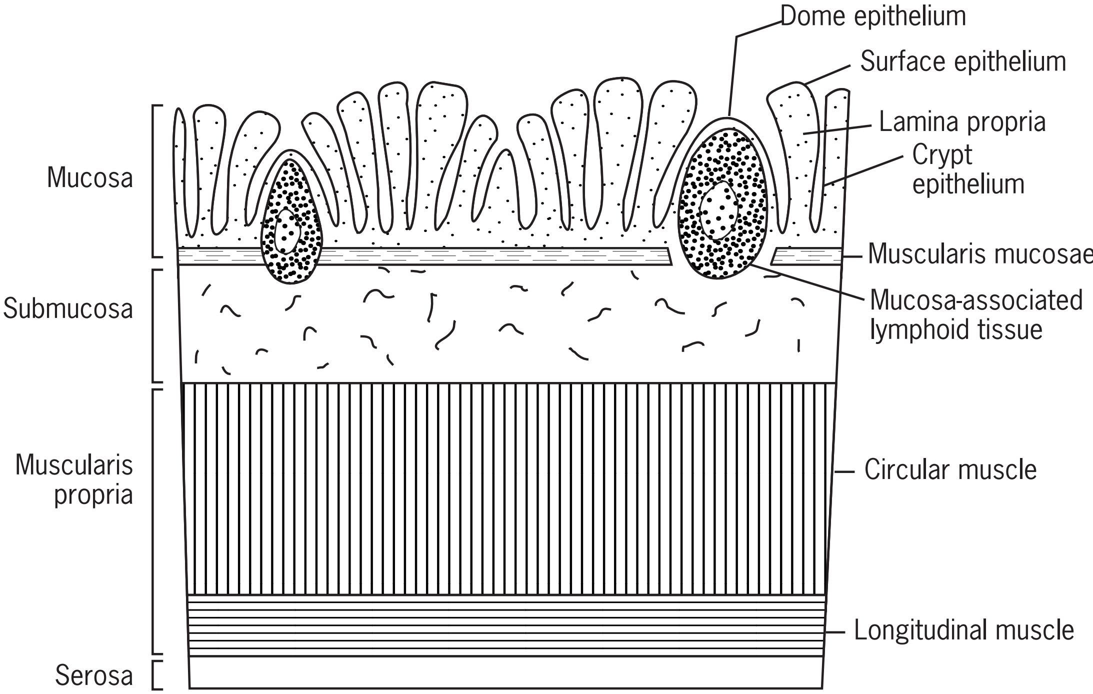

Figure 2 Layers forming wall of large intestine.

epithelium, a delicate connective tissue or lamina propria and a thin sheet of muscle called the muscularis mucosae. The epithelium comprises secretory crypts and an absorptive surface layer. In the small intestine, but not the colon or rectum, the area of the surface epithelium is greatly increased by the formation of finger-like villi.

The columnar epithelium comprises columnar cells, goblet cells, endocrine cells and Paneth cells (the latter are limited to the small intestine and proximal colon). These cells are derived from a common precursor or stem cell. The lower crypt includes the replicative compartment. Maturing cells migrate up the crypt and reach the surface epithelium within a matter of days where they undergo apoptosis.

TUMOUR PATHOLOGY

In this section, a brief overview will be given of the types of tumour that may occur in the lower intestinal tract, both cancerous and benign. The rest of this chapter will focus upon the most common and important cancer: carcinoma of the colon and rectum.

Types of Tumour

The types of tumour reflect the normal tissues that contribute to the structure of the intestinal tract (Jass and Sobin, 1989).

Epithelial Tumours

The columnar or glandular epithelium of the intestinal tract gives rise to benign and malignant neoplasms termed adenoma and adenocarcinoma, respectively. The colon and rectum are by far the most common sites of both adenoma and adenocarcinoma in the lower intestinal tract. Most adenocarcinomas arise in a pre-existing adenoma and these lesions may be viewed as a neoplastic continuum. However, only about 5% of adenomas will transform into adenocarcinomas. Multiple adenomas occur in the colon, rectum, duodenum and appendix in the rare autosomal dominant condition familial adenomatous polyposis (FAP) which is caused by mutation of the Adenomatous Polyposis Coli (*APC*) gene.

Certain types of epithelial polyp that have traditionally been regarded as non-neoplastic may occur in the intestinal tract. They are noted here (**Table 1**) because it is now appreciated that these lesions may show clonal genetic alterations and under certain circumstances may be precancerous. These polyps may be either single, occur in small numbers or be so numerous that the term polyposis is used. The commonest epithelial polyp is the hyperplastic polyp and occurs principally within the distal colon and rectum. These small polyps are characterized histologically by a saw-tooth or serrated crypt outline. While regarded as innocuous lesions, colorectal cancer has been associated with the rare condition hyperplastic polyposis in which the polyps are large and distributed throughout the colorectum.

Two types of epithelial polyp are classified as hamartomas (a maldevelopment in which epithelial and connective tissues are arranged in a haphazard manner). One of these occurs as part of the autosomal dominant Peutz–Jeghers syndrome (germ-line mutation of *STK11*). Peutz–Jeghers polyps are multiple and tend to be most numerous within the small intestine. Juvenile polyps are the second type of hamartoma and occur in the colon and rectum either singly, in small numbers or multiply in the autosomal dominant condition juvenile polyposis (germ-line mutations identified in *DPC4/Smad4*). Both Peutz–Jeghers syndrome and juvenile polyposis are associated with an increased risk of intestinal cancer. Endocrine cell tumours are considered in the chapter Systemic Oncology of the Endocrine Organs.

The lower anal canal is lined by squamous epithelium. Squamous cell carcinoma may arise from this site. Although uncommon, the frequency of this cancer is increasing in both males and females. Human papillomavirus (types 16 and 18) has been implicated in the aetiology; risk factors and mechanisms are similar to those underlying squamous cell carcinoma of the female genital tract (see the chapter *Systemic Oncology of the Female Reproductive System*).

Table 1 Nature and distribution of epithelial polyps of the intestinal tract

Type	Nature	Site[a] Small intestine	Appendix	Colon	Rectum
Adenoma Tubular Tubulovillous Villous	Neoplastic	S	S	U	U
Hyperplastic	Unknown	N	S	S	U
Peutz-Jeghers	Hamartoma	U	N	S	S
Juvenile	Hamartoma	S	N	U	U
Inflammatory	Inflammatory	N	N	U	S

[a]U = usual site; S = site of occurrence; N = not found (or uncommon).

Lymphoid Tumours

Lymphoid tissue is distributed throughout the intestinal tract with notable collections in the terminal ileum known as Peyer's patches. Mucosa-associated lymphoid tissue (MALT) is organized differently from nodal lymphoid tissue in terms of both structure and function. Lymphoid neoplasms are malignant by definition and those arising in MALT are known as MALTomas and are derived from B-lymphocytes. The stomach does not normally contain lymphoid tissue, yet MALTomas are more common in this organ than the intestine (see the chapter *Systemic Oncology of the Upper Gastrointestinal Tract*). A special type of MALToma occurs in the small intestine and affects populations around the Mediterranean and in the Middle East. The neoplastic B-lymphocytes secrete α heavy chains (a component of immunoglobulin class A) and the lymphoma is also known as α heavy chain disease or immunoproliferative small intestinal disease (IPSID). Two additional B-lymphocyte lymphomas of the intestinal tract are Burkitt lymphoma occurring mainly in Africa and principally affecting the ileocaecal region and mantle cell lymphoma presenting as multiple mucosal polyps throughout the gastrointestinal tract. There is also a rare T-cell lymphoma which mainly affects the proximal jejunum and is most common in people of Northern Europe. Many of these lymphomas are associated with gluten-sensitive enteropathy or coeliac disease.

Stromal Tumours

Despite the large amount of smooth muscle and connective tissue in the wall of the intestinal tract, stromal tumours are uncommon. Gastrointestinal stromal tumours (GISTs) were considered to be tumours of smooth muscle in the past, but most are now known to express the phenotype of a pacemaker cell found in the muscle coat (interstitial cell of Cajal). Behaviour is unpredictable but large size and a high mitotic rate are markers of malignancy. Bona fide smooth muscles occur in the rectum; most are small and benign.

Secondary (Metastatic) Cancer

The intestinal tract is not a common site of metastatic cancer. The small intestine is the main site for metastases and melanoma, breast and lung cancer are the principal primary sources.

EPIDEMIOLOGY

Colorectal cancer is a leading cause of cancer death, second only to lung cancer in the West. It is responsible for 55 000 deaths per year in the USA. There were around 875 000 new cases worldwide in 1996, accounting for 8.5% of all cancers diagnosed in that year. Incidence rates vary by at least a factor of 20 between countries, with the highest rates being found in the West and the lowest in the developing world (Potter, 1999). Although these differences are exaggerated by competing causes of mortality in developing countries, such as infectious disease and other types of cancer, age-adjusted statistics show that the low incidence is genuine. Colon and rectal cancers share many environmental risk factors, but differences exist also. Colonic cancer occurs with approximately equal frequency in males and females whereas rectal cancer is at least twice as common in males.

Time trends indicate rapid increases in incidence in countries or populations that have adopted Western lifestyles in recent years. Examples include Japan, urban China and male Polynesians in Hawaii. Colonic cancer seems to be more sensitive to these changes than rectal cancer. Migrant studies have shown that populations migrating from low-risk to high-risk countries rapidly acquire the incidence rates of the adopted country, sometimes within the migrating generation. For example, one of the highest rates in the world is seen among Hawaiian Japanese (Haenszel, 1961).

Colorectal cancer is age related, colonic cancer more so than rectal. There will be competing causes of mortality in ageing populations and the mean age at presentation in most hospital series falls within the range 65–75 years. The age relationship, common to many types of solid cancer, is a reflection of the time-related multistep evolution of cancer. The stepwise accumulation of genetic errors in somatic cells requires a particular passage of time. In individuals who inherit one of the causative genetic errors, each somatic cell is already primed (or one step ahead). Such individuals develop multiple neoplasms and at an early age. This is observed in several forms of hereditary colorectal cancer (see below).

AETIOLOGY

The aetiology of colorectal cancer is not known but the brief account of descriptive epidemiology given above indicates the involvement of both environmental influences and genetic factors. The major shifts in incidence following migration were once taken as evidence of the overwhelming importance of the environment. Nevertheless, individuals inhabiting high-risk areas may live to advanced years without even developing a minute adenoma (the earliest visible signs of colorectal neoplasia). Conversely, an inherited genetic mutation may lead to early onset disease in an inhabitant of a low-risk area. The modern approach to unravelling the aetiology of colorectal cancer integrates lifestyle factors and genetic constitution within the discipline of molecular epidemiology.

Dietary and Lifestyle Factors

Vegetables and Fibre

Particular dietary practices have been associated with colorectal cancer in defined groups of subjects (cohort studies) or comparing affected cases with matched controls (case-control studies) (Trock *et al*., 1990). However, these studies demonstrate associations rather than specific causality. Diets high in vegetables (raw, green or cruciferous) are protective although the nature of the specific agent is unclear. High on the list is fibre (the complex carbohydrate constituent of plant cell walls), which could act by diluting or binding potential carcinogens in the lumen of the bowel. Fibre is poorly digested in the small intestine but is fermented by bacteria in the proximal colon to generate short-chain fatty acids, notably butyrate. Resistant starch (that is not digested in the small bowel) is another source of butyric acid. Butyrate serves as an essential respiratory nutrient for colonic epithelium and its lack may be a factor in the aetiology of colorectal cancer. Butyrate may also serve as a protective factor in its capacity as a differentiating agent. Vegetables are high in folate and absence of this vitamin may also serve as a risk factor.

Meat and Fat

Estimates of risk of colorectal cancer have been either increased or null in cohort and case-control studies examining the role of dietary meat and fat. It appears that total protein consumption is relatively unimportant whereas meat preparation (processing or heavy cooking) may generate carcinogens such as heterocyclic amines. Additionally, saturated fat of animal origin may be associated with increased risk (Potter, 1999).

Calcium and Bile Acids

Epidemiological studies and intervention data indicate a protective role for dietary calcium. A possible mechanism may be the conversion of ionized fatty acids and faecal bile acids into insoluble salts. Deoxycholic and lithocholic acid are bacterially deconjugated bile acids that have been shown to serve as promoters or co-mutagens in experimental studies of colonic carcinogenesis. Faecal bile acid levels have in turn been correlated with meat consumption.

Selenium

This essential trace element is a component of the enzyme glutathione peroxidase which catalyses the removal of intracellular hydrogen peroxide. Deficiency of selenium occurs when diets lack whole grains and vegetables or when soil levels are low. A protective role is supported by epidemiological and intervention studies.

Smoking and Alcohol

Higher risks of colonic (not rectal) cancer and adenomas have been associated with a long history of smoking. The association with alcohol is less clear, beer being implicated in rectal cancer in males.

Non-steroidal Anti-inflammatory Drugs (NSAIDS)

NSAIDS, including aspirin, have been shown to lower the risk of colorectal cancer in cohort and case-control studies. Sulindac causes adenomas to regress in FAP and stabilizes the disordered apoptotic ratio that occurs in the normal colorectal mucosa of subjects with FAP. (See the chapter *Dietary Genotoxins and Cancer*.)

Genetic Factors–High-prevalence Polymorphisms

N-Acetyltransferases (NAT1, NAT2) and Cytochrome P450 (CYP) Enzymes

The weak effects of diet upon cancer risk might be increased by genetic factors. For example, at least three enzymes (NAT1, NAT2 and CYP1A2) influence the metabolism of heterocyclic amines produced in the course of cooking meat at high temperatures and hydrocarbons contained in tobacco smoke. Particular genetic polymorphisms affect the activities of these enzyme systems, but consistent correlations between genotypes, lifestyle factors and risk have not been demonstrated to date (Potter, 1999).

Methylenetetrahydrofolate reductase (MTHFR)

Folate may serve as a protective factor through influencing methylation of DNA and the size of the nucleotide pool required for DNA synthesis and repair. The polymorphic enzyme MTHFR appears to increase the risk of colorectal neoplasia in subjects with a particular genotype (TT) and a low-folate diet (Potter, 1999). Some tumour suppressor genes are silenced through hypermethylation of the promoter region. However, this mechanism applies mainly to the subset of colorectal cancers showing DNA microsatellite instability (MSI).

Genetic Factors–Rare Inherited Syndromes

Familial Adenomatous Polyposis (FAP)

About 1 in 8000 individuals carries a mutation in the tumour suppressor gene *APC*, either inherited (75%) or acquired as a new mutation (25%). The disease manifests as an autosomal dominant trait in which affected individuals develop many hundreds and usually thousands of colorectal adenomas in their teens. By the age of 50, one or

more of these polyps is likely to have transformed into a carcinoma. The severity of the disease in terms of polyp numbers depends upon the nature of the germline mutation and modifying influences of other genes. Extracolonic manifestations occur, notably duodenal adenoma and carcinoma, fibromatosis (aggressive but non-metastasizing tumour composed of fibroblasts), benign bone tumours, sebaceous cysts of the skin, pancreatic cancer, thyroid cancer, hepatoblastoma (primary liver tumour recapitulating embryonic liver) and tumours of the central nervous system.

Inactivation of the normal or wild-type *APC* gene, by either mutation or loss, is sufficient to initiate and allow further growth of adenomas. The germ-line mutation leads to subtle growth disturbance of the normal colorectal mucosa by a dominant negative effect (not requiring mutation or loss of the normal copy of the gene). These changes include an increased rate of crypt fission and a disordered distribution of cells undergoing apoptosis (more in the crypt base and less on the epithelial surface) (Wasan *et al*., 1998; Keller *et al*., 1999). The *APC* gene mediates its normal function (the control of growth, differentiation and proliferation) through the *wnt* signalling pathway.

I1307K Mutation of APC

This mutation, found only in Ashkenazi Jews, creates a repetitive poly-A sequence that is subject to replication error, in turn causing protein truncation. Small numbers of adenomas and cancers occur in affected family members.

Hereditary Non-Polyposis Colorectal Cancer (HNPCC)

This autosomal dominant condition is caused by mutation of one of a family of DNA mismatch repair genes. The most frequently implicated are *hMLH1* and *hMSH2* followed by *hMSH6*, *hPMS1* and *hPMS2*. The germ-line mutation is nearly always inherited rather than new to an individual. Nevertheless, an obvious family history may not be apparent in small families as penetrance (the extent to which a mutated gene is expressed phenotypically) is not 100%. The frequency of disease causing mutations in particular populations may be exaggerated by founder effects (where a particular affected individual has been succeeded by multiple, large generations within a relatively sparsely populated region). Approximately 2% of individuals developing bowel cancer in the West do so on the basis of HNPCC. Since around one in 20 individuals will develop colorectal cancer, the population frequency of disease-causing mutations must be around 1 in 1000.

The first step leading to neoplasia in HNPCC is somatic mutation or loss of the second (wild-type) mismatch repair gene. Some genes, such as *TGFβRII* and *BAX*, contain short repetitive tracts that serve as targets for mismatch errors occurring during DNA replication. If the DNA repair mechanism is not operating adequately, the mismatch mutations will not be repaired. Particular mutations, for example in *TGFβRII*, will initiate the development of a neoplastic clone. Most mismatch errors, however, occur in non-coding repetitive tracts or microsatellites. The resulting microsatellite instability does not drive carcinogenesis but is a useful biomarker for HNPCC.

Approximately 70% of subjects carrying an HNPCC germ-line mutation will develop colorectal cancer by the age of 65 years and at a mean age of 45 years. Extracolonic cancers may develop in the uterus (endometrium), ovary, stomach, small intestine, central nervous system and urinary tract (pelviureter). Benign sebaceous gland adenomas may occur in the facial skin (the combination of sebaceous adenoma and colorectal cancer has been called Muir–Torre syndrome but is part of the HNPCC spectrum). The majority of colorectal cancers arise in adenomas. Although adenomas do not occur in large numbers in HNPCC, an individual adenoma carries a high risk of progressing to cancer and does so within a short timeframe. This accounts for cancer multiplicity and the clinical impression of *de novo* origin of cancer. Paradoxically, the colorectal cancers in HNPCC are relatively non-aggressive in terms of their potential for metastasis. Around 60% of colorectal cancers arise in the proximal colon (caecum, ascending or transverse colon) (Lynch *et al*., 1996).

Germline Mutation of TGFβ Type II Receptor

This is a rare cause of familial colorectal cancer.

Chronic Inflammation

The risk of colorectal cancer is increased in subjects with chronic or longstanding inflammation of the large intestine, notably due to ulcerative colitis and Crohn's disease. A possible mechanism may be genetic damage by reactive oxygen species (superoxide, H_2O_2 and hydroxyl radicals), in turn generated by the inflammatory mediators released by inflammatory cells such as neutrophils and macrophages. Cycles of inflammatory damage and healing may also increase the rate of epithelial proliferation or change the microenvironment so that cells are more susceptible to the effects of luminal carcinogens.

SCREENING AND PREVENTION

The prevention of colorectal cancer may be achieved by primary means including lifestyle adjustments or taking preventive medication (chemoprevention) or by screening asymptomatic subjects for risk factors that can be reduced or neutralized. The concept of prevention can be broadened to include the prevention of radical surgery (since

early stage colorectal cancer can be cured by local or conservative surgery) or prevention of death (since advanced cancer can be cured if it is treated at a sufficiently early stage). Screening can result in unnecessary investigation and promote needless anxiety if the test lacks specificity and is therefore associated with a high false-positive rate. Furthermore, if a cancer is detected earlier than it would otherwise have been but not early enough to allow spread and death to be prevented, the test will not have improved mortality rates. The resultant increase in survival is apparent only. Bringing forward the diagnosis of cancer in this way is known as lead time bias. The main approaches to screening include: (1) testing faeces for occult blood, (2) endoscopic examination of the mucosal lining of the large bowel and (3) demonstration of a high-risk genetic mutation.

Faecal Occult Blood Testing

The premise underlying this test is that larger adenomas and early cancers may bleed to a minor extent that goes unnoticed but is identified by a sensitive test for haemoglobin. A positive result is followed by a colonoscopy and removal of small lesions. Larger lesions may require surgery. Cancers detected in asymptomatic subjects are relatively early (in terms of their limited extent of spread) and the net result of removing adenomas and early cancers is a reduction in mortality in the study group as compared with a matched unscreened group. The reduction in mortality from colorectal cancer in randomized controlled trials has ranged from 15% to 33%. Amongst fully compliant participants the mortality reduction is of the order of 40% (Hardcastle *et al*., 1996; Kronborg *et al*., 1996).

Occult blood is not specific for neoplasia and neoplasms may not necessarily bleed. Specificity and sensitivity might be increased by testing for other products such as mutated DNA. K-*ras* mutations can be detected in stool samples but only a subset of colorectal cancers has K-*ras* mutation. One would need to test for a range of mutations to pick up all cancers, but the laboratory costs would be considerable.

Endoscopy

There is retrospective evidence as well as evidence from prospective adenoma follow-up trials that adenoma removal prevents colorectal cancer. Endoscopy allows precancerous adenomas to be visualized and removed before they can transform into cancers. Since no more than 5% of adenomas will become cancerous, it is necessary to destroy or remove 20 to prevent one cancer. The cost effectiveness is increased by offering endoscopy only to subjects at moderate to high risk (e.g. by virtue of a positive family history). However, most colorectal cancers occur in subjects without a strong family history. At least 50% of colorectal cancers occur within the range of the flexible sigmoidoscope. It has been suggested that a single sigmoidoscopic examination between the ages of 55 and 64 years would have an important impact on morbidity and mortality due to cancer of the rectum and sigmoid colon (Atkin *et al*., 1998). Retrospective data suggest that subjects with small adenomas in the distal colon and rectum are at little risk of developing further neoplasms or of having more proximal adenomas. However, subjects with larger and/or multiple adenomas would require a full colonoscopy and additional colonoscopic surveillance (Atkin *et al*., 1992).

Some would argue that screening only the rectosigmoid region is unacceptable and that a full screening colonoscopy should be offered as the first step in screening. The drawbacks are that colonoscopy is more expensive and technically demanding and proximal cancers are less aggressive and more age-related. An alternative approach is 'virtual colonoscopy' achieved by computed tomography colonography which can detect remarkably small lesions. Colonoscopy would then be required to biopsy and treat the lesion.

Colonoscopic surveillance is also offered to subjects with chronic inflammatory bowel disease, particularly ulcerative colitis. The precancerous lesion is known as dysplasia, which appears macroscopically as a flat, velvety area or a raised sessile mass or may be invisible. The risk of associated or subsequent cancer is then high and colectomy is indicated.

Genetic Screening and Predictive Testing

This is offered to subjects with autosomal dominant syndromes predisposing to colorectal cancer: familial adenomatous polyposis (FAP) and hereditary non-polyposis colorectal cancer (HNPCC). The steps are similar in both conditions. After counselling and obtaining consent the causative mutation is detected in an affected family member. This is achieved in about 70% of FAP families and 50% of HNPCC families. After counselling, DNA samples from at-risk family members are screened for the mutation. Mutation-negative subjects are at no increased risk compared with the general population and require no further preventive management. Prophylactic surgery is required for FAP and this is generally performed in the mid-teens. The operative approach is either total colectomy with ileorectal anastomosis or proctocolectomy with construction of an ileo-anal pouch anastomosis. The former is preferred unless there is an extensive carpet of rectal adenomas, but the rectum will then require endoscopic surveillance. Rectal excision with ileo-anal pouch anastomosis will often be performed in later years. At-risk or mutation positive members of HNPCC families require one- to two-yearly colonoscopic surveillance from the third decade. If surgery is undertaken for a large adenoma or cancer, a total colectomy is the preferred

option because of the high risk of developing additional cancers.

Dietary Intervention

A measure that is likely to be associated with general compliance is the addition to the diet of a cheap and palatable ingredient, particularly if this can be added safely to a product that is widely consumed anyway. Of the possible protective dietary factors that have been identified so far, resistant starch would be one of the easiest to accommodate in the diet. A rich natural source is unripe bananas, but resistant starch can be added to bread or sprinkled on food without altering its taste.

Chemoprevention

Cohort and case-control studies have demonstrated the protective role of aspirin and other non-steroidal anti-inflammatory drugs (NSAIDS) (Potter, 1999). These are believed to act through the inhibition of cyclo-oxygenase (COX) which is involved in the synthesis of prostaglandin (converts arachidonic acid to prostaglandin G_2). The more specific COX antagonists (sulindac) have been shown to cause adenomas to regress in FAP and to restore the altered apoptotic index in the normal-appearing mucosa of FAP subjects to normal. The molecular mechanisms underlying these interesting observational data are unknown. A drawback of NSAIDs is their gastrointestinal side-effects. COX-2 is not expressed by normal colonic epithelial cells but is upregulated in cancer cells. The latest generation of selective COX-2 antagonists was developed in order to achieve therapeutic or preventive effects without accompanying gastrointestinal disturbance. At this stage it is not known if the more selective components will be as effective as their broad-spectrum counterparts, but preliminary data are encouraging.

The most obvious use of chemoprevention is in subjects at high risk of colorectal cancer. Cost, safety and efficacy will determine if such an approach to cancer prevention can be generalized. Subjects with FAP have been observed to develop bowel cancer while taking sulindac.

PREINVASIVE LESIONS

Adenoma

The most important preinvasive lesions in the colorectum in terms of frequency and potential for malignant change are the benign neoplasms or adenomas (Muto *et al*., 1975). The evidence is as follows: (1) adenomas show a spectrum of changes ranging from low-grade dysplasia through to high-grade dysplasia (or carcinoma-*in-situ*), (2) longitudinal studies demonstrate malignant transformation with time (in situations where the adenoma is not removed), (3) adenoma and carcinoma share similar demographic data and risk factors, (4) removal of adenomas reduces the frequency of cancer and (5) the genetic changes in adenomas are also present in carcinomas.

Macroscopic Features

Adenomas mainly present as polypoid growths that may be sessile or pedunculated. They are usually sessile elevations when less than 5 mm but increasing growth is associated with the formation of a stalk composed of normal mucosa and submucosa. A minority remain as flat or even depressed lesions which may be difficult to detect at colonoscopy without the use of dye spraying and high-resolution magnification. The head is darker than the surrounding normal mucosa in larger adenomas and becomes lobulated, resembling a baby cauliflower. A rare presentation is as a large sessile (broad-based) mass with a soft, shaggy surface. These are described as villous adenomas, although the finger-like villi seen in two-dimensional sections are in reality leaf-like folds.

Microscopic Features

Adenomas are typed as tubular, tubulovillous and villous according to the predominant architectural pattern (**Figure 3**) (Jass and Sobin, 1989). Tubules are lined by columnar epithelium and embedded within lamina propria where they proliferate by branching. Villi (in reality leaves) comprise a covering of columnar epithelium and a core of lamina propria. By forming complex, brain-like folds of epithelium, the surface area of a villous adenoma may be considerable and lead to significant loss of fluid and electrolytes. Tubulovillous adenomas combine both architectural patterns.

The morphological changes that distinguish adenoma from normal include disordered architecture, cytological atypia and abnormal differentiation. The combination of changes has been described as dysplasia and may be graded as mild, moderate and severe or (in a two-grade system) low grade and high grade (**Figure 4**). Mild or low-grade dysplasia deviates little from the normal whereas severe or high-grade dysplasia approximates to carcinoma-*in-situ*. The terms intra-epithelial neoplasia and dysplasia are synonymous. Because of its aggressive connotation the term 'carcinoma-*in-situ*' is generally omitted from diagnostic reports. The risk of cancer developing in an adenoma is associated with architecture (extent of villosity), grade of dysplasia and size of the adenoma (Muto *et al*., 1975).

For the purposes of drawing a diagnostic distinction between adenoma and adenocarcinoma, a rule has been developed that is unique to the lower intestinal tract. In order to diagnose cancer there must be invasion across the line of the muscularis mucosae into the underlying submucosa. For other epithelial surfaces, cancer is diagnosed when there is invasion across the basement membrane. The reasons for this difference in approach are pragmatic and practical. First, the potential to metastasize is not realized

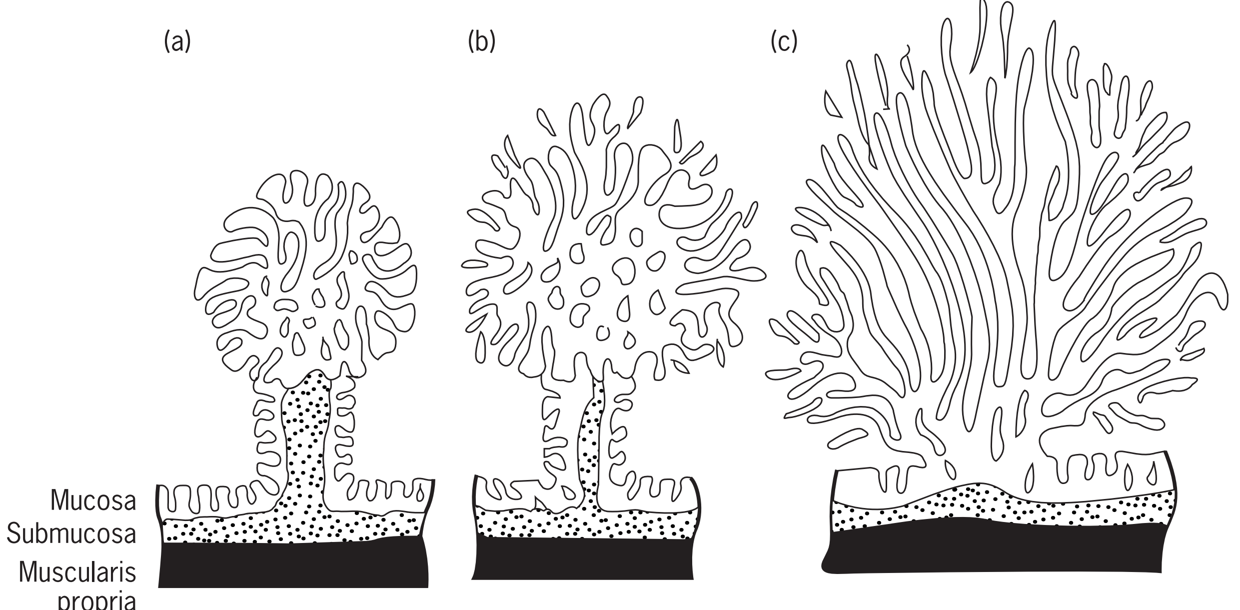

Figure 3 (a) Tubular, (b) tubulovillous and (c) villous adenoma of large intestine.

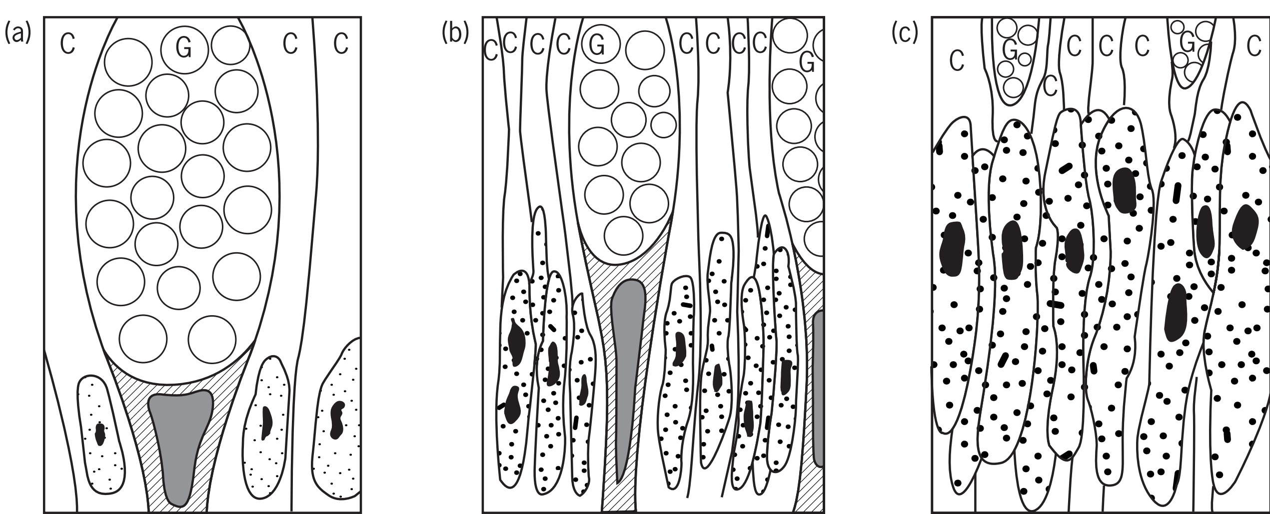

Figure 4 Normal epithelium of (a) large bowel, (b) low-grade dysplasia and (c) high-grade dysplasia. There is progressive loss of differentiation of goblet cells (G) and columnar cells (C) accompanied by nuclear enlargement, crowding, stratification and hyperchromatism.

until there has been submucosal invasion. Second invasion across the basement membrane into surrounding lamina propria is both unusual and difficult to diagnose at the light microscopic level. Invasion across the basement membrane is generally apparent only in the case of poorly differentiated adenocarcinoma, but it is unusual for early cancer arising in an adenoma to be poorly differentiated.

Early Morphogenesis

In squamous and transitional epithelial surfaces, a neoplastic clone is conceived as arising within and replacing the normal epithelium by lateral spread. While such a process may also occur within columnar epithelium, at least some if not the majority of colorectal adenomas originate through a different mechanism. Micro-reconstruction studies in the normal-appearing mucosa from subjects with familial adenomatous polyposis have demonstrated neoplastic crypts occurring as a bud from the side of a normal crypt, in other words recapitulating the normal process of crypt fission (Nakamura and Kino, 1984). The bud forms a tubule as it migrates up the crypt column to open finally on to the epithelial surface. This unicrypt adenoma then undergoes fission to form a microadenoma (**Figure 5**).

(a) (b) (c) (d) (e)

Figure 5 Formation of adenoma as an outpouching from normal crypt.

It is possible to identify microscopic epithelial lesions by their abnormal crypt openings using a combination of dye and magnification of the surface epithelium. The choice of dye will depend on whether this is performed by dissecting microscope *in vitro* (e.g. methylene blue) or during colonoscopy (e.g. indigo carmine). These microscopic lesions are known as aberrant crypt foci. A minority are microadenomas; most are minute hyperplastic polyps.

Serrated Adenomas

This subgroup of adenomas is distinguished from the usual adenoma by combining the serrated or saw-tooth crypt outline of the hyperplastic polyp with the cytological changes of an adenoma. Additionally, the proliferative compartment of a serrated adenoma remains in the lower crypt whereas proliferative cells are found within the upper crypt and surface epithelium in the usual adenoma. Serrated adenomas are also characterized by an overexpression of secretory or gel-forming mucins including MUC2 (intestinal) and MUC5AC (gastric). Serrated adenomas are probably more closely related to hyperplastic polyps than adenomas. Mixed polyps including both hyperplastic and serrated adenomatous components may be found. Furthermore, microsatellite markers have demonstrated clonal relationships between the two components. The high frequency of DNA microsatellite instability also distinguishes serrated adenomas from traditional adenomas (Iino *et al*., 1999).

Dysplasia

In inflammatory bowel disease, dysplasia occurs as an ill-defined or diffuse lesion that may be flat or raised as a sessile mass but lacking the sharp demarcation of an adenoma. Although the term dysplasia has been applied to both the diffuse lesions found in inflammatory bowel disease and the circumscribed neoplasia of an adenoma, differences between the two forms of dysplasia exist with respect to histological appearances, molecular genetics and natural history.

GROSS APPEARANCES

Colorectal cancers are relatively well circumscribed with little growth beyond their macroscopically visible borders. A cancer may appear as a mass protruding into the bowel lumen, as an ulcer with a raised edge or as a band-like stricture causing narrowing of the bowel. Protuberant masses are more common in the caecum and ascending colon. The bowel contents are fluid in this region and obstruction is uncommon. Chronic bleeding from the ulcerated surface leads to the symptoms of iron deficiency anaemia and palpation of a mass in the right iliac fossa will point to the likely diagnosis. Cancers arising in the splenic flexure and left colon are often associated with stricturing that leads to the symptoms of partial or complete bowel obstruction. Cancers of the rectum are often ulcerating and may present with the passage of bright red blood per rectum or the sensation of incomplete evacuation. On section the cancer appears as a mass of relatively firm, pale tissue replacing the normal bowel wall structures. The mucinous subset has a grey, gelatinous cut surface reflecting the accumulated secretory mucin.

HISTOPATHOLOGY

Type

About 90% of colorectal cancers are adenocarcinomas composed of glandular structures containing variable amounts of mucin. About 10% secrete large amounts of mucin (constituting at least 50% of the tumour volume) and are known as mucinous adenocarcinomas. The signet ring cell carcinoma is a rare form of mucinous carcinoma in which the cells are discohesive and contain abundant intracellular mucin which pushes the nucleus towards the cell membrane (giving a signet ring appearance) (**Figure 6**). Loss of the adhesion molecule E-cadherin is responsible for the discohesion of signet ring cells. Undifferentiated carcinoma is exceedingly uncommon.

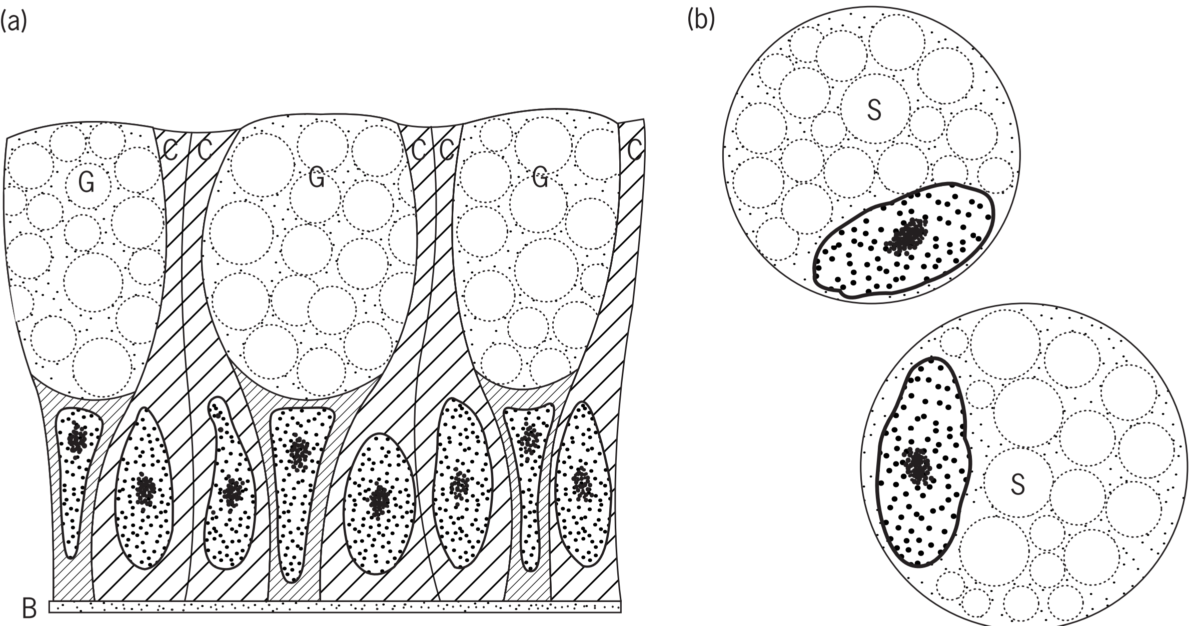

Figure 6 (a) Normal colorectal epithelium and (b) signet ring cell carcinoma. G = goblet cell and C = columnar cell in normal epithelium; S = signet ring cell carcinoma cells; B = basement membrane.

Grading

The grading of adenocarcinoma as well (grade 1), moderately (grade 2) and poorly (grade 3) differentiated is based primarily on the extent to which recognizable glands are formed (**Figure 7**). In well-differentiated adenocarcinoma, the glands are regular and the epithelium resembles adenomatous tubules. In moderately differentiated adenocarcinoma, the glands show complex budding, irregular outpouching or gland-within-gland structures. In poorly differentiated adenocarcinoma, glands are highly irregular or distorted. Cells may be arranged in solid clusters or cords. Undifferentiated carcinomas are graded as 4.

Invasive Margin

About 80% of colorectal cancers have a reasonably well circumscribed invasive margin whereas 20% show widespread dissection of normal structures and often extensive invasion around nerves and within small vessels (**Figure 8**).

Venous Invasion

The presence of tumour within large venous channels increases the risk of metastatic spread to the liver via the portal vein.

Immune Response

Lymphocytes may be conspicuous as part of a band-like arrangement of inflammatory cells at the growing margin

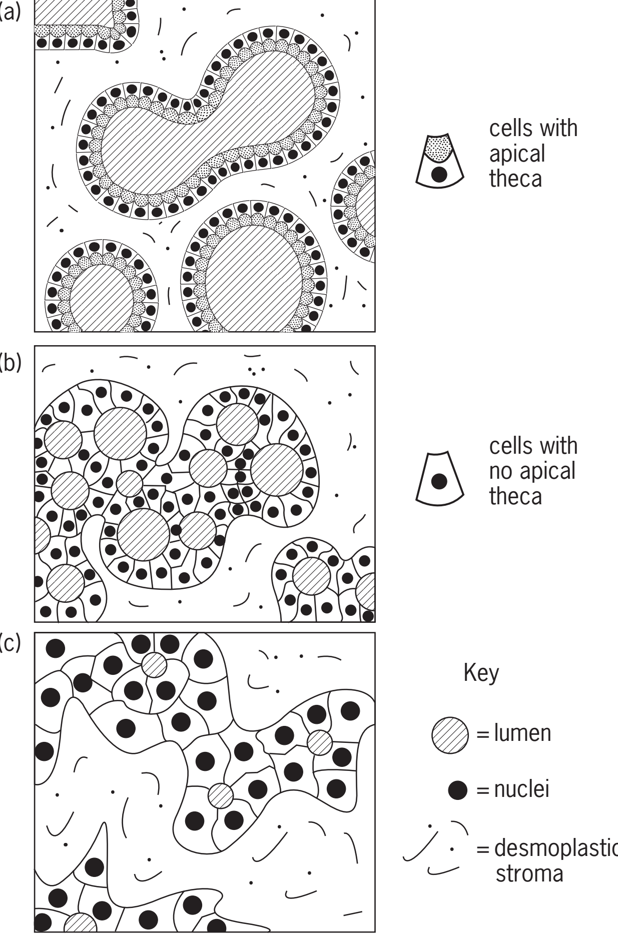

Figure 7 (a) Well, (b) moderate and (c) poor differentiation in adenocarcinoma of the large intestine.

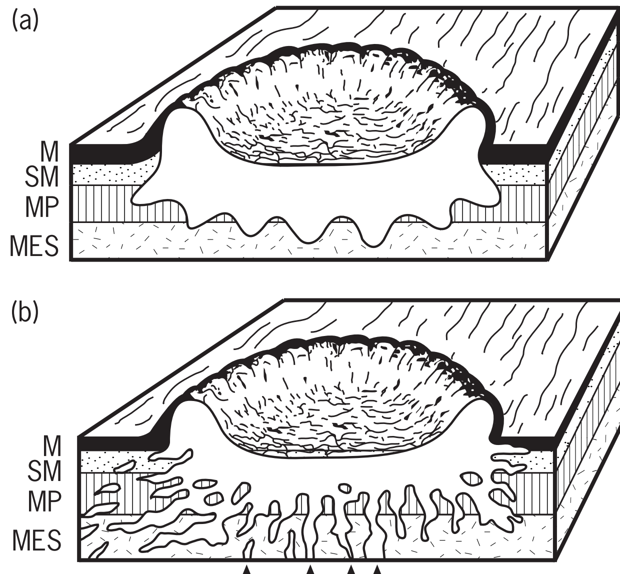

Figure 8 (a) Expanding versus (b) infiltrating adenocarcinoma of the large intestine. M = mucosa; SM = submucosa; MP = muscularis propria; MES = mesentery. Arrows indicate points of surgical transection of cancer.

(B and T cells), as nodular aggregates (B cells with a cuff of T cells) in the surrounding submucosa or serosa, within the tumour stroma (B and T cells) or infiltrating the malignant epithelium (tumour infiltrating T lymphocytes). These patterns often co-exist and are associated with hyperplasia of the regional lymph nodes.

Ultrastructure and Immunohistochemistry

In general these do not provide diagnostically or prognostically useful information but immunohistochemistry combines with the molecular genetic approach (see below) to generate key insights into basic biological mechanisms. The diagnostic use of antibodies to the DNA mismatch repair proteins is described below.

MOLECULAR GENETIC FINDINGS

Colorectal cancer has provided more fundamental insights than any other solid tumour in the search to uncover the genetic basis of cancer. The well-documented adenoma–carcinoma sequence provides a simple model that is accessible to observation and investigation. Additionally, the two major forms of hereditary colorectal cancer, FAP and HNPCC, were directly responsible for the discovery of important cancer genes through classical linkage studies and positional cloning (*APC* and the DNA mismatch repair genes, respectively). (See also the chapter *Inherited Predispositions to Cancer*.)

Genetic Instability

Molecular genetics is a rapidly expanding field. One of its major contributions to date has been the realization that colorectal cancer is not a single disease, but multiple diseases driven by separate molecular pathways. The impact of this realization upon epidemiology, aetiology, prognosis and treatment is only just being appreciated. The pathways are at least in part determined by the nature of the primary fault that drives carcinogenesis: the state of genetic instability. This state is caused by the disruption of checkpoint mechanisms in the cell cycle that normally ensure the maintenance of genomic fidelity during cell division. Genetic instability occurs in at least two major and distinct forms in colorectal cancer: chromosomal instability and DNA instability (Lengauer *et al*., 1998).

Chromosomal Instability

The majority (70%) of colorectal cancers arise through this pathway. An early genetic change is disruption of the Wnt signalling pathway, generally through biallelic inactivation of *APC* which explains the initiation and early growth of adenomas. K-*ras* mutation occurs in a subset and drives further clonal expansion. The key transition from adenoma to carcinoma is driven in many cases by biallelic inactivation of *TP53*. Other tumour suppressor genes on 18q, 1p and 8p are implicated (hence suppressor pathway). Aneuploidy is acquired around the transition from adenoma to carcinoma suggesting that chromosomal instability is the mechanism for overcoming this rate-limiting step in the evolutionary sequence. DNA microsatellite instability is not present, hence these cancers have been termed microsatellite stable (MSS).

DNA Instability and MSI-H Cancers

This mechanism is implicated in HNPCC in which there is a germ-line mutation of a DNA mismatch repair gene (see above). DNA instability also occurs on a sporadic basis in about 15% of colorectal cancers. The usual mechanism is silencing of the DNA mismatch repair gene *hMLH1* through methylation of its promoter region. The biomarker for this subtype is widespread DNA microsatellite instability (MSI) or MSI-high (MSI-H). Other genes are methylated also, but the mechanism underlying the methylator phenotype is unknown. Breakdown of the DNA mismatch repair mechanism results in mutation of genes with short mononucleotide repeats in their coding sequences: *TGFβRII*, *BAX*, *IGF2R*, *caspase 5*, *Tcf-4*, *axin*, *CDX-2* and *BCL-10* (hence mutator phenotype). Involvement of *APC*, K-*ras* and

TP53 is uncommon in sporadic MSI-H cancers. MSI-H cancers show a predilection for the proximal colon and a tendency to occur in elderly women. They are more likely to be mucinous and to express the secretory mucin core proteins MUC2 and MUC5AC (like serrated adenomas). They are also more likely to be poorly differentiated, have a well circumscribed invasive margin and show an enhanced immune reaction including tumour-infiltrating lymphocytes (TIL) (Jass *et al.*, 1998).

Loss of expression of DNA mismatch repair proteins can now be demonstrated with antibodies to hMLH1, hMSH2, hMSH6 and hPMS2. This will greatly assist in the management of HNPCC and identification of MSI-H cancers.

Mild Mutator Pathway

It has been suggested that all colorectal cancers will show minor microsatellite instability if a sufficient number of microsatellite markers is used to test for the mutator phenotype. Nevertheless selected dinucleotide and tetranucleotide markers are sensitive to cancers with low levels of MSI (MSI-L). These cancers differ from MSS cancers in their lower frequency of BCL2 expression, nuclear expression of β-catenin and 5qLOH and higher frequency of K-*ras* mutation, DNA methylation (for example the DNA repair gene *MGMT*) and lymphocytic infiltration. MSI-L cancers are in other respects like MSS cancers, showing high frequencies of APC mutation and allele loss at 17p and 18q (Jass *et al.*, 1999). In view of the multiple differences between MSS, MSI-L and MSI-H cancers, it is prudent to distinguish them carefully as a primary step in the characterization of colorectal cancer. Indeed, the failure to do so has led to oversimplification and confusion that is only now beginning to be resolved.

Pathways in Inflammatory Bowel Disease

Mutation of *TP53* and aneuploidy occur in early stages of neoplastic progression in ulcerative colitis (Potter, 1999).

PROGNOSTIC FACTORS

The outcome for a patient with colorectal cancer will depend upon (1) clinical factors such as age, gender, health status and mode of clinical presentation, (2) the extent of spread of cancer at the time of diagnosis and (3) biological properties of the cancer, both histopathological and molecular. Of these, staging classifications based upon the extent of spread cancer (**Figure 9**) provide the most reproducible and important guide to prognosis.

TNM Classification of Colorectal Cancer

Definitions of T, N and M categories are shown in **Table 2**. The data may be converted into four stages (with the equivalent Dukes pathological stage) as follows:

1. Stage I (Dukes A, Fig. 9(a)): cancer confined to bowel wall (T1 or T2) with no spread to lymph nodes (N0) or distant spread (M0).
2. Stage II (Dukes B, Fig. 9(b)): cancer extends beyond muscle coat (T3 or T4) with no spread to lymph nodes (N0) or distant spread (M0).
3. Stage III (Dukes C, Fig. 9(c)): cancer (any T) spreads to lymph nodes (N1 or N2) with no distant spread (M0).
4. Stage IV (no Dukes equivalent but called D subsequently): cancer (any T and any N) involving distant sites (M1).

Table 2 TNM Classification (American Joint Commission on Cancer/Union Internationale Contra Cancre, 1997)

Primary tumour (T)	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma-*in-situ* or high-grade dysplasia
T1	Tumour invades submucosa
T2	Tumour invades muscularis propria
T3	Tumour invades through the muscularis propria into subserosa or into non-peritonealized pericolic or perirectal tissue
T4	Tumour directly invades other organs or structures and/or perforates visceral peritoneum
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1–3 regional lymph nodes
N2	Metastasis in four or more regional lymph nodes
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

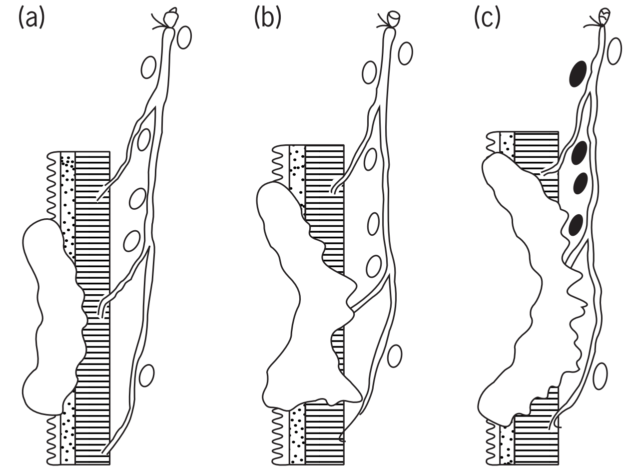

Figure 9 Dukes classification of rectal cancer.

The 5-year survival (non-cancer deaths excluded) is around 100% for stage I, 80% for stage II, 50% for stage III and 10% for stage IV. Distribution of cancers by stage is around 15% stage I, 35% stage II, 40% stage III and 10% stage IV. Prognosis is therefore uncertain (50% 5-year survival) for 40% of patients with stage III disease.

Histopathological Factors

Tumour type, grade, invasive margin, venous invasion and immune response (see above) have all been shown to be of prognostic significance. In multivariate (Cox regression) analyses only invasive margin, venous invasion and immune response have been shown to provide additional (independent) prognostic data beyond that achieved by staging alone. The Jass prognostic classification developed for curative cases of rectal cancer (**Table 3**) utilizes invasive margin and peritumoral lymphocyte infiltration in addition to direct spread and lymph node spread. The Jass system minimizes the number of uncertain prognostic cases (Jass *et al*., 1987). However, histopathological features are subjective and prone to interobserver variation.

Molecular and Genetic Factors

Microsatellite Status

Sporadic MSI-H cancers are associated with a good outcome and an independent prognostic effect has been demonstrated for stage III colorectal cancer. This will explain, at least in part, the adverse effects associated with molecular and genetic changes found in non-MSI-H cancers. These include K-*ras* mutation, 17p and 18q loss and increased expression of COX-2 and VEGF. The classification of colorectal cancer as MSS, MSI-H and MSI-L must precede the exploration of other prognostic markers, the effects of which could well be subsidiary to or explained by the major molecular pathways.

Other Prognostic Markers

The classes of molecule that have been linked to prognosis include enzymes involved in matrix degradation and their inhibitors (cathepsin L, urokinase, tissue-type plasminogen activator, tissue inhibitors of metalloproteinases), gene products involved in apoptosis (BCL2, survivin), cell surface molecules (CD44, ICAM1, galectin 3) and a variety of metabolic enzymes (GLUT1 glucose transporter, manganese–superoxide dismutase, thymidylate synthetase, ornithine decarboxylase).

CLINICAL MANAGEMENT

Initial Consultation and Diagnosis

The management of colorectal cancer begins with a process of consultation. This will vary according to the mode of presentation. The consultation may be motivated by altered bowel habit, present as an acute abdominal emergency due to obstruction or perforation or be precipitated by the diagnosis of cancer in an asymptomatic subject participating in a screening program. Regardless of the mode of presentation, frequent, clear and instructive communication is necessary to ensure the best outcome for the patient.

The main approach to treatment is a surgical one, but this is preceded by preoperative assessment to establish the diagnosis and provide information on the stage of the disease. A mass in the lower rectum need not always be a carcinoma. It could be a variety of benign lesions, a lymphoma or an upward-spreading squamous cell carcinoma of the anal canal (lesions that are not usually treated by rectal excision). Therefore, biopsy and a histopathological diagnosis are mandatory steps in the case of rectal masses and highly desirable for colonic tumours. The methods of investigation to achieve a diagnosis include digital examination, sigmoidoscopy, barium enema and colonoscopy.

Table 3 Jass prognostic classification for curative rectal cancer (UICC/TNM stages I–III): (A) scores for variables and (B) derivation of prognostic groups from total score

A

Variable	Score
Spread beyond rectal wall (muscularis propria)	1

Lymph node metastasis	1
>4 lymph nodes with metastasis	1

B

Total score per case (0–5)	Prognostic group (I–IV)	5-year survival (%)	Frequency (%)
0–1	I	95	30
2	II	80	30
3	III	50	20
4–5	IV	25	20

Preoperative Staging

Colonic Cancer

Most patients with a colonic cancer do not require preoperative staging; the extent of tumour spread is better evaluated during laparotomy and by pathological examination of the resected specimen. A preoperative computerized tomography (CT) scan will occasionally be useful for identifying the extent of locally advanced disease.

Rectal Cancer

Preoperative staging is important for both planning surgery and establishing the need for preoperative adjuvant chemoradiotherapy. Apart from digital examination, the most important investigative technique is endorectal ultrasound, which provides a high-resolution image of the individual layers of the rectal wall and the destruction of one or more of these layers by tumour.

Distant Metastases

Routine chest X-ray, liver scanning by CT or ultrasound and serum levels of the tumour marker carcinoembryonic antigen (CEA) are used to gauge the presence of distant spread. This may assist in determining prognosis.

Early Colorectal Cancer

There is no strict definition in terms of extent of spread. The term refers to cancer that is sufficiently small and localized to be safely managed by conservative surgery, namely local excision as opposed to the radical approach required for advanced cancer. In practice, most early colorectal cancers have spread no further than the submucosa. An early cancer may be a small focus of malignancy within an adenoma which can be treated by simple polypectomy at the time of colonoscopy. It may also be a small ulcerating cancer in the lower rectum where the alternative to a disc excision of the rectal wall is radical excision of the rectum and anus (abdominoperineal excision) and establishment of a permanent colostomy. Local excision of a cancer is a safe and curative option provided that the excision is complete (there is no cancer at the surgical margin), the cancer is not poorly differentiated and there is no invasion of vascular spaces. Malignant adenomas with unfavourable features may warrant further treatment but this is individualized on the basis of the health, age and wishes of the patient.

Surgery for Colon Cancer

The principle underlying surgical treatment is to resect the segment of bowel bearing the cancer together with the mesentery carrying the blood supply and lymphatic drainage. The feeding arteries are ligated as close as possible to their sites of origin. For a cancer of the right colon, the right colic, ileocolic and right branch of the middle colic vessels are ligated and divided close to their origins and the proximal colon is then resected. For cancers of the left colon, the inferior mesenteric and ascending left colic vessels are ligated and a left hemicolectomy is performed. Intestinal continuity is restored by anastomosis using sutures or staples.

Surgery for Rectal Cancer

In the past this was often treated by an abdominoperineal excision of rectum and anus and the construction of a permanent colostomy. It is now often possible to resect most of the rectum and anastomose the proximal colon to the distal rectum or even to the upper anal canal, a procedure called an anterior resection. When the anstomosis is very low in the pelvis, it is usual to divert the faeces from it temporarily by fashioning a proximal loop ileostomy that is closed after around 12 weeks. It is still necessary to perform an abdominoperineal excision if the cancer is poorly differentiated, a distal margin of clearance of at least 2 cm cannot be achieved or the anal sphincter mechanism is not adequate for continence.

Adjuvant Therapy for Colon Cancer

Approximately 50% of subjects with stage III or Dukes C colon cancer will relapse with distant metastases and die within 5 years of surgery. This is explained by the presence of occult hepatic metastases at the time of surgical treatment. The aim of an adjuvant approach is to destroy these metastases at a time when they are of microscopic dimensions and therefore more amenable to cytotoxic therapy. Randomized controlled trials have to date demonstrated significant improvements in survival with the combination of 5-fluorouracil and leucovorin (folinic acid) that have not been bettered by any alternative regimen. A 6-month course is recommended.

Adjuvant Therapy for Rectal Cancer

Two major adverse outcomes are observed in rectal cancer: distant metastases (as for colon cancer) and local recurrence of the disease within the pelvic cavity. Recurrent pelvic cancer is incurable and will spread within the pelvis to cause pain, bleeding and urinary tract obstruction. Factors influencing local recurrence are the extent of spread of cancer beyond the rectal wall and the competence of the surgeon. Unacceptably high levels of variation in outcome have been demonstrated between surgeons (McArdle and Hole, 1991). Sharp dissection of the mesorectum ensuring that its thin fascial (connective tissue) covering is not breached is advocated as a measure to reduce the risk of incomplete

removal of cancer. However, local recurrence will continue to be a problem for the more locally advanced cancers regardless of surgical skills. For this reason, radiotherapy is recommended for locally advanced rectal cancer and this has been shown to reduce the incidence of local recurrence in randomized controlled trials. It is therefore usual to offer combined radiotherapy and chemotherapy (e.g. 5-fluorouracil) to patients with stage II and III rectal cancer.

Radiotherapy may damage normal tissues, causing long-term complications. The risks of damaging the small intestine are reduced if radiotherapy is given preoperatively. Preoperative radiotherapy (combined with chemotherapy) can be offered selectively on the basis of preoperative staging. The advantages of this approach are that the cancer may be downstaged (partially eradicated) and sometimes completely eradicated. Preoperative radiotherapy may also render surgery less technically difficult and may even convert an apparently incurable cancer to a curable one. Pathological staging of the resected specimen will be less reliable owing to destruction of both tumour and lymphoid tissue (Wheeler *et al*., 1999).

Recurrent and Distant Disease

This is usually incurable although patients with only a few hepatic metastases have been cured by excising the deposits of tumour with a clear margin. Local recurrence is also salvageable on occasion, particularly if it is at the site of the anastomosis. Local recurrence is otherwise managed by palliation with radiotherapy and/or chemotherapy as well as adequate pain relief.

The Future

In addition to the development of more effective cytotoxic compounds (e.g. Oxaliplatin and CPT-11), immunotherapy and gene therapy offer new hope for the future. These approaches depend on an understanding of cancer biology and must overcome the problems posed by tumour heterogeneity and drug resistance. Until we learn how to prevent the disease altogether, surgery will continue as the main treatment option for advanced colorectal cancer. Despite this, modern management of colorectal cancer is increasingly viewed as a team exercise involving oncologists, radiotherapists, radiologists, endoscopists, geneticists, pathologists and stoma therapists as well as surgeons. The informed participation of the patient is also integral to successful management.

Chapter 39

Liver, Gall Bladder and Extrahepatic Bile Ducts

Peter Paul Anthony

Royal Devon and Exeter Hospitals and University of Exeter, Exeter, UK

CONTENTS

- Normal Development and Structure
- Pathology: Tumours of the Liver
- Hepatocellular (Liver Cell) Carcinoma
- Hepatoblastoma
- Cholangiocarcinoma (Intrahepatic and Hilar Bile Duct Carcinoma)
- Biliary Cystadenoma and Cystadenocarcinoma
- Mixed Hepatocellular Carcinoma and Cholangiocarcinoma
- Metastatic Tumours
- Sarcomas of the Liver
- Benign Tumours and Tumour-like Lesions
- Tumours of the Gall Bladder
- Tumours of the Extrahepatic Bile Ducts

NORMAL DEVELOPMENT AND STRUCTURE

Elements of the liver first appear at the beginning of the fourth week of gestation and its development is largely complete by the twelfth week. The parenchymal component (hepatocytes, biliary system and gall bladder) derive from the liver bud or hepatic diverticulum of the endodermal intestinal canal and the connective tissue framework and vessels from the mesenchyme of the septum transversum. The liver is also a major site for haematopoiesis throughout intrauterine life. Hepatocytes produce α-fetoprotein during the first trimester, after which they gradually switch to albumin. These events are, to a varying extent, reproduced in certain tumours: the morphological changes in hepatoblastoma, haematopoiesis in angiosarcoma and, most important, a switch back to α-fetoprotein in hepatocellular carcinoma.

The liver lies almost completely under the protection of the rib cage on the right and is firmly attached to the diaphragm above and loosely to the stomach and duodenum below by the lesser omentum. It is traditionally divided into right, left, caudate and quadrate lobes, which are visually recognizable, but, if one considers vascular supply and biliary drainage, it consists of nine autonomous segments, the limits of which guide the surgeon when carrying out partial hepatectomy or resection. The liver receives a dual blood supply: venous blood from the portal vein and arterial blood from the hepatic artery. Some tumours are predominantly supplied via the portal vein (e.g. angiosarcoma) and others via the hepatic artery (e.g. hepatocellular carcinoma). Blood flows out of the liver via the hepatic veins into the inferior vena cava, close to the heart. Branches of the intrahepatic bile duct system join up to form the main hepatic duct which, when it receives the cystic duct of the gall bladder, becomes the common bile duct and this drains bile into the second part of the duodenum.

Concepts of the microscopic structure of the liver have progressed from the purely anatomical, the portal 'lobule' of Mall described in 1906, to the functional unit or 'acinus' of Rappaport which was defined in 1954; the latter makes more sense. **Figure 1** shows a simplified view of the arrangement of the various components. The centre of the acinus is the portal tract which carries the smallest branches of the portal vein and of the hepatic artery. These flow into specialized vascular channels called sinusoids which run between plates of hepatocytes and are lined by endothelium. They contain phagocytic Kupffer cells. The sinusoids are separated from the liver cells themselves by the space of Disse which, in turn, contains perisinusoidal or Ito cells and scanty Type I and III collagen which constitutes the connective tissue (reticulin) framework of the liver. The main function of the perisinusoidal cells is the production of extracellular matrix proteins. The sinusoids drain into the terminal hepatic venules which unite to form the hepatic veins. The third structure in the portal tract is the first, smallest branch of the intrahepatic bile duct

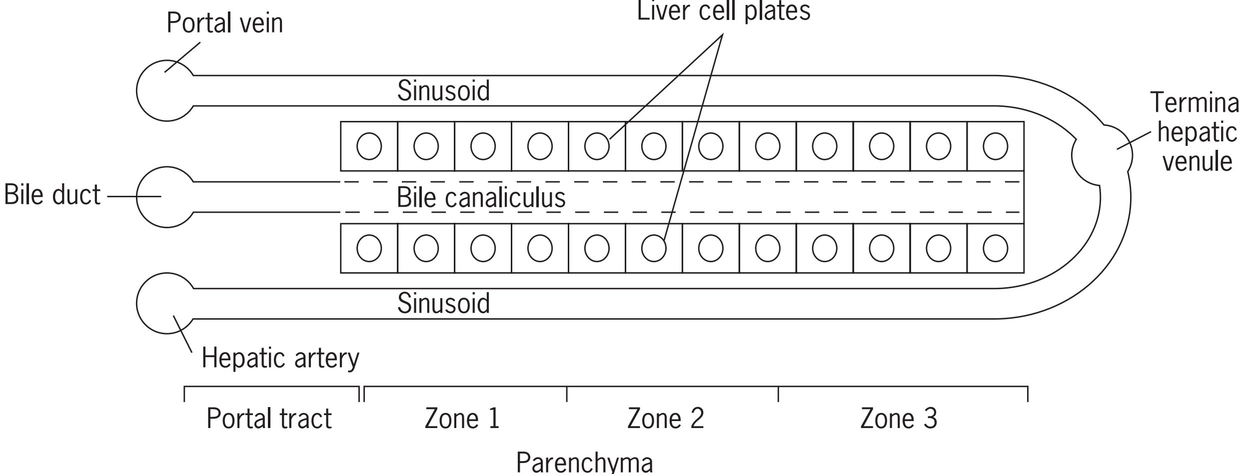

Figure 1 Microanatomy of the liver, showing portal tract with bile duct, hepatic artery and portal vein, liver cell plates with intervening sinusoids and the terminal hepatic vein.

Note: A two-dimensional diagram does not allow for the display of three-dimensional arrangements, e.g. both portal veins and hepatic arteries drain into the same sinusoids.

system which drains bile from the intercellular canaliculi between hepatocytes towards segmental bile ducts and, eventually, the common bile duct. Hepatocytes are roughly four-sided and are arranged in complex, continuous plates, being joined on two sides by other hepatocytes; the other two sides face the sinusoids or form the bile canaliculi.

Our understanding of the structure and function of the microscopic organisation of the liver is still evolving and there are several modifications and refinements. For example, the cells of the plates can be divided into Zones 1, 2 and 3 from those closest to the portal tracts (Zone 1) to those nearest to the terminal hepatic venules (Zone 3). Hepatocytes in Zone 1 are the youngest and those in Zone 3 the oldest: they proceed in this direction from birth to death by apoptosis in approximately 200 days. This is the concept of the 'streaming liver' created by Zajicek in 1985. As hepatocytes move they also display differences in function, suffer a fall in the supply of oxygen and nutrients and become more vulnerable. The site of origin of both hepatocytes and bile duct cells lies between the portal tract and liver parenchyma, the domain of stem cells.

Hepatocytes are the most complex cells in the body. They have a centrally placed nucleus and a cytoplasm rich in organelles and are capable of performing many storage, metabolic, synthetic, detoxifying and excretory functions. Bile ducts not only conduct bile but also modify it to its final effective form. The endothelial cells of the sinusoids are fenestrated, which allows the transport of nutrients to the hepatocytes. Kupffer cells and liver-specific lymphocytes are part of the mononuclear phagocytic system of the body and perisinusoidal Ito cells are capable of fibrogenesis.

This account is only a brief outline of the development, structure and function of the liver to allow the reader to relate specific tumours at this site to their cell of origin and to normal structures which they recapitulate albeit in an aberrant fashion. For a comprehensive account, refer to MacSween and Scothorne (1994).

PATHOLOGY: TUMOURS OF THE LIVER

The term 'hepatoma' is often used loosely to describe any primary tumour in the liver but it has no precise meaning. Many different types arise which are designated by their cell of origin (Anthony, 1994). The commonest is liver cell or hepatocellular carcinoma, followed by bile duct or cholangiocarcinoma and various sarcomas, of which angiosarcoma is the most important. Benign tumours are uncommon. **Table 1** shows a detailed classification of liver tumours but only those that are common and/or are of interest will be discussed and the rest referred to only briefly.

Our knowledge of the world-wide distribution of tumours is based on data derived from cancer registries in many countries. These have been published in successive volumes of the series *Cancer Incidence in Five Continents*, the latest of which appeared in 1997 (Parkin *et al*., 1997). The variability in incidence of liver tumours is almost entirely due to the large numbers of hepatocellular carcinoma in tropical Africa and South-East Asia. Cholangiocarcinoma is less common and occurs with much the same frequency everywhere except in South-East Asia. Other tumour types are rare. Overall, malignant liver tumours rank eighth in the list of all cancers, sixth in men and eleventh in women. Hepatocellular carcinoma accounts for most cases and kills around one million people in the world every year.

The outlook for hepatocellular carcinoma, cholangiocarcinoma and angiosarcoma is poor and nearly all patients die unless the tumour is detected early. Results

Table 1 Abbreviated WHO Classification of primary tumours of the liver

Type	Benign	Malignant
Epithelial tumours	Hepatocellular adenoma Bile duct adenoma Bile duct cystadenoma Biliary papillomatosis	Hepatocellular carcinoma Cholangiocarcinoma Bile duct cystadenocarcinoma Hepatoblastoma
Non-epithelial tumours	Haemangioma Angiomyolipoma Other benign tumours	Haemangiosarcoma Malignant epithelioid haemangioendothelioma Embryonal sarcoma Rhabdomyosarcoma Other sarcomas, lymphoma
Tumour-like lesions	Cysts Focal nodular hyperplasia Mesenchymal hamartoma Peliosis Inflammatory myofibroblastic tumour	

are improving with hepatoblastoma and the childhood sarcomas.

HEPATOCELLULAR (LIVER CELL) CARCINOMA

Hepatocellular carcinoma is defined by the World Health Organisation as a malignant tumour composed of cells resembling hepatocytes but abnormal in appearance; a plate-like organisation around sinusoids is common and is nearly always present somewhere in the tumour (Ishak *et al*., 1994).

Epidemiology

The remarkable geographical variability in the frequency of this tumour has attracted the attention of epidemiologists since the middle of the twentieth century. The data have been regularly summarized and updated over the years (Simonetti *et al*., 1991; Okuda, 1993; Anthony, 1994; Akriviadis *et al*., 1998; Bosch *et al*., 1999). Yearly incidence rates and mortality figures are almost the same as patients, other than those whose tumour is detected at an early stage by screening, die within a few weeks or at most months. In broad terms, countries may be divided into three groups: those with low, intermediate and high incidence rates. The highest frequencies are seen in South-East Asia and tropical Africa where the tumour is the commonest or next commonest of all cancers. The lowest rates are found in Western countries, South America and the Indian subcontinent. Intermediate rates prevail in Japan, the Middle East and the Mediterranean area. The possible role of racial and genetic factors has been examined and discounted in favour of environmental factors, notably chronic infections with the hepatitis B and C viruses and exposure to aflatoxin. The incidence of the tumour appears to be rising in many areas, e.g. USA, Japan and Southern Europe.

Males predominate over females in a ratio of 2–4 to 1; generally, the higher the incidence, the higher is the rate between the genders. The mean age in high-incidence areas is in early to middle adulthood and Africans develop the tumour earlier than Asians. This is largely due to the acquisition of hepatitis B virus infection at or near birth. Patients in low- and intermediate-incidence areas are in late adulthood or old age. Cirrhosis of the liver is often associated with the tumour and is considered to be the greatest risk factor.

Whites, wherever they live, have a low incidence, even in Africa and South-East Asia, where hepatocellular carcinoma is rampant in the native population. They appear to be protected by maintaining the life style of their home countries. The same is not true of Indians who have settled in Singapore or Hong Kong since the end of the nineteenth century: their incidence rate is roughly double that in their home country. Chinese are at high risk wherever they live, e.g. in Europe or North America, but this decreases after the second generation as they adopt the environment of their new countries. The black population of the USA, West Indies and Brazil shows an incidence that is only marginally above that of whites amongst whom they have lived since the beginning of the slave trade in the seventeenth century. All of these phenomena can be explained by the prevalence rates of chronic infection with hepatitis B and, to a lesser extent, hepatitis C viruses. Small variations in tumour incidence have been observed in racially homogeneous countries such as Greece, Spain and Switzerland, which are due to differences in rates of alcoholic cirrhosis, smoking and exposure to chemicals. It is interesting to note that, although over 100 compounds, both man-made and naturally occurring, are known to be carcinogenic to rodents,

few of these seem to affect humans, with the exception of aflatoxin, which is an important risk factor in Kenya and Swaziland.

Aetiology

The list of aetiological agents is long and is shown in **Table 2**, but some are more important than others. This is indicated in terms of the prevalence of the agent and the magnitude of the risk attached to it. The effect of most of them is to proceed from the normal state of the liver to the cancerous through cirrhosis, but the likelihood of this varies (Simonetti *et al*., 1991; Okuda, 1993; Akriviadis *et al*., 1998). Chronic hepatitis B and C account for four-fifths of cases of hepatocellular carcinoma followed by aflatoxin, chronic alcoholism, smoking and a number of other aetiologies in a minority (Anthony, 1994; Bosch *et al*., 1999). However, a few metabolic disorders such as haemochromatosis and tyrosinaemia carry a surprisingly high risk. Also, the presence of more than one agent greatly increases the likelihood of malignancy.

Hepatitis B Virus (HBV)

HBV is one of a group of viruses known as Hepadnaviruses which affect humans (HBV) and certain animals such as the woodchuck (WHV), ground squirrel (GSHV) and duck (DHV). All of these cause liver disease: acute and chronic hepatitis, cirrhosis and hepatocellular carcinoma, in their respective hosts. In humans, transmission is mainly via blood or blood products, contaminated instruments, male homosexual contact and, most important, from mother to infant at birth. HBV is a partly double-stranded DNA virus possessing a genome consisting of four open reading frames which encode for four different proteins, surface (HBsAg) and core (HBcAg) antigens, DNA polymerase and the X protein. The 'e' antigen (HBeAg) is closely associated with HBcAg. Replication takes place through reverse transcriptase and the virus is capable of integration into the host cell's genome. Most of the antigens and antibodies directed against them are demonstrable in the serum at one time or another during acute and chronic infections and the pattern of their presence is predictive of course, stage of disease and outcome. Levels of these 'marker' proteins decline in time as replication ceases and the virus becomes undetectable, but it remains in an integrated form in the nuclei of liver cells. The risk of malignant transformation relates both to the infective, replicative phase when continuing liver cell damage leads to hepatitis and cirrhosis, and to the non-replicative, integrated phase when carcinogenic events occur (Idilman *et al*., 1998; Chen and Chen, 1999; Schafer and Sorrell, 1999).

Table 2 Aetiology of hepatocellular carcinoma (male : female=2–4 : 1)

Agent	Prevalence	Magnitude of risk
HBV	High	High
HCV	High	High
Alcohol	High	Low
Chemicals and drugs	High	Low
Aflatoxin	Low	Moderate
Membranous obstruction of IVC	Low	Moderate
Haemochromatosis	Moderate	Moderate
AAT deficiency	Low	Low
Tyrosinaemia	Low	High
Glycogen storage disease	Low	Low
Porphyria	Low	Low

Chronic HBV infection is common in tropical Africa, South-East Asia and Oceania; it is uncommon in Western Europe, North America and Australia and an intermediate prevalence is seen in the Mediterranean countries, the Middle East and India. Indeed, maps can be constructed to show almost identical frequencies of HBV carriage rates and incidence of hepatocellular carcinoma, as this virus accounts for up to two-thirds of all cases of the tumour and more in some areas. It is generally accepted that a particularly high risk of chronic infection, with the subsequent development of cirrhosis and hepatocellular carcinoma, is associated with infection at or near birth or in childhood, which happens in tropical Africa and South-East Asia. Elsewhere, those most commonly affected are adults in high-risk groups, e.g. intravenous drug addicts, homosexuals, prostitutes and inmates of prisons or mental institutions. Individuals who received transfusions of blood and blood products prior to the institution of effective screening of donors in the 1980s are also at risk. Most of those who have chronic infection remain symptomless for many years and are known as carriers.

The strength of the association of HBV and hepatocellular carcinoma, however, rests on multiple lines of evidence which are listed in **Table 3**. Numerous case-control studies were carried out in the 1970s and 1980s to show a much higher prevalence of HBV markers in the blood of patients with hepatocellular carcinoma than in controls, whether these were healthy individuals or hospital patients with other types of diseases including cancer. Infection precedes the development of the tumour by two to three decades on average and long-term follow-up studies established the measure of the risk. The best known of these was carried out on government employees in Taiwan, a high-incidence area for both HBV infection and hepatocellular carcinoma. They were chosen because all had life insurance policies provided by the State and an accurate record of causes of illness and death was readily available. The relative risk of developing the tumour, by

Table 3 Hepatitis viruses and hepatocellular carcinoma

	HBV	HCV
Infection is associated with tumour (case/control)	Yes	Yes
Infection precedes tumour (follow-up)	Yes	Yes
Tumour DNA contains viral genomic element (integration)	Yes	No
Tumour in culture produces viral component	Yes	No
Virus transforms cells in culture	No	No
Virus produces tumours in transgenic mice	Yes	Yes
Virus induces tumours in animals	Yes	No
Eradication of virus leads to decrease of tumour	Yes	Not known

those who tested positive for HBV markers at the outset over those who did not, turned out to be nearly 100-fold 10 years later (Beasley, 1988), a much higher figure than the relative risk of lung cancer in smokers over non-smokers. Replicative HBV is not detectable in hepatocellular carcinoma tissue or cell lines but antigenic components such as HBsAg rarely are. The virus is not directly oncogenic in the sense that it does not transform cells in culture. However, it does produce hepatocellular carcinomas when its genome is incorporated in the germ line of mice in transgenic experiments. HBV-like hepadnaviruses also produce the tumour in their respective hosts, particularly the woodchuck. The most important event in hepatic carcinogenesis by HBV is its integration in the DNA of liver cell nuclei. No consistent site exists and it appears to be random and multiple. However, insertion of HBV in the genome leads to its destabilization and chromosomal abnormalities are common, a process known as insertional mutagenesis. In addition, two transactivating proteins have been identified; one is encoded for in the pre-S2 region of the gene coding for HBsAg and the other is the HBX protein. Of the two, the latter is of greater interest (Feitelson and Duan, 1997; Idilman *et al*., 1998; Chen and Chen, 1999). Transactivation in this context means the ability to modify the action of host genes at a distance from the integration site. Most hepatocellular carcinomas contain oncogenes (e.g. *ras*, *myc*, *fos*) and/or anti-oncogenes or tumour suppressor genes (e.g. *p53*, *Rb*) which have been made by HBX to be overexpressed or inactivated. These events, in turn, lead to changes in growth factors, cell cycle regulators and DNA repair which are relevant to carcinogenesis but no coherent pathway has yet been elucidated. Mass vaccination of infants against HBV in high-risk areas such as Taiwan and the Gambia began in the mid-1980s and has proved to be effective in preventing chronic infection, with a fall in the number of childhood hepatocellular carcinomas to a quarter of the previous level. (See the chapter *Human DNA Tumour Viruses*.)

Hepatitis C Virus (HCV)

HCV is a single-stranded RNA virus which shows marked genetic heterogeneity and at least six major subtypes are known, of which Ib is thought to be the most likely to lead to chronic liver disease. Whilst it is associated with only about one-sixth of all cases of hepatocellular carcinoma world-wide, this proportion is higher and rising in some areas, notably Japan and, to a lesser extent, Spain, Italy and the Middle East (Idilman *et al*., 1998; Bosch *et al*., 1999; Colombo, 1999). The infection is usually acquired in adult life via transfusion of blood and blood products or by the use of contaminated instruments and syringes by intravenous drug abusers. Perinatal and sexual transmission are unimportant. The onset of malignancy is preceded by cirrhosis in 90% of cases. The course is long, 20–40 years from infection to tumour, and patients are affected in late middle to old age. **Table 3** shows that HCV is definitely associated with hepatocellular carcinoma in case-control and follow-up studies, but the pathogenesis is unknown. As it is an RNA virus, which does not possess a reverse transcriptase enzyme, it cannot integrate into the nuclei of liver cells. Instead, the risk of malignancy is associated with continued viral replication, liver cell death and stimulus to proliferation which lead to cirrhosis. However, hepatocellular carcinoma develops in a minority of cases without preceding cirrhosis and, therefore, a direct oncogenic effect cannot be ruled out. Accumulation of HCV core protein is thought to be the most likely mechanism. The co-existence of chronic HBV infection and alcoholism greatly increases the risk of malignancy. Attack rates of HCV infection have been reduced by screening of blood donors and the widespread use of disposable syringes but no vaccine is available and, because of the antigenic versatility of the virus, it may take many years yet to develop.

Other Hepatotropic Viruses

Hepatitis A, E, G and TT viruses are not associated with hepatocellular carcinoma, nor are herpes and other viruses that may rarely cause hepatitis. The delta agent (hepatitis D virus) can only co-infect with HBV and has no independent role.

Alcohol

A history of chronic alcohol abuse is frequently obtained in patients with cirrhosis and hepatocellular carcinoma, particularly in Europe, North America and Japan. Alcohol is not, by itself, a carcinogenic agent and it only exerts an effect through inducing cirrhosis. The risk is increased by concomitant HBV or HCV infection and, to a lesser extent, by smoking (Simonetti *et al*., 1991; Okuda, 1993; Bosch *et al*., 1999).

Chemicals and Drugs

Hundreds of chemicals – some purely experimental, others industrial – can produce liver tumours in rodents but epidemiological studies have shown that few, if any, are relevant to humans. Those that have caused most concern are nitrites, hydrocarbons, solvents, organochlorine pesticides and polychlorinated biphenyls (International Agency for Research on Cancer, 1972–1999). Tumours that develop after the administration of high doses of chemicals in short-term animal experiments may represent false-positive results for carcinogenicity because they produce a rapid mitogenic response. Damage to nuclear DNA is not repaired in the circumstances and it is 'fixed' by mitosis, leading to permanent mutation. The same chemicals in low doses do not stimulate mitosis in humans and therefore no harm results. Studies of occupational hazards have also produced inconclusive results. Therapeutic drugs are introduced after stringent testing procedures and few have proved to be carcinogenic and only in a small number of cases. They include oral contraceptives and anabolic–androgenic steroids, danazol and cytoproterone acetate. The radiological contrast agent thorium dioxide (Thorotrast) and the industrial contaminant vinyl chloride monomer (VCM) can be added to the list.

Aflatoxins

A hot, humid climate and prolonged storage encourage the growth of moulds on foodstuffs, notably of *Aspergillus fumigatus*, which produces toxic metabolites known as aflatoxins. Dietary exposure over long periods of time has led to an increased incidence of hepatocellular carcinoma in parts of sub-Saharan Africa and Southern China. The risk is increased by concomitant infection with HBV but aflatoxins are, by themselves, carcinogenic. A specific G to T mutation at the third base of codon 249 of the *p53* gene is a hallmark of exposure and it is seen in a high proportion of cases of hepatocellular carcinoma in these areas (Simonetti *et al.*, 1991; Bosch *et al.*, 1999; Wogan, 1999). (See the chapter *Mechanisms of Chemical Carcinogenesis*.)

Membraneous Obstruction of the Inferior Vena Cava

Reports have appeared from South Africa, Japan and Taiwan of an association between abnormalities of the inferior vena cava and hepatocellular carcinoma. The incidence of the lesion, which may be either congenital or acquired, is difficult to assess as it is seldom sought and is easily overlooked (Anthony, 1994).

Congenital Abnormalities and Metabolic Disorders

A large number of inherited conditions have been recognized as possible causes of hepatocellular carcinoma. These include Alagille's syndrome, ataxia–telangiectasia, familial polyposis of the colon, hereditary haemorrhagic telangiectasia, familial cholestatic cirrhosis, neonatal hepatitis/biliary atresia, neurofibromatosis and Soto syndrome. All of these are rare and some cases may have been pure chance associations (Anthony, 1994).

Inborn errors of metabolism are not all rare and some carry a surprisingly high risk of hepatocellular carcinoma (European Association for the Study of the Liver, 1999). It is interesting that this tumour is the only malignancy that complicates these disorders regularly. Genetic haemochromatosis is an autosomal recessive iron storage disorder associated with two mutations in the *HFE* gene: *C282Y* and *H63D*. The frequency in the general population is 0.5–1.0% in Northern Europe but lower elsewhere. The accumulation of iron leads to cirrhosis which then may be complicated by hepatocellular carcinoma, especially in males. The relative risk is about 100 over that of normal individuals. α-1-Antitrypsin deficiency is associated with neonatal jaundice and cirrhosis in early childhood and with emphysema and cirrhosis in adult life. Inheritance is under the control of *Pi* (protease inhibitor) genes of which the Z variant is the most important. Male adults with cirrhosis are at an increased risk of developing hepatocellular carcinoma but the magnitude of this is debated. Tyrosinaemia carries an almost 100% risk of hepatocellular carcinoma by the age of 10 years if patients survive that long. It is now recommended that hepatectomy and liver transplantation be carried out by 2 years of age. Glycogen storage disease and porphyria syndromes are rare and the risk of malignancy is low.

Precancerous Changes in the Liver, Screening and Prevention

Cirrhosis itself is a precancerous condition but the magnitude of the risk varies with aetiology, i.e. it is high with HBV and HCV but low with alcohol. Sustained proliferation of liver cells consequent upon chronic hepatitis B and C or the daily ingestion of a hepatoxic agent such as alcohol over many years seems to be the most likely mechanism of carcinogenesis as it predisposes the cell to accumulate DNA abnormalities. Proliferation prevents the repair of any damage to DNA and it is then 'fixed' and transmitted to the progeny. The 'right' combination of sites of damage that results in neoplastic transformation is a rare event, hence it takes time for the tumour to develop.

In addition, several microscopic and architectural abnormalities have been described and assigned a precancerous role (Anthony, 1994). Cellular changes such as large-cell dysplasia (meaning liver cells with enlarged, hyperchromatic, polyploid nuclei) have been held to be associated with an increased risk of malignant change for many years, especially in studies from Africa, Italy and France. Structurally abnormal and often large liver nodules

in cirrhosis have been termed macroregenerative nodule, adenomatous hyperplasia and dysplastic nodule (**Figure 2**). These, especially when associated with cytological atypia (nuclear enlargement, prominent nucleoli, increased nucleo-cytoplasmic ratio), acinar, gland-like structures, nodules within nodules, and growth into areas of fibrosis, have been held to be directly precancerous lesions. Small-cell dysplasia has also been described in these nodules. However, dysplastic nodules may be difficult to distinguish from early, small hepatocellular carcinomas.

It must be pointed out that hepatocellular carcinoma does not always develop from cirrhosis with or without large nodules and dysplastic changes and, therefore, these abnormalities do not constitute obligate and exclusive pathways of liver carcinogenesis in humans. They are clinically useful, however, as they indicate an increased risk and the need for close supervision, which allows early intervention before overt development of tumours in cirrhotic patients (Okuda, 1993; Schafer and Sorrell, 1999; Hirohashi *et al*., 2000).

The best preventive measure for hepatocellular carcinoma is elimination of the causative agent (primary prevention). Vaccination against HBV is highly effective in reducing chronic infection with this virus and has resulted in a reduction of tumour incidence in countries with nation-wide programmes such as Taiwan. A vaccine against HCV is not yet available but the virus has now been eliminated from blood used for transfusion by screening of donors. It is also possible to reduce exposure to aflatoxin by improving conditions of food storage. However, hundreds of millions of people remain for whom such measures are too late.

Secondary prevention means the identification of individuals considered to be at highest risk. In practice, this means those with cirrhosis due to chronic infection with HBV and HCV and large nodular lesions with or without dysplastic changes. The most effective means are regular ultrasound examination and estimation of serum levels of α-fetoprotein, the role of repeat liver biopsies being more controversial. Individuals with early, small tumours can then successfully be treated by surgery: resection or transplantation.

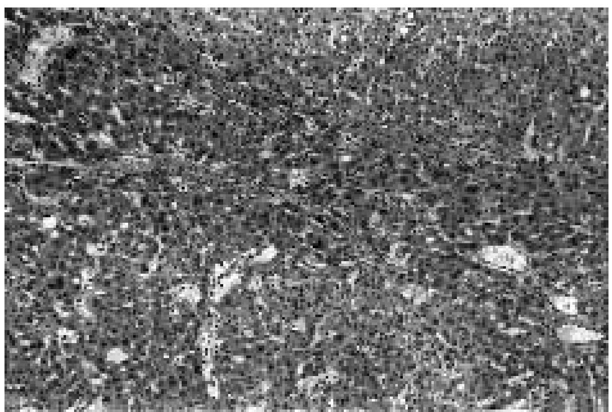

Figure 2 The interior of a cirrhotic 'dysplastic' nodule. Liver cell plates vary in thickness, their arrangement is disorganized and those in the middle of the field show nuclear enlargement.

Macroscopic and Microscopic Pathology

These have been described in detail over the years (Craig *et al*., 1989; Anthony, 1994; Ishak *et al*., 1994; Kojiro *et al*., 2000).

The Macroscopic Pathology of Hepatocellular Carcinoma

Most early tumours detected by screening with ultrasound and estimation of serum α-fetoprotein levels are small, usually <2 cm, solitary, and histologically well differentiated. Tumours that present with symptoms are >2–3 cm and usually much larger and are increasingly less well differentiated as they grow. A classification devised in the early twentieth century distinguishes three forms. The most common is multinodular in which more or less rounded, sharply demarcated, yellow–green nodules of tumour are scattered throughout the liver which is usually cirrhotic. Massive tumours are large, solitary, necrotic masses, sometimes with small, satellite nodules in the vicinity, often in an otherwise normal liver. Partial or complete encapsulation may be seen. Diffuse tumours replace the entire liver without the formation of a discrete mass. At autopsy, these patterns frequently co-exist (**Figure 3**). Rarely, the tumour is pedunculated or even outside the liver: these arise from accessory lobes or from ectopic liver tissue.

Hepatocellular carcinomas have an arterial blood supply but both portal and hepatic veins proliferate alongside, resulting in arterio-venous communications. Consequently, intra- and extrahepatic spread can take place in all directions, commonly to all parts of the liver, via the hepatic veins to the inferior vena cava and the right atrium of the heart and to the stomach and the oesophagus. This vascular spread is characteristic of hepatocellular carcinoma and is always seen in advanced cases at autopsy (**Figure 3**). Lymphatic spread to portal lymph nodes and beyond occurs in about one-third of cases. Involvement of major bile ducts and dissemination within the peritoneal cavity are much less common. Distant metastases are usually found in the lungs, adrenals, pancreas, kidney, ovary and bone.

A frequently debated issue is multicentricity of hepatocellular carcinoma, namely the simultaneous development of separate primary tumours, usually in a cirrhotic liver. This undoubtedly occurs as evidenced by studies of differences in patterns of HBV DNA integration and in

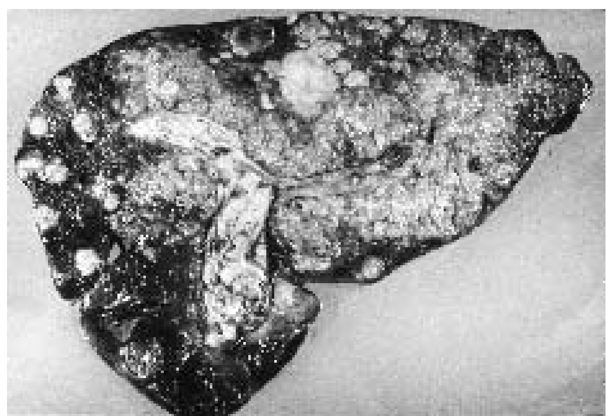

Figure 3 Cut surface of advanced hepatocellular carcinoma at autopsy. Most of the liver is replaced by tumour nodules. The triangular structure in the middle is the main portal vein and its two branches which are filled with tumour.

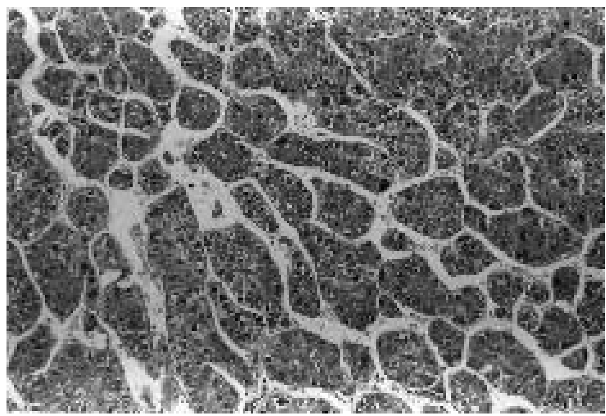

Figure 4 The microscopic appearances of hepatocellular carcinoma resemble those of the normal liver. The tumour is arranged in thick plates which are separated by sinusoids. Malignancy is manifested by the thickness of the plates and the variability in size and shape of nuclei.

dissimilar mutations of oncogenes and tumour-suppressor genes. However, separate tumours can also develop by vascular spread from the same primary source.

Microscopic Features: Histological Patterns and Cytological Variants, Ultrastructure and Special Techniques

The main microscopic characteristic of hepatocellular carcinoma is its resemblance to the normal liver, both in its plate-like growth pattern separated by sinusoids and its cytological appearances (**Figure 4**). Certain architectural and cytological variants have been recognized in the World Health Organisation classification (Ishak *et al.*, 1994) which are helpful for diagnosis but have no other, i.e. clinical or biological, significance.

The commonest architectural pattern is the plate-like or, as seen in two-dimensional histological sections, trabecular. Tumour cells grow in cords that vary in thickness from two to three to many cells. These are separated by sinusoids lined by flat endothelial cells. Kupffer cells are absent or reduced in number. Collagen fibres are increased in Disse's space surrounding the sinusoids and a basement membrane forms, i.e. they become 'capillarized'. The pseudoglandular pattern may result from dilatation of bile canaliculi or from central breakdown of cells in otherwise solid trabecula; the contents are bile or proteinaceous fluid. Compact, solid or scirrhous patterns are rare and develop from compression, scarring and chemo-radiotherapy. The term 'sclerosing hepatic carcinoma' has been applied to tumours associated with hypercalcaemia.

The commonest cytological variant is hepatic or liver-like. Tumour cells are polygonal, with vesicular nuclei and prominent nucleoli. The cytoplasm is finely granular and more basophilic than that of normal liver cells. Bile canaliculi may be seen. Pleomorphic cells show marked variation in nuclear size, shape and staining. Clear cells have a seemingly empty cytoplasm. This may be due to accumulation of water, fat or glycogen. Sarcomatoid tumours form spindle and giant cells. Recently, a small-cell variant has also been described. Recognition of these cytological variants is diagnostically important so that they can be distinguished from metastatic tumours of similar appearance: renal cell carcinoma, soft tissue sarcoma and carcinoma of the lung, respectively.

A number of intracellular inclusions may be seen. Globular hyaline bodies are small, round and often acidophilic. They usually consist of α-1-antitrypsin. Mallory bodies, similar to those seen in alcoholic liver disease, are made up of altered cytokeratins.

Grading of hepatocellular carcinoma into well-, moderately and poorly differentiated tumours is traditional but it is less important than stage for prognosis.

Special staining techniques commonly employed include silver impregnation, which demonstrates the deficiency of the reticulin framework in hepatocellular carcinoma in contrast to normal or cirrhotic liver and hepatocellular adenoma in which it is normal or increased (**Figure 5**). Others are the PAS reaction for the demonstration of glycogen and trichrome methods for cytoplasmic inclusions.

Electron microscopy is relatively little used nowadays owing to the need for fresh tissue, long time of preparation and expense. However, the ultrastructural features of hepatocellular carcinoma are useful for diagnosis. Numerous mitochondria, a well-developed endoplasmic reticulum and, most of all, the presence of intercellular bile canaliculi are pathognomonic.

Immunocytochemistry, however, has replaced electron microscopy in the investigation of liver tumours. It can be done on formalin-fixed, paraffin-embedded tissues and it

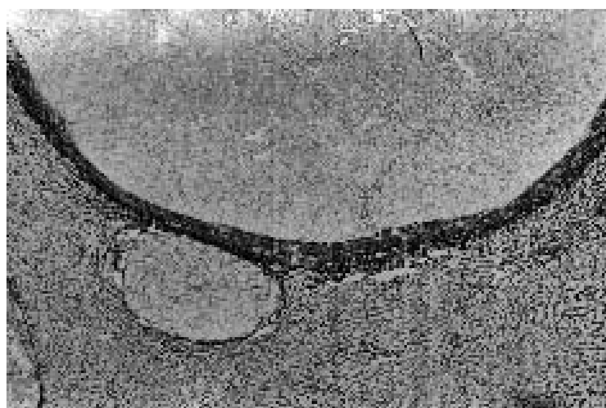

Figure 5 The curved band in the middle is the capsule of a hepatocellular carcinoma. The normal connective tissue framework of the non-tumorous liver is present below whilst it is almost completely absent in the tumour above. Note also that the tumour has broken through the capsule.

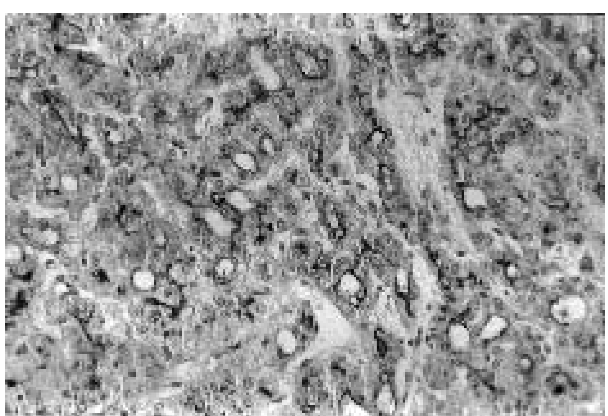

Figure 6 The darkly staining irregular circles and branching structures are bile ductules, stained by peroxidase-labelled polyclonal antisera against CEA/ biliary glycoproteins.

is quick and cheap. The demonstration of normal 'export' proteins such as α-1-antitrypsin, albumin, fibrinogen, ferritin and methallothionein is useful in identifying a tumour as being of liver cell origin. Normal adult liver cells express cytokeratins Nos 8 and 18 as defined in Moll's catalogue whereas bile duct cells contain these and Nos 7 and 19 in addition. The latest addition to liver cell markers is Hep Par1 (Leong *et al.*, 1998). The specificity of α-fetoprotein is high but its sensitivity is low. It is usually only demonstrable in tumour tissue when the serum levels are high, in excess of 5000 ng mL^{-1}. Carcinoembryonic antigen is widely distributed in glandular tissues in the body and polyclonal antibodies raised against it react with biliary glycoproteins. This allows the demonstration of bile canaliculi without recourse to electron microscopy (**Figure 6**).

Fine needle aspiration cytology is a useful diagnostic aid in expert hands, especially when smears are combined with histology of centrifuged needle washings which may contain tiny tissue fragments.

Molecular Genetic Findings

Hepatic carcinogenesis has been extensively studied for many years in experimental animals, usually rodents, by the use of chemicals. Results have led to the concept of multistep neoplastic development from initiation through promotion to progression. This is summarized in **Table 4**. Most of the chemicals used are not likely to play a part in the pathogenesis of human hepatocellular carcinoma, the experiments were short term and the phenotypic changes seen in animals are not definitely identified in humans. As evidence for the causative role of viruses began to emerge, attention has switched to mechanisms of viral carcinogenesis. These are presented in **Figure 7**. The possible pathways of hepatitis B and C viruses and of aflatoxin have been discussed already. Both **Tables 4** and **Figure 7** are somewhat wishful and idealized since such evidence as we have is patchy. Broadly speaking, the genetic changes in carcinogenesis at any site are multiple and cumulative and their phenotypic expressions are not easily identified. What we have at present is an incomplete mosaic from which most of the pieces are missing. However, they can be broken down into alterations in cell cycle regulation, growth factors, oncogenes, tumour-suppressor genes and epigenetic changes, such as telomerase activity. All of these have been investigated in hepatocellular carcinoma and found to be acting abnormally in a varying proportion of cases (Feitelson and Duan, 1997; Geissler *et al.*, 1997; Idilman *et al.*, 1998; Chen and Chen, 1999; Hirohashi *et al.*, 2000).

Completion of the cell cycle requires the successive activation of cyclin-dependent protein kinases which are opposed by their inhibitors. The latter allow for DNA repair. Altered expression leads to the uncontrolled growth of liver cells. Growth factors are generally polypeptides that act at short range via signal transduction pathways across cell membranes. Insulin-like growth factor II (IGF-II) may be an early marker of malignant transformation whilst transforming growth factor α (TGFα) may play a role in its maintenance. Transformed hepatocytes are resistant to transforming growth factor β (TGFβ), which inhibits cell proliferation. In human hepatocellular carcinoma, oncogene (*ras*, *myc*, *fos* families) activation is a rare and tumour-suppressor gene (*p53*, *Rb*) activation is a late event. The most important epigenetic change perhaps is increased telomerase activity which immortalizes the cell.

None of these changes are 'stand-alone' events: they interlock and co-act to produce genomic instability which is amply supported by many chromosomal abnormalities found in hepatocellular carcinoma.

Table 4 Chemical hepatic carcinogenesis (multistep neoplastic development)

Initiation	Metabolic conversion of proximate to ultimate carcinogen
	Damage to DNA, organelles, membranes
	Fixation of abnormality by cell proliferation
Promotion	Inhibition/selection: clonal expansion
	Altered cell populations:
	Enzyme changes
	Hyperplastic nodules
	Autonomous neoplastic nodules
Progression	Metastases and death
	Increased cell turnover all-important

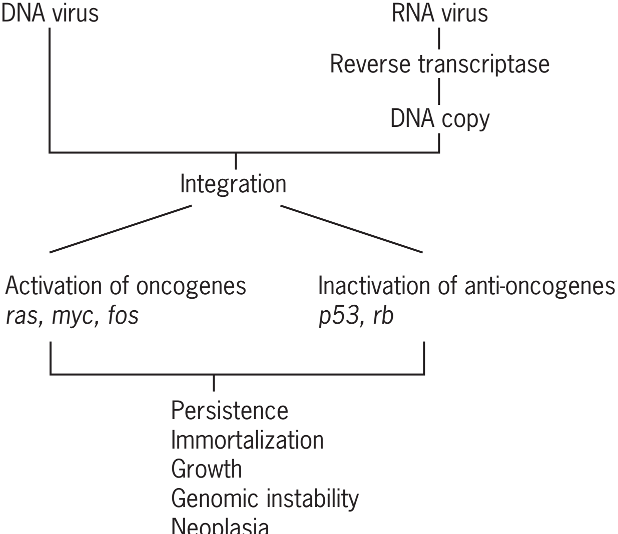

Figure 7 Viral hepatic carcinogenesis

Prognostic Factors

The outlook for hepatocellular carcinoma patients presenting with symptoms is poor, most specialized centres reporting a < 5% survival rate amongst those considered suitable for treatment. Better results can be obtained in patients with small, asymptomatic tumours. Good prognostic indicators are a serum α-fetoprotein level below 100 ng mL^{-1}, a solitary tumour, size < 5 cm and preferably < 2 cm, lack of portal or hepatic vein involvement, early stage in terms of the TNM classification and well-preserved liver function (Okuda, 1993; Akriviadis *et al*., 1998; Schafer and Sorrell, 1999).

Presentation, Clinical Diagnosis and Management

In Western countries and particularly in Japan, patients are middle aged or elderly, have had cirrhosis for years and the onset of malignancy is heralded by a sudden deterioration of their condition. In tropical Africa and Asia, patients are often young adults and cirrhosis is first discovered at the same time as the tumour, which is often large and the course is fulminant. Common presenting features are lethargy, pain, hepatomegaly or a mass, fever, weight loss and, in the case of large tumours, rupture and intraperitoneal haemorrhage. Some patients experience a variety of paraneoplastic syndromes such as hypoglycaemia, erythrocytosis and hypercalcaemia.

The most useful laboratory test is a serum α-fetoprotein level over 2–400 ng mL^{-1}, which is found in ~80% of cases. Frequently used imaging methods are ultrasound, computed tomography and magnetic resonance imaging (Okuda, 1993; Akriviadis *et al*., 1998; Curley, 1998).

Treatment modalities include surgical resection, hepatic artery embolization or chemotherapy, percutaneous injection of alcohol and total hepatectomy followed by liver transplantation. The respective roles of local attempts at tumour removal or destruction and hepatectomy with transplantation have not been finally determined yet and each has its advocates. Once the tumour has spread outside the liver, no form of therapy is effective.

An intriguing aspect of hepatocellular carcinoma is spontaneous regression which has been reported on occasions over the years.

Fibrolamellar Carcinoma

This is a distinctive type of hepatocellular carcinoma that affects adolescents and young adults of either gender. It is not associated with cirrhosis, serum α-fetoprotein is seldom raised and < 10% of patients show evidence of HBV or HCV infection. Despite all this, fibrolamellar carcinoma is of liver cell origin (Anthony, 1994; Ishak *et al*., 1994; Hirohashi *et al*., 2000).

Patients present with malaise, weight loss and a palpable mass, which is usually solitary and often large, 5–25 cm. The tumour cells are large, with vesicular nuclei and granular, pink cytoplasm, due to the presence of numerous mitochondria. Cytoplasmic globules and 'pale bodies' commonly represent α-1-antitrypsin and fibrinogen,

respectively. Bile droplets, copper and copper-associated protein may be present. Bile canaliculi may be difficult to demonstrate. An abundant fibrous stroma, arranged as lamellae of coarse collagen is characteristic and is a *sine qua non* requirement for diagnosis. This fibrous incarceration of the tumour has been held to be responsible for its slow growth and favourable prognosis.

The surgical resectability rate is high and the 5-year survival figures are in the region of 50%.

HEPATOBLASTOMA

This is the most frequently occurring liver tumour in children with a peak incidence in the second year of life. A few present at birth or develop in early adolescence. Males are twice as commonly affected as females. Hepatoblastoma consists of immature liver cells in varying stages of development and a mesenchymal component that is frequently osteoid (Anthony, 1994; Ishak *et al*., 1994; Stocker and Conran, 1997). One-third of patients with hepatoblastoma have a congenital anomaly (hemihypertrophy, cleft palate, talipes, cardiac or renal malformation), a syndrome (Beckwith–Widemann and Down) or other childhood tumour (nephroblastoma). There is also an increased incidence in familial adenomatous polyposis. Chromosomal abnormalities are common.

The usual presentation is with failure to thrive, loss of weight and a rapidly enlarging abdominal mass. The serum α-fetoprotein level is almost invariably high. Virilization is seen in a small minority, due to production of chorionic gonadotrophin by the tumour. Increased urinary excretion of cystathionine occurs in about half of cases.

Hepatoblastoma usually forms a single mass and is often large when first detected, up to 25 cm. It is well circumscribed, with a thin capsule and a partly solid, partly cystic, fibrous, gelatinous or haemorrhagic cut surface. The epithelial component consists of embryonal, foetal, occasionally adult-like liver cells or glandular structures and keratinizing squamous cells. The commonest mesenchymal elements are undifferentiated spindle cells and osteoid but cartilage, bone and striated muscle may be seen. Rarely, anaplastic small cells, neuroendocrine differentiation and melanin production are present. Extramedullary haematopoiesis is common. Immunocytochemistry shows a wide range of differentiation pathways.

Most hepatoblastomas fall into the epithelial or mixed epithelial and mesenchymal categories (**Figure 8**) but a more detailed classification defines six categories: epithelial (pure foetal, combined foetal and embryonal, macrotrabecular, small cell undifferentiated), mixed epithelial and mesenchymal and mixed with teratoid features (Stocker and Conran, 1997). These categories have limited prognostic significance.

Although half of patients are inoperable at presentation and one-fifth have pulmonary metastases, pre-operative chemotherapy allows local resection or total hepatectomy followed by transplantation to be carried out in $> 90\%$ of cases. The overall survival rate is 65–70%. A rapid fall of serum α-fetoprotein levels after surgery is a particularly good prognostic sign.

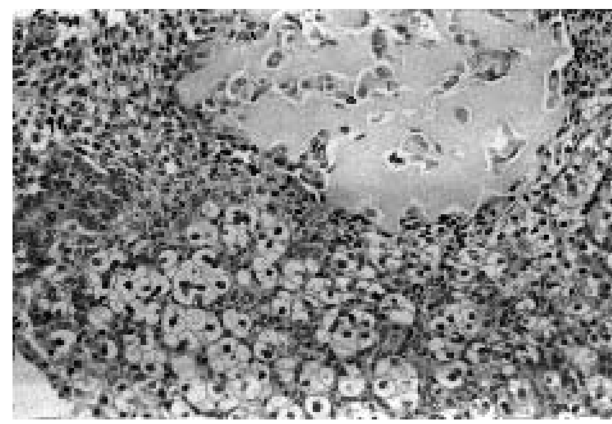

Figure 8 Dark and clear foetal-type cells of hepatoblastoma, mesenchymal spindle cells and structureless osteoid (bone matrix).

CHOLANGIOCARCINOMA (INTRAHEPATIC AND HILAR BILE DUCT CARCINOMA)

Cholangiocarcinoma is a malignant tumour composed of structures resembling bile ducts (Ishak *et al*., 1994). It may be intrahepatic, arising from small bile ducts within the liver or hilar, arising from large bile ducts near the porta hepatis. The clinical presentation is somewhat different according to location. The pathology is simple: all these tumours are mucus secreting adenocarcinomas (Anthony, 1989, 1994; Nakanuma *et al*., 2000).

Epidemiology

Cholangiocarcinoma is much less common than hepatocellular carcinoma and constitutes about 15% of all liver cancers (Parkin *et al*., 1997). It is distributed equally throughout the world except in South-East Asia, particularly Thailand, Laos, Korea, Hong Kong and Canton, where its incidence is increased. This is due to the high prevalence of liver fluke infestation in these areas. Patients are middle aged to elderly, there is no gender difference and the tumour is not associated with cirrhosis.

Aetiology

Liver Fluke Infestation

Infestation with the liver flukes *Opistorchis viverrini* in Thailand and Laos and *Clonorchis sinensis* in

Korea, Hong Kong and Canton is the major cause of cholangiocarcinoma in these high-incidence areas. The life cycle of liver flukes requires poor environmental conditions with infested human waste discharged into stagnant water, take-up by snails as intermediate hosts and the habit of eating raw or undercooked fish which themselves have become infested. A heavy parasite load is acquired over many years and results in cholangitis, liver abscess and cholangiocarcinoma. The presence of liver flukes may not, in itself, be carcinogenic and nitrosamines, derived from diet, may act as cofactors.

Hepatolithiasis

Intrahepatic biliary stones are frequently associated with clonorchiasis but not with opistorchiasis. Cystic lesions of bile ducts may also be complicated by stones.

Chronic Inflammatory Bowel Disease

Cholangiocarcinoma is a significant complication of long-standing ulcerative colitis commonly preceded by sclerosing cholangitis.

Congenital Anomalies of the Biliary Tree

These include cystic dilatation of the biliary tree or Caroli disease, choledochal cysts, biliary microhamartomas and anomalies of the union between the main pancreatic and common bile ducts.

Thorotrast

This once commonly used radiological contrast medium is best known for causing angiosarcoma of the liver but, in recent years, cholangiocarcinomas have also been observed.

Precancerous Changes, Screening and Prevention

The best studied precancerous changes are those associated with liver flukes and biliary stones (**Figure 9**). These consist of adenomatous hyperplasia, dysplasia with multilayering, nuclear enlargement and hyperchromasia and carcinoma-*in-situ* without invasion (Nakanuma *et al*., 2000). Cell kinetic studies have shown increasing proliferative activity along this sequence and the acquisition of genetic abnormalities.

There is no effective screening method for cholangiocarcinoma and prevention consists of reducing the incidence of liver fluke infestation, surveillance of individuals with known high-risk factors and surgical removal of choledochal cysts which carry a particularly high risk of malignant change.

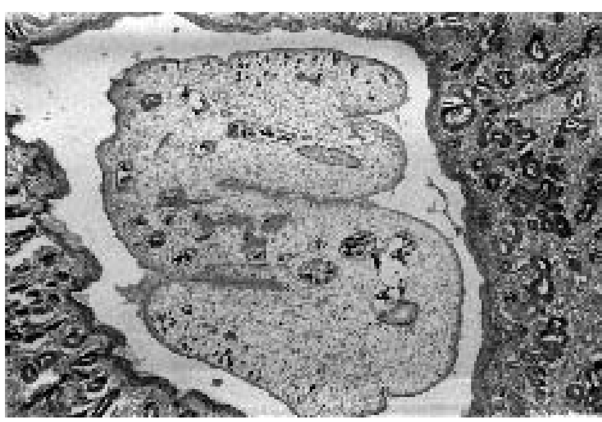

Figure 9 A female *Clonorchis sinensis* fluke lying in a bile duct, the lining of which shows glandular adenomatous hyperplasia. The small, dark, oval objects in the worm's body are eggs.

Macroscopic and Microscopic Pathology

The Macroscopic Pathology of Cholangiocarcinoma

The gross appearance of intrahepatic tumours is of a grey–white, tough, scirrhous type of growth which is often solitary but may be multinodular, or a combination of both. Central necrosis, scarring and calcification may be seen. Finger-like extensions around the main mass represent spread along portal tracts. Metastatic spread is common, to regional lymph nodes, lungs and the peritoneum. Tumours in the hilum present as ill-defined nodules, strictures or, rarely, as an intraductal papillary growth. The flow of bile from the liver is often obstructed and the liver is stained green whilst the gall bladder and common bile ducts are empty.

Microscopic Features: Histological Patterns, Ultrastructure and Special Techniques

Most cholangiocarcinomas are mucus-secreting adenocarcinomas of a tubular pattern and an abundant fibrous stroma is characteristic (**Figure 10**) (Colombari and Tsui, 1995). PAS diastase-resistant or mucicarmine-positive mucus is readily demonstrable and tumour cells express carcinoembryonic antigen in their cytoplasm as well as on their luminal border. The tumour may also grow in solid cords and form papillae. Rarely, it is of signet ring or clear cell type. Large amounts of extracellular mucus are sometimes formed in which tubulopapillary fragments of tumour appear to float freely. Tumours associated with stones, cysts or bile duct anomalies may be adenosquamous or purely squamous. Sarcomatoid cholangiocarcinoma is rare.

Electron microscopy is seldom used in the diagnosis of cholangiocarcinoma. It shows glandular characteristics: lack

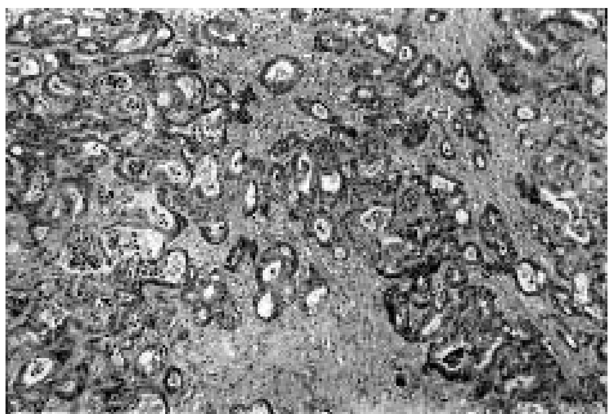

Figure 10 Cholangiocarcinoma made up of abnormally branching bile duct-like structures, separated by a dense fibrous stroma.

of organelles, presence of tonofilaments and a basal lamina.

Immunocytochemistry is used mainly to distinguish cholangiocarcinoma from metastatic adenocarcinoma and, less commonly, from hepatocellular carcinoma. The most useful are demonstration of different cytokeratin patterns for the former and Hep Par 1 for the latter (Leong *et al*., 1998).

Molecular Genetic Findings

Mutations of the *ras* oncogene and the *p53* tumour-suppressor gene are the most common genetic abnormalities in cholangiocarcinoma followed by over-expression of c-*erbB-2* (Nakanuma *et al*., 2000).

Prognostic Factors

Early detection of cholangiocarcinoma is difficult and most patients present with advanced tumours. Lymph node involvement, positive margins and bilobar distribution are associated with high recurrence rates after surgical resection. Patients with unrelieved obstruction of major hepatic ducts and those with cysts and stones may die of complications, e.g. sepsis or liver failure, before the tumour itself becomes evident.

Presentation, Clinical Diagnosis and Management

Malaise, abdominal pain and weight loss are common symptoms of intrahepatic tumours whilst hilar tumours cause unremitting obstructive jaundice. Ultrasound and computer-assisted tomography show the location of the tumour which can then be biopsied for a definitive diagnosis. Only a small minority of patients are suitable for surgical resection and other forms of treatment, e.g. radio- or chemotherapy, are ineffective.

BILIARY CYSTADENOMA AND CYSTADENOCARCINOMA

These are rare tumours. Their pathology is virtually identical with that of similar tumours seen in the ovary and, occasionally, in the pancreas. Most are mucinous and a minority are serous. Patients present with solitary masses which may be fairly large but they are usually amenable to surgical resection and the results are good.

MIXED HEPATOCELLULAR CARCINOMA AND CHOLANGIOCARCINOMA

The presence of both bile secretion and mucus production must be present, supported by appropriate immunocytochemical markers, for such a diagnosis to be made. Effective treatment is seldom possible and the prognosis is poor.

METASTATIC TUMOURS

These are nearly always secondary carcinomas and the common primary sites are the colon, rectum, upper gastrointestinal tract, pancreas, lung and breast. Liver metastases indicate advanced disease and most patients die within a few weeks or at most months. Colonic and, especially, rectal carcinoma metastases may be solitary or few in number and worthwhile results have been achieved by partial hepatectomy.

SARCOMAS OF THE LIVER

These are all rare but angiosarcoma, childhood sarcomas and malignant lymphoma are the most important (Ishak, 1997).

Angiosarcoma

The cause of this tumour is unknown in most cases but a minority are associated with exposure to the once popular radiological contrast agent Thorotrast (thorium dioxide), arsenic and the industrial contaminant vinyl chloride monomer. Thorium is radioactive with a half-life of approximately 400 years and, when injected, most of it is taken up by the liver. In addition to angiosarcoma, hepatocellular carcinoma and cholangiocarcinoma have also been observed. Particles of Thorotrast are readily visualized in histological sections as coarse, pink–brown granules (**Figure 11**).

Angiosarcoma of the liver is always fatal and at autopsy it appears as ill-defined, spongy and haemorrhagic, or greyish–white fibrous nodules which replace the entire

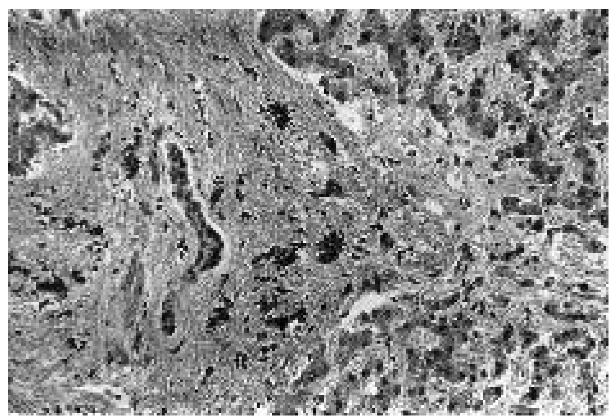

Figure 11 The dark granular material next to a portal bile duct is Thorotrast. There is much fibrosis, separating the liver cell plates around but angiosarcoma has not yet developed.

Figure 12 Reddish, dark and white (fibrous) angiosarcoma replaces the entire liver.

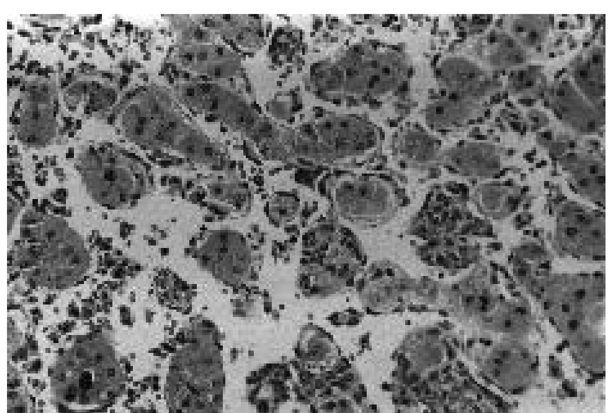

Figure 13 Dark, spindle and polygonal cells of angiosarcoma grow over the surface of liver cell plates in a scaffold-like or tectorial fashion.

liver (**Figure 12**). The histological appearances are variable but the most characteristic is a scaffold-like or tectorial growth of spindle cells on the surface of liver cell plates which eventually atrophy and disappear (**Figure 13**). Immunocytochemistry shows that tumour cells react with endothelial markers such as CD31, CD34 and Factor VIII related antigen or von Willebrand factor.

Another, distinctive form of malignant vascular tumour is epithelioid haemangioma, which occurs in the liver, lung, skin and bone and has a much better prognosis than angiosarcoma.

Childhood Sarcomas

These are embryonal sarcoma and rhabdomyosarcoma. They are much less common than hepatoblastoma. Their prognosis has been hopeless until recently but aggressive treatment combining surgical excision, chemotherapy and radiation has led to 5-year survival rates of around 15%.

Primary Malignant Lymphoma

All types of lymphoma may secondarily involve the liver in their advanced stage and the prognosis is then poor. However, it is increasingly recognized that lymphoma can also be primary in the liver and the outcome, with appropriate treatment, is much more favourable. They are all non-Hodgkin lymphomas of B or T cell lineage. Some have been associated with HBV or HCV infections and AIDS.

BENIGN TUMOURS AND TUMOUR-LIKE LESIONS

The most important benign tumour of the liver is hepatocellular adenoma. The majority of cases occur in young to middle-aged women who have taken oral contraceptive steroids for years or in individuals of either gender on long-term treatment with androgenic/anabolic steroids. Hepatocellular adenoma is often symptomatic, may grow to a large size, and rupture, giving rise to life-threatening intraperitoneal haemorrhage. The relationship of focal nodular hyperplasia to oral contraceptive steroids is much less certain and is often an asymptomatic, incidental finding. Inflammatory myofibroblastic tumour is an intriguing entity, the nature of which is not fully understood, i.e. whether inflammatory or neoplastic, but surgical excision is curative. Many other types of benign tumour have been described but they are all rare or clinically unimportant (Anthony, 1994).

TUMOURS OF THE GALL BLADDER

Nearly all tumours at this site are mucus secreting adenocarcinomas (Albores-Saavedra and Henson, 1986).

The incidence of carcinoma of the gall bladder is variable in different parts of the world and amongst ethnic groups. Overall, it ranks fourth amongst cancers of the digestive tract, after those of the colo-rectum, stomach and pancreas. The highest frequency is seen in South West American Indians and it is also common in Mexico, Chile, Bolivia and Israel.

South West American Indians apart, who seem to have a genetic predisposition to gall bladder carcinoma, the most important predisposing factor in most countries is chronic inflammation of the gall bladder associated with stones (cholelithiasis). Secondary factors are old age, female gender, obesity, abnormalities of bile and lipoprotein metabolism and multiple pregnancies which, themselves, predispose to gall stone formation. There is also a link with chronic inflammatory bowel disease, anomalous pancreaticobiliary duct union and the typhoid carrier state.

Carcinoma of the gall bladder is commonly preceded by epithelial hyperplasia, dysplasia and carcinoma-*in-situ*. Malignant change may also develop in tubular or villous adenomas. Rarely, biliary papillomatosis affects the gall bladder, the intra- and extrahepatic bile ducts and even the pancreatic duct system and carcinomas can arise at any of these sites.

There is no effective screening method for gall bladder carcinoma and the only means of prevention is prophylactic cholecystectomy which has been advocated for high-risk groups such as American Indian females beyond middle age.

Carcinoma of the gall bladder is often a silent disease and the tumour is discovered incidentally at cholecystectomy or else the symptoms are those of cholecystitis or cholelithiasis. These include intolerance of fatty meals, right upper quadrant abdominal pain and intermittent nausea or vomiting. Weight loss and jaundice are indicative of advanced disease. Ultrasonography and computed tomography are used in the assessment of patients with symptoms attributable to gall bladder disease.

Macroscopically, carcinoma of the gall bladder may appear as diffuse thickening of the wall, an ill-defined nodule or a polyp. Microscopically, most tumours are well to moderately differentiated adenocarcinomas with a tubular or tubulo-papillary pattern. Mucus secretion is nearly always demonstrable. Intestinal (with endocrine, Paneth and goblet cells), mucinous (with much extracellular mucin), signet ring, clear and small-cell variants are recognized. Ultrastructural or immunocytochemical studies are not particularly useful for diagnosis: the features are those of an adenocarcinoma occurring at many sites.

The majority of gall bladder carcinomas express mutated *p53* tumour-suppressor gene. *Ras* and other oncogene mutations are late events. Amplification of the c-*erbB-2* gene has also been found.

Surgical excision is the only effective method of treatment. The best results are obtained before the gall bladder wall has been breached. Direct extension into the liver and regional lymph node metastasis are indicators of a poor prognosis. Ultimately, patients die of disseminated disease with direct, lymphatic and blood-borne spread to many possible sites in the body.

TUMOURS OF THE EXTRAHEPATIC BILE DUCTS

As in the gall bladder, the commonest tumour in the extrahepatic bile ducts is an adenocarcinoma. About half arise in the common hepatic, cystic and upper common bile ducts, one quarter in the middle and one-tenth in the lower common bile duct; the rest are diffuse or multiple tumours. In general, the prognosis is worse for carcinomas of the proximal than of the middle or distal segments of the extrahepatic biliary tree. Most patients are elderly and males are more commonly affected than females, in contrast to carcinoma of the gall bladder. Cholelithiasis is not a risk factor. Ulcerative colitis, malunion of the main pancreatic and common bile ducts, congenital malformations such as choledochal cyst, pre-existing adenomas and papillomas are well-known predisposing factors. The onset of invasive malignancy may be preceded by dysplasia and carcinoma-*in-situ*, which are sometimes seen next to it in operative specimens. Most patients present with obstructive jaundice, some with ascending cholangitis and a few with blood in the bile (haemobilia). At laparotomy, extrahepatic bile duct carcinoma appears as a polyp, a stricture or a diffuse thickening. Histologically, most are tubular or tubulo-papillary adenocarcinomas with a fibrous stroma. A good histological grade has been claimed to confer a prognostic advantage but this is not universally accepted. Spread to adjacent structures or lymph node metastasis are indicative of a poor prognosis. The only effective treatment is complete surgical excision.

NORMAL DEVELOPMENT AND STRUCTURE

As is true for many organs, an understanding of the embryology of the pancreas can lead to a better understanding of the diseases that affect the gland. The five parts of the pancreas (head, uncinate, neck, body and tail; **Figure 1a**) develop from two separate outpouchings of the embryological foregut (Solicia *et al*., 1997). The first outpouching, called the 'ventral anlage,' will give rise to most of the head and uncinate process of the pancreas. The second outpouching, called the dorsal anlage, will form the tail, body and inferior (lower) portion of the head of the gland.

These two anlages and their duct systems normally fuse by the eighth week of gestation to form a single organ. The main pancreatic duct, called the 'duct of Wirsung,' is normally formed when the duct in the dorsal anlage fuses with the duct in the ventral anlage at a point close to the duodenum. Because the ventral anlage also forms the common bile duct, the main pancreatic duct usually drains into the duodenum in conjunction with the common bile duct (**Figure 1b**). A remaining portion of the dorsal duct forms the accessory pancreatic duct, called the 'duct of Santorini' and this accessory duct usually drains separately into the duodenum.

The adult pancreas comes to rest in the centre of the abdomen, housed between the duodenum and spleen. The head of the pancreas is closely associated with the duodenum. The uncinate process forms a groove above which important blood vessels, the superior mesenteric artery and vein, pass. The neck, body and tail comprise the parts of the pancreas that are successively closer to the spleen (see **Figure 1a**).

Macroscopically, the pancreas is a single organ. Microscopically, however, the pancreas contains two distinct components, each with an important function (**Figure 2**). The 'exocrine' pancreas secretes digestive enzymes into the duodenum, while the 'endocrine' portion of the pancreas secretes hormones, such as insulin, into the

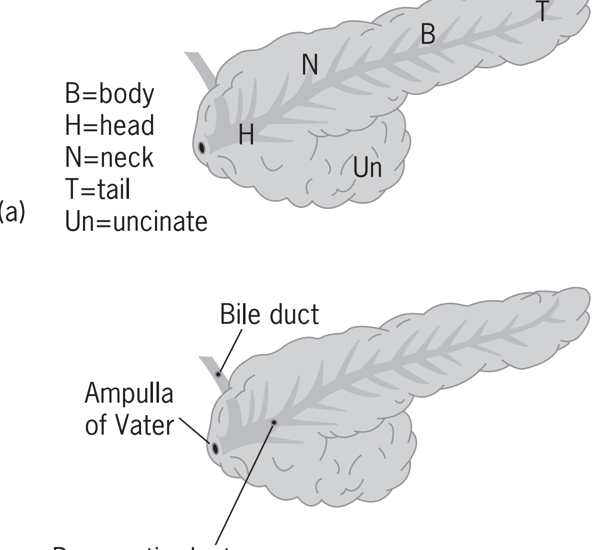

Figure 1 Structure of the adult pancreas. The head is that portion of the pancreas closest to the duodenum, the tail the portion closest to the spleen (a). Note that the main pancreatic duct joins the distal common bile duct at the ampulla of Vater (b). (Adapted from an original medical illustration by Jennifer Parsons, with permission.)

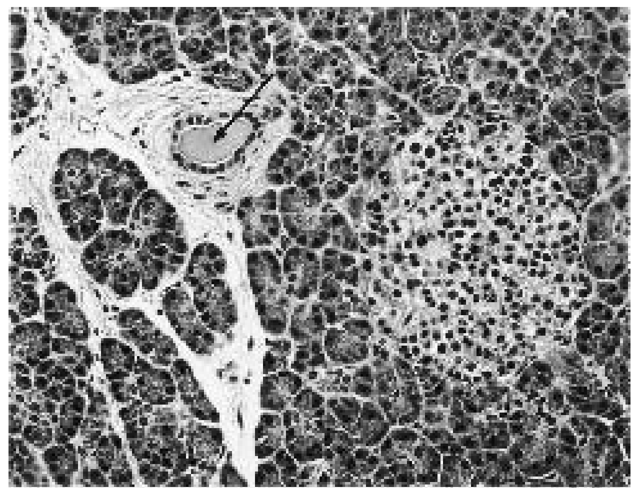

Figure 2 Microscopic section of normal pancreas. The acini comprise the bulk of the exocrine pancreas. The acini produce digestive enzymes which are released into small ductules (arrow) and from there the enzymes travel into the duodenum. The islets of Langerhans (nodule on right) form the endocrine pancreas. They release hormones such as insulin directly into the bloodstream.

bloodstream. The pancreas has cells specialized for each of these tasks, as well as the cells needed to support and nourish the organ (connective tissue, blood vessels).

The exocrine structures of the pancreas include the acini and ducts (**Figure 2**). Acini, which comprise over 80% of the pancreatic mass, are lobular units that secrete fluids rich in bicarbonate and enzymes into small ductules. These small ductules merge to drain their contents into larger ducts, which in turn merge into even larger ducts. This arborizing pattern continues to the level of the main and accessory pancreatic ducts, and the digestive enzymes of the exocrine pancreas are thereby released into the duodenum.

The endocrine portion of the pancreas consists of the islets of Langerhans (**Figure 2**). Although a normal pancreas contains over one million of these islets, they comprise only 1–2% of the organ mass (Solcia *et al.*, 1997). Approximately 70% of the cells in normal islets are α cells, 20% are β cells and 10% are δ cells. The α cells secrete the hormone glucagon, the β cells secrete the hormone insulin and the δ cells secrete the hormone somatostatin.

The various neoplasms of the pancreas can be best understood if one keeps these structures of the normal pancreas in mind.

TUMOUR PATHOLOGY

Cancer of the pancreas is not one disease. Instead, it is a number of different diseases broadly classified under one umbrella term (Klöppel *et al.*, 1996; Solcia *et al.*, 1997). For example, primary, metastatic and systemic tumours can all involve the gland. Primary cancers arise in the pancreas. Metastatic cancers originate in other organs and spread to the pancreas secondarily. Systemic malignancies derive from the blood or lymph nodes and, by definition, simultaneously involve multiple sites, one of which may be the pancreas.

This section provides an overview of the many types of neoplasms that can arise in or spread to the pancreas. It focuses on primary pancreatic neoplasms, which can be benign (tumours which usually do not spread and which usually will not lead to a patient's death), borderline (tumours for which behaviour is difficult to predict) or malignant (tumours which, if untreated, will spread beyond the gland and lead to the patient's death). Not surprisingly, if we remember the dual composition of the normal pancreas, primary pancreatic neoplasms can show either endocrine or exocrine (non-endocrine) differentiation. The non-endocrine neoplasms can be further subclassified into solid or cystic. For example, ductal adenocarcinoma, the most common primary pancreatic malignancy, is a non-endocrine, solid neoplasm. Needless to say, each of the various pancreatic neoplasms is grossly, microscopically and clinically distinct. Therefore, understanding the pathology of pancreatic cancer forms the cornerstone for rational patient diagnosis, treatment and prognostication.

The following sections will describe the most common types of tumours of the pancreas. Wherever possible, the classification systems published by the Armed Forces Institute of Pathology (AFIP) and by the World Health Organisation (WHO) will be followed (see **Table 1**) (Klöppel *et al.*, 1996; Solcia *et al.*, 1997).

Solid Non-endocrine Neoplasms

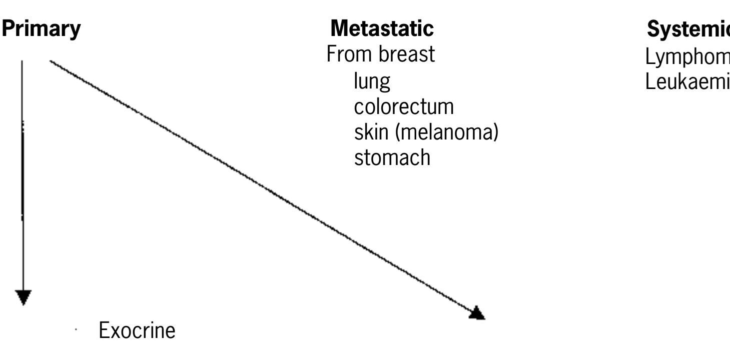
Ductal Adenocarcinoma

Gross and Microscopic Features

Ductal adenocarcinoma is the most common malignancy of the pancreas, accounting for almost three-quarters of all primary cancers (Solcia *et al.*, 1997). Most, but not all, ductal adenocarcinomas arise in the head of the pancreas (Solcia *et al.*, 1997; Hruban *et al.*, 2000). These tumours are infiltrative (**Figure 3; see colour plate section**), firm masses. Those that arise in the head of the pancreas often obstruct and dilate the distal common bile and pancreatic ducts. As a result, many patients with pancreatic cancer develop jaundice, a yellowish discoloration of the skin and eyes caused by obstruction of the flow of bile. Microscopically, ductal adenocarcinomas are composed of infiltrating glands of various shapes and sizes surrounded by reactive connective tissue (**Figure 4a**). The cancer cells may contain abnormal mitotic figures and the nuclei of these cells can show marked pleomorphism (variation in size and shape) and hyperchromasia (increased nuclear staining).

Most ductal adenocarcinomas grow into nerves (**Figure 4b**) and blood vessels, and it is therefore

Table 1 Histological classification of tumours of the pancreas. (Adapted from Solcia *et al.*, 1997.)



Exocrine		Endocrine
	Benign	
1. Serous cystadenoma 2. Mucinous cystadenoma 3. Intraductal papillary–mucinous adenoma		1. Well- or moderately-differentiated islet cell tumour
	Borderline	
1. Borderline mucinous cystic tumour 2. Borderline intraductal papillary–mucinous tumour 3. Solid pseudopapillary tumour		1. Well- or moderately differentiated endocrine neoplasm of uncertain malignant potential
	Malignant	
1. Ductal adenocarcinoma 2. Osteoclast-like giant-cell tumour 3. Mucinous cystadenocarcinoma 4. Serous cystadenocarcinoma 5. Intraductal papillary–mucinous carcinoma 6. Acinar cell carcinoma 7. Pancreatoblastoma 8. Medullary carcinoma		1. Well- or moderately differentiated endocrine carcinoma 2. Poorly differentiated carcinoma (small-cell carcinoma, high-grade neuroendocrine carcinoma)

not surprising that many patients with pancreatic cancer develop severe back pain. In addition, most ductal adenocarcinomas spread to lymph nodes (Solcia *et al.*, 1997). Ductal adenocarcinomas also frequently spread to other organs ('metastasize') (Solcia *et al.*, 1997; Hruban *et al.*, 2000). This spread to lymph nodes and other organs greatly reduces the effectiveness of surgery in the treatment of pancreatic cancer and, not unexpectedly, patients with metastases do significantly worse than do patients without them (Yeo *et al.*, 1995; Solcia *et al.*, 1997; Hruban *et al.*, 2000). Unfortunately, most patients with pancreas cancer do not come to clinical attention until after their cancers have spread. Overall survival from ductal adenocarcinoma is therefore extremely poor, with average survival time of about 6 months.

Special Features: Histological Precursors

One of the more important findings in the pathology of ductal adenocarcinoma of the pancreas has been the identification of the morphological precursors to invasive cancer. Called 'pancreatic intraepithelial neoplasias' (or PanINs for short), these precursors arise in the small pancreatic ducts and ductules, and they are composed of mucin-producing cells with varying degrees of nuclear and architectural atypia. A complete description of the various PanINs as well as numerous examples can be found on the Web (http://pathology.jhu.edu/pancreas_panin). As shown in **Figure 5**, PanINs progress from flat lesions to papillary lesions to atypical papillary lesions to carcinomas *in situ* (non-invasive carcinoma) and finally to invasive cancers (Cubilla and Fitzgerald, 1976; DiGiuseppe *et al.*, 1996; Hruban *et al.*, 2000).

Several lines of evidence suggest that PanINs are the precursors of infiltrating pancreatic ductal adenocarcinoma, just like adenomas are the precursors of infiltrating cancer in the colon. First, PanINs are frequently found in pancreata adjacent to infiltrating cancers (Cubilla and Fitzgerald, 1976). Second, isolated clinical case reports have suggested that PanINs can progress to infiltrating cancer over time (Brat *et al.*, 1998). For example, Brat *et al.* reported three patients who developed infiltrating ductal adenocarcinomas months to years after high-grade PanINs

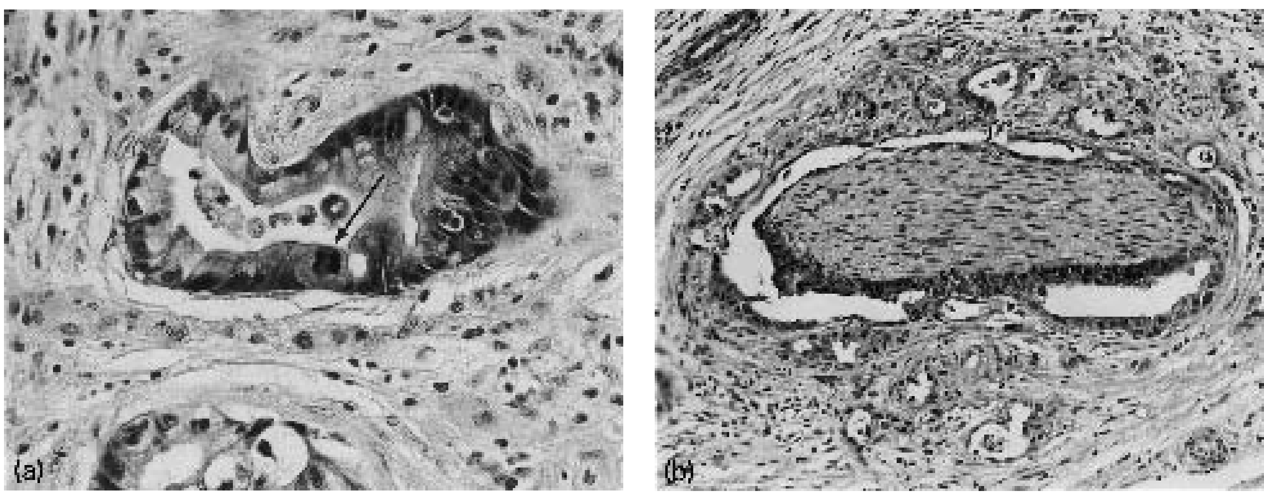


Figure 4 Microscopic section of infiltrating ductal adenocarcinoma. Note how the cancer cells form irregular glands and note the presence of an atypical mitotic figure (arrow) (a). Ductal adenocarcinomas often invade around nerves (b).

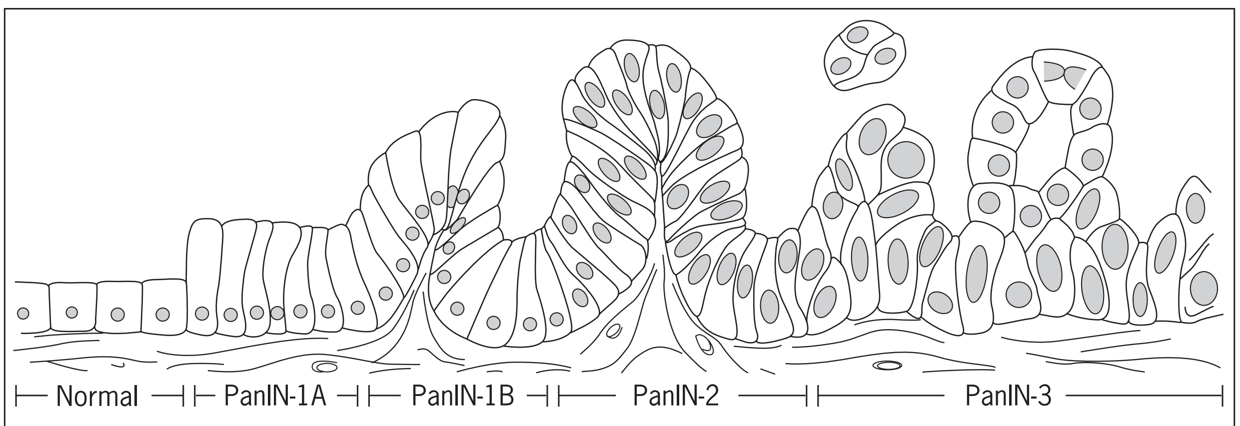

Figure 5 Illustration depicting the progression from normal pancreatic duct (left), to flat duct lesion without atypia (PanIN-1A), to papillary duct lesion without atypia (PanIN-1B), to papillary duct lesion with atypia (PanIN-2), to carcinoma-*in-situ* (PanIN-3). (Adapted from an original medical illustration by Jennifer Parsons, with permission.)

were identified in their pancreata. Third, PanINs display many of the same fundamental genetic changes (mutations in the K-*RAS*, *HER-2/neu*, *BRCA2*, *p16*, *p53* and *DPC4* genes) as do infiltrating adenocarcinomas (Caldas *et al*., 1994; DiGiuseppe *et al*., 1994a, b; Day *et al*., 1996; Moskaluk *et al*., 1997; Willentz *et al*., 1998) (see Molecular Genetics).

An understanding of PanINs and the development of this progression model is important because it suggests that the detection of precursor lesions and curable early pancreatic cancers should one day be possible (Caldas *et al*., 1994). Early detection is especially important in the case of ductal adenocarcinoma of the pancreas because, as mentioned earlier, most pancreatic cancers have already spread beyond the pancreas when they come to clinical attention.

Medullary Carcinoma

Gross and Microscopic Findings

Although historically grouped with ductal adenocarcinomas, medullary carcinomas are a newly recognized subtype of pancreatic cancer with distinct gross and microscopic appearances. Grossly, these neoplasms may be relatively well circumscribed. Microscopically, they have poorly defined cellular boundaries ('syncytial growth pattern') and expanding, rather than infiltrating, tumour borders (Goggins *et al*., 1998). Most also have extensive necrosis.

Special Features: Genetics

Medullary carcinomas are important to recognize because they are genetically distinct tumours, in that they frequently have 'microsatellite instability' (MSI) and wild-type K-*RAS*

genes (Goggins *et al*., 1998). (see Molecular Genetics). These data are atypical for the usual ductal adenocarcinomas, which nearly universally harbour K-*RAS* gene mutations and seldom if ever have MSI (Hruban *et al*., 1993). In addition, the authors have recently shown that patients with medullary carcinomas often have a familial history of cancer and that medullary carcinoma may be a sign of an inherited propensity to develop cancer. Medullary carcinomas also may be associated with an outcome better than that for ductal adenocarcinomas, but more study is necessary (Goggins *et al*., 1998).

Acinar Cell Carcinoma

Gross and Microscopic Findings

Acinar cell carcinomas are usually large and most arise in the head of the pancreas (Klimstra *et al*., 1992; Solcia *et al*., 1997; Hruban *et al*., 2000). In contrast to the infiltrative appearance of ductal adenocarcinomas, acinar cell carcinomas typically have smooth borders. Microscopically, the neoplastic cells in acinar cell carcinomas form small glands, called acini. The cells are pink and granular. These carcinomas usually express the digestive enzymes trypsin, lipase, chymotrypsin and/or amylase, and staining for these substances may be helpful in distinguishing acinar cell carcinomas from other neoplasms that arise in the pancreas. Electron microscopy will reveal the presence of zymogen granules in the neoplastic cells (Klimstra *et al*., 1995). Zymogen granules are the granules which hold or package the digestive enzymes in normal acinar cells.

Special Features: Clinical Presentation

While most patients with acinar cell carcinomas present with non-specific symptoms, as many as 20% develop the clinical syndrome of subcutaneous fat necrosis. This dramatic syndrome is characterized by a skin rash (erythema nodosum-like), peripheral eosinophilia (increased numbers of eosinophils in the blood) and/or polyarthralgias (joint pain involving multiple joints) (Solcia *et al*., 1997). These latter signs and symptoms are caused by the release of massive amounts of the digestive enzyme lipase into the bloodstream by the neoplasm (Klimstra *et al*., 1992). The mean survival for patients with acinar cell carcinoma of the pancreas is only 18 months (Klimstra *et al*., 1992; Solcia *et al*., 1997).

Osteoclast-like Giant-cell Tumour (OCGT)

Gross and Microscopic Findings

OCGTs are typically well circumscribed, yellow–pink and fleshy. By light microscopy these tumours are composed of striking giant cells containing multiple nuclei (multinucleated giant cells) dispersed among bland tumour cells with only one nucleus (mononuclear cells) (Solcia *et al*., 1997; Hruban *et al*., 2000). The multinucleated giant cells in OCGTs closely resemble osteoclasts, a type of cell found in resorbing bone. The multinucleated giant cells in OCGTs express the macrophage markers KP-1 and Mac-387, while the bland mononuclear tumour cells variably express the epithelial marker cytokeratin.

Special Features: Genetics

The striking resemblance of the multinucleated giant cells in OCGTs to the osteoclasts normally found in bone confused pathologists for years. Are these distinctive tumours ductal adenocarcinomas which had elicted an unusual reaction, or are OCGTs more closely related to bone tumours? The answer has come from genetic analysis. OCGTs frequently harbour activating point mutations in codon 12 of the K-*RAS* gene and, as discussed in the Molecular Genetics section, K-*RAS* gene mutations are one of the most common genetic alterations in ductal adenocarcinomas (Hruban *et al*., 1993; Westra *et al*., 1998). These data help establish that OCGTs are really carcinomas which elicit a non-neoplastic, giant-cell response (Westra *et al*., 1998). Osteoclast-like giant cell tumours of the pancreas are unrelated to bone tumours. The survival rate from OCGTs is somewhat better than that for ductal adenocarcinoma (Solcia *et al*., 1997).

Pancreatoblastoma

Gross and Microscopic Features

Pancreatoblastomas have striking gross and microscopic appearances. They are large, necrotic and white–grey (Klimstra *et al*., 1995; Solcia *et al*., 1997; Hruban *et al*., 2000). Microscopically, pancreatoblastomas contain back-to-back, small cells with round nuclei (Klimstra *et al*., 1995). In this sea of small cells are embedded nests of swirled cells, called 'squamoid corpuscles' (**Figure 6**).

Special Features: Clinical Presentation

This rare neoplasm occurs primarily in children, with an age range of 1–15 years (Klimstra *et al*., 1995). It has therefore been referred to as 'pancreatic carcinoma of infancy.' The survival rate for patients with pancreatoblastomas is better than it is for patients with infiltrating ductal adenocarcinomas (Klimstra *et al*., 1995). Unfortunately, very little is known about what causes these tumours to develop in children.

Cystic Non-endocrine Neoplasms

Serous Cystadenoma and Serous Cystadenocarcinoma

Gross and Microscopic Findings

Grossly, serous cystadenomas are large, spongy tumours filled with a watery fluid. They often contain a central, calcified scar (Compagno and Oertel, 1978a). By light microscopy, a layer of simple cuboidal (square-shaped) cells with uniform nuclei can be seen lining the cysts (**Figure 7**) (Solcia *et al*., 1997; Hruban *et al*., 2000).

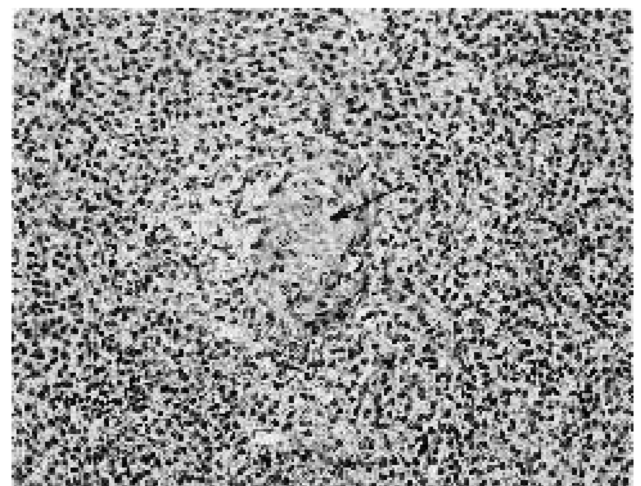

Figure 6 Microscopic section of a pancreatoblastoma. Note the prominent squamous corpuscle (arrow).

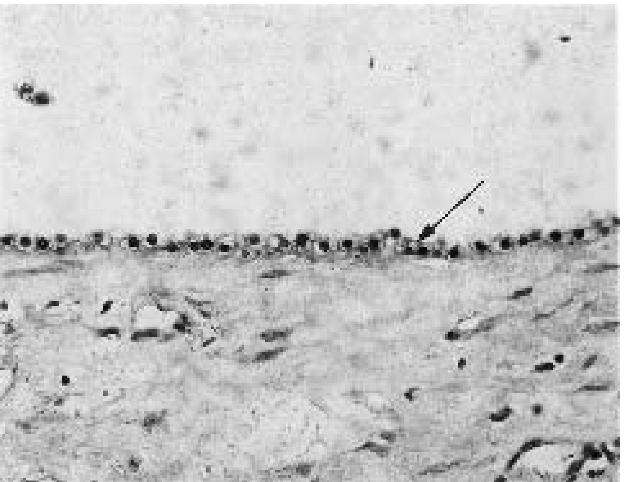

Figure 7 Microscopic section of a serous cystadenoma. The cysts (empty space at top of photograph) in serous cystadenomas are relatively small and are lined by cuboidal, cleared-out cells (arrow).

Because the cells contain large amounts of glycogen, they stain strongly with the periodic acid–Schiff (PAS) stain.

Special Features: Clinical Presentation and Prognosis

These neoplasms are more common in women than in men, and the average age at diagnosis is in the seventh decade. Patients with von Hippel–Lindau syndrome develop serous cystadenomas more frequently than the general population (Solcia *et al*., 1997). The vast majority of serous cystic neoplasms are benign and patients with even very large (football-sized) serous cystadenomas can be cured of their disease if their tumours are surgically removed (Compagno and Oertel, 1978a; Solcia *et al*., 1997). Recently, however, there have been a few isolated case reports of aggressive behaviour in serous cystic neoplasms ('serous cystadenocarcinomas').

Mucinous Cystic Neoplasms

Gross and Microscopic Findings

In contrast to the relatively homogeneous appearance and behaviour of serous cystadenomas, mucinous cystic neoplasms of the pancreas are morphologically and clinically heterogeneous (Albores-Saavedra *et al*., 1987; Solcia *et al*., 1997; Hruban *et al*., 2000). Grossly mucinous cystic neoplasms are large tumours composed of cysts filled with tenacious fluid (mucin) (Compagno and Oertel, 1978b). The cysts are lined by tall, mucin-producing cells (**Figure 8**); expectedly, stains for mucin are positive. In some women a dense layer of spindle-shaped cells (stroma) resembling ovarian stroma surrounds the epithelial cells. The clinical significance of this finding is not clear, but it has been used to suggest a common origin for some neoplasms of the ovary and pancreas.

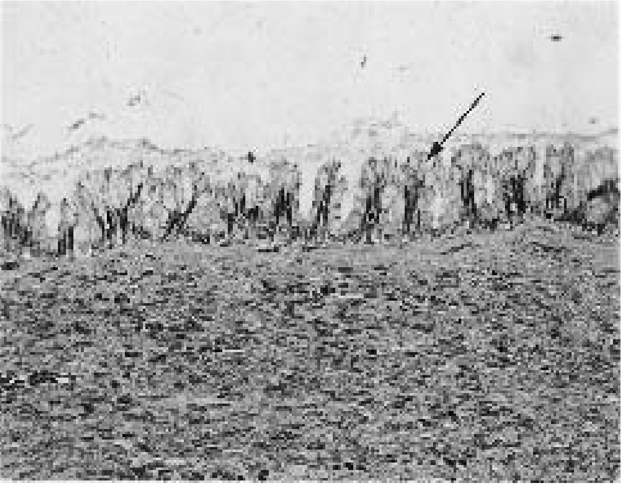

Figure 8 Microscopic section of a mucinous cystic neoplasm. The cysts (empty space at top of photograph) in a mucinous cystadenoma are larger than the cysts found in serous cystadenomas and the cysts in mucinous cystic neoplasms are lined by tall cells producing mucin (arrow). These cells sit on a dense stromal layer that resembles ovarian stroma (bottom portion of the figure).

Mucinous cystic neoplasms can be divided into three groups, mucinous cystadenomas, borderline mucinous cystic neoplasms and mucinous cystadenocarcinomas (Klöppel *et al*., 1996; Solcia *et al*., 1997). Mucinous cystadenomas contain a single layer of cells lacking significant atypia. In borderline mucinous cystic neoplasms, the cells may form finger-like projections (papillae) and complex architectural patterns. The cells in these tumours show significant atypia (e.g. loss of nuclear polarity and

pleomorphism), but no carcinoma is seen. When an *in situ* carcinoma or an invasive carcinoma is present, the diagnosis of a 'mucinous cystadenocarcinoma' should be made. Importantly, otherwise benign-appearing mucinous cystic neoplasms may harbour small foci of invasive carcinoma (Compagno and Oertel, 1978b). Therefore, when possible, mucinous cystic neoplasms should be completely resected surgically, and the surgical pathologist should entirely submit and carefully examine the neoplasm. Failure to do so may explain the occasional reports of metastasizing 'mucinous cystadenomas' (Compagno and Oertel, 1978b; Wilentz *et al*., 1999).

Special Features: Clinical Presentation and Prognosis

Mucinous cystic neoplasms are more common in women than they are in men and the mean age at diagnosis is in the late fifth decade (Compagno and Oertel, 1978b; Solcia *et al*., 1997; Hruban *et al*., 2000). The prognosis for patients with mucinous cystic neoplasms depends on the presence of invasive carcinoma. The authors recently showed that all patients with non-invasive mucinous cystic neoplasms are cured if their tumours are completely resected (Wilentz *et al*., 1999). In addition, while invasive mucinous cystadenocarcinomas are fully malignant tumours, patients with these neoplasms usually live longer than do patients with typical solid infiltrating ductal adenocarcinomas (Wilentz *et al*., 1999). In fact, approximately 50% of patients who have had an invasive mucinous cystadenocarcinoma completely resected will live at least 5 years. This survival rate is much better than the survival rate for infiltrating ductal adenocarcinomas of the pancreas, underscoring the importance of correct pathological classification in patient prognostication and treatment.

Intraductal Papillary Mucinous Neoplasm (IPMN)

Gross and Microscopic Findings

IPMNs are frequently papillary (finger-like) neoplasms that arise in the main pancreatic duct system. By light microscopy, dilated pancreatic ducts are lined by tall, mucin-secreting cells that form papillae (**Figure 9**). Approximately 25% of these tumours are associated with an invasive adenocarcinoma. These invasive cancers often show abundant extracellular mucin production and are called 'colloid' or 'mucinous' adenocarcinomas.

The WHO and the AFIP grading schemes include a three-tiered classification for IPMNs, similar to that for mucinous cystic neoplasms (Klöppel *et al*., 1996; Solcia *et al*., 1997). 'Intraductal papillary mucinous adenomas' are IPMNs without significant cytological or architectural atypia. 'Borderline IPMNs' show a moderate amount of atypia. Finally, 'papillary mucinous carcinoma' is the designation given to those tumours in which the intraductal lesion displays significant cytological and architectural

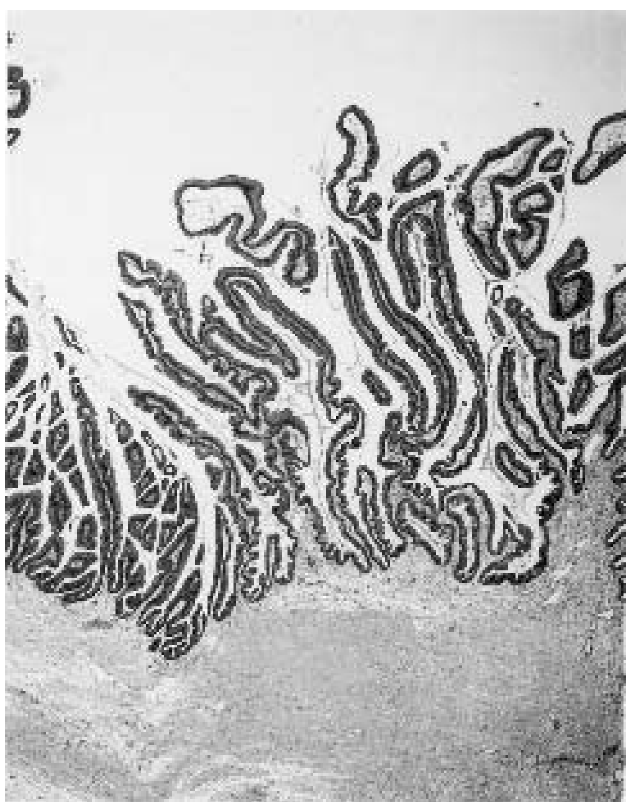

Figure 9 Microscopic section of an intraductal papillary mucinous neoplasm (IPMN). IPMNs are characterized by prominent papillary projections into the dilated pancreatic ducts.

atypia (carcinoma-*in-situ*) or in which an invasive cancer is identified (Klöppel *et al*., 1996; Solcia *et al*., 1997).

Special Features: Clinical Presentation and Prognosis

IPMNs occur with approximately equal frequency in both genders. Their origin in the main pancreatic duct or one of its branches helps distinguish IPMNs from mucinous cystic neoplasms, and it also helps explain why patients with IPMNs are often found to have mucin oozing from the ampulla of Vater, if they are examined endoscopically. The prognosis for patients with IPMNs is probably very similar to that of mucinous cystic neoplasms, but more study is needed (Solcia *et al*., 1997; Hruban *et al*., 2000).

Solid-pseudopapillary Neoplasm

Gross and Microscopic Findings

Solid pseudopapillary neoplasms form large, well-demarcated masses that are cystic, haemorrhagic and necrotic (Solcia *et al*., 1997; Hruban *et al*., 2000). Microscopically the tumour shows solid, cystic and papillary components. The solid areas are composed of nests of small, pink cells

with bland nuclei. The cysts are formed by pools of blood and the papillae usually have vascular cores.

Special Features: Clinical Presentation and Prognosis

Remarkably, almost all solid-pseudopapillary neoplasms of the pancreas occur in women in their 20s (Solcia *et al*., 1997; Hruban *et al*., 2000). Fortunately, most patients with solid pseudopapillary neoplasms survive for many years after surgical resection; however, metastases do occur, and surgeons should try to remove these neoplasms completely.

Endocrine Tumours

Endocrine tumours, also known as islet cell tumours, account for only 1% of all pancreatic neoplasms (Solcia *et al*., 1997; Hruban *et al*., 2000). Unlike their exocrine counterparts, the majority of endocrine neoplasms of the pancreas are not easily divisible into distinct subtypes highly predictive of behaviour (Solcia *et al*., 1997). Sometimes even a combination of gross, microscopic, immunohistochemical and clinical findings cannot definitively predict the overall malignant potential of one of these lesions. The exception is poorly differentiated endocrine carcinoma (high-grade neuroendocrine carcinoma, small-cell carcinoma), which is unequivocally malignant.

Well- and Moderately Differentiated Endocrine Neoplasms (Islet Cell Tumours)

Gross and Microscopic Findings

Well- and moderately differentiated endocrine neoplasms can be benign ('adenoma'), borderline ('neoplasm of uncertain malignant potential') or malignant ('carcinoma'). Grossly all three types of well- and moderately differentiated endocrine neoplasms are usually solid and well circumscribed. They contain uniform cells with granular nuclei (**Figure 10**). The cells can form ribbons, cords, tubules, sheets or nests. The tumours usually stain for the endocrine markers chromogranin, synaptophysin and neuron-specific enolase (NSE). Electron microscopy reveals 100–400-nm neurosecretory granules within the neoplastic cells. These granules are similar to the granules found in normal endocrine cells and they are easily distinguished from the much larger zymogen granules found in acinar cell carcinoma of the pancreas (Solcia *et al*., 1997; Hruban *et al*., 2000).

The best way to determine if a well- or moderately differentiated endocrine neoplasm is benign, borderline or malignant is to look at its behaviour. Microscopic findings such as cytological and architectural atypia are not as helpful. Therefore, well- and moderately differentiated endocrine tumours that show gross extension to other organs, that invade into large blood vessels or that metastasize are prima facie low-grade malignancies. Unfortunately, some endocrine neoplasms that do not show these characteristics later behave in a malignant fashion. There has therefore been a great deal of interest in developing *indirect* markers of malignancy (Solcia *et al*., 1997). When gross local extension, large-vessel invasion or metastasis is not seen, pathologists can apply these indirect markers (size of the tumour, mitotic rate, microscopic invasion of blood vessels and nerves) to assess whether a lesion is benign, borderline or malignant. These markers should be applied with the realization that indirect markers are imperfect markers of malignancy (Solcia *et al*., 1997; Hruban *et al*., 2000).

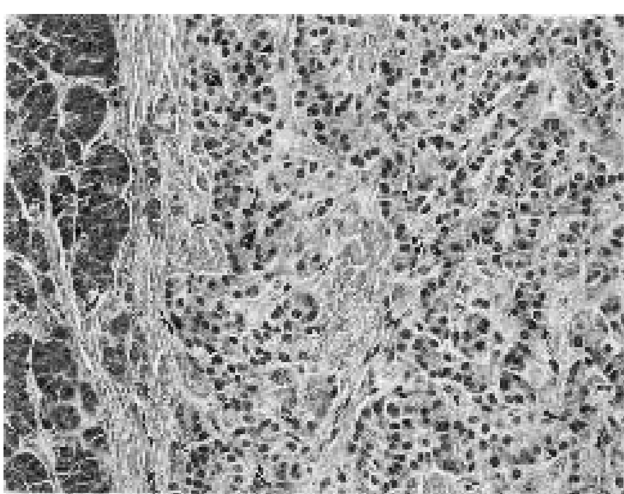

Figure 10 Well-differentiated neuroendocrine neoplasm. In this microscopic section the normal pancreas is to the left and the tumour to the right.

Special Features: Hormone Production

Remarkably, and often dramatically, endocrine neoplasms of the pancreas can produce excessive quantities of many of the same hormones normally produced in small quantities by the islets of Langerhans. Some patients with endocrine neoplasms therefore develop striking symptoms. For example, patients with insulin-producing tumours (insulinomas) can present with marked hypoglycaemia (low blood sugar), headaches, weakness, dizziness and/or seizures. Patients with tumours which produce the hormone gastrin (gastrinomas) can develop the Zollinger–Ellison (ZE) syndrome, characterized by gastric hyperacidity, multiple, recurrent peptic ulcers, gastro-oesophageal reflux and diarrhoea. Tumours that produce VIP (VIPomas) can lead to the Verner–Morrison or WDHA syndrome, which primarily results in watery diarrhoea, hypokalaemia (low potassium levels) and achlorhydria (or hypochlorhydria). Patients with glucagon-producing tumours (glucagonomas) experience a striking, symmetrical skin rash ('necrolytic migratory erythema') on their buttocks, groin, perineum, thighs and distal extremities. Patients with somatostatin-producing tumours (somatostatinomas) present with diabetes mellitus, cholelithiasis (gallstones), diarrhoea, hypochlorhydria, weight loss and anaemia.

Clinical presentation is very important in evaluating a well- or moderately differentiated endocrine neoplasm. Although 10% of glucagon-cell, somatostatin-cell, gastrin-cell and VIP-cell tumours discovered incidentally while the patient was being evaluated for some other problem are malignant, the majority of the *same* tumours are malignant if hormone production by the tumour produces a clinically recognizable syndrome (Solcia *et al*., 1997). The exception is an insulin-producing tumour: only 10% of all insulin-producing neoplasms are malignant, regardless of clinical presentation.

Multiple Endocrine Neoplasia Syndrome, Type 1 (MEN1 Syndrome)

The multiple endocrine neoplasia syndrome, type 1 (MEN1), or Werner's syndrome, deserves special mention. This syndrome is characterized by concomitant multiple hyperplasias and neoplasias of the parathyroid gland (up to 97% of patients), pancreas (80%) and anterior pituitary (50%) (Solcia *et al*., 1997). The MEN1 syndrome can be inherited in an autosomal dominant pattern or it can occur sporadically. The syndrome results from a germ-line mutation or deletion in the *MEN1* gene on the long arm of chromosome 11 (11q13) (Lubensky *et al*., 1996).

As many as 80% of patients with MEN1 develop pancreatic tumours, most frequently gastrinomas, and it therefore should not be surprising that the Zollinger–Ellison syndrome occurs in at least one-third of MEN1 patients (Solcia *et al*., 1997). Insulinomas (approximately 25% of MEN1 patients), VIPomas, glucagonomas and growth hormone-releasing tumours are less common in patients with this syndrome. (See also the chapter *Inherited Predispositions to Cancer*.)

Poorly Differentiated Endocrine Neoplasms (High-grade Neuroendocrine Carcinomas, Small-cell Carcinomas)

Gross and Microscopic Features

Poorly differentiated endocrine neoplasms account for only 2% of all pancreatic endocrine tumours (Solcia *et al*., 1997; Hruban *et al*., 2000). Grossly these tumours are infiltrative, haemorrhagic, necrotic and grey–white. The cells have extremely high nuclear-to-cytoplasmic ratios. Nuclear moulding, where nuclei wrap around one another, is prominent. The mitotic rate is extremely high (Solcia *et al*., 1997).

Special Features: Prognosis

These tumours are unquestionably malignant, and patients with them have extremely poor survival rates.

Primary Mesenchymal Tumours

Benign and malignant mesenchymal (connective tissue) tumours of the pancreas are extremely rare. However, schwannomas (benign tumours of the nerve sheath), leiomyosarcomas (malignant tumours showing smooth muscle differentiation), liposarcomas (malignant tumours showing fat differentiation) and malignant fibrous histiocytomas (malignant tumours showing fibrous and histiocytic differentiation) of the pancreas have been reported. The diagnostic criteria for these neoplasms are the same as they are for mesenchymal tumours arising in other sites. Generally, survival rates for patients with sarcomas are low, as they are for sarcomas primary to other locations. (See also the chapter *Soft Tissues*.)

Metastatic Malignancies

Masses in the pancreas need not have arisen in the pancreas. They may arise in other organs and only later spread (metastasize) to the pancreas. The most common metastases to the pancreas originate in the breast (20%), lung (19%), colorectum (10%), skin (melanoma, 9%) and stomach (7%) (Solcia *et al*., 1997).

Systemic Malignancies

Leukaemia and lymphoma simultaneously involve more than one site, one of which may be the pancreas. In fact, the pancreas is sometimes the presenting site for these malignancies. Of the 67 patients with systemic malignancies involving the pancreas reviewed by Cubilla and Fitzgerald (1976), three-quarters had lymphomas and one-quarter had leukaemias.

EPIDEMIOLOGY AND AETIOLOGY

Because ductal adenocarcinomas are the most common malignancy in the pancreas, and the most is known about ductal adenocarcinomas, the remainder of discussion in this chapter will centre around this type of cancer unless specified otherwise. As outlined in **Table 2**, a number of risk factors have been identified for the development of pancreatic cancer (Gold and Goldin, 1998). These include older age, cigarette smoking, family history of pancreas cancer, previous gastric surgery, chronic pancreatitis, diabetes mellitus, occupational exposure to certain chemicals, radiation exposure and a diet high in fat and low in fruits and vegetables (Gold and Goldin, 1998).

More than 80% of pancreatic cancers occur between the ages of 60 and 80, and cases before the age of 40 are rare (Solcia *et al*., 1997; Gold and Goldin, 1998). Those that do occur at a younger age are usually special variants of pancreatic cancer, such as the pancreaticoblastoma, which occurs primarily in children (Klimstra *et al*., 1995). Pancreatic cancer is more common in men than in women and in blacks than in whites (Solcia *et al*., 1997). Of interest, pancreatic cancer may occur more frequently in individuals of Jewish descent (Gold and Goldin, 1998). As will

Table 2 Risk factors for pancreatic cancer

Patient characteristics
Older age
Male gender
Black race
Jewish ancestry
Family history of pancreatic cancer
Diabetes mellitus
Chronic pancreatitis
Patient behaviour
Cigarette smoking
Diet low in fruits and vegetables
Diet high in fat
Occupational exposure to certain chemicals
Radiation exposure

be discussed in greater detail in the Molecular Genetics section, this may be because of the high prevalence of inherited mutations in the second breast cancer gene (*BRCA2*) in Ashkenazi Jews (Ozcelik *et al*., 1997).

Cigarette smoking has been clearly established as a risk factor for pancreatic cancer. The increased risk of developing pancreatic cancer in smokers is 2–5-fold over non-smokers, and the risk increases with the number of cigarettes smoked. Importantly, those who stop smoking can quickly reduce their risk for developing pancreatic cancer. For example, Ghadirian *et al*. (1991a) conducted a population-based case-control study of pancreatic cancer in Montreal, Canada, and found that, depending on the number of cigarettes already smoked in a lifetime, patients can reduce their risk of pancreatic cancer as much as threefold by stopping smoking. Remarkably, Mulder *et al*., (1999) have estimated that a moderate reduction in smoking in Europe could save as many as 68 000 lives that will otherwise be lost to pancreatic cancer between 1999 and 2020. Clearly, smoking plays a major role in the development of pancreatic cancer.

While smoking is a habit we can control, family cancer history is something we cannot. Researchers at The Johns Hopkins Hospital and others have found that familial inheritance plays a significant role in the development of some pancreatic cancers (Hruban *et al*., 1998). The evidence for this comes from three areas. First, there have been a number of isolated case reports of pancreas cancer aggregating in certain families (Hruban *et al*., 1998). For example, one of former President Carter's parents, his brother and two of his sisters all died from pancreatic cancer. While these reports suggest that there is a genetic (inherited) basis for the development of pancreatic cancer, the occurrence of multiple cancers in a family could be just bad luck. A number of investigators have therefore conducted case-control studies of pancreatic cancer. For example, Ghadirian *et al*. (1991b) conducted a population-based case-control study of pancreatic cancer in the Francophone community of Montreal, Canada, and found that 7.8% of the patients with pancreatic cancer reported a positive family history of pancreatic cancer, compared with only 0.6% of the controls. This 13-fold difference between cases and controls did not appear to be due to environmental factors such as smoking, strongly suggesting the genetic transmission of an increased risk of developing pancreatic cancer. The National Familial Pancreas Tumour Registry (NFPTR) at Johns Hopkins, and other registries like it, were therefore established to track families with multiple pancreatic cancers (Hruban *et al*., 1998). The NFPTR is perhaps the largest of these registries and it is truly an international registry with 719 kindred enrolled as of July 1, 2001. These kindred come from the United States, Europe and Australia, and include 284 families in which two or more first-degree relatives have been diagnosed with pancreatic cancer. This registry provides an invaluable resource to scientists studying the genetics of familial pancreatic cancer (see the Molecular Genetics section). Furthermore, a prospective study of the families enrolled in the NFPTR has demonstrated that the first-degree relatives of patients with familial pancreatic cancer have an increased risk of developing pancreatic cancer themselves. Tersmette *et al*. (2001) studied the families enrolled in the NFPTR. They found that if two family members had been diagnosed with pancreatic cancer at the time of enrollment into the NFPTR, then the risk of other previously healthy family members developing a new pancreatic cancer was 18-fold greater than expected. This risk increased to 56-fold when three or more family members had pancreatic cancer at the time the family enrolled in the registry. The *prospective* development of pancreatic cancer in these families clearly establishes that inherited susceptibility plays a significant role in the development of pancreatic cancer in some families.

Those wishing to learn more about the NFPTR and those wishing to register may contact the National Familial Pancreas Tumour Registry, c/o Dr Ralph Hruban, The Johns Hopkins Hospital, 401 N. Broadway, Baltimore, MD 21231, USA. E-mail: kbrune@jhmi.edu.

The final line of evidence establishing the genetic transmission of an increased risk of developing pancreatic cancer is the identification of some of the genes responsible for familial pancreatic cancer. These genes include *BRCA2*, *p16*, *STK11/LKB1* and *cationic trypsinogen* (Goggins *et al*., 1996; Whitcomb *et al*., 1996; Ozcelik *et al*., 1997; Su *et al*., 1999). These genes will be discussed in greater detail in the Molecular Genetics of Pancreatic Cancer section.

Previous gastric surgery has also been identified as a risk for pancreatic cancer. This association has been extensively studied by Offerhaus *et al*. (1998). They studied several groups of patients, both from the United States and from Europe, and found that patients who had peptic ulcer surgery have a 2–5-fold increased risk of developing pancreatic cancer, especially if the surgery was more than

20 years earlier. The reason for this increased risk is not clear, but it has been hypothesized that increased levels of cholecystokinin and the increased production of nitrosamines in the operated stomach may play a role.

Diet may also contribute to the development of pancreatic cancer (Gold and Goldin, 1998). Diets high in fruits and vegetables have shown to reduce the risk of pancreatic cancer, whereas diets high in fat increase the risk. The mechanism for this has not been established, however, Stolzenberg-Solomon *et al*. (1999) have shown that vitamins such as folate may play a role. They conducted a nested case-control study of a large cohort of male Finnish smokers and found that serum folate and pyridoxal-5′-phosphate concentrations have an inverse dose–response relationship with pancreatic cancer. Additional dietary factors that have been studied include alcohol and coffee consumption; however, there is insufficient evidence to support either as a causal factor in the development of pancreatic cancer (Stolzenberg-Solomon *et al*., 1999).

Finally, two medical conditions, diabetes mellitus and chronic pancreatitis, have also been implicated in the development of pancreatic cancer (Stolzenberg-Solomon *et al*., 1999). Both of these are complex factors to study. Not only have these factors been implicated in the development of pancreatic cancer, but cancer of the pancreas can also destroy normal pancreatic tissues and thus cause both diabetes and pancreatitis. The mechanism by which pancreatic cancer produces diabetes is not well defined; however, some have suggested that amylin production by pancreatic cancer may contribute to the development of diabetes. The increased risk of pancreatic cancer is, however, clear in familial pancreatitis (Whitcomb *et al*., 1996). Familial pancreatitis is caused by inherited mutations in the cationic trysinogen gene and affected family members develop severe recurrent bouts of pancreatitis at a young age. These patients have been shown to have a 40% lifetime risk of developing pancreatic cancer.

SCREENING AND PREVENTION

Screening

Population-based screening programmes have been shown to improve survival of breast, colon and cervical cancer. In contrast, the pancreas is a relatively inaccessible organ and current screening tests for pancreatic cancer are not effective. Nonetheless, there is an enormous need for such a test. Most patients with pancreatic cancer have a dismal prognosis because they do not come to clinical attention until after the disease has spread beyond the pancreas. This need for an effective screening test is perhaps felt most by those with an increased risk for developing pancreatic cancer, such as individuals with an inherited predisposition to develop the disease. These would include individuals with inherited genetic abnormalities in cancer-causing genes, such as *BRCA2, p16* and *STK11/LKB1* and individuals with familial pancreatic cancer of unknown cause (Goggins *et al*., 1996; Hruban *et al*., 1998; Su *et al*., 1999). The importance of screening for pancreatic cancer can be seen in the survival statistics for pancreatic cancer surgery. Patients who have their cancer surgically resected and who are found to have small tumours confined to the gland ('node-negative disease, negative margins and tumours <2 cm') have a 5-year survival of ~25% (Yeo *et al*., 1995). By contrast, most (~85%) patients with pancreatic cancer do not present to their doctor until after their cancers have grown so large that they are inoperable at the time of diagnosis, and patients with inoperable cancer have an average survival of only 6 months.

A great deal of effort is therefore being focused on research efforts for the early detection of pancreatic cancer in asymptomatic high-risk individuals. It is logical that with advances in the molecular genetics of pancreatic cancer and technological advances in endoscopy and radiology, more accurate screening tests for pancreatic cancer will soon become available.

Three groups of diagnostic tests could be applied to screening for pancreatic cancer: (1) radiological methods, (2) tumour markers and (3) endoscopic methods.

Radiological Methods

Radiological methods are the most commonly used methods to diagnose pancreatic cancer. The accuracy of radiology has improved in recent years. Computerized tomography (CT) scanning is commonly the first test used to image the pancreas (Bluemke *et al*., 1995). One recent advance in CT imaging has been the development of spiral or helical CT. This new imaging technique allows the radiologist to obtain higher resolution images in three dimensions. Currently, helical CT and magnetic resonance imaging (MRI) diagnose pancreatic cancer with a sensitivity of ~90%. The ~10% of cancers missed using CT scanning are often those tumours that cause mild diffuse enlargement of the pancreas rather than a discrete mass. In addition, the very small cancers, those less than 1–2 cm in diameter, are often not visible using CT or MRI.

Many pancreatic cancers that are not visualized on CT can be seen using endoscopic ultrasound (EUS). During EUS the endosonographer introduces an endoscope through the patients' mouth, through the stomach and into the duodenum. The tip of this endoscope contains an ultrasound transducer. The pancreas lies adjacent to the stomach and duodenum; this approach therefore allows the endosonographer to obtain close-up images of the pancreas. The main variable determining the quality of the EUS image obtained is the skill and experience of the endosonographer. The sensitivity of endoscopic ultrasound is at least as good as that of helical CT or MRI for

visualizing pancreatic lesions. EUS has an advantage over CT in that the pancreas can also be biopsied using fine needle aspiration (FNA) techniques through the same endoscope, enabling multiple samples to be taken painlessly from any suspicious lesions encountered.

Endoscopic retrograde cholangiopancreatography (ERCP) is a valuable diagnostic and therapeutic tool for managing pancreatic diseases. During ERCP the gastroenterologist again passes an endoscope through the patient's mouth, through the stomach and into the duodenum. Once the tip of the scope is in the duodenum, the endoscopist can visualize the ampulla of Vater, the site where the pancreatic and bile ducts enter the duodenum. A small catheter is then placed through the endoscope and through the ampulla of Vater into the biliary and pancreatic ducts. By injecting radio-opaque dye into the catheter, abnormalities are accurately identified with ERCP. Unfortunately, small lesions in the parenchyma of the pancreas, especially those that have minimal effects on the duct system, can be missed at ERCP, and ERCP is not without risks. ERCP can be complicated by acute pancreatitis (~1/20 procedures), bleeding, complications of sedation, perforation and occasionally even death (< 1/500). The risks associated with undergoing an ERCP therefore preclude its use as a general screening test.

Other imaging modalities under investigation as tests for pancreatic cancer diagnosis include positron emission tomography (PET) scanning and intraductal ultrasound. While the availability of PET is limited, intraductal ultrasound is used to help interpret suspicious findings on ERCP. With the latter procedure, a catheter with an ultrasound probe at its tip is placed into the pancreatic or biliary duct during ERCP. Ultimately these probes may be helpful in identifying very early carcinomas.

In general, radiological imaging of the pancreas is useful in diagnosing pancreatic cancer in a patient for whom there is a high degree of suspicion. The methods are, however, either too expensive or too invasive to be used in the general population as screening tests. (See the section on *Diagnostic Imaging and Image-Guided Intervention*.)

Tumour Markers

Given the limitations of current radiological tools, much effort has been put into identifying molecular markers that have the potential to be sensitive and specific for pancreatic cancer.

An ideal marker would be both highly sensitive (it would correctly identify almost everyone who has pancreatic cancer) and specific (positive tests are only seen in patients with cancer) for pancreatic cancer and it could be applied to samples obtained relatively non-invasively. Although a large number of potential tumour markers have been evaluated, none of them yet have been shown to be sufficiently sensitive or specific for use in a screening setting for pancreatic cancer.

The tumour markers most studied are the carbohydrate antigen 19-9 (CA19-9), K-RAS and telomerase.

CA 19-9

CA19-9 is a valuable tumour marker for following the therapeutic response in patients who are being treated for pancreatic cancer (Ritts and Pitt, 1998). In this setting, CA19-9 levels correlate well with tumour volume and response to therapy. However, CA19-9 is not useful as a screening test for early pancreatic cancer. First, only patients with certain blood types are capable of making CA19-9. Approximately 10–15% of individuals do not secrete CA19-9 because of their Lewis antigen blood type. In addition, CA19-9 levels may be within the normal range while the cancer is still at a small and asymptomatic stage and conversely CA19-9 levels may be elevated in benign biliary or pancreatic conditions. These limitations also apply to related carbohydrate antigens such as CA-125, KAM17.1, CA2.2, CA-50 and CA-242.

K-RAS

K-*RAS* gene mutations are present in ~90% of pancreatic cancers (see Molecular Genetics below) and these mutations can be detected in specimens obtained distant from the cancer such as pancreatic juice, duodenal fluid, stool and blood using sensitive mutation assays (Hruban *et al.*, 1993; Caldas *et al.*, 1994). Unfortunately, a number of limitations preclude the use of K-*RAS* as a screening marker. First, K-*RAS* gene mutations are not specific for pancreatic cancer and also occur in the small non-invasive pancreatic duct lesions (PanINs) that are prevalent in individuals of increasing age. In autopsy series, PanINs can be found in as many as 10–30% of individuals, especially in smokers. Similarly, K-*RAS* gene mutations have also been reported in chronic pancreatitis (Caldas *et al.*, 1994). Clearly, mutant K-*RAS* is not a specific marker of pancreatic cancer. By contrast, circulating mutant K-*RAS* genes in the blood is much more specific for pancreatic cancer and is detectable in blood samples from 25 to 65% of patients with pancreatic cancer. However, the presence of mutant K-*RAS* in the blood may be a late event as it correlates with inoperable pancreatic cancer, with a poor prognosis and relapse after surgical resection.

Telomerase

Telomerase is an exciting new potential marker for pancreatic cancer. Telomerase is an enzyme which helps maintain the ends (telomeres) of chromosomes. Telomerase activity is lost in most normal cells after embryonic development while as many as 90% of cancers and some inflammatory cells express telomerase. Since telomerase is expressed in inflammatory cells, it may not be sufficiently specific for use as a cancer-screening marker. Nonetheless, several groups have reported that as many as 90% of patients with pancreatic cancer have measurable telomerase activity in their pancreatic juice (Suehara *et al.*, 1997),

and telomerase may yet prove to be a relatively sensitive and specific marker for differentiating benign from malignant lesions of the pancreas.

Identifying New Markers

Several novel approaches have been used to identify new markers that might be specific for pancreatic cancer. One of these approaches that is particularly exciting is serial analysis of gene expression (SAGE). SAGE generates a quantitative list of the genes that are expressed by a tissue (Zhang *et al*., 1997). Using SAGE, comparisons can be made between the expression of genes in cancer and normal tissue and a list of genes can then be generated that are highly over-expressed in the cancer relative to the normal (Zhang *et al*., 1997). One marker identified using this approach is tissue inhibitor metalloproteinase 1 (TIMP-1). When used in combination with CA19-9, measurements of TIMP-1 levels in the blood can distinguish patients with pancreatic cancer from controls with greater sensitivity and specificity than CA19-9 alone. Recently, SAGE has been used to discover other additional exciting markers of pancreatic cancer, including prostate stem cell antigen (Argani *et al.*, 2001).

Another powerful technology likely to enhance the prospects for finding cancer-specific markers is gene expression arrays. Gene expression arrays contain arrays of many thousands of genes gridded on to small templates such as a glass slide. Therefore, a tissue or sample can be probed to see if it contains any one of thousands of genes simultaneously using just one slide. It is therefore now easier to obtain gene expression profiles of cells from cancer and these profiles can be compared with the gene expression patterns of non-cancerous cells. For both SAGE and microarrays, complex analytical and statistical software programs are required to interpret complex gene expression data and results require confirmation using other experimental approaches. Nonetheless, both are exciting techniques which my help in the development of novel screening tests for early pancreatic cancer.

DNA Methylation

DNA is frequently methylated in mammalian DNA. Methylation refers to the addition of single carbon groups and methylation occurs at specific sites in DNA called CpG islands. Regions of DNA rich in CpGs are frequently found in the portion of genes which control the expression of the gene (the promoter). When CpG islands are methylated in a promoter of a gene, it can inhibit transcription of that gene by preventing RNA polymerase and the RNA transcription machinery from producing messenger RNA. Hence DNA methylation is a common mechanism for regulating gene expression. Both selective hyper- and hypomethylation of DNA are known to occur in cancer.

Several techniques have been used to screen cancers for methylation abnormalities. DNA methylation changes in cancer can be detected even when they are admixed with many more copies of normal DNA. DNA methylation is therefore being studied as a possible screening tool for the early detection of cancer. For example, DNA methylation of the *p16* gene has been found in the sputum of patients with early lung cancer (Belinsky *et al*., 1998).

Several genes (mostly tumour-suppressor genes) have recently been shown to be selectively hypermethylated in a subset of pancreatic cancers. These genes include *p16* and *hMLH1*.

Prevention

Unfortunately, there are no good published clinical trials for the prevention of pancreatic cancer. As the genetic and environmental factors responsible for pancreatic cancer have become more defined, so to has the need for preventive strategies become apparent.

Several approaches to prevention can be considered. First, general health measures are prudent such as avoiding smoking and alcohol consumption and maintaining a balanced diet. Balanced diets should be low in fat and high in fruits and vegetables. Second, groups with a high risk of developing pancreatic cancer can be enrolled into screening programmes as these programmes become available. Third, chemopreventive strategies should be tested on high-risk populations. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) and COX-2 inhibitors have chemopreventive activity in a variety of animal and clinical studies, and epidemiological studies suggest that NSAIDs protect against colorectal, oesophageal and gastric cancer. Many cancers, including pancreatic cancer, overexpress the enzyme COX-2, the likely target of NSAIDs, and COX-2 inhibitors have been shown to decrease the growth of pancreatic cancers in animal models (Molina *et al*., 1999). Finally, prophylactic pancreatic resection may be appropriate for a very few individuals at very high risk of developing pancreatic cancer (Brentnall *et al*., 1999). Two groups of individuals with the highest risk of developing pancreatic cancer are patients with hereditary pancreatitis (lifetime risk of pancreatic cancer 30–40%) and patients with idiopathic familial pancreatic cancer (individuals with three or more first-degree relatives with pancreatic cancer have a lifetime risk of pancreatic cancer of ~20%). To ensure protection against pancreatic cancer in this setting, prophylactic total pancreatectomy may be indicated, but this is a very high-risk procedure. Total pancreatectomy is associated with significant short-term and long-term morbidity and mortality, including brittle diabetes, and for this reason it is rarely performed.

MOLECULAR GENETICS

The last 10 years have seen a revolution in our understanding of the molecular genetics of pancreatic cancer. In

Table 3 Genes involved in the development of apparently sporadic pancreatic cancer

Gene	% of Cancers	Chromosome	Mechanism of alteration[a]
Oncogenes			
K-*RAS*	90	12p	Point mutation
AKT2	10–20	19q	Amplification
AIB1	65	20q	Amplification
HER/2-neu	70	17q	Overexpression
Tumour-suppressor genes			
p16	95	9p	HD, LOH and IM, PM
p53	50–70	17p	LOH and IM
DPC4	55	18q	HD, LOH and IM
BRCA2	5–10	13q	Germline with LOH
MKK4	4	17p	HD, LOH and IM
LKB1/STK11	5–6	19p	LOH and IM, HD
TGFβR1 and *TGFβR2*	4	9q,3p	HD
DNA mismatch repair genes			
MSH2	<4	2p	Unknown
MLH1	<4	3p	Unknown

[a] HD = homozygous deletion; LOH = loss of heterozygosity; IM = intragenic mutation; PM = promoter hypermethylation.

a few short years, pancreatic cancer has gone from one of the most poorly understood diseases to one of the best. It is now clear that pancreatic cancer is a genetic disease. The genetic alterations which lead to the development of pancreatic cancer can be inherited (see Epidemiology and Aetiology section) or acquired and the genes affected can be classified into three broad groups: oncogenes, tumour-suppressor genes and DNA mismatch repair genes (see **Table 3**).

Oncogenes

Oncogenes are genes which, when *activated* by mutation or overexpression, possess transforming (cancer-causing) properties. The oncogenes which have been shown to play a role in the development of pancreatic cancer include the K-*RAS*, *HER2-neu*, *AKT2*, *AIB1* and *MYB* genes (Hruban *et al*., 1993; 1998; Day *et al*., 1996). The K-*RAS* gene resides on chromosome 12p and it is activated by point mutation in ~90% of the cancers (Hruban *et al*., 1993). The *HER2-neu* gene on chromosome 17q is overexpressed in ~70% of pancreatic cancers and amplification of *AKT2* on chromosome 19q, *AIB1* on 20q and *MYB* on chromosome 6q has been reported in a smaller percentage of the tumours (Day *et al*., 1996). The demonstration that these oncogenes are activated in pancreatic cancer is important for a number of reasons. First, these genes are potential targets for novel therapies. For example, in order for the K-*RAS* gene product to be functional, it must first be activated by the enzyme farnesyl transferase. Several groups have already developed farnesyl transferase inhibitors, some of which may be effective in treating pancreatic cancer. Similarly, mutated K-Ras peptides have been used as vaccines to treat pancreatic cancers. Second, as discussed in the section on tumour markers, activated oncogenes are potential targets for gene-based screening tests for pancreatic cancer. For example, mutant K-*RAS* genes shed from a pancreatic cancer have been detected in pancreatic and duodenal fluids and in the stool of patients with pancreatic cancer (Caldas *et al*., 1994; Brentnall *et al*., 1999). Such gene-based screening tests are exciting because they could potentially detect as few as one mutant copy of a gene admixed with 10 000 normal copies of that same gene (see Screening and Prevention). Third, the patterns of alterations in oncogenes can provide a clue as to what caused the alterations and therefore what caused the cancer. For example, we and others have shown that activating point mutations in K-*RAS* are slightly more common in cancers obtained from smokers then they are in cancers obtained from non-smokers (Hruban *et al*., 1993). This finding can be likened to finding the fingerprint of cigarette smoke in a cancer. It helps establish who the criminal is.

Tumour-suppressor Genes

The second class of genes which are altered in pancreatic cancer are the tumour-suppressor genes. Tumour-suppressor genes are genes which encode for proteins which normally function to restrain cell proliferation, so the *loss* of their activity may lead to unrestrained cell growth. The tumour-suppressor which have been shown to be inactivated in pancreatic cancer include *p16* (in 95% of the cancers), *p53* (in 75%), *DPC4* (in 55%), *BRCA2* (in 10%), *MKK4* (in 4%), *RB1* (in $<5\%$), *LKB1/STK11* (in 4%) and the transforming growth factor β receptor genes I and II (**Table 3**) (Schutte *et al*., 1995, 1997; Goggins *et al*., 1996; Hahn *et al*., 1996; Ozcelik *et al*., 1997; Rozenblum *et al*., 1997; Hruban *et al*., 1998; Wilentz *et al*., 1998; Su *et al*., 1999). Tumour-suppressor genes, like other autosomal

Table 4 Known causes of familial pancreatic cancer

Syndrome[a]	Gene	Chromosome	Familial characteristics
Breast cancer 2	*BRCA2*	13q	Breast cancer and pancreatic cancer
Peutz-Jeghers	*STK11/LKB1*	19p	Pigmented spots on lips
FAMMM	*p16*	9p	Multiple moles, melanoma and pancreatic cancer
HNPCC	Multiple	Multiple	Non-polyposis colon cancer, other cancers
Familial pancreatitis	Cationic trypsinogen	7q	Recurrent episodes of pancreatitis starting at a young age

[a] FAMMM = familial atypical multiple mole melanoma; HNPCC = hereditary non-polyposis colorectal cancer.

genes, are inherited in pairs; a maternal copy and a paternal copy. Both of these copies (called 'alleles') of a tumour-suppressor gene must be inactivated for there to be loss of function of the gene product, i.e. tumour-suppressor genes act as recessive genes. In pancreatic cancer, the inactivation of both alleles of a tumour-suppressor gene occurs by one of three mechanisms: (1) loss of one allele ('loss of heterozygosity') coupled with a mutation within (intragenic) the second allele; (2) loss of both copies of the gene ('homozygous deletions'); and (3) loss of one copy (LOH) coupled with epigenetic inactivation of the second copy (hypermethylation of the gene's promoter) (Schutte *et al*., 1997).

The identification of the tumour-suppressor genes involved in the development of pancreatic cancer is important for a number of reasons. First, the identification of the pathways inactivated when a tumour-suppressor gene is mutated may provide new targets for treatment. For example, inactivation of the *DPC4* tumour-suppressor gene is relatively specific for pancreatic cancer and several potential targets within this pathway have been identified which could be used to develop new chemotherapeutic agents (Hahn *et al*., 1996). Second, the demonstration that specific tumour-suppressor genes are inactivated in pancreatic cancers has proved a critical advance in our understanding of the causes of familial pancreatic cancers (Hruban *et al*., 1998). To understand why this is true, one most go back over 20 years to Alfred Knudson's seminal research on retinoblastoma. He studied childhood eye cancers (retinoblastomas) and hypothesized that the gene that caused sporadic (non-familial) retinoblastoma also caused familial retinoblastoma. In the familial form of the cancer, affected family members inherit one defective copy of the gene. As a result, they have only one good copy of the gene remaining. If this second copy is inactivated (mutated) later in life, then the cancer develops. Cancers are therefore common in these families. This is analogous to going up in the space shuttle with one functioning computer and one broken computer. If something goes wrong with the good one, there is no backup. By contrast, in non-familial (sporadic) forms of the cancers, the patients inherit two good copies of the gene. Only the rare cases in which both copies are inactivated later in life does the cancer develop.

Knudson's hypothesis appears to operate for pancreatic cancer. Kern and colleagues at Johns Hopkins have demonstrated that some forms of familial pancreatic cancer are caused by germ-line (inherited) mutations in tumour-suppressor genes. As summarized in **Table 4**, the genes which are targeted in familial pancreatic cancer include *BRCA2*, *STK11/LKB1* and *p16* (Goggins *et al*., 1996; Su *et al*., 1999). Patients who inherit a defective copy of one of these genes are more likely to develop a cancer later in life because they begin life with only one, instead of the usual two, functional copies of the gene. Should that good copy be inactivated, gene function would be lost. For example, Goggins *et al*. (1996) studied a large series of patients with pancreatic cancer and found that 7% had a germ-line (inherited) mutation in the second breast cancer gene (*BRCA2*). These patients presumably developed their pancreatic cancer when a cell in their pancreas lost the second, only remaining, good copy of the *BRCA2* gene (Goggins *et al*., 1996; Ozcelik *et al*., 1997). Similarly, germ-line mutations in the *p16* gene predispose to both pancreatic cancer and melanoma (Hruban *et al*., 1998); and germ-line mutations in the *STK11/LKB1* gene to pancreatic cancer and a rare syndrome called the 'Peutz–Jeghers' syndrome (Su *et al*., 1999).

The discovery of the genes responsible for some forms of familial pancreatic cancer represents a critical advance, because it means that members of families in which there has been an aggregation of cancer can now be genetically tested. Those found to carry a mutation in one of these genes can be more carefully screened for cancer or may even choose prophylactic surgery, while those found not to carry of a mutation can be relieved of their anxiety.

Mismatch Repair Genes

The final class of genes which play a role in the development of pancreatic cancer are the DNA mismatch repair genes. The products of DNA mismatch repair genes function to ensure the fidelity of DNA replication. Inactivation of DNA mismatch repair genes can therefore be thought of as analogous to having a drunk mechanic inspect your car. The failure of this mechanic to fix problems can have a devastating long-term effect. Remember that every time a cell divides it must copy all three billion DNA base pairs. Errors are made, and if the enzymes which help repair these errors are inactivated, these errors will not be repaired. Over time, this will lead to the accumulation of mutations

in both oncogenes and tumour-suppressor genes and therefore in the development of cancer. The inactivation of a DNA mismatch repair gene in a cancer produces a characteristic change in DNA called 'microsatellite instability', (MSI) and Goggins *et al*. (1998) have recently demonstrated MSI in ~4% of pancreatic cancers. These cancers are remarkable because as discussed in the section on tumour pathology, they appear to have a distinct microscopic appearance ('medullary phenotype') and because these cancers may have a different response to certain chemotherapeutic agents (Goggins *et al*., 1998).

Thus, there has been a revolution in our understanding of the molecular genetics of pancreatic cancer. This understanding is already being applied to the development of new screening tests for pancreatic cancer and new treatments for the disease, and it has led to a better understanding of why pancreatic cancer aggregates in some families.

PROGNOSTIC FACTORS

Overall, pancreatic cancer has the worst prognosis of all the common forms of cancer. Affected patients have a median survival of only ~6 months and less than 5% of patients live to 5 years. Given such dismal statistics, it is not surprising that few markers are available which can identify patients with a good prognosis. Among the subgroup of patients who undergo a surgical resection of the head of the pancreas (Whipple procedure, or pancreaticoduodenectomy), several prognostic factors influence outcome. The size of the carcinoma, the presence or absence of positive margins (cancer extending to where the surgeon cut), the histological grade (how closely it resembles normal tissue under the microscope) and the presence of lymph node metastases predict survival (Yeo *et al*., 1995). In addition, Allison *et al*. (1998) have shown that tumour DNA content (ploidy) also has prognostic significance and, as discussed in the Pathology section, histological classification can be an important predictor of prognosis. Finally, because of their late presentation, pancreatic carcinomas involving the tail and body of the pancreas have a poorer prognosis than cancers of the head of the pancreas.

OVERVIEW OF PRESENT CLINICAL MANAGEMENT

The management of pancreatic cancer depends on several factors, including the patient's symptoms, the performance status of the patient, the histological classification of the patient's tumour, the stage of the disease (whether or not it has spread beyond the gland) and the presence of complications. The diagnosis of pancreatic cancer is usually suspected from complaints of progressive obstructive jaundice (a yellow discoloration of the skin), profound weight loss and pain in the abdomen or mid-back. Less often patients can present with diabetes mellitus, thrombophlebitis migrans (blood clots developing at multiple sites), depression or evidence of metastatic disease. Generally, the diagnosis is established using CT (Bluemke *et al*., 1995), EUS or ERCP with histological (or cytological) confirmation. If curative resection is considered, staging investigations using EUS or angiography are performed, searching for evidence of spread to lymph nodes, to the peritoneum (the lining of the abdomen) or to the liver and for signs of large blood vessel involvement (invasion of the splenic or portal vein). Helical CT with contrast usually provides good assessment of the status of the blood vessels around the pancreas.

Pancreatic Adenocarcinoma

Surgery (Whipple resection) remains the only realistic curative modality for pancreatic cancer (Yeo *et al*., 1995). The Whipple procedure involves the resection of the head of the pancreas, the duodenum, lower common bile duct, local lymph nodes and peripancreatic tissue. This is not an easy operation. Operative mortality rates vary considerably with the experience of the surgeon, but mortality rates in expert centres are an acceptable 2–3%. Unfortunately, even this radical surgery is not curative in most cases. Most individuals who undergo Whipple operation will ultimately die of their disease with a median survival after surgery of ~18 months. Therefore, many patients who undergo a curative resection for pancreatic adenocarcinoma also receive adjuvant (post-operative) chemoradiotherapy (Yeo *et al*., 1995). Some centres are also investigating the potential benefit of neoadjuvant (pre-operative) chemoradiotherapy.

There are few chemotherapeutic agents that are active against pancreatic cancer. Agents such as gemcitabine, taxotere, 5-fluorouracil and others are effective in only 10–20% of patients with the disease. A number of experimental approaches are therefore being tried, including herceptin to target overexpression of the ErbB2 receptor (Day *et al*., 1996), angiogenesis inhibitors and gene therapies which can deliver immunomodulators, prodrugs and tumour-suppressor genes. One of the more novel approaches is a vaccine approach developed by Jaffee *et al.* (2001) at Johns Hopkins, who have developed a pancreatic cancer vaccine that recruits the patients' own immune system to fight the cancer.

It is also important to consider the quality of life for patients with this disease. Pain control is important and can be achieved with the use of opiate analgesia, which can be given in the form of infusion pump. In addition, 'nerve blocks' may be effective in some patients. This procedure involves the destruction of the nerves around the pancreas ('coeliac axis nerve block') and it is achieved by injecting 100% alcohol percutaneously, intraoperatively or during EUS into the nerve bed.

Weight loss is also a common problem for patients with pancreatic cancer. Many patients lose their appetite and the normal taste of food as a result of byproducts (anorectic factors) released from the cancer. In addition, food may not be adequately digested if the pancreas fails to release sufficient pancreatic enzymes owing to pancreatic duct obstruction. Such patients may benefit from taking pancreatic enzyme supplements. However, most patients with pancreatic cancer will lose weight even if they are eating and digesting their food sufficiently. This may be because pancreatic cancers often release cachectic factors (tumour lipid mobilizing factors, proteolysis-inducing factors) which cause muscle and fat breakdown. Such profound weight loss causes weakness and can shorten survival. This cancer-related weight loss can be refractory to treatment, but appetite stimulants may help the anorexia and fish oil supplements appear promising for reversing the cachexia. In the laboratory, fish oils appear to block the effects of cancer on muscle and fat wasting.

Another frequent complication of pancreatic cancer is common bile duct obstruction. Biliary drainage can relieve symptoms of obstruction and it can be achieved with biliary stents introduced during ERCP or percutaneously (percutaneous transhepatic cholangiography (PTC)). Biliary stents can be placed as an outpatient procedure with minimal patient discomfort and they can provide good short-term palliation of symptoms. Unfortunately, such stents frequently block off due to progressive tumour growth.

Pancreatic Neuroendocrine Carcinoma

Patients with islet cell (or neuroendocrine) carcinomas usually present either with symptoms due to hormone hypersecretion or in the context of multiple endocrine neoplasia (MEN) type I or MEN type II. Common presentations are refractory peptic ulcer disease, hypoglycaemia (low blood sugar), carcinoid syndrome (flushing, diarrhoea and asthma), secretory diarrhoea, hypercalcoemia (elevated serum calcium levels) and bone pain and a necrolytic skin rash. These symptoms arise from oversecretion of gastrin, insulin, serotonin (and histamine and other peptides), vasoactive intestinal peptide (VIP), parathyroid hormone or glucagon, respectively. Rarely, other peptides are released, such as somatostatin, pancreatic polypeptide, CRF, GRF or neurotensin. With the appropriate clinical suspicion, diagnosis of the presence of a neuroendocrine carcinoma can be achieved by measuring the levels of the islet cell hormones in the blood. Because they can be small (1 cm or less), multiple and they may involve the duodenum, islet cell tumours can be hard to identify radiologically. EUS is the best test for localizing these tumours. When possible, surgical resection is performed to treat these tumours, but surgery may not be possible if the patient has multiple foci of metastatic disease. Somatostatin analogues are very effective in combating the release of secretory peptides usually observed with these tumours. Patients with gastrinomas usually undergo total gastrectomy, although proton pump inhibitor therapy has reduced the need for this operation. In addition to somatostatin analogues, hyperglycaemic agents such as diazoxide are used to limit hypoglycaemia in patients with inoperable insulinomas.

Finally, chemotherapeutic agents such as streptozocin, 5-fluorouracil and interferon are often used for patients with inoperable islet cell tumours.

CONCLUSIONS

Pancreatic cancer is one of the deadliest of all cancers. The average life expectancy for patients with pancreatic cancer is only 6 months. While there are no effective therapies or screening tests currently available, we believe that the revolution which has occurred in our understanding of the genetics of pancreatic cancer will soon be translated into new effective screening tests, novel treatments and a better understanding of why pancreatic cancer aggregates in some families.

- Molecular Genetic Findings
- Prognostic Factors
- Overview of Clinical Management

NORMAL DEVELOPMENT AND STRUCTURE

The endocrine organs represent a group of tissues that have, as their primary function, the production and secretion of hormones. They are generally classified into three broad categories:

1. peptide hormone-producing;
2. steroid hormone-producing;
3. thyroid hormone-producing.

Most endocrine cell types fall into the first category. This group of endocrine tissues is composed of cells that have a characteristic neuroendocrine morphology (DeLellis and Tischler, 1998). They have sufficient neural differentiation structurally and functionally that they have been called 'paraneurons' and have been classified as the APUD (amine precursor uptake and decarboxylation) system. In earlier literature it was suggested that they derive from the neural crest embryologically; however, this has not been proved for all members of this group of cells, many of which arise from the primitive endoderm. Nevertheless, functionally they act as neuron-like cells that secrete peptides that are often also produced by neurons. The relationship between these cells and neurons is rather like the comparison between wireless and conventional communication. Neurons produce messengers that are released at synapses and activate receptors in adjacent cells, while neuroendocrine cells produce the same types of messengers that are released into the bloodstream to activate cells throughout the body. The wide array of peptide hormones that they produce is essential for regulation of most metabolic and reproductive functions. These cells are found in classical endocrine organs, such as the pituitary, parathyroid and adrenal medulla, and as members of the dispersed endocrine system scattered within other organs, such as the calcitonin-secreting C cells of the thyroid and the endocrine cells of the lung, gut and pancreas.

The steroid hormone-producing cells are primarily found in the adrenal cortex and the gonads (Sasano, 1998). They also have a distinct morphology that reflects their primary function of conversion of cholesterol into the various mineralocorticoid, glucocorticoid, androgenic and oestrogenic hormones. They are of mesodermal origin arising from the coelomic epithelium that gives rise to the adrenal and the genital ridge.

The thyroid hormone-producing cells are modified epithelial cells derived from the oral endoderm that invaginate from the base of tongue (Murray, 1998). They are specifically involved in the synthesis of thyroglobulin and its iodination to form thyroid hormones.

TUMOUR PATHOLOGY

Tumours of the endocrine system reflect their origin in the three types of endocrine cells.

Tumours of neuroendocrine cells arise either in classical neuroendocrine tissues, such as pituitary,

parathyroid or adrenal medulla, or in other tissues where the dispersed cells reside, such as thyroid, lung, gut or pancreas. These lesions exhibit a wide spectrum of biological behaviours. They may be slowly growing, well-differentiated neoplasms that are considered benign (adenomas), because they do not metastasize. The most aggressive neoplasms are poorly differentiated (small-cell) carcinomas that are rapidly lethal. Many tumours fall into intermediate categories and the prediction of outcome can be very difficult. The term 'carcinoid,' meaning 'carcinoma-like,' was originally introduced by Oberndorfer in 1907, and the terminology has been applied to well-differentiated neuroendocrine tumours and to tumours that result in the classical 'carcinoid syndrome' that results from serotonin excess. The use of this terminology, however, has caused great confusion because of the wide diversity of hormone activity and biological behaviour among these tumours that cannot all be conveyed by this classification. Since many of these ultimately prove to be malignant, this terminology has fallen out of favour. These tumours may be clinically silent in terms of hormone function, but they are almost always found to produce and store hormones. Some elaborate hormones that give rise to colourful clinical syndromes of hormone excess; the pattern of hormone production may be eutopic to the tissue of origin or ectopic, reflecting derepression of genes that are expressed in related cells.

Tumours of steroid hormone-secreting cells usually arise in the adrenals or gonads and very rarely arise in other sites where embryological remnants are found. They are generally classified as benign adenomas or malignant carcinomas based on features of differentiation, hormone production and invasion. Well-differentiated and generally benign tumours express mature steroid hormones. Tumours that are less well differentiated and exhibit malignant behaviour tend to lose the complex enzymatic pathways required for mature hormone production, but often produce hormone precursors of various types. Nevertheless, the functional behaviour of these tumours is not strict enough to allow classification as benign or malignant. These tumours are usually limited to the production of steroid hormones and almost never produce peptide hormones ectopically.

Tumours of thyroid follicular cell derivation are the most common neoplasms of the endocrine system. They include benign follicular adenomas, well-differentiated papillary or follicular carcinomas, poorly differentiated 'insular' carcinomas and dedifferentiated anaplastic carcinomas. Among human malignancies, they include the most benign and nonlethal occult papillary microcarcinomas that are found incidentally in up to 24% of the adult population, and one of the most rapidly lethal malignancies, the anaplastic carcinomas that frequently result in death by strangulation in less than 6 months.

EPIDEMIOLOGY

Tumours of endocrine differentiation are considered to be rare and, as such, the epidemiological data are weak. There are, however, several statistics of note.

Pituitary tumours are reported to be found in about 20% of the general population (Asa, 1998). Many of the studies have reported the identification of these lesions as incidental findings at autopsy, or as radiological findings in the asymptomatic 'normal' population. The true incidence of clinically significant lesions is not known. Some forms of pituitary neoplasia, including corticotroph adenomas causing Cushing's disease and prolactinomas, are more common in women than in men, but overall there is no sex predilection of pituitary neoplasia. These lesions tend to increase with age and are rare in children (Asa, 1998).

Primary hyperparathyroidism is most often due to parathyroid neoplasia and is reported to occur in 1% of the adult population (Apel and Asa, 2001). The true incidence of parathyroid adenomas is not known, however. Parathyroid carcinomas are rare. Benign lesions are more common in women than in men and are primarily found in middle-aged to elderly women. In contrast, carcinoma does not have a predilection for women and some studies indicate onset about one decade earlier than benign parathyroid tumours.

Pheochromocytomas of the adrenal medulla have a reported incidence of 2–8 per million per year and extra-adrenal paragangliomas are even rarer. These lesions have no sex predilection and are rare in children (Lack, 1997; Tischler, 1998).

Well-differentiated tumours of the dispersed endocrine system are rare. Tumors of thyroid C cells, medullary thyroid carcinomas, represent about 5% of thyroid cancers that predicts a prevalence of about 1–2 per 100 000 (LiVolsi, 1990; Moley, 2000). Tumours of the endocrine pancreas have an estimated prevalence of 1 in 100 000 (Klöppel *et al.*, 1998). These lesions show no sex predilection and are very rare in children. Small-cell carcinoma of the lung, the most poorly differentiated endocrine neoplasm of this type, represents one of the four major types of lung cancer, the second most common cancer in men and women and the number one cancer mortality site (Greenlee *et al.*, 2000); this variant has an annual incidence of almost 10 per 100 000 population.

Although adrenal cortical nodules are identified as incidental findings in 0.6–1.3% of asymptomatic individuals, clinically significant adrenal neoplasms are more rare and adrenal cortical carcinoma has an estimated incidence of only about 1 case per million population (Lack, 1997). There is a slight female preponderance. The incidence has a bimodal distribution in the first and fifth decades.

As indicated above, thyroid cancer is the commonest endocrine malignancy, representing 1–2% of all cancers

(LiVolsi, 1990; Murray, 1998; Asa and Bedard, 2000). It is about three times more common in women than in men and currently represents the tenth most common malignancy in women (Greenlee *et al*., 2000).

AETIOLOGY

The aetiology of most endocrine tumours is not known. A small minority is due to inherited genetic defects. The genes responsible for the multiple endocrine neoplasia (MEN) syndromes, *MEN-1* and *MEN-2*, have been cloned and characterized, and the mutations have clarified our understanding of mechanisms of disease. MEN-1 is a classical example of germ-line inheritance of a mutant tumour-suppressor gene (TSG), menin (Komminoth, 1999). It is an autosomal dominant disorder with variable penetrance; the variability of tumour development in pituitary, parathyroids, pancreas and occasionally other sites of the dispersed endocrine system in individual patients is due to the requirement for loss of the intact allele encoding the tumour suppressor. In contrast, MEN-2 is the best example of inheritance of a mutant proto-oncogene. The gene responsible for this disease encodes the transmembrane receptor tyrosine kinase Ret (Mulligan and Ponder, 1995). The identification of an activating Ret mutation in members of kindreds is now accepted as an indication for prophylactic thyroidectomy in early childhood, since these individuals will develop medullary thyroid carcinoma that can metastasize and is lethal in more than half of patients. Moreover, distinct *ret* mutations are associated with distinct clinical phenotypes. Mutations in exons 10 and 11 that encode the extracellular domain of the Ret protein are implicated as the cause of familial medullary thyroid carcinoma alone. Specific mutations, usually in exon 11 involving codon 634, are associated with MEN-2A and specifically codon 634 mutations replacing cysteine with arginine are more often associated with parathyroid disease and pheochromocytoma that characterize this disease complex. Activating mutations in exon 16 that replace a codon 918 methionine with threonine alter the tyrosine kinase domain of Ret and result in MEN-2B, a more aggressive variant of MEN-2 with mucosal neuromas and a marfanoid habitus in addition to tumours of thyroid C cells, parathyroids and adrenal medulla.

The aetiology of thyroid carcinomas of follicular epithelial cells is not entirely known, but there is evidence of a causal role for radiation (LiVolsi, 1990; Murray, 1998; Asa and Bedard, 2000). This is true of radiation therapy, for example in patients who have received external beam radiotherapy for malignancies of the head and neck and also for cosmetic therapy for facial acne. It is also true in populations exposed to radioactive fallout from nuclear disasters, such as in Japan after the nuclear bomb disasters and in Ukraine and Belarus after the Chernobyl episode. The exposure to radioactivity has its highest impact in the young, and the disease is more often multifocal than in sporadic cases; however, the prognosis in patients who have been exposed to radiation does not appear to differ from those with no history of radiation (Brierley and Asa, 2001). Radiation has been implicated as causative of *ret/PTC* gene rearrangements that are thought to play a role in the genesis of thyroid carcinomas (Nikiforova *et al*., 2000). Diet has also been implicated in the development of thyroid cancer; populations with low iodine intake develop goitres and have a higher incidence of follicular carcinoma, but most investigators now recognize dietary iodine insufficiency as the reason for a higher incidence of follicular as opposed to papillary carcinomas. In other words, there is no evidence that it increases the incidence of cancer; rather it alters the morphological variant of well-differentiated thyroid carcinoma.

SCREENING AND PREVENTION

Screening for endocrine tumours has really only been applied systematically in cases of familial disease. Members of kindreds have traditionally been screened using biochemical analysis of hormone hypersecretion. More recently, the addition of genetic information has allowed earlier and definitive identification of carriers in families with known mutations. Patients with MEN-1 have variable disease patterns, so that genetic identification results in continued and careful surveillance of affected family members. Patients with activating mutations of the *ret* proto-oncogene will almost certainly develop medullary thyroid carcinoma, a disease that is lethal if not detected early or prevented, and therefore current guidelines recommend prophylactic thyroidectomy in childhood, usually by age 5 years for those with MEN-2A or FMTC, and at or around age 1 year for those with the more aggressive mutation of MEN-2B. Some families have unidentified mutations and hormonal screening remains the standard mechanism of tumour detection, with the addition of radiological investigation where indicated.

Screening for thyroid tumours is usually part of the physical examination since the thyroid is readily accessible on palpation of the neck. When a thyroid nodule is detected, the most valuable technique to evaluate these lesions is the cytological examination of a fine-needle thyroid aspirate (Murray, 1998; Asa and Bedard, 2000). It can clearly identify some patients who will require surgery and most of those who are unlikely to require surgery. Cytological examination can very quickly impart a diagnosis of *papillary carcinoma*, *medullary carcinoma*, *lymphoma*, *anaplastic carcinoma* or *metastatic carcinoma*. In contrast to these clearly malignant lesions, the majority of thyroid aspirates yield a benign diagnosis, which is either *thyroiditis* or *colloid nodule*, a benign hyperplastic process

with abundant colloid storage. Nevertheless, there is a population of patients whose thyroid aspirates yield abundant follicular epithelial cells, sometimes with atypia; these lesions cannot be classified based on cytology alone and surgery is required to allow thorough analysis of these *follicular lesions* to identify or exclude invasive behaviour that distinguishes benign from malignant neoplasms.

GROSS AND HISTOPATHOLOGY, IMMUNOHISTOCHEMISTRY AND ULTRASTRUCTURE

Tumours of Neuroendocrine Cells

The morphology of endocrine tumours varies with the type and location of the lesion.

Tumours of neuroendocrine cells are generally well-delineated but unencapsulated lesions that have a characteristic histopathology. They are composed of small nests, trabecula or sheets of epithelial cells in a highly vascular stroma (**Figure 1a; see colour plate section**). They occasionally form gland-like structures. The stroma may, in some instances, form amyloid. The tumour cells usually have poorly defined cell borders and abundant cytoplasm that may contain eosinophilic, amphophilic or basophilic granules. Characteristically, the nuclei of tumour cells are bland; nuclear pleomorphism that generally defines malignancy in other epithelial tumours is not a reliable indicator of aggressive behaviour. The more poorly differentiated carcinomas have less cytoplasm, lack granularity and have larger more hyperchromatic nuclei.

These lesions are readily classified by the immunohistochemical localization of common markers of neuroendocrine differentiation (**Table 1**) (Wick, 2000). They almost uniformly stain for synaptophysin, a 38-kDa molecule that is associated with synaptic vesicles of neurons and neuroendocrine cells (**Figure 1b; see colour plate section**). Most contain chromogranins, proteins associated with secretory granules. There are two families of chromogranins, A and B; to classify these lesions appropriately one needs to identify both chromogranins. Moreover, chromogranin immunoreactivity is directly related to the number of secretory granules that may be scarce in poorly differentiated tumours. Other markers of neuroendocrine differentiation include CD57 (Leu7), neural cell adhesion molecule (NCAM; CD56), neuron-specific enolase (NSE) and Protein Gene Product 9.5 (PGP 9.5) that stain variable subpopulations of endocrine lesions and some, such as NCAM and NSE, also stain some non-endocrine tumours. Of course, the structure–function correlations of these lesions are best defined by their immunoreactivity for specific peptide hormones or, in the case of hormones that cannot be localized (such as adrenaline and noradrenaline), the enzymes involved in hormone production (such as tyrosine hydroxylase).

The ultrastructure of these lesions is highly characteristic (**Figure 1c; see colour plate section**). The tumour cells have well developed rough endoplasmic reticulum, reflecting the levels of peptide hormone synthesis, prominent Golgi complexes that are responsible for packaging of hormones for secretion and membrane-bound secretory granules that store hormones for secretion in response to stimulation. The development of these organelles varies with cell differentiation and hormonal activity; the numbers of secretory granules reflect the balance between synthesis, storage and secretion. The morphology of secretory granules is generally reflective of cell type and hormone content, and experts in the field of electron microscopy can classify neuroendocrine cells based on these ultrastructural parameters.

Pituitary tumours (Asa, 1998) and tumours of the adrenal medulla and extraadrenal paraganglia (Lack, 1997; Tischler, 1998) are generally considered benign unless there is evidence of metastatic spread. In contrast, tumours of the dispersed endocrine system, including medullary thyroid carcinomas and endocrine tumours of the lung and gut, are not reliably considered benign (Capella *et al.*, 1995); even in the absence of invasion, there may be delayed recurrence or metastasis. It can be difficult to distinguish tumours of the parathyroid glands from hyperplasia (Apel and Asa, 2001). In this tissue, the diagnosis of malignancy in a neoplasm usually relies on identification of vascular invasion or metastasis.

The current approach to the classification of tumours of the dispersed neuroendocrine system is based on three principles: (i) the diagnosis should be based on the microscopic features of the lesion but must incorporate useful immunohistochemical data; (ii) tumours should be distinguished according to the differentiated cell type and site of origin; and (iii) tumours should be subdivided based on biological behaviour, into benign, low-grade malignant and high-grade malignant lesions; the last include poorly differentiated endocrine carcinoma and the so-called ‘small-cell’ or ‘oat-cell’ carcinomas. The determination of malignant potential is based on architectural and cytological features including invasion as outlined below:

- cytological features;
- ploidy, proliferation markers;
- pattern of hormone production
  eutopic vs ectopic, α-subunit;

Table 1 Diagnosis of neuroendocrine tumours

General	Synaptophysin, chromogranins NSE, CD57, NCAM (CD56), PGP 9.5 Hormones Specific Eutopic Ectopic

- invasion;
  capsular, adjacent tissues, perineural, vascular;
- metastases.

The location and hormone content of individual lesions are of importance, especially in the classification of tumours of histological low-grade malignancy, the 'well-differentiated endocrine carcinoma,' where these additional pieces of information aid in predicting the likelihood of metastatic behaviour.

The wide spectrum of clinical symptomatology associated with these lesions is attributed to the numerous peptide hormones that can be elaborated by the cells of the diffuse endocrine system. A limited example is included in **Table 2** that identifies some of the cell types, hormones and syndromes associated with tumours of the gastroenteropancreatic system.

Tumours of Steroid-Hormone-Producing Cells

Tumours of steroid hormone-producing cells are usually solitary, bright-yellow lesions (**Figure 2a; see colour plate section**) with areas of haemorrhage and necrosis (Lack, 1997; Lack, 1998). They are composed of usually monotonous cells with well-defined cell borders and abundant clear cytoplasm (**Figure 2b; see colour plate section**). Immunohistochemistry does not play a major role in identifying these lesions; however, occasionally it is not possible to confirm steroidogenic differentiation of poorly differentiated tumours on histological grounds alone. These lesions characteristically exhibit nuclear reactivity for the nuclear transcription factor steroidogenic factor-1 and cytoplasmic reactivity for inhibin-α. They also stain for various enzymes involved in the steroidogenic pathways. Ultrastructural examination can be helpful; the cells usually have very well developed smooth endoplasmic reticulum and cytoplasmic lipid droplets (**Figure 2c; see colour plate section**). In addition, the mitochondria have tubulovesicular cristae that are a hallmark of steroidogenic cells.

Nodules in the adrenal cortex are very common and may be hyperplastic or attributable to vascular insufficiency; it can be difficult to distinguish hyperplasia from neoplasia; the criteria for this distinction, although not always applicable, are outlined in **Table 3**. When dealing with unequivocal neoplasms, the diagnosis of malignancy can be very difficult. Cytological atypia is not an indicator of malignancy. Size is an important predictor of biological aggressiveness. Again, however, the distinction of benign from malignant lesions usually depends on the identification of invasion, with extension beyond a capsule into adjacent tissue, vascular invasion or metastasis as the features predicting malignant behaviour. These lesions may be associated with hormone excess syndromes; in some cases, hormonal activity can predict biology. It is, for example, extremely rare for adrenal cortical tumours associated with Conn's syndrome to be malignant. In contrast, adrenal tumours associated with feminization in males are invariably malignant. Most malignancies of these tissues are not associated with hormone excess as their primary manifestation; however, it is not unusual to identify production of steroid hormone precursors by tumour cells when this is examined.

Table 2 Classification of gastroenteropancreatic endocrine cells and tumours

Hormone	Cell type	Clinical syndrome
Insulin	B	Hypoglycaemia
Glucagon/glucagon-like peptides (GLP)	A/L	Diabetes mellitus; skin rash
Somatostatin	D	Somatostatinoma syndrome
Gastrin	G	Zollinger–Ellison syndrome
Pancreatic polypeptide	PP	?
Vasoactive intestinal peptide (VIP)	?	Verner–Morrison syndrome
Secretin	S	(watery diarrhoea hypokalemia achlorhydria (WDHA), pancreatic cholera)
Prostaglandins	?	?WDHA
Serotonin	EC	Carcinoid syndrome
Cholecystokinin (CCK)	I	?
ACTH/MSH; CRH	?	Cushing syndrome
Vasopressin	?	Diabetes insipidus
Growth hormone-releasing hormone (GRH); growth hormone (GH)	?	Acromegaly

Tumours of Thyroid Follicular Cell Derivation

Tumours of thyroid follicular cell derivation are common and are probably the best characterized endocrine neoplasms; however, in this field too there is controversy

Table 3 Hyperplasia vs Neoplasia in Endocrine Tissues

Hyperplasia	Neoplasia
Multiple	Solitary
Poorly encapsulated	Encapsulated
Architectural heterogeneity	Uniform architecture
Cytological heterogeneity	Cytological homogeneity
Comparable areas in adjacent gland	Different from surrounding gland
No compression of surrounding gland	Compresses surrounding gland

concerning diagnostic criteria (LiVolsi, 1990; Rosai *et al.*, 1992; Murray, 1998; Asa and Bedard, 2000).

Follicular Nodules of the Thyroid

Follicular nodules may be hyperplastic, benign follicular adenomas or malignant lesions which include follicular carcinoma and follicular variant papillary carcinoma.

Like in parathyroid and adrenal cortex, *hyperplasia* may be extremely difficult to distinguish from *neoplasia*. As shown in **Table 3**, there are rigid criteria for this distinction; however, in many instances the disease is not as defined as classical teaching has suggested. Generally, hyperplasia is a multifocal disorder in which lesions are poorly encapsulated. The nodules of nodular hyperplasia exhibit architectural as well as cytological heterogeneity and this is truly the hallmark of this disease. In contrast, a follicular neoplasm generally represents a solitary encapsulated lesion that is uniform both in cytology and architecture. Architecturally these lesions may be macrofollicular, in which case they are somewhat difficult to distinguish from hyperplastic nodules; microfollicular lesions are more cellular and worrisome but may also represent part of the spectrum of hyperplasia. Clonality studies have indicated that classical teaching may, in fact, be wrong. Although multinodular hyperplasia is expected to be a polyclonal disease, the dominant nodules in multinodular goitres are often monoclonal, raising serious doubts about our diagnostic criteria. Moreover, the evidence of clonal proliferation in sporadic nodular goitre indicates that the thyroid is a site for the hyperplasia–neoplasia sequence. Nevertheless, clinical experience has shown us that most of these lesions remain entirely benign.

The criteria for the diagnosis of *malignancy in a follicular neoplasm* require the presence of vascular or capsular invasion (**Figure 3a; see colour plate section**). Nuclear and cellular atypia and mitotic figures may be present in adenomas and also in carcinomas and therefore cytological characteristics are not helpful in this regard. Follicular carcinomas cannot, therefore, be distinguished from follicular adenomas by fine-needle aspiration cytology. However, there are additional tools that facilitate this diagnosis; for example, a novel marker of malignancy in these lesions is HBME-1, a monoclonal antibody directed against an unknown epitope that is expressed in malignancy but not benign thyroid follicular epithelial cells. More recently, another marker of follicular carcinoma is the detection of PPARγ that is aberrantly expressed due to a gene rearrangement that places PPARγ under the control of the thyroid transcription factor Pax 8 in follicular carcinoma (Kroll *et al.*, 2000).

Follicular carcinomas exhibit a wide range of biological behaviours that are reflected by morphological criteria. Capsular invasion is usually divided into two groups. *Widely invasive follicular carcinomas*, which are usually identifiable as invasive grossly, and certainly are not difficult to recognize as invasive microscopically, carry a poor prognosis with a 25–45% 10-year survival. In contrast, the more common scenario is that of minimal capsular invasion. This requires very careful and thorough examination of the entire capsule of the follicular neoplasm by the pathologist. *Minimally invasive follicular carcinoma* is identified by total thickness invasion through the capsule superficially into the adjacent parenchyma but not widely beyond the capsule. Borderline lesions include those with invasion into the capsule beyond the bulk of the lesion but not through the full thickness of the capsule or situations in which islands of tumour are trapped within a capsule, associated with perpendicular rupture of collagen. The finding of nests, cords or individual tumour cells within a tumour capsule leads some pathologists to the diagnosis of minimally invasive follicular carcinoma; however, this may represent an artifact in a patient who has undergone fine-needle aspiration biopsy, with trapping by fibrosis or displacement of tumour cells into the capsule. The pathologist is therefore advised to search carefully for evidence of fine-needle aspiration biopsy in the adjacent tissue. This would include finding focal haemorrhage, deposition of haemosiderin-laden macrophages and the presence of granulation tissue and/or fibrosis, all of which would indicate a needle biopsy site and the possibility of artifactual invasion rather than genuine invasion.

The careful search for minimally invasive carcinoma is time consuming and difficult for even the most diligent pathologist. Recent data suggest that this search may be unnecessary, since it would appear that patients with minimally invasive carcinoma have almost a 100% 10-year survival rates and therefore some argue that this disease does not need to be distinguished from follicular adenoma. Nevertheless, the investigators who have reported these data have treated their patients for carcinoma rather than for benign disease. Rather than endorsing a cavalier approach that would entail less work for the pathologist, it behoves us to recognize the presence of potential malignancy, to treat the patient appropriately, but also to identify the excellent prognosis that these lesions carry after appropriate management.

Vasculoinvasive follicular carcinomas are aggressive and require management accordingly.

The last few decades have seen a decrease in the incidence of follicular thyroid carcinoma, probably due to dietary iodine supplementation. However, misdiagnosis of this tumour continues. Benign lesions, such as partly encapsulated hyperplastic nodules or nodules exhibiting pseudoinvasion after fine-needle aspiration, are often overdiagnosed as malignant; papillary carcinomas with follicular architecture are often misinterpreted as follicular carcinoma. The clinical features, pathophysiology, and biological behaviour of follicular cancer differ significantly from those of the entities with which it is often

confused. Only careful histopathological classification will allow correct evaluation of treatment options and prognosis.

Papillary Lesions

Papillary nodules of the thyroid are usually malignant but occasional benign papillary tumours are identified.

Papillary Hyperplasia

Papillary lesions are seen focally in *nodular goitre* with or without associated hyperfunction; 'hot' nodules are usually associated with increased uptake on radionucleotide scan.

The so-called '*papillary hyperplastic nodule*' most likely represents a benign neoplasm of the thyroid. These are said to occur most commonly in teenage girls. They present as solitary nodules and may be associated with clinical hyperfunction. *Benign papillary neoplasms* in adults may result in clinical toxicity and a 'hot' nodule on radionuclide scanning. These lesions are encapsulated, often show central cystic change and have subfollicle formation in the centres of broad oedematous papillae. They are distinguished from papillary carcinoma by lack of nuclear atypia (see below).

Papillary Carcinoma

Papillary carcinoma comprises more than 80% of thyroid epithelial malignancies in countries where goitre is not endemic. The name 'papillary carcinoma' is historic and often is misleading. In fact, the architecture of these neoplasms varies from an almost pure papillary pattern to a pure follicular pattern; many tumours have a mixed papillary and follicular pattern. It is now recognized that the diagnosis of papillary carcinoma is based on cytological criteria, as specified in the WHO classification on thyroid tumours, 'a distinctive set of nuclear characteristics' that can be listed as follows:

- crowded, overlapping 'shingle-tile' appearance;
- large, elongated nuclei;
- irregular nuclear outline;
- etched, folded or moulded nuclear membrane;
- nuclear grooves;
- pale vacuolated nucleoplasm;
- peripheral margination of chromatin;
- bare or marginated nucleoli; and
- nuclear cytoplasmic pseudoinclusions.

These characteristics are illustrated in **Figure 3b; see colour plate section**. No one specific feature is absolutely diagnostic of papillary carcinoma; usually, one relies on a constellation or combination of nuclear features for the diagnosis. These nuclear features may be accompanied by more easily recognized psammoma bodies and the presence of high molecular weight cytokeratins, which are readily localized in formalin-fixed paraffin-embedded tissue when microwave antigen retrieval is applied. Identification of high molecular weight cytokeratins confirms the suspected diagnosis of papillary carcinoma in approximately 60% of cases. Other markers of papillary carcinoma include HBME-1 (see Follicular Nodules of the Thyroid, above) and Ret. The Ret tyrosine kinase, that is expressed in thyroid C cells and exhibits somatic activating mutations in medullary thyroid carcinomas and germ-line activating mutations in MEN-2, is usually not expressed in thyroid follicular epithelial cells. However, there are several variants of gene rearrangements, known as *ret/PTC*, that result in expression of the C-terminus of Ret in papillary carcinoma. Detection of such a rearrangement by immunostaining for Ret can facilitate diagnosis in difficult cases.

Thyroid tumours exhibiting the nuclear characteristics of papillary carcinoma diffusely or multifocally should be diagnosed as papillary carcinoma rather than as follicular carcinoma. These lesions share certain clinical characteristics such as biological indolence and an excellent prognosis with a 20-year survival rate of 95% or better. Papillary carcinomas invade lymphatics, leading to a high percentage of regional lymph node metastases. Metastases beyond the neck are unusual in common papillary carcinoma and probably only occur in about 5–7% of cases.

Aggressive Tumours of Follicular Cell Derivation

Specific morphological features can identify tumours that are more aggressive than the usual well-differentiated follicular or papillary malignancies derived from follicular epithelial cells. For example, the *tall cell variant of papillary carcinoma* is recognized to behave in a much more aggressive fashion. These tumours have a height to width ratio that exceeds 3:1. Tumours that exhibit this feature in more than 30% of the tumour mass generally are found in older patients who have extrathyroidal extension and these patients have a guarded prognosis.

The identification of insular dedifferentiation marks a tumour that requires much more aggressive management. *Insular carcinoma*, also known as *poorly differentiated carcinoma*, is a tumour that exhibits a behaviour intermediate between well differentiated thyroid cancer and anaplastic carcinoma. These lesions are identified by their architectural growth pattern; they form solid nests of epithelial cells that resemble neuroendocrine carcinoma more than a follicular lesion (**Figure 3c; see colour plate section**), however, they generally contain thyroglobulin immunoreactivity to characterize their differentiation.

Anaplastic thyroid carcinomas are composed of undifferentiated cells that may exhibit three general patterns but most tumours manifest mixed morphology. The most common type is the *giant cell variant*; as the name suggests, these tumours are composed predominantly of large cells with abundant cytoplasm and bizarre, often multiple,

hyperchromatic nuclei. The *squamoid variant* is composed of large cells that form nests, resembling squamous carcinoma. *Spindle cell anaplastic carcinomas* have a fascicular architecture and dense stromal collagen with spindle-shaped tumour that may resemble fibrosarcoma. In all three variants, mitotic figures and atypical mitoses are frequent. There is usually extensive necrosis and, in some cases, necrosis may be so extensive that the only viable tumour is around blood vessels. Anaplastic carcinomas are highly infiltrative, destroying thyroid tissue and invading skeletal muscle, adipose tissue and other perithyroidal structures. Blood vessel invasion and thrombosis with or without tumour cell involvement are frequent. These lesions usually have no immunoreactivity for markers of thyroid cells and are often a diagnosis of exclusion.

The reported association between well-differentiated thyroid carcinoma and anaplastic carcinoma ranges from 7 to 89% of cases; however, the lower figures are probably underestimates, attributable to inadequate sampling. The data suggest that anaplastic carcinoma originates most often in an abnormal thyroid; the tumour has a higher incidence in regions of endemic goitre and a history of goitre is reported in over 80% of cases. As stated above, nodular goitre is often the site of monoclonal proliferation, the first step in the hyperplasia–neoplasia sequence. However, it is difficult to document transformation of a benign lesion to a malignant tumour. Insular carcinoma appears to be intermediate in the spectrum, and may represent a transition form. The association of papillary carcinoma, particularly the more aggressive tall cell variant, with anaplastic tumours has also been described. The factors underlying dedifferentiation in thyroid tumours remain to be established; age and radiation have been implicated. Clearly, most well-differentiated thyroid lesions do not undergo such transformation. A pattern of genetic mutations resulting in oncogene activation or loss of tumour suppressor gene activity has been proposed to correlate with the stepwise progression from adenoma to carcinoma and through the dedifferentiation process in thyroid. The significance of microscopic anaplastic change is controversial; some people have suggested that focal microscopic anaplastic dedifferentiation does not alter prognosis, but others have shown that this finding alone is statistically significant as a marker of aggressive behaviour.

MOLECULAR GENETIC FINDINGS

The technique of clonality assessment using X chromosome inactivation patterns has evolved from the Lyon hypothesis, which states that only one X chromosome is active in any female somatic cell; the inactivation occurs early in embryogenesis and persists throughout the lifespan of the cell and its progeny. Traditionally, X chromosome inactivation was determined by the phenotypic expression of isoenzymes of glucose-6-phosphate dehydrogenase (G6PD), a protein encoded on that chromosome. Heterozygosity for this gene, however, is present in only a small proportion of black females, limiting the application of this technique. A molecular approach to the determination of clonality takes advantage of X chromosome inactivation patterns using DNA restriction fragment length polymorphisms (RFLPs). Activated genes can generally be distinguished from their inactive counterparts because of differences in the degree of methylation of cytosine (C) residues which are typically hypomethylated in active genes. X chromosome genes which have been utilized for these studies include hypoxanthine phosphoribosyltransferase (HPRT), phosphoglycerate kinase (PGK) and M27β. Molecular analyses have proved that most endocrine neoplasms are monoclonal.

Although the genetic basis of the inherited endocrine tumours is now understood, the genetic abnormalities underlying the far more common sporadic tumours are not clear (Asa and Ezzat, 1998). In fact, mutations of the common oncogenes and tumour-suppressor genes that have been implicated in other malignancies, such as *ras* and *p53*, are rare in endocrine tumours (Ezzat and Asa, 1998).

Proto-oncogenes are normal cellular genes that play an essential role in the proliferation and differentiation of normal cells. They function at each step of signal transduction pathways as growth factors (e.g. c-*sis*), membrane receptors (e.g. c-*erb*-B, c-*neu*, c-*fms*), GTP-binding proteins (e.g. *ras* family) and nuclear proteins (e.g. c-*myc*, c-*fos*). Proto-oncogenes may be activated by point mutations, translocations or increased expression. Genetic alteration in these genes leads to sustained activation of the gene product in the absence of the normal control mechanisms. Activated oncogenes have been associated with a large number of human tumours, e.g. N-*myc* amplification in neuroblastomas and K-*ras* point mutations in colonic carcinomas.

Ras proteins are involved in transducing signals from the cell surface to a number of ligand–receptor complexes. The commonest mutational sites alter the GTP-binding domain (codons 12/13) or more rarely the GTPase domain (codon 61). Point mutations of all three *ras* genes (H-, K- and N-) are rare in endocrine tumours of all kinds.

Although activating mutations of the *ret* proto-oncogene have been implicated as the cause of familial medullary thyroid carcinoma and MEN-2, activating *ret* mutations are not frequently identified as somatic events in sporadic tumours of the dispersed neuroendocrine system. They are found in a minority of sporadic medullary thyroid carcinomas and pheochromocytomas.

The only endocrine oncogene that has been proved in any consistent fashion in sporadic endocrine tumours is the α-subunit of the Gs protein (Lyons *et al*., 1990). G-proteins are heterotrimeric membrane-anchored peptides that play a

central role in transducing signals from the cell surface ligand–receptor complexes to the downstream effectors. The α-subunit dissociates from the β- and γ-subunits of Gs when GTP displaces its bound GDP, stimulates adenylyl cyclase to produce cyclic AMP from ATP. Cyclic AMP (cAMP) in turn activates c-AMP-dependent protein kinases, increases intracellular calcium transport and may potentiate the effect of activated inositol phospholipid-dependent protein kinases. The weak intrinsic GTPase activity of Gsα and the action of GTPase-activating peptides (GAPs) dissociates GTP from Gsα and terminates the response. Additionally, the multiple structural and functional isoforms of adenylyl cyclase underscore the complexity of this redundant system of signal transduction coupling and provides some insight into the array of potential sites of somatic mutations which could alter both cell division and hormone production. Indeed, one of the earlier and most exciting molecular defects to be described in endocrine tumours involved the single point mutations in two critical domains of the Gsα subunit of GTPase codon 201 where Arg is switched to a Cys or codon 227 where Gln is replaced with Arg. Substitutions at these codons (the *gsp* mutation) activate adenylyl cyclase by inhibiting the hydrolysis of GTP and thereby maintaining Gsα in a constitutively activated state. Activating mutations of this protein are reported to occur in 30% of pituitary growth hormone-producing adenomas (Spada *et al*., 1992) and in a large proportion of hyperfunctioning thyroid adenomas (Suarez *et al*., 1991; Goretzki *et al*., 1992). Marked elevation in *Gs*α mRNA levels have been documented in insulin-secreting pancreatic endocrine tumorus. In all of these situations, they predict benign but endocrinologically hypersecretory lesions.

Over-expression of genes which act as inhibitors of the apoptotic process may also act as oncogenes. In some studies, the oncogenes c-*myc*, *bcl-2*, c-*erb*-B-2 and c-*jun* have been shown to be frequently expressed in human gastroenteropancreatic endocrine tumours. The expression of these oncogenes may represent pathogenic events in the generation, malignant transformation and progression of gastroenteropancreatic endocrine tumours.

Products of tumour-suppressor genes (TSGs) can alter transcription factor activity, thereby modulating physiological growth by arresting cell division in the G_1 phase. This delay may allow for repair of genomic damage or may trigger apoptotic cell death. Deletion or reduced expression of TSGs appear to be a commonly shared mechanism in human tumorigenesis.

The p53 protein plays a role in cell cycle regulation; point mutations, deletions or rearrangements in the *p53* gene which result in an altered protein are considered to be among the commonest genetic mutations in human neoplasms and have been implicated in tumour progression in several types of cancer. Progressive transformation to the malignant phenotype may be the result of mutational inactivation of the *p53* TSG. Indeed, p53 mutations appear to play a role in the pathogenesis of some tumours of the dispersed endocrine system, including those arising from the appendix, and carcinomas of the parathyroids and adrenal cortex. They are a late event in thyroid cancer where they are found primarily in anaplastic carcinomas.

In patients with multiple endocrine neoplasia type 1, loss of heterozygosity (LOH) in tumours has been mapped to 11q13. The *MEN-1* tumour-suppressor gene was recently cloned at this chromosomal site. Mutations of menin are not found in most sporadic tumours of the tissues involved in MEN-1: pituitary, parathyroids and pancreas (Komminoth, 1999). *MEN-1* gene mutations have been found in some sporadic tumours of the dispersed endocrine system, primarily gastroenteropancreatic endocrine tumours including 44% of sporadic gastrinomas and 19% of insulinomas, but also in lung endocrine tumours. This region of 11q13 contains several other genes that are also known to be associated with tumorigenesis and may be implicated in the development of tumours that show a high frequency of LOH in this region.

The retinoblastoma (*Rb*) gene has been implicated in the pathogenesis of parathyroid carcinomas (Apel and Asa, 2001). Although animal models suggest that it should be important in pituitary tumorigenesis, there is no evidence for *Rb* loss or alteration in human pituitary adenomas (Asa and Ezzat, 1998). A small number of case reports have emerged describing deletions and possible rearrangements of the *Rb* gene in the very rare insulin-producing carcinomas. Deletions of the putative Wilms tumour and the transformation suppressor gene k-*rev*-1 have also been described in an insulinoma.

The gene conferring predisposition to familial adenomatous polyposis coli (FAP) has been identified (*APC*) and mapped to chromosome 5q21. Somatic mutations in *APC* have also been identified in sporadic pancreatic, colorectal and gastric carcinoma. This gene may play a role in the development of thyroid carcinomas in affected members of families with FAP; however, this remains unproved (Soravia *et al*., 1999). There is no evidence for a pathogenetic role for APC in sporadic thyroid tumours.

Other genomic mutations that have been described in human endocrine tumorigenesis include chromosome 10 or 17 monosomy, and loss of the adhesion molecule DCC (deleted in colonic carcinoma).

Activating mutations of receptors that regulate hormone synthesis and secretion, long anticipated as the molecular solution to the problem of endocrine tumorigenesis, have been likewise disappointing (Ezzat and Asa, 1998). Only in some cases of hyperfunctioning thyroid adenomas have such activating mutations, in this case of the thyrotropin receptor (Porcellini *et al*., 1994; van Sande *et al*., 1995; Krohn *et al*., 1998), proved to be associated with disease.

The molecular genetics of thyroid carcinoma are a model for understanding the role of genetic mutations in tumorigenesis and the application of that knowledge to diagnosis. The unique chromosomal rearrangements

involving the *ret* proto-oncogene (*ret/PTC* gene rearrangements) are found in papillary carcinomas; however, these are early events, found most frequently in occult papillary microcarcinomas that are biologically insignificant lesions. Follicular carcinomas are now thought to involve another novel gene rearrangement involving the thyroid transcription factor Pax-8 and the *PPAR-*γ gene. However, the factors that predict growth and metastasis in these common well-differentiated malignancies are unknown and therefore the rational management of patients remains unscientific. Ras mutations are rare but their impact on biological behaviour is controversial; they may be involved in tumour progression. p53 mutations are late events that have been described only in anaplastic carcinomas.

The data indicate that endocrine tumorigenesis is the result of novel genetic events. The conventional approach of screening tumours for known oncogenes and TSGs has been attempted but with little success. Clearly, these tumours have the potential to clarify new mechanisms of tumour development.

PROGNOSTIC FACTORS

Prognostic factors in neuroendocrine tumours are generally extent of disease and sometimes involve patterns of hormone production. Some genetic factors are also predictive; for example, familial medullary thyroid carcinoma (FMTC), with or without the association of MEN-2A syndrome, has a better survival than that associated with MEN-2B syndrome and has been associated with better survival than sporadic medullary thyroid carcinoma. However, in patients matched for age, extent of tumour and lymph node involvement, survival is similar for those with the hereditary and sporadic medullary thyroid carcinomas. Any differences in survival of hereditary and sporadic cases may be due to earlier diagnosis in high-risk patients that are screened for hereditary medullary thyroid cancers. Although presenting at an earlier age, patients with MEN-2B have more advanced disease and poorer survival than those with MEN-2A. Younger age and female gender are generally reported as favourable prognostic indicators in this disease. The presence of lymph node involvement affects survival adversely, as does extension through the thyroid capsule. The most important predictive factor for survival is biochemical cure, measuring calcitonin after surgery. However, a decrease in the calcitonin level may indicate progression to a poorly differentiated tumour. Carcinoembryonic antigen (CEA) has also been used as a marker for disease progression in medullary thyroid carcinoma; a short CEA doubling time is associated with rapidly progressive disease.

Concerning the prognosis of tumours of steroid hormone-secreting cells, adrenocortical adenomas generally take longer to diagnose than carcinomatous counterparts. These adenomas usually cause Cushing syndrome, but can also result in virilization, Conn syndrome, or no endocrinological symptoms. 'Nonfunctional' tumours probably merely secreted insufficient steroids to cause signs and symptoms. Unfortunately, small tumour size and 'benign' histological features are not sufficient predictors of clinical behaviour. Among malignant tumours, a high proliferative index as identified by MIB-1 or Ki-67 labelling is thought to predict shorter disease-free survival.

The most useful prognostic markers in well-differentiated carcinomas of thyroid follicular epithelium are patient variables, tumour size and extent of disease. Age is the single most important prognostic factor. Patients under the age of 45 years usually have an excellent prognosis; in contrast, those over 45 years of age generally have a poorer outlook. Sex has also been said in the past to be an important determinant of tumour biology but more recent studies have suggested that there is no major difference in the behaviour of these carcinomas in men and women. Tumour size is exceedingly important. Tumours smaller than 1 cm are common and appear to be different biologically than larger tumours; a recent study has shown that occult papillary carcinomas are identified in up to 24% of the population in thyroids that are removed for nonmalignant or unrelated disease. In contrast, tumours larger than 1 cm are thought to be of clinical significance and those larger than 3 cm generally have a poorer prognosis than do smaller tumours. The presence of cervical lymph node metastases, whether microscopic or identified clinically, is thought to increase the risk of recurrence of disease but has been shown to have no impact on mortality. Extrathyroidal extension, in contrast, predicts a worse prognosis and the presence of distant metastases is the hallmark of an aggressive tumour that will bear the potential for high mortality. In patients who have metastatic disease, the site of metastases, the size of metastases and the ability to take up radioiodine are important factors. The value of novel molecular markers in determining the prognosis of differentiated thyroid cancer remains to be established.

OVERVIEW OF CLINICAL MANAGEMENT

In most instances, the diagnosis of neuroendocrine tumours is based on the identification of hormone excess or radiographic identification of a mass lesion. Some neuroendocrine tumours can be difficult to localize and visualize. They have in common, however, the expression of somatostatin receptors as a distinguishing feature. While the subtype of the five distinct receptors varies among different endocrine tumours, they all bind somatostatin. This feature has provided a novel tool for the imaging of these lesions and their metastases, using a radiolabelled somatostatin analogue, [^{111}In]octreotide. It allows the diagnosis of neuroendocrine tumours and localization of occult metastases or, in some patients with metastatic disease, an occult primary lesion.

Surgery remains the treatment of choice for tumours of the dispersed endocrine system. In patients with localized disease, it can be curative.

In many cases, advanced neuroendocrine neoplasms follow an indolent course. Hepatic metastases are common, and although they can cause significant pain or, in some patients, incapacitating hormone hypersecretion, hepatic metastases are usually asymptomatic. The appropriate timing and efficacy of interventions, including hepatic artery embolization (HAE) and/or cytoreductive surgery remain controversial. While some studies have indicated that earlier resection of the primary tumour was associated with prolonged survival, those with liver involvement by tumour were least likely to benefit from surgical resection. Five-year survival rates range from 40 to 80%. Both HAE and surgical resection provide excellent palliation of hormonal and pain symptoms. In selected patients, surgical resection of hepatic metastases may prolong survival, but this is rarely curative.

The expression of somatostatin receptors by these lesions provides a therapeutic tool. Somatostatin tends to inhibit hormone synthesis and secretion, and there is evidence that it may also inhibit cell proliferation. Native somatostatin, however, has a short half-life and cannot be used therapeutically. Several years ago, a long-acting analogue, octreotide, became available for clinical use as a therapeutic tool; this agent required daily subcutaneous injection. More recently, a longer acting repeatable (LAR) preparation of the somatostatin analogue has been developed with activity lasting nearly 28 days. Its therapeutic efficacy, tolerability, and safety in patients with pituitary and gastroenteropancreatic neuroendocrine tumours have been established. In patients with acromegaly due to pituitary growth hormone excess and in some with functional carcinoid tumour, Zollinger–Ellison syndrome and glucagonoma syndrome the analogue normalizes hormone levels and reduces symptoms. Tumour size does not change significantly and may increase in the rare patient on long-term therapy. The side-effect profile includes transient gastrointestinal upset. Longer term complications include possible worsening of glucose intolerance into frank diabetes mellitus and/or gallstone formation. Another long-acting somatostatin analogue, lanreotide, has also been evaluated, and when compared with the older subcutaenous octreotide preparation, both agents appear to be equally efficacious in terms of symptom control. Thus, it appears that longer acting somatostatin analogues have good therapeutic efficacy, tolerability and safety in the treatment of neuroendocrine tumours. The current analogues, however, lack tumoricidal properties, which limits their overall impact on disease burden. The decision to incorporate this therapy in patients with symptoms related to neuropeptide hyersecretion is usually straightforward. The role of these agents alone or as part of chemotherapeutic agents in patients without neuropeptide hyersecretion symptoms is far less clear.

It has also been suggested that high activities of a radiolabelled somatostatin analogue may have a radiotherapeutic effect. In one recent study, patients with known disseminated neuroendocrine tumours were administered between 1.3 and 4.6 GBq of [^{111}In]octreotide for up to five doses over a 1-year period. The treatments were well tolerated. Further work with this and other radioisotopes including yttrium are now being performed to assess efficacy.

Neuroendocrine tumours are generally very resistant to chemotherapy and therefore chemotherapy is rarely recommended for control or palliation. A larger number of chemotherapeutic agents have been used as single agents or in combination. Streptozotocin (STZ), or glycosamine nitrosourea originally derived from streptomyces has been in use for three decades since initially being found to be active in pancreatic endocrine tumours. Current schedules in common use are the combination of STZ with doxorubicin or 5-fluorouracil (5-FU). Response rates vary according to the type of neuroendocrine malignancy; for example, rates as high as 80% have been reported with metastatic gastrinoma.

Second-line regimen incorporating VP-16 and cisplatin have also been evaluated with useful activity and palliation in some patients.

Tumours of steroid hormone-secreting cells are usually treated surgically. Patients with adrenocortical adenoma are generally cured by surgical tumour resection. Occasional patients with carcinoma experience long survival despite incomplete resection of their tumours, but most patients succumb to recurrent disease with metastases noted within the first 2 years following diagnosis. The adrenocorticolytic medication mitotane provides some temporary relief from cortisol excess in some patients.

Tumours of thyroid follicular epithelium are also most amenable to surgical resection but aggressive surgery is not usually indicated. These lesions have a unique affinity for iodine uptake and therefore microscopic residual disease is usually ablated by administration of radioactive iodine. As thyroid tumours lose their differentiation, one of the manifestations is reduction or loss of expression of the sodium iodide symporter that that is responsible for the success of this form of therapy. Therefore, lack of radioiodine uptake can occasionally mean that disseminated disease is of a less differentiated type. In patients with poorly differentiated or anaplastic carcinomas, or those with gross residual disease of differentiated carcinoma that is not amenable to complete surgical excision, there is a role for external beam radiotherapy.

NORMAL DEVELOPMENT AND STRUCTURE

The female breast (**Figure 1**) is a heterogenous structure which overlies the pectoralis major and minor muscles covering the chest wall. The resting mammary gland consists of 5–10 major duct systems which are arranged in a segmental, roughly radial pattern. These duct systems are subdivided into lobules, which are the functional units of the mammary parenchyma. Each ductal system drains through an individual lactiferous sinus. Successive branching leads to terminal ducts distally, which end blindly prior to puberty. With the onset of menarche (first appearance of the menstrual cycle), the terminal ducts proliferate distally, giving rise to lobules consisting of a cluster of epithelium-lined ductules or acini. Each terminal duct and its ductules compose the terminal duct lobular unit (TDLU) (**Figure 2; see colour plate section**) (Lawrence, 1992; Cotran *et al*., 1999).

The majority of the breast stroma consists of dense fibroconnective tissue admixed with adipose fatty tissue, called interlobular stroma, containing elastic fibres supporting the large ducts. The lobules themselves are enclosed by loose delicate myxomatous stroma that is hormonally responsive and contains scattered lymphocytes (intralobular stroma) (Cotran *et al*., 1999).

Histologically, the intact ducts are composed of an inner layer of cuboidal to low columnar epithelial cells, surrounded by a discontinuous layer of myoepithelial cells, enclosed by a basement membrane (**Figure 3**). It is the inner layer of epithelial cells within the TDLU that gives rise to the common forms of breast cancer.

The lymphatic drainage of the breast is primarily to the axilla, while a minor portion of it courses to the internal mammary nodes (Lawrence, 1992).

EPIDEMIOLOGY AND RISK FACTORS

The incidence of breast cancer in developed countries is 200–250 per 100 000 women per year. One of nine women in the United States will develop breast cancer in her lifetime; one-third of these women will succumb to the disease, resulting in almost 50 000 deaths yearly (Cotran *et al*., 1999). The incidence increases with age with an average age at diagnosis of approximately 65 years. Age-adjusted incidence rates are rising, probably due in large part to an increase in mammographic screening and the changing epidemiological profile of women (White *et al*., 1990). Recognizing risk factors can help identify high-risk patients who need more intense monitoring as well as provide insight into the pathogenesis of the disease (Masood, 1996a). **Table 1** lists the best recognized risk factors. Women in North America and European countries have the highest rates of breast cancer, and those in Asian and African countries have the lowest (Kelsey and Horn-Ross, 1993). Breast cancer only rarely occurs in males.

About 10–15% of cases of breast cancer have a family history of breast or ovarian cancer (Thompson, 1994). With the identification of the breast cancer susceptibility genes *BRCA1* and *BRCA2* on chromosomes 17 and 13, respectively, a genetic predisposition clearly exists. However, many women with a family history of breast cancer do not carry mutations in one of these genes. The gene products of *BRCA1* and *BRCA2* are multifunctional proteins involved in maintaining genomic stability and the response to DNA damage, transcriptional regulation and cell proliferation (Unger and Weber, 2000; Welsch *et al*., 2000). Mutations in these genes are associated with a marked increase in the overall risk of developing breast cancer and a marked decrease in the age of onset. Specific mutations are more common in some ethnic groups (such as the Ashkenazi Jews) (Masood, 1996a; Cotran *et al*., 1999).

AETIOLOGY

Specific cellular changes occur in the progression to breast cancer. The earliest genetic lesions have been identified in morphologically normal breast epithelium near the site of a carcinoma, and usually large chromosomal deletions (Deng *et al*., 1996). In addition, one of the earliest detectable changes is the loss of normal regulation of cell number, resulting in epithelial hyperplastic lesions. Next, genetic instability occurs in multifocal small clonal populations of cells that can be recognized histologically as atypical hyperplasia. Complete replacement of the normal ducts by atypical cells characterizes carcinoma *in situ*; at this point, there are often (but not always) alterations in specific genes, such as the oestrogen receptor gene, *TP53*, *HER-2/neu/erbB-2*, and cyclin D (Devilee *et al*., 1994). Invasion of the surrounding stroma indicates an invasive neoplasm; although this process must be marked by alterations in specific genes leading to dysregulation of proteases, cell adhesion factors and angiogenic factors, the genetic lesions are not well understood. Similarly, the changes seen in breast cancer cells present in metastatic lesions are not well understood, although a recent report suggests that up-regulation of specific chemokines may account for specific organ propensities for harbouring metastases from breast carcinoma (Muller *et al*., 2001). It is hoped that microarray studies will shed light on these processes (Perou *et al*., 1999; Sgroi *et al*., 1999).

SCREENING

Education and diligent breast self-examination improve the possibility of early breast cancer detection. However, regular mammography is the cornerstone of effective screening for breast cancer. Early breast cancers have an excellent prognosis, with increased long-term survival. The American Cancer Society recommends an annual physical examination, beginning at age 40 years, accompanied by screening mammography at 1–2 year intervals until the age of 50, and yearly at age 50 and older (Masood, 1996a). Minimally invasive techniques such as fine-needle

Table 1 Risk factors for developing breast cancer

High risk (>4 times general population)	Moderate risk (2–4 times general population)	Slight risk (1–2 times general population)
Personal history of prior breast cancer	First-degree relative with history of breast cancer	Onset menarche <12 years of age
Family history of bilateral, premenopausal or familial cancer syndrome	Upper social/economic class	Moderate alcohol intake
Proliferative breast disease with atypia	Prolonged uninterrupted menses	
	Postmenopausal obesity	
	Personal history of prior carcinoma of ovary or endometrium	
	Proliferative breast disease with no atypia	

aspiration biopsy (FNAB) (**Figure 4; see colour plate section**) and core-needle biopsy can be used further to classify and assess lesions deemed radiographically 'suspicious' for malignancy. These procedures can be performed with or without radiographic guidance and can provide valuable information regarding which patients require surgical excision, radical treatment or simple follow-up (Masood, 1996b).

DIAGNOSIS

Generally, palpable breast lesions are felt by a patient or discovered by a physician during physical examination. Breast cancer often presents as an irregular, rock-hard mass with ill-defined margins that invade adjacent tissues (**Figure 5; see colour plate section**). The mass usually is not moveable and is inseparable from adjacent tissues. Rarely, patients may show diffuse induration of the breast skin due to the presence of tumour in dermal lymphatics; this is called inflammatory carcinoma. Non-palpable lesions are detected by imaging techniques (mammography with or without ultrasound). Physical exam and radiologic studies can, at best, establish a clinical suspicion of cancer; however, a firm diagnosis of cancer is made only by the pathologist. Pathologic studies include cytologic evaluation of FNAB material or histologic evaluation of tissue obtained by core needle biopsy or surgical excision (Lawrence, 1992; Masood, 1996a,b). (See also chapter *Breast Imaging and Diagnosis*.)

COMMON BENIGN LESIONS

Benign 'masses' or 'mass-like areas' occur far more frequently than cancer, at a rate of almost 10 : 1. Atypical clinical presentation of benign lesions leads to a clinical suspicion of carcinoma, for which pathological confirmation is warranted (Lawrence, 1992). Several benign lesions can mimic the clinical presentation of cancer, as follows.

Fibroadenoma

This is the most commonly occurring benign tumour of the female breast. These lesions are seen in women who are between the ages of 20 and 35 years, and are composed of hormonally sensitive glandular and stromal tissue. Grossly, these tumours are well circumscribed and have a solid, whorled, greyish white, bulging cut surface, with slit-like spaces. Histologically, these benign growths are composed of fibroblastic stroma resembling intralobular stroma, along with epithelial-lined ductal structures that tend to be cystic, elongated or flattened (**Figure 6; see colour plate section**). These tumours lead to a mild increase in the risk of subsequent breast cancer. Surgical excision is curative (Rosai, 1989; Lawrence, 1992; Masood, 1996b; Cotran *et al*., 1999).

Fibrocystic Change

This represents the single most common disorder of the breast and it accounts for more than half of all surgical operations on the female breast. It occurs most frequently between the ages of 25 and 45 years, with a peak incidence just before menopause, and rarely developing after menopause. Hormonal imbalances are considered to be basic to the development of this disorder. Grossly, the involved tissue has a whitish, poorly circumscribed fibrotic appearance, alternating with cystic structures. Histologically, there are alternating areas of fibrosis, cyst formation, apocrine metaplasia, ductal hyperplasia and adenosis (**Figure 7; see colour plate section**). In the absence of significant ductal hyperplasia (also termed proliferative breast disease), fibrocystic changes do not elevate the risk of developing cancer. Once there is histological confirmation of the diagnosis, no further treatment is warranted (Rosai, 1989; Lawrence, 1992; Masood, 1996b; Cotran *et al*., 1999).

Other Benign Lesions

Between lesions such as fibroadenoma and fibrocystic change on the one hand and cancer on the other, there exists a range of breast lesions that impart an increased risk of subsequent carcinoma. These include proliferative breast disease (e.g. ductal epithelial hyperplasia), sclerosing adenosis and papillomatosis (**Figure 8; see colour plate section**), to name a few. These lesions are beyond the scope of this chapter and the reader is referred to the Further Reading section for further discussion of these entities.

DUCTAL CARCINOMA *IN SITU* (DCIS)

The number of cases of DCIS has increased rapidly over the past 20 years with the advent of mammographic screening. The lesion consists of a malignant population of epithelial cells that are confined by the basement membrane. However, these cells can spread throughout a regional ductal system, producing extensive segmental lesions, or later develop into invasive cancer. DCIS may or may not be grossly apparent (Rosai, 1989). Two general classes of DCIS are recognized, as follows.

Comedo DCIS

This is characterized by distended ducts, solid sheets of high-grade malignant cells and central necrosis (**Figure 9; see colour plate section**). The necrotic

material often calcifies and is radiographically detectable. This form of DCIS has a greater malignant potential than other forms.

Non-comedo DCIS

This is the more common form and can have nuclear grades ranging from low to high. The malignant cells have a monomorphic appearance, necrosis and calcifications may be present. Histological variants include solid (**Figure 10; see colour plate section**), cribriform, papillary and micropapillary (Masood, 1996b; Cotran *et al*., 1999). For further discussion of these variants, see the Further Reading section.

PAGET DISEASE OF THE NIPPLE

This is a variant of carcinoma *in situ* in which the nipple skin is involved. Clinically, the patient often presents with a scaling or eczematous lesion of the nipple. Histologically, cancer cells are seen in between normal epithelial cells of the epidermis of the skin. Paget disease of the nipple is the result of intraepithelial spread from an underlying intraductal carcinoma in nearly all cases; in about half of cases there is an associated infiltrating carcinoma.

LOBULAR CARCINOMA *IN SITU* (LCIS)

LCIS is also known as lobular neoplasia. It usually is not grossly evident and is often an incidental finding in breast tissue removed for other reasons. Histologically, the lobules are distended and completely filled by relatively uniform, round, small- to medium-sized cells. Marked atypia, pleomorphism and mitotic activity are usually absent. LCIS is often multifocal in nature and is thought of more as a 'marker' of breast cancer rather than a direct precursor. This is due to the fact that women diagnosed with LCIS have a marked increase in the risk of developing invasive lobular or ductal carcinoma in their lifetimes (Rosai, 1989; Masood, 1996b; Cotran *et al*., 1999).

INVASIVE DUCTAL CARCINOMA, NOT OTHERWISE SPECIFIED (NOS)

This type of carcinoma represents the 'prototype' breast cancer and includes the majority of carcinomas (70–80%) that cannot be classified under any other subtype. Usually presenting as a fixed firm mass with a 'stellate' or 'spiculated' appearance on mammography, it grossly is tan-white with a firm, often gritty consistency and raggedly infiltrating, poorly defined borders (**Figure 11; see colour plate section**).

Histologically, the infiltrating edge of the tumour extends beyond what is visible grossly, warranting ample excision of normal tissue. The tumour itself consists of malignant ductal epithelial cells disposed in cords, solid nests, tubules, anastomosing masses and mixtures of all these patterns (**Figure 12; see colour plate section**).

The cells invade into the surrounding fibrofatty tissue and by elaborating certain chemical signals, stimulate the adjacent fibrous tissue to proliferate (desmoplastic response), giving the tumour its firm consistency. The histological grading of the tumour is based on mitotic count, cytological atypia and degree of tubule formation. Well-differentiated (low histological grade) tumours often display minimal atypia, low mitotic activity and have prominent tubule formation. Poorly differentiated tumours often have marked cytological atypia, prominent mitotic activity and a solid pattern of growth.

Other distinct histological variants of invasive ductal carcinoma include medullary carcinoma, colloid (mucinous) carcinoma, tubular carcinoma (**Figure 13; see colour plate section**) and papillary carcinoma (Rosai, 1989; Cotran *et al*., 1999). For further discussion of these variants, see the Further Reading section.

INVASIVE LOBULAR CARCINOMA

This type of invasive cancer comprises only 5–10% of primary breast carcinomas. It tends to be multicentric within the same breast, with a diffusely infiltrative pattern and tends to be bilateral far more frequently than other subtypes. Grossly, the tumour can be rubbery and poorly defined, or gritty hard with an infiltrating border, similar to ductal carcinoma. Histologically, the 'classical' appearance is that of small epithelial cells with little pleomorphism, that invade in strands only one cell thick (often referred to as 'Indian filing' (**Figure 14; see colour plate section**)). Signet ring cells (i.e. cells in which intracytoplasmic mucin pushes the nucleus to the periphery, resembling a signet ring) are common (Masood, 1996b; Cotran *et al*., 1999).

OTHER TUMOURS OF THE BREAST

Cystosarcoma phyllodes is a rare mixed stromal and epithelial neoplasm that may be benign or malignant. The size varies from 1 cm to >10 cm. The epithelial component is similar to that seen in fibroadenoma, whereas the stromal component is more cellular and has greater mitotic activity. The degree of malignancy is estimated by the degree of cellularity, mitotic rate and cytological atypia. Rarely, benign soft tissue tumours and sarcomas may occur as

primary tumours in the breast. In addition, malignant lymphomas may present in the breast.

SPECIAL STUDIES/PROGNOSTIC INDICATORS

By far the most important prognostic indicator is the stage of the tumour, particularly the lymph node status. When axillary nodes are uninvolved, 10-year disease-free survival approaches 80%, but falls to as low as 10% if 10 or more nodes are involved. Increased size of the metastatic deposit and invasion of the metastasis through the lymph node capsule convey a worse prognosis. A poor prognosis is also associated with locally advanced disease (i.e. skin and skeletal muscle involvement), increased tumour size, histological evidence of lymphovascular invasion and high histological grade (more poorly differentiated) tumours. Some specific histological subtypes of invasive cancer (colloid, tubular, medullary, lobular and papillary) actually are associated with a better prognosis than the 'not otherwise specified' (NOS) subtype (Masood, 1996a; Cotran *et al*., 1999).

Special studies can be performed on cytological or solid tissue specimens submitted to the pathology laboratory. The proliferation rate can be assessed by flow cytometry to determine the fraction of cells actively synthesizing DNA and by immunohistochemistry to detect cellular proteins (such as Ki-67) expressed during the cell cycle. A higher proliferative rate is associated with tumours of more aggressive biologic behaviour. DNA content can be determined by flow cytometry analysis or image analysis. Aneuploid tumours have a slightly worse prognosis. The presence of oestrogen and progesterone hormone receptors within tumuor cells is associated with a better prognosis than those tumours that are receptor-negative. This is due to the high regression rate of receptor-positive tumours in response to hormonal manipulation (i.e. tamoxifen, discussed below). Hormone receptor studies can be performed by immunohistochemical methods (**Figure 15; see colour plate section**).

Loss of function of tumour-suppressor genes such as *TP53* (often detected by an increase in immunostaining of inactivated p53 protein) and increased expression of oncogenes such as *Her-2/neu* are commonly seen in association with other poor prognostic factors. Overexpression of *Her-2/neu* has been correlated with a shorter disease-free interval and shorter overall survival in node-positive or node-negative breast cancers. Patients can also be offered Herceptin (see below), based on *Her-2/neu* tissue studies. p53 and Her-2/neu testing can be performed by immunohistochemical methods (**Figure 16; see colour plate section**) or fluorescent *in situ* hybridization (FISH) studies (Rosai, 1989; Cotran *et al*., 1999; Masood and Bui, 2000).

TREATMENT

Previously, the long-held theory of orderly regional to systemic progression resulted in aggressive local treatment, i.e. radical mastectomy (which included the resection of both pectoralis major and minor muscles). Now, a further understanding of the biology of breast cancer has supported an opposing theory, which states that breast cancer has a nonorderly progression to early systemic spread from inception (Lawrence, 1992). Studies have shown equivalent survival data when modified radical mastectomy (which only removes the pectoralis minor muscle) is compared with lumpectomy (excision of the lesion, with a surrounding rim of normal breast tissue) with or without adjuvant therapy (Masood, 1996a). That being said, surgical therapy still remains the foundation of breast cancer treatment. The extent of the initial surgical procedure is determined by the histological grade of the tumour, clinical stage at presentation and the patient's desire for breast conservation and reconstruction, if appropriate. Axillary nodes are routinely sampled or completely dissected to determine the presence of local–regional metastasis (Lawrence, 1992). Radiation therapy has been employed as a postoperative adjunct (especially in connection with the more limited surgical resections), sometimes as the primary treatment and for the control of locally advanced or recurrent disease (Rosai, 1989). Adjuvant chemotherapy is used in the control of regional (axillary) or systemic metastatic disease. Chemotherapy has also been used in the preoperative treatment of larger, high histological grade breast cancers with or without the presence of axillary metastasis. Tamoxifen, which functionally blocks oestrogen receptors in tumour cells which express them, is used in similar settings to other chemotherapeutic agents (Masood, 1996a; Lawrence, 1992). There also appears to be a role for tamoxifen even in the absence of nodal metastasis. The use of the drug herceptin, which targets cells that overexpress Her-2/neu, has found widespread use in patients with recurrent disease, whose tumours over express the *Her-2/neu* oncogene (Masood and Bui, 2000).

Chapter 43

Female Reproductive System

Beth Euscher, Carl Morisson and Gerard Nuovo
Ohio State University Medical Center, Columbus, OH, USA

CONTENTS

- Normal Development and Structure
- Pathology of the Cervix
- Pathology of the Endometrium
- Uterine Stromal Tumours
- Pathology of the Ovary

NORMAL DEVELOPMENT AND STRUCTURE

The female genital tract consists of the ovaries, fallopian tubes, surrounding adnexa, uterus, vagina, and vulva. Despite their proximity and their similarities in many aspects, such as response to oestrogen and progesterone, the female genital tract actually represents the combination of three distinct regions during embryogenesis. These include the ovaries, which begin as midline structures that migrate to the peritoneal cavity, the Mullerian system, which gives rise to the endometrium, myometrium, cervix and outer part of the vagina, and the ectodermal system, from which the vulva and part of the vagina originate. The mesonephric system, which plays a role in filtration of impurities in early foetal development, is also represented in the female genital tract as rests which are often found in the adnexa around the fallopian tube and in the lateral wall of the cervix; these rarely cause clinically relevant pathology.

PATHOLOGY OF THE CERVIX

Tumour Pathology

Squamous cell carcinoma is the most common tumour of the cervix, accounting for nearly 75% of the tumours from this region. This, of course, is consistent with the observation that the strong majority of premalignant lesions of the cervix are derived from squamous cells, termed squamous intraepithelial lesions (SILs). There are several histological subtypes within the category of squamous cell carcinoma of the cervix. The most common type is moderately well differentiated squamous cell carcinoma, where rare cells show the keratinization diagnostic of this tumour. Less common is poorly differentiated squamous cell carcinoma, where keratin formation is very difficult to find with routine haematoxylin and eosin stain. Interestingly, extremely rare in the cervix is well differentiated squamous cell carcinoma, where keratin pearls and individual cell dyskeratosis are abundant. This is in sharp contrast to the vulva, where well differentiated squamous cell carcinoma is very common. In the vulva, this type is rarely associated with infection by human papillomavirus (HPV) (Nuovo *et al*., 1991). This may explain why this type is so rare in the cervix for, as will be discussed below, over 98% of cervical cancers contain HPV DNA (Crum and Nuovo, 1991; Nuovo, 1994).

Another rare type of carcinoma found in the cervix is small cell carcinoma (**Figure 1**). This very rare variant has a poor prognosis, and is histologically equivalent to the very common small cell carcinoma of the lung. Such tumours are called neuroendocrine tumours, as they are commonly associated with the production of proteins that are part of the endocrine system, such as synaptophysin or chromogranin. (See also chapter *Endocrine Organs*.)

The other type of carcinoma found in the cervix is adenocarcinoma. About 25% of cancers of the cervix are of this type. Although the premalignant variant (adenocarcinoma *in situ*) is a well recognized entity, it is common to find SIL associated with adenocarcinoma of the cervix. This implies that the two entities share a common origin, which is indeed the case as will be discussed in the section Aetiology. Another important point that highlights the relatedness between adenocarcinoma and squamous cell carcinoma of the cervix is the fact that they both originate in the exact same location – the transformation zone of the cervix (Crum and Nuovo, 1991; Nuovo, 1994). There are several subtypes of adenocarcinoma of the cervix. The most common type is a moderately well differentiated

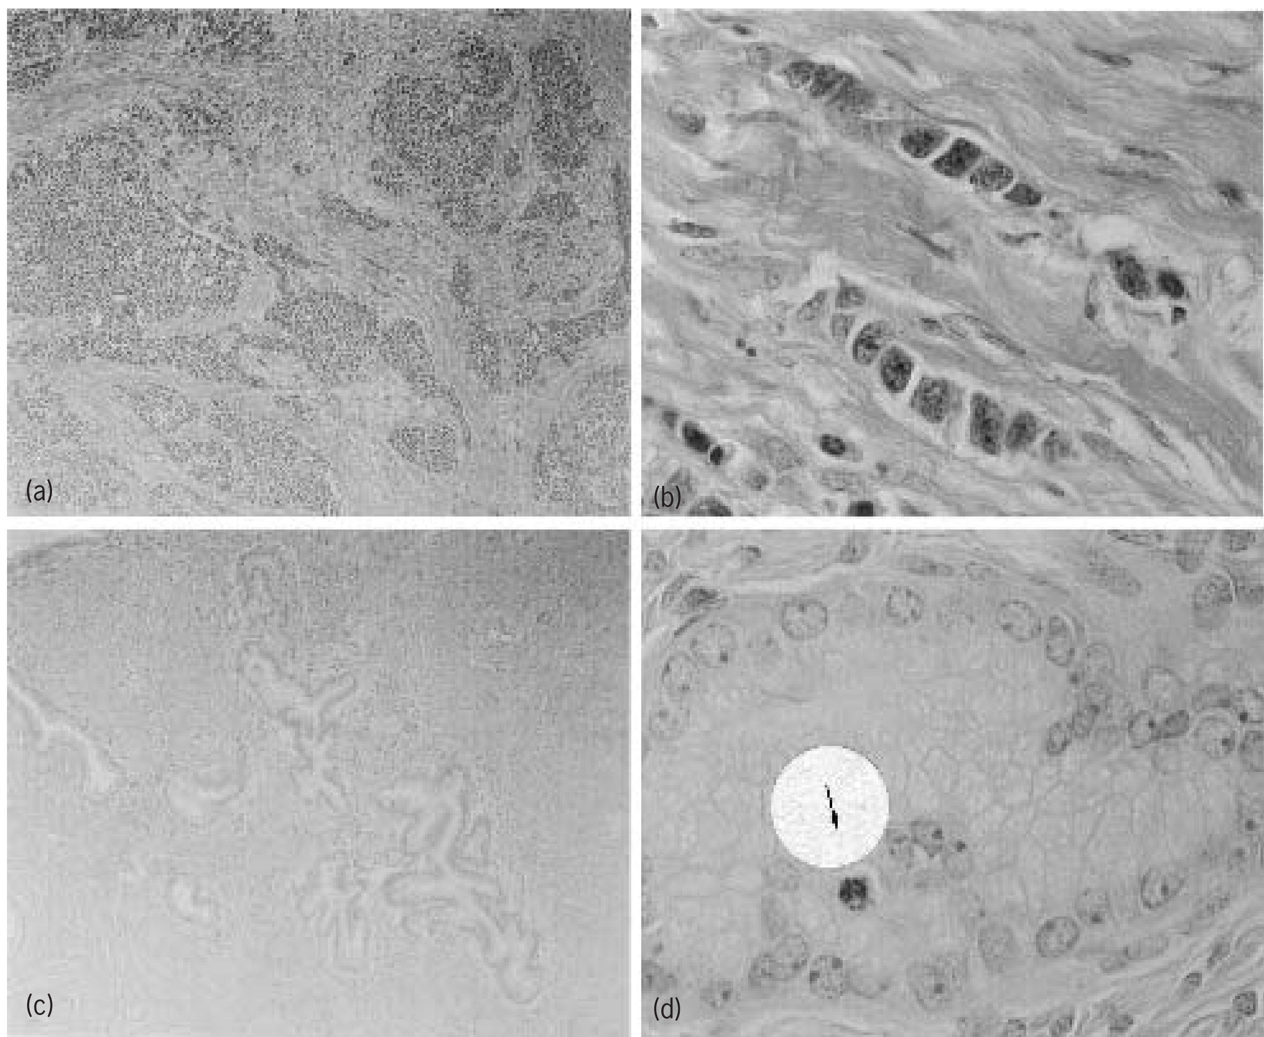

Figure 1 Histology of unusual carcinomas of the cervix. Panel (a) shows the pattern of growth of a small cell carcinoma. At higher magnification (b) note the lack of cytoplasm and nuclear molding. Panel (c) shows the well-formed glands which, however, are invading the underlying stroma. Note the mitotic figure ((d), arrow), characteristic of this tumour, called adenoma malignum. Both lesions contained HPV and showed areas of squamous cell dysplasia.

lesion in which mucous production is easily documented by special stains, such as the mucicarmine or PAS stain (**Figure 2**). At times, such tumours will show cribriform formation, similar to what is evident in endometrial adenocarcinomas. Further, like adenocarcinoma of the endometrium, squamous metaplasia is often identified. As might be expected, it may be difficult – indeed impossible – to differentiate a primary endocervical cancer from an endometrial cancer that has invaded into the endocervix. Similarly, it may be very difficult to differentiate a primary endometrial adenocarcinoma from an endocervical primary that has invaded into the endometrium. These are important clinical distinctions, as they relate to the stage of the disease, which ultimately is the most important indicator of the prognosis of the woman. There is, however, a very simple way to distinguish between endocervical and endometrial adenocarcinoma. This can reliably be done with HPV testing, as endocervical cancer invariably contains HPV whereas endometrial cancer does not contain the virus (**Figure 2**). There are a few other types of endocervical adenocarcinoma to recognize. One is the clear cell variant, which looks histologically identical with the much more common renal cell carcinoma. Interestingly, this is the only type of adenocarcinoma of the cervix that is not found in the transformation zone or associated with HPV. It has been associated with DES exposure *in utero*; it is worth stressing that this is a very rare variant. Also, one should recognize the papillary variant of endocervical adenocarcinoma. On histological analysis, it looks identical with the common papillary serous carcinoma of the ovary (described later). It carries a poor prognosis. Finally, one should realize that the endocervix is the site of a rare variant of adenocarcinoma, very well differentiated, called adenoma malignum. The term adenoma stresses the

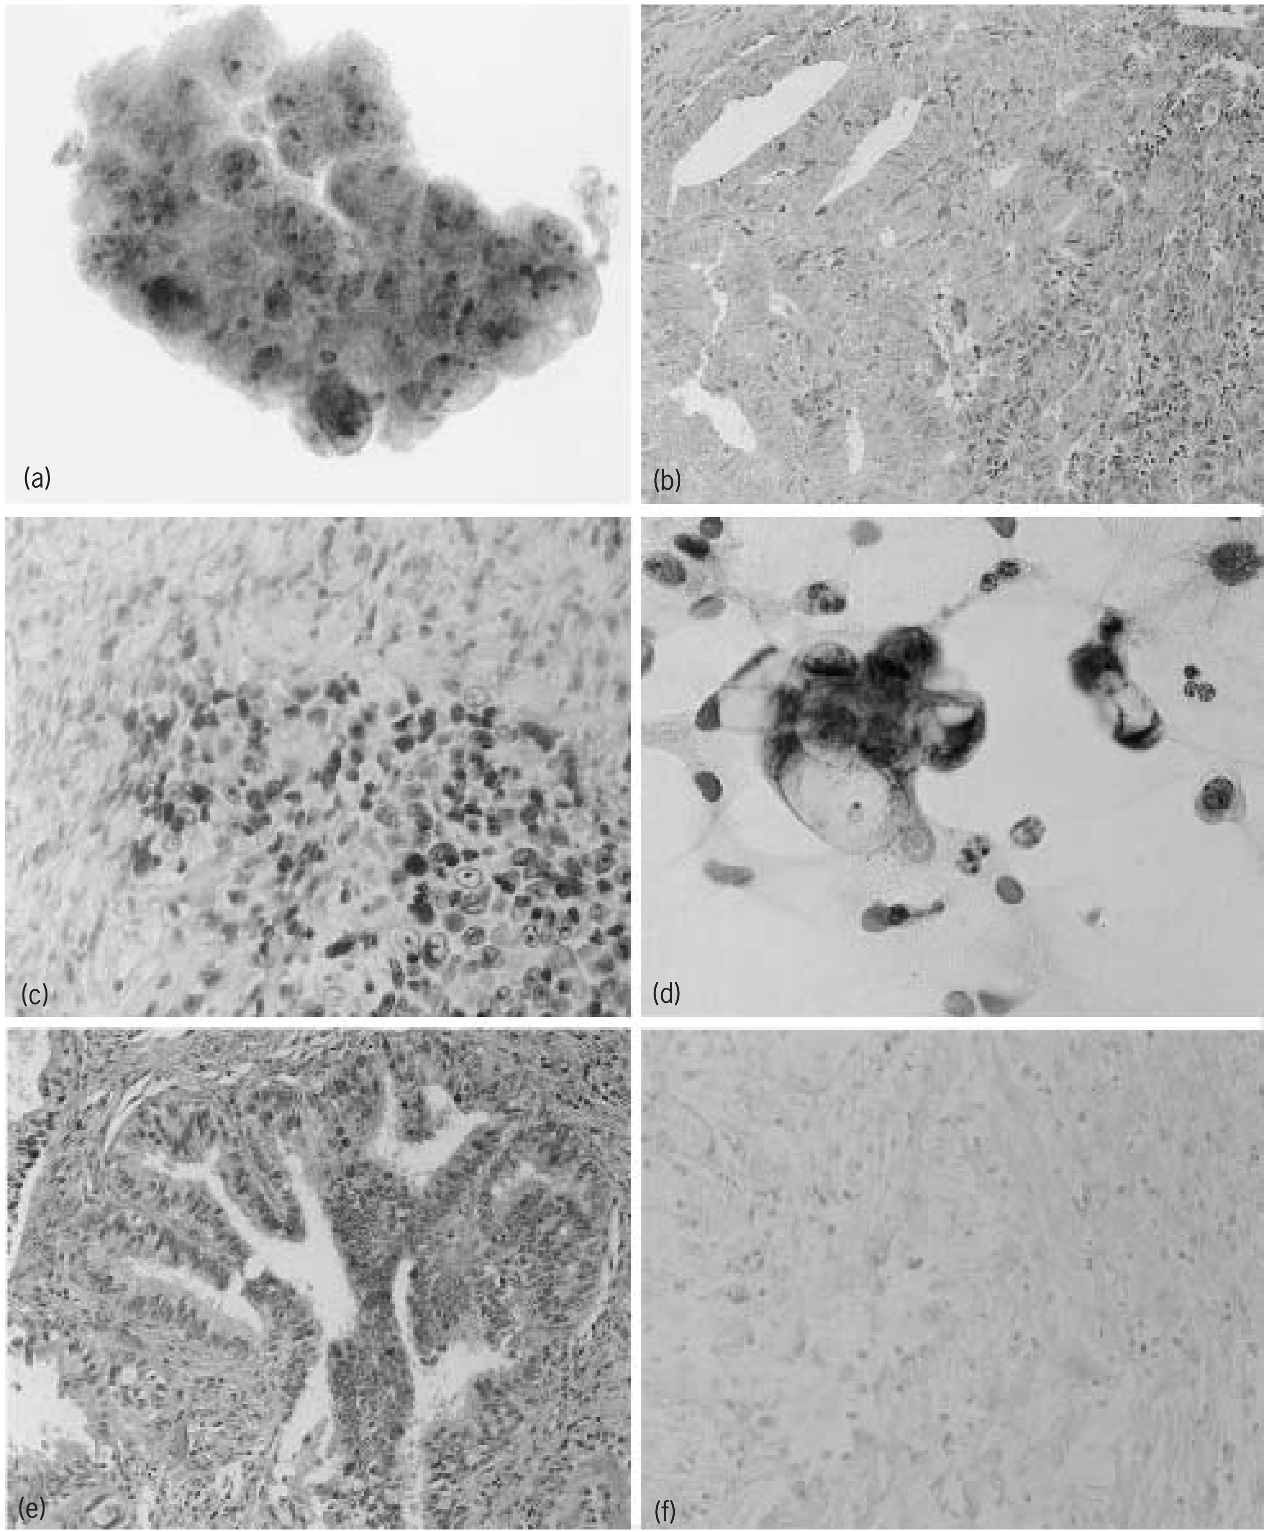

Figure 2 Differentiation between adenocarcinoma of the cervix and endometrium. Panel (a) shows the cytology of an adenocarcinoma from a Pap smear; note the variable cell density. The histology shows similar disorganisation (b); the lesion contains HPV 18 (panel (c), dark-staining cells are positive) confirming that the lesion is from the cervix. Compare this to the cytology ((d), Pap smear of the cervix) and histology (e) of a similar appearing tumour that was in the endometrium. HPV testing showed this to be HPV negative (f), confirming that it was an endometrial cancer.

fact that the glands are remarkably bland in appearance. Two features, mitotic activity (which is a very good marker of adenocarcinoma of the cervix) and branching, or claw-like glands infiltrating the stroma, are what allow one to differentiate adenoma malignum from normal endocervical glands (**Figure 1**).

Epidemiology

The cervix is unique in how well the epidemiology of cancers and precancers at this site are understood. Simply put, the epidemiological data for years have pointed to a sexually transmitted factor. Many years ago, before molecular techniques were so widely available, nearly every agent of sexually transmitted diseases (STDs) was implicated. In the early 1980s herpes simplex virus was a leading candidate (Crum and Nuovo, 1991; Nuovo, 1994). It would take the advent of molecular cloning and hybridization to realize that the actual agent was a virus, HPV. HPV is a small DNA virus – it contains only about 8000 base pairs – which cannot be grown in the laboratory. Its fastidious nature and small size are very well suited to study by molecular hybridization techniques. HPV will be discussed in detail in the Aetiology section. As noted above, it is well documented that the primary risk factor for a woman for developing cervical cancer is her number of sexual partners. This does not relate just to the actual number of her sexual partners, but also the number of female partners for the males with whom she has had sexual relations; this is the so-called 'high-risk male.' Clearly, if a man has had many partners this would put any given woman at higher risk of acquiring any sexual disease as compared with a man who has no other sexual partner. It also follows that groups where monogamy is strictly practiced, as is true of certain religious sects, or women who have not had sexual intercourse, such as nuns, are at very low if not zero risk for developing cervical cancer. Many other factors have been related to increased risk of SIL or cervical cancer, including cigarette smoking, but none has shown the strong correlation related to venereal transmission. It should be added that viruses related to HPV are common in many mammals, including monkeys, where a clear sexual spread has been documented (Crum and Nuovo, 1991; Nuovo, 1994).

Whereas HPV is very tropic for squamous epithelium and it cannot survive long without contact with such tissue, it follows that barrier methods of contraception may be useful in preventing the spread of this disease. Although this has been documented, the protection does not appear to be complete. Given the strong correlation between HPV infection and sexual transmission, an obvious question is whether any sites other than the genital tract show a high relationship between squamous tumours and HPV infection. Indeed, there are two other sites where the association is as strong as in the cervix, namely the periungual region (fingernail bed) of the fingers and, to a lesser extent, the toes and the conjunctiva (Eliezri *et al.*, 1990). Whether cancers at these sites are acquired sexually is unclear, although they do contain the same HPV types as found in the cervix and cases of co-existent cervical dysplasia and periungual dysplasia have been documented. Although tumours of the oral cavity and head and neck region in general have been associated with HPV infection, the association is much less, as is the correlation between sexual risk factors (oral sex) and tumours at these sites. In head and neck tumours, cigarette smoking and alcohol use are the most important risk factors.

Aetiology

As indicated above, the aetiological agent of cervical cancers and SILs is HPV. Of course, not all women exposed to HPV develop cervical SILs or cancer, but infection by the virus is prerequisite for SILs (and ultimately cancer) to develop. A great deal of attention has been given to the function of the different genes (called open reading frames (ORFs)) of HPV, to understand better what is the actual mechanism whereby this virus induces cervical SILs and cancers. HPV, as noted above, is a small virus and has seven early ORFs (E1–E7) and two ORFs that appear later in the infectious cycle (L1 and L2). As might be expected, the late ORFs are involved with production of the protein capsid coat that covers the virus immediately before it leaves the cell. Several of the early ORFs have been shown to be essential for the oncogenic effects of HPV using *in vitro* models. Specifically, ORFs E6 and E7 are capable of transforming normal squamous cells into cells that look identical with dysplastic squamous cells. However, E6 and E7 are not capable of making the normal squamous cells become invasive, that is, malignant. For this to happen, other molecular events must occur, as will be discussed below under Molecular Genetic Findings. It is now clear how E6 and E7 function. They both are capable of binding to and thus inhibiting the action of two important tumour suppressor gene products, p53 and Rb. Both p53 and Rb function to keep a cell's growth in an organized mode. If these proteins are blocked, the cell starts to proliferate at a much higher rate, which is evident under the microscope as hyperplasia. Further, the cells show enlarged, hyperchromatic nuclei that are the features of dysplasia on microscopic examination (Crum and Nuovo, 1991; Nuovo, 1994).

As noted above, there are about 20 HPV types that may be found in cervical SILs. It can be seen from **Table 1** that these types predominate in low-grade SILs. Fewer HPV types are found in the high-grade lesions and invasive cancers. This has an important implication when analysing for HPV.

Table 1 Correlation of HPV type and histology (%)

	HPV 6/11	HPV 16	HPV 18	HPV 31/35/51	HPV other[a]
Cervix					
Low grade SIL	18	34	3	28	17
High grade SIL	0	77	2	18	3
Cancer:					
Squamous cell	0	55	30	10	5
Adeno	0	31	66	2	1
Vulva/penis					
Low grade	96	1	0	0	3
High grade	0	92	0	7	1

[a] HPV other refers to HPV 33, 40, 41, 42, 43, 44, 45, 51, 52, 56, 68 and 70.

Screening and Prevention

Screening for cervical SIL is an excellent example where routine prevention has greatly reduced the incidence of a cancer. In the United States where cytological screening is common, cervical cancer is a relatively rare disease, with an incidence of about 15 000 cases per year, which is far below the rate for other cancers in women, such as breast cancer and lung cancer. However, in other countries where routine cytological screening is not done, such as in Columbia, cervical cancer is the leading cause of cancer death in women. Of course, the screening test for cervical SILs is the Papanicolaou smear (Pap smear). However, a newer test has been proposed for the purpose of screening for cervical SILs, namely HPV testing (Crum and Nuovo, 1991; Nuovo, 1994).

The function of the Pap smear is to have a cytotechnologist examine under the microscope a large sample of the surface cells of the cervix. It is very important to understand the histology and dynamics of the cervix. The cervix contains two distinct types of epithelium, the squamous cell and the glandular cell. The glandular cell layer is one cell thick, whereas the squamous cell layer is many cells (usually around 10–15 layers) thick. The thicker the epithelium, the whiter it appears on gross or macroscopic examination, owing to the masking of the underlying blood vessels. Hence the outer portion of the cervix (called the ectocervix), lined by squamous cells, is white, whereas the inner portion of the cervix (called the endocervix), lined by glandular cells, is pink. The key concept to remember is the transformation zone, which is the area where the squamous epithelium and glandular epithelium meet. At the transformation zone, the squamous cells replace the glandular cells owing to a process called squamous metaplasia (**Figure 3**). In that HPV usually initially infects the metaplastic squamous cells, it follows that cervical SILs originate in the transformation zone. With this realization, one can see why it is so important that the clinician take a sample from the transformation zone when a Pap smear is done. To document that this has happened, the cytotechnologist looks for either the metaplastic squamous cells or the endocervical glandular cells, because if he/she sees the latter, it is assumed that the clinician must have also sampled the transformation zone. Failure to see either cell type raises the question of whether the transformation zone was not sampled, and if so it is more likely that if a SIL was present, it may have been missed (Crum and Nuovo, 1991; Nuovo, 1994).

Figure 3 depicts the normal epithelial cells that are seen on a Pap smear. These include two types of mature squamous cells, called the superficial and the intermediate cells. These terms refer primarily to cytoplasmic features, such as colour, which are under the influence of oestrogen and progesterone, in the cervix and to a greater degree in the vagina. The parabasal cell is rarely seen in the Pap smear, as in most cases it is not present near the surface and hence not likely to be sampled. The parabasal cell can be seen in atrophy, where the mature squamous cells are much reduced in number owing to the marked reduction in the amount of oestrogen and progesterone. The metaplastic squamous cell was described above. Finally, the glandular cells, often present in well-defined groups that resemble a honeycomb, should be evident on a Pap smear (**Figure 3**). Other cell types are commonly found in the Pap smear. These include several types of inflammatory cells, such as the neutrophil, lymphocyte and macrophage. Large numbers of neutrophils at times indicate acute cervicitis, which can be due to many causes including infection by *Candida* or *Trichomonas*. HPV does not cause an acute infection.

Most laboratories that deal with Pap smears taken as a screening test from primarily premenopausal women report that around 90% of the smears are within normal limits or negative for malignant cells. It is important to stress that findings such as inflammation and the associated squamous cell changes (**Figure 3**), often called reparative or reactive, are considered within normal limits at least in the context of precancers of the cervix (Crum and Nuovo, 1991; Nuovo, 1994). Of course, if there is severe inflammation and an organism such as *Trichomonas* or *Candida* is identified, this needs to be reported, but even such cases may be signed off as ‘negative for malignant

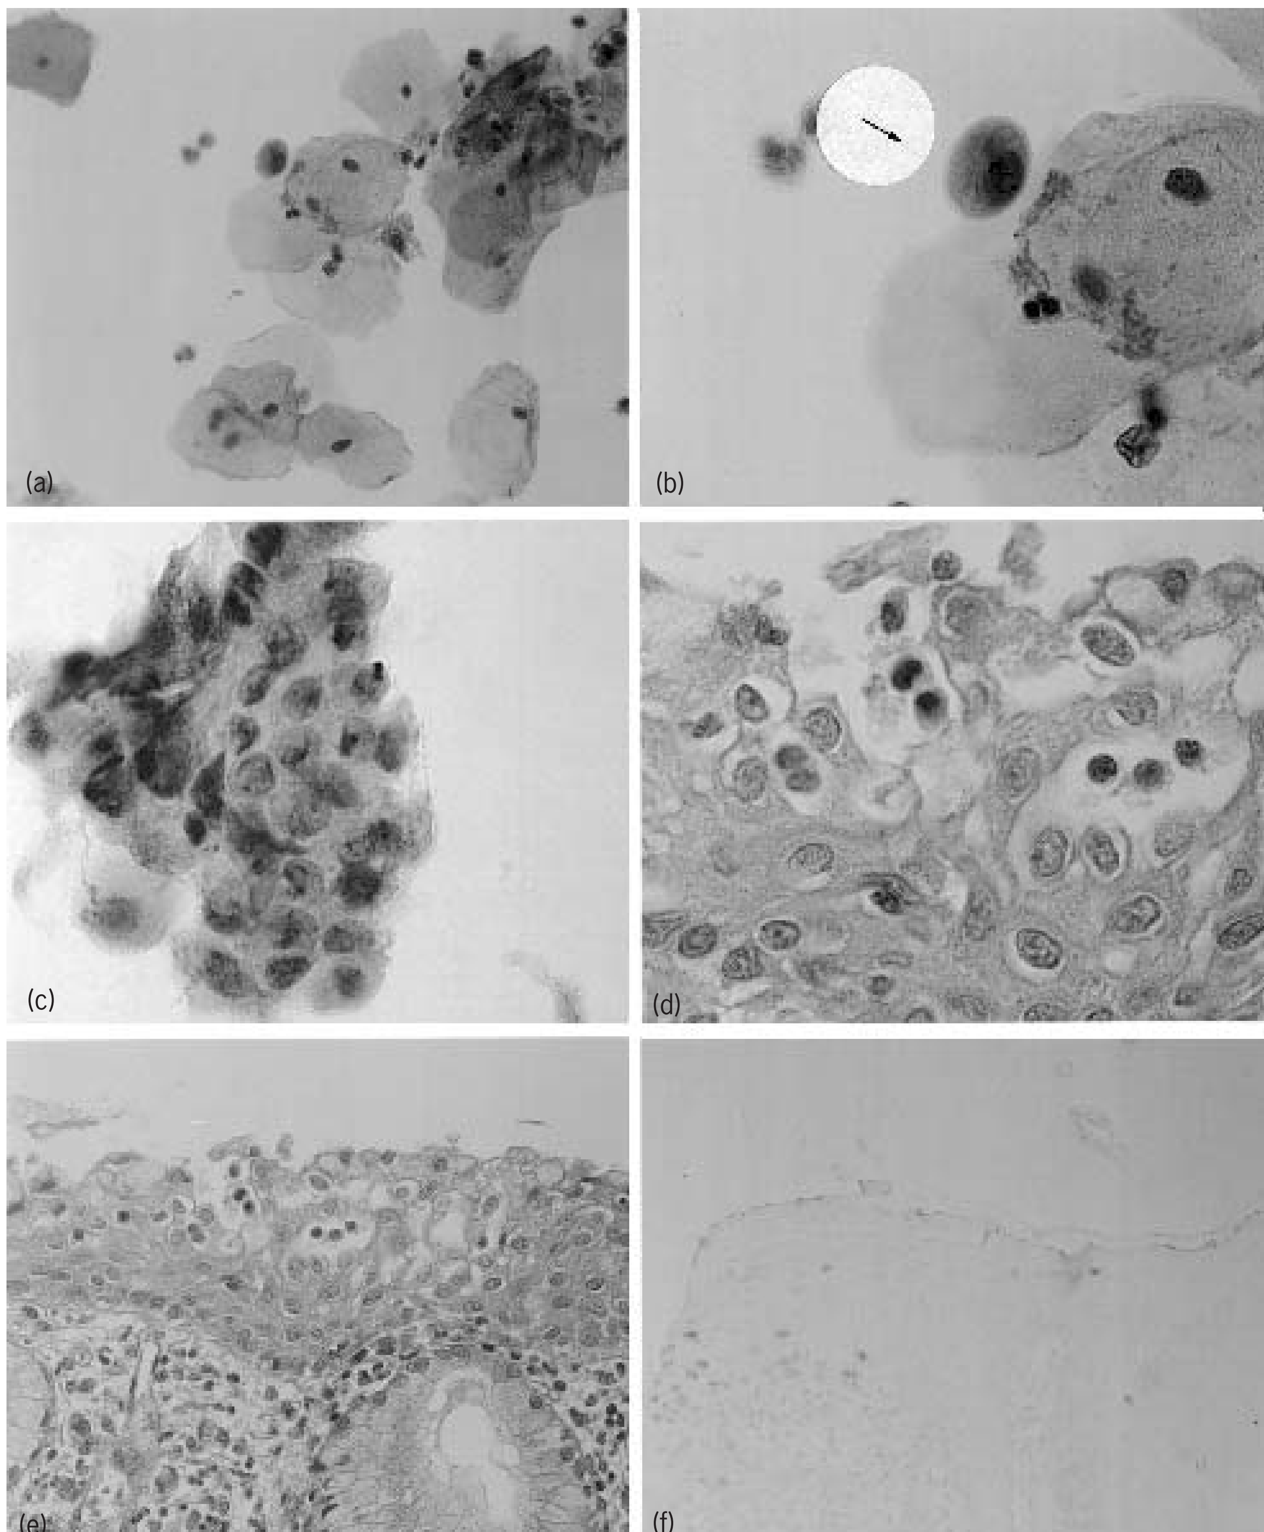

Figure 3 Morphological findings in the normal cervix. Panel (a) shows the squamous cells of a normal Pap smear; note the large amount of cytoplasm and small nucleus. Panel (b) shows the benign metaplastic cell with its small vacuoles (arrow). In panel (c), the honeycombed appearance of benign endocervical cells is apparent. The corresponding histology shows squamous metaplasia ((d) and, at lower magnification, (e)) which, as expected, are negative for HPV using *in situ* hybridization (f). Note that the nuclei are very uniform in squamous metaplasia.

cells,' with a comment that severe inflammation and a specific organism are identified. About 5–8% of Pap smears will be called ASCUS (atypical squamous cells of undetermined significance). This means that the cytological changes suggest but are not diagnostic of SIL. The remainder of Pap smears are diagnosed as SIL, most of these being low-grade SILs.

The diagnosis of low-grade SIL on a Pap smear is made on the basis of two cytological changes: (1) a large, well-defined perinuclear halo surrounded by a thin, clear-cut rim of cytoplasm; (2) enlarged nuclei that show hyperchromaticity (that is, increased darkness on the Pap stain). An example of low-grade SIL is provided in **Figure 4**. Note that the nucleus, although increased in size, is still surrounded by ample cytoplasm.

The diagnosis of high-grade SIL on a Pap smear is made on the basis of two cytological changes: (1) a high nuclear to cytoplasmic ratio (2) a marked increase in the chromaticity of the nucleus. An example of high-grade SIL is provided in **Figure 5**. Note that the nucleus shows an irregular distribution of chromatin and that, overall, there is a substantial increase in chromaticity. It should be added that irregularities in the contour of the nuclear membrane are also considered a diagnostic feature of high-grade SILs, and may also be seen in low-grade lesions. It is considered that the increased pressure that the cells are subjected to in the preparation of the ThinPrep makes such nuclear membrane irregularities common, including in many cases of cells that are clearly not SIL (G. J. Nuovo, unpublished observations). Hence, although abrupt changes or notches in the nuclear membrane are a feature of SIL in the conventional Pap smear, it is considered that they are not a reliable marker of such in the ThinPrep smear.

When the classical changes of low-grade or high-grade SIL are evident on a Pap smear, the diagnosis can be made easily and without equivocation. The difficulty arises when the Pap smear shows features suggestive but not diagnostic of SIL, i.e. ASCUS. There are four conditions which are the cause of most cases of ASCUS: reactive changes due to inflammation in mature squamous cells (mimic of low-grade SIL), reactive changes due to inflammation in immature metaplastic cells (mimic of high-grade SIL), SIL (usually low-grade) and atrophy. Let us examine each of these conditions.

Reactive changes in mature squamous cells are probably the most common cause of ASCUS. Inflammation in the cervix is common and can be due to many agents, such as *Candida* and *Trichomonas*, although in many cases a specific aetiological agent cannot be identified. Whenever there is inflammation, the mature squamous cells will usually demonstrate two cytological changes: a small perinuclear halo which does not show a clear-cut condensed rim of cytoplasm and a slightly enlarged nucleus. However, the enlarged nucleus does not show enough hyperchromaticity to warrant a diagnosis of low-grade SIL. Often, the nucleus will show a nucleolus and/or a nuclear groove, which are useful clues that one is dealing with reactive changes and not true SIL. The difficulty arises when inflammation occurs in the setting of a SIL. It takes experience to be able to 'factor out' the reactive changes in the cells and decide if there still is adequate atypia to warrant a diagnosis of SIL.

Reactive changes in immature metaplastic cells are also a common cause of ASCUS, especially in the ThinPrep sample. It will be recalled that squamous metaplasia is a ubiquitous process in the cervix. When there is associated inflammation, which is also common, the metaplastic cells will demonstrate an increased nuclear to cytoplasmic ratio. It is important to realize that metaplastic cells commonly show darkened nuclei, which of course is also a feature of high-grade SILs. The most reliable way to differentiate high-grade SIL from reactive immature squamous metaplasia is to realize that the latter will show a strong uniformity in the nuclear chromaticity from one cell to the next (**Figure 3**). It is just as important to realize that there are cases when it can be difficult to decide whether the chromaticity is uniform or variable enough to warrant a diagnosis of high-grade SIL versus reactive squamous metaplasia – in such cases, of course, the diagnosis of ASCUS is completely appropriate.

Atrophy is characterized by an increase in the nuclear to cytoplasmic ratio, but not perinuclear halos. Thus, it can mimic a high-grade SIL. The key is to realize that atrophic cells will not have hyperchromatic nuclei.

A common cause of ASCUS is SIL. In some cases, there simply are not enough dysplastic cells for the cytopathologist to make an unequivocal diagnosis of SIL. This may well be a sampling issue, where either the lesion was too small and not enough cells were present for a definitive diagnosis or the SIL was not adequately scraped during the procurement of the Pap smear. In other cases, the cytological changes are not considered to be clear-cut enough for this diagnosis; this often is the case for low-grade lesions. Indeed, it has been well documented that low-grade SILs due to the so-called benign HPV types 6 and 11 often do not show the classical cytological features of low-grade SIL but rather may be interpreted as normal cells, or more commonly, ASCUS (Nuovo, 1994). How does one differentiate true SILs, either low or high-grade, from their mimics? Although some groups have tried to make this distinction on cytological criteria, or using immunohistochemistry for nonspecific markers of increased cell proliferation, in the authors' opinion these variables are not sensitive enough. There is a very sensitive and specific way to make the distinction of ASCUS – benign versus true SIL – namely by HPV testing.

HPV testing is often done with a method called the hybrid capture technique. This is a very sensitive test that is similar to the older dot blot hybridization assays. In these tests, the cells are destroyed and their DNA is retrieved. A sample of the DNA is then hybridized with HPV DNA or RNA probes, and the complex is detected in a variety of

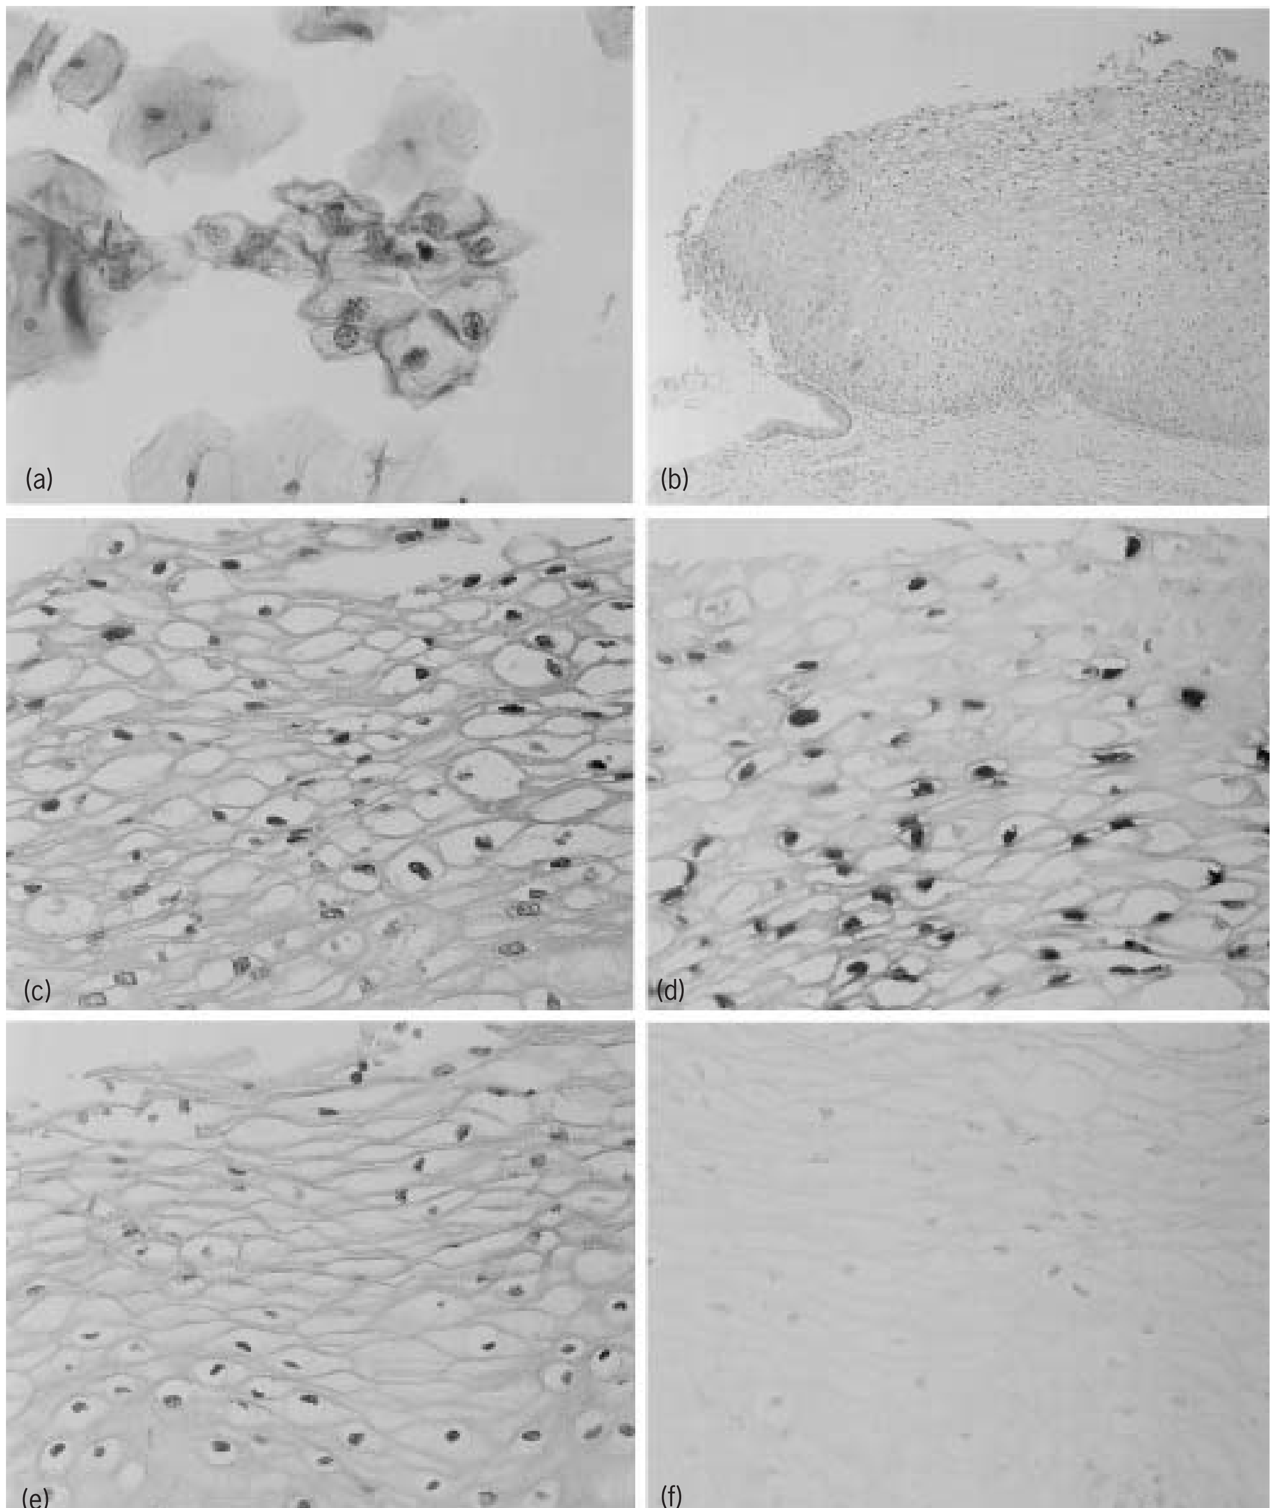

Figure 4 Morphological findings in low-grade SIL. Panel (a) shows the classical large, well-defined perinuclear halos and enlarged nuclei of a low grade SIL. Panels (b) and (c) (higher magnification) show the variable cell density, varying sized and shaped halos and nuclear variability towards the surface that are characteristic of the disease. The lesion contains a large amount of HPV 51 ((d), dark-staining cells mark HPV). Note the well-ordered appearance of the adjacent epithelium (e) that is HPV negative by *in situ* hybridization (f).

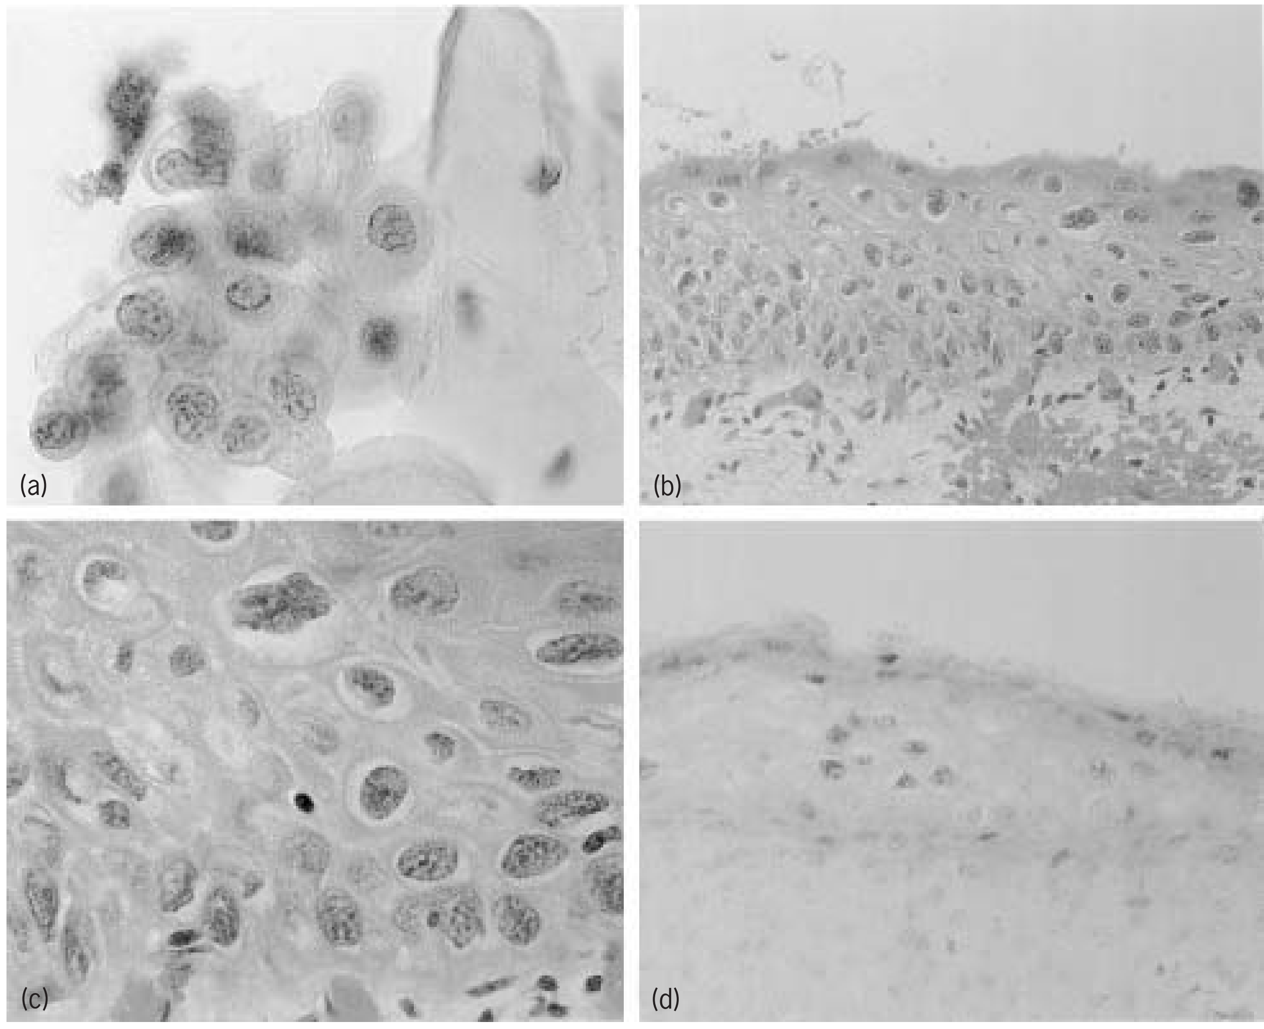

Figure 5 Morphological findings in high-grade SIL. Panel (a) shows the Pap smear; note the hyperchromaticity of the cells and the sharp, abrupt indentations in the nuclear membrane. The biopsy shows a relatively thin epithelium (b) that contains highly atypical cells showing variable cell density and concomitant nuclear atypia (c). HPV 16 is present (d), but in smaller numbers compared with the low-grade SIL (**Figure 4**).

ways (formerly using radioactivity, now more commonly using enzymes complexed to the HPV probes that either cause a colour or light emission to mark the presence of HPV in the sample) (Nuovo, 1997). If enough HPV probes are included to detect most of the 20 HPV types that can be found in the cervix (see **Table 1**), then this system will detect HPV in over 90% of cases of SIL, even if they are called ASCUS. The problem with this test is that they also detect HPV in the absence of ANY cytological changes. That is, about 15–20% of women will have HPV detected with this test, even if there Pap smears are completely normal. Thus, such tests have relatively low specificity. In that it is not clear what the significance is of detecting HPV in the setting of a normal cervix (i.e. a cervix without SIL), and most clinicians do not recommend treatment when HPV is found in this setting, it would be useful to have a test with high sensitivity, but better specificity so as not to detect HPV when no SIL is present.

HPV detection by *in situ* hybridization offers certain advantages over the more sensitive techniques of polymerase chain reaction (PCR) or dot blot hybridization/hybrid capture. First, the HPV is directly detected within intact cells, and thus one can correlate the cytological findings with the viral results. Second, with a probe cocktail that can detect most HPV types, over 90% of low-grade SILs will be positive. Finally, it is very rare (less than 1%) to detect HPV by *in situ* hybridization in a normal-appearing cell from the cervix (Crum and Nuovo, 1991; Nuovo, 1994). We undertook a study that tested all cases of ASCUS for HPV by *in situ* hybridization where there was a biopsy within 6 months of the Pap smear. The data are presented in **Table 2**. Note that the detection of HPV by *in situ* hybridization was an excellent way to differentiate cases of ASCUS associated with a biopsy where only benign reactive changes were seen (HPV negative) from those where an actual SIL was evident on biopsy (HPV positive).

Table 2 Correlation of detection of HPV by *in situ* hybridization with the cytology and, for cases of ASCUS, clinical outcome

Pap smear diagnosis	HPV detection
Normal	1/25 (4%)
SIL	22/25 (88%)
ASCUS (Total)	20/40 (50%)
ASCUS with biopsy proven SIL within 6 months	17/21 (81%)
ASCUS with biopsy negative for SIL within 6 months	3/19 (16%)

Gross/Histopathology/ Immunohistochemistry/EM

The gross findings of the cervix are viewed under magnification using a device called the colposcope. Colposcopy typically involves looking at the cervix from 4× to 25× after applying a weak solution of acetic acid. The acetic acid solution will remove the mucous and highlight any areas where there is increased cellular density which will appear dark white (hence acetowhite lesions). Recall that the outer part of the cervix nearest the vagina (the portio) is white and the endocervix pink because the former is covered by a thick multilayer of squamous cells which masks the underlying blood vessels, which is responsible for the pink colour of the endocervix. It is important to realize that any process which causes a focal increased density of cells in the cervix, be it SIL, inflammation or squamous metaplasia, will produce an acetowhite patch. Hence the presence of such is simply an indicator for the colposcopist as to where to biopsy, and is not diagnostic of a SIL. To diagnose a SIL, a biopsy must be done.

The histological findings of low- and high-grade SIL are shown in **Figures 4** and **5**. Note that in either case, one uses the presence of a disorganized growth pattern (i.e. variable cell density, where some of the cells are closely packed and in other areas some of the cells are widely spread apart) as the most useful feature to diagnose a SIL on biopsy. It is important to stress that this is a low-power (4× or 10×) pattern to view under the microscope. Newcomers to the field often make the mistake of focusing their attention on the cytological details at high magnification. Although useful to see hyperchromatocity, one can usually make the diagnosis on histological grounds at low magnification, using the organisation of the cells as the key variable.

The immunohistochemical analysis of SILs is for the most part non-specific. That is, one can detect in greater number certain proteins that are indicative of the increased cellular proliferation evident in SILs, such as Ki-67. As indicated above, there is one highly sensitive and specific immunohistochemical stain for SILs, namely HPV detection. However, HPV detection via the protein coat of the virus is not very sensitive, as in many cases the virus does not produce enough of its capsid for detection by this method, especially in high-grade SILs and cancers (Crum and Nuovo, 1991; Nuovo, 1994). HPV DNA detection by *in situ* hybridization on biopsies, as on Pap smears, is very sensitive and specific. **Figures 4** and **5** show examples of the detection of HPV by *in situ* hybridization in SILs and cervical cancer. Two important points need to be stressed. First, there are cases where the histological changes are suggestive but not diagnostic of low-grade SIL. These are often biopsies where there is a lot of inflammation and where the Pap smear is called ASCUS. In these instances, HPV testing by *in situ* hybridization is a very reliable way to differentiate those tissues that actually are SIL from its mimics. The importance of this cannot be overstated, given that an over-diagnosis of SIL can cause serious emotional distress for the patient. In the authors' opinion, such equivocal cases should be signed off with the HPV *in situ* test; positive is low-grade SIL and negative is nonspecific reactive changes, negative for SIL (Crum and Nuovo, 1991; Nuovo, 1994). Second, the number of virus particles in high-grade SILs and, especially, invasive cancers is much reduced relative to low-grade SILs. To detect the virus reliably in invasive cervical cancer, one must use either PCR or, if one wishes to localize the virus to a specific cell type, PCR *in situ* hybridization.

Electron microscopy findings in SILs are often nonspecific; actual viral protein is detected occasionally in low-grade SILs as it is in this condition where numerous viral particles may be made. In low-grade SILs, electron microscopy shows that the perinuclear halo consists of a clear zone where the cytoplasm and cell organelles have been pushed to the outer aspect of the cell. Electron microscopy is not a useful method for detecting HPV infection of the cervix.

Molecular Genetic Findings

The molecular genetic findings of SILs centre around two important onco-proteins made by the virus, called E6 and E7. These proteins are capable of inhibiting two important proteins, specifically p53 and Rb, respectively. The E6 and E7 proteins from the oncogenic HPV types, such as HPV 16 and 18, are much more avid in their inhibition of p53 and Rb than the benign HPV types, such as HPV 6 and 11. However, it is now clear that other suppressor gene products, that are not apparently inhibited at all by HPV, are more commonly inhibited in the evolution of cervical cancer. Specifically, p16 is inactivated in nearly all cells in high-grade SILs and cancers, whereas such lesions contain many cells where p53 and Rb are still active, as the virus did not produce either E6 or E7 in those specific cells (Nuovo *et al*., 1999). Finally, it is now clear

that certain host RNAs are selectively increased or decreased in production as lesions progress from SIL to cancer, and again this appears to be independent of HPV interactions. Matrix metalloproteases (MMPs) are enzymes that help cells digest collagen, as is needed in healing of tissue damage. Cervical cancer cells make more MMPs and less of their inhibitors (TIMPS) as they progress from microinvasive cervical cancer (with its good prognosis) to invasive and metastastic cervical cancer (Crum and Nuovo, 1991; Nuovo, 1994).

Prognostic Factors

The primary prognostic marker of cervical cancer is its stage, which is how far it has infiltrated local tissues. It is important to stress that neither HPV type nor histological/cytological findings can accurately predict which SILs will progress and which will regress. The only exception to this statement is the observation that low-grade SILs that contain HPV 6 or 11 usually, if not always, regress.

Overview of Present Clinical Management

About 10 years ago, the treatment for cervical SILs was a simple office procedure called cryotherapy. The key clinical factor was whether the entire lesion could be visualized at colposcopy. If it could not, then the transformation zone of the cervix had to be removed surgically (called cone knife cone biopsy) to document that the lesion was not invasive in the canal and to remove it completely. However, if, as in most cases, the SIL could be seen in its entirety with the colposcope, then a simple 5-min office procedure could eradicate the virus and the lesion in about 90% of women. Over the last 10 years, this has shifted from cryotherapy to using laser ablation, which is equally effective but more expensive. Over the last several years, many gynaecologists have switched to a modified cone biopsy (usually smaller) using a metal loop and electrocautery procedure (LEEP). This procedure usually removes the entire lesion, but may have to be done in an operating room under general anaesthesia. The recurrence rates after LEEP are similar to those seen after cryo- or laser therapy (Crum and Nuovo, 1991; Nuovo, 1994).

The management of cervical cancer depends on stage. For microinvasive cancer, a cone biopsy or LEEP is curative. For more deeply invasive cancers, either surgery plus chemotherapy or, at times, radiotherapy are indicated. Death is usually due to renal failure secondary to obstruction of the ureters by the tumour. Studies using vaccines against HPV to treat cervical cancer are too preliminary but do not appear to be very effective, perhaps reflecting the decreased role of HPV at this advanced stage.

PATHOLOGY OF THE ENDOMETRIUM

This part of the chapter will focus on tumours of the endometrium and myometrium. In order to understand endometrial pathology, it is important to appreciate the effects of oestrogen and progesterone on the normal endometrium. It is the balance of these hormones that allows for normal function of the endometrium such as preparation for embryo implantation and normal menstrual cycles. Oestrogen stimulates proliferation (and thus mitotic activity) in the glands and stroma. Progesterone inhibits mitotic activity, and rather stimulates secretions in the glands and changes in the stroma called predecidualization, where the cells acquire more cytoplasm. The key point to remember is that unopposed oestrogen will induce continued mitotic activity and gland growth, which is a central point in the development of endometrial tumours (Deligdisch, 2000).

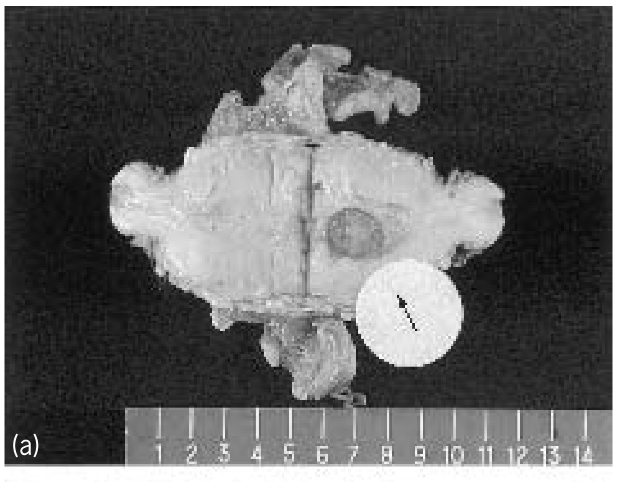
Tumour Pathology

A variety of tumours and tumour-like conditions can occur in the uterus. **Table 3** gives a list of the more commonly encountered tumours in the uterus.

Endometrial polyps are benign, localized lesions which protrude into the endometrial cavity (**Figures 6 and 7**) and represent focal hyperplasia of the endometrium. Variable amounts of endometrial glands, fibrous stroma and blood vessels will be present. If a significant amount of smooth muscle is present, the polyp is referred to as an adenomyomatous polyp. Polyps are common, occurring most frequently in women 40–50 years old; the presenting symptom is often abnormal uterine bleeding. Tamoxifen

Table 3 Commonly encountered uterine pathology

Benign endometrial lesions
Endometrial polyp
Tamoxifen-associated polyp
Adenomyomatous polyp
Decidual polyp
Simple hyperplasia
Premalignant lesion
Complex endometrial hyperplasia
Malignant endometrial lesions
Type I (oestrogen-associated)
Endometrioid adenocarcinoma
Type II (oestrogen-independent)
Papillary serous carcinoma
Clear-cell carcinoma
Benign myometrial tumour
Leiomyoma
Uterine sarcomas
Mixed mullerian tumour
Leiomyosarcoma
Endometrial stromal sarcoma



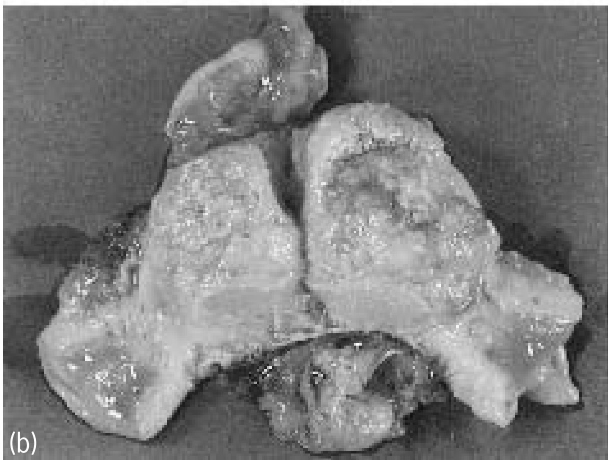


Figure 6 Macroscopic appearance of uterine polyps. Panel (a) shows the macroscopic appearance of a benign polyp (arrow). Panel (b) shows a polypoid endometrial adenocarcinoma that protrudes into the endometrial cavity. Note that the carcinoma is larger, has a less uniform appearance, and has foci of haemorrhage and necrosis.

(an antioestrogen used to treat breast cancer) is clearly linked to the development of endometrial polyps (Nuovo, 1994). Relative progesterone excess can cause a stromal proliferation evident clinically as a decidual polyp (**Figure 7**, which also shows the different histologic features seen in endometrial polyps).

While polyps represent a localized overgrowth of endometrium and stroma, certain precancerous lesions affect the endometrial cavity, diffusely leading to a thickened endometrium, which can simulate a tumour. Endometrial hyperplasia, a condition in which the proportion of endometrial glands is increased relative to endometrial stroma, is a well-defined step in the development of the most common types of endometrial cancer. Endometrial hyperplasia develops under conditions of oestrogen excess. The single most important factor in determining the likelihood of progression of hyperplasia to

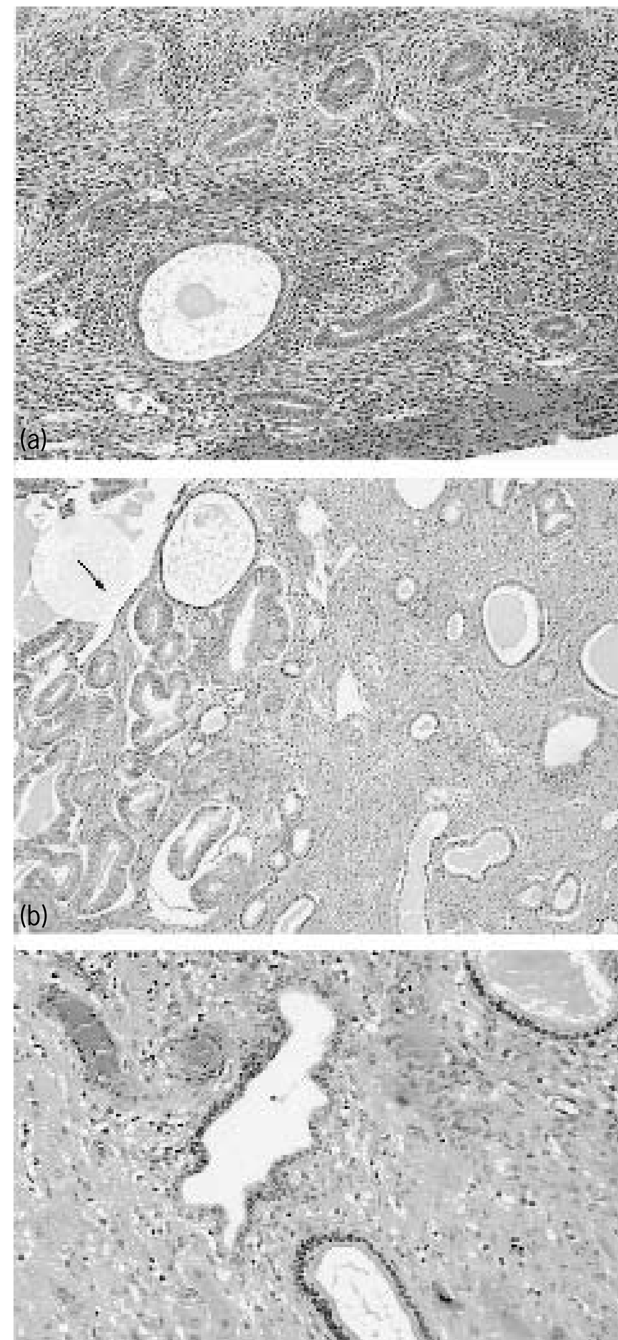

Figure 7 Microscopic appearance of uterine polyps. Note the fibrotic stroma, endometrial glands, which are relatively increased compared to the stroma, and the thick-walled blood vessels characteristic of a benign endometrial polyp (a). In panel (b) (an endometrial polyp from a woman taking tamoxifen for breast cancer), note that the glands are dilated and there is a small focus of endometrioid adenocarcinoma (arrow). This is a common finding in endometrial polyps associated with tamoxifen. Panel (c) shows a so-called decidual polyp, due to the effects of progesterone. Note how the stromal cells are large, plump with ample eosinophilic cytoplasm.

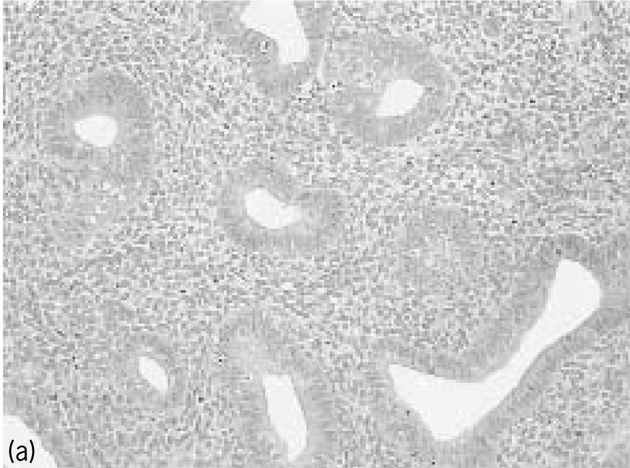
carcinoma is the presence of atypia, both cytological and architectural. Whereas hyperplasia-containing glands with simple architecture with normal gland cytology (simple hyperplasia) has been associated with a 1% cancer progression risk, hyperplastic glands with complex architecture and cytological atypia (complex atypical hyperplasia) has a 29% cancer progression risk (Burke *et al*., 1996). **Figure 8** shows the histological spectrum of endometrial hyperplasia.

Tumours of the endometrium account for 95% of uterine neoplasms (Burke *et al*., 1996). The endometrioid subtype of endometrial adenocarcinoma accounts for nearly 90% of endometrial carcinomas (Burke *et al*., 1996). Endometrioid adenocarcinoma most commonly appears as a large polypoid lesion protruding into the endometrial cavity and may be detectable as an enlarged uterus on bimanual examination. There may be associated haemorrhage and necrosis (**Figure 6**). Histologically, well-differentiated tumours resemble normal endometrium but contain very complex glandular architecture, lack intervening endometrial stroma, and have cytological atypia. Areas of confluent, malignant cells may be seen as tumours become less well differentiated, and it is the percentage of these areas which are evaluated when assigning grade. Tumours with > 50% solid growth are considered poorly differentiated, or high grade. It is not uncommon for endometrioid adenocarcinomas to show areas of squamous or, less commonly, mucinous differentiation. It is important to realize that this does not adversely affect prognosis. Also, areas of squamous differentiation are not included when considering the percentage of solid growth within a tumour (Burke *et al*., 1996). **Figure 9** shows the histological features of endometrioid adenocarcinoma and some of its variants/ mimics.



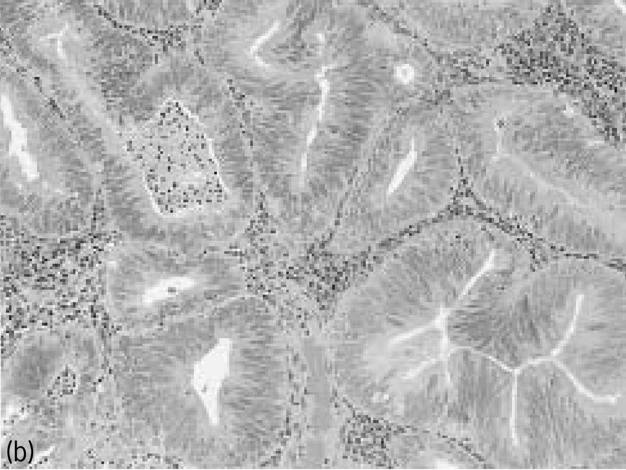


Figure 8 Histological appearance of endometrial hyperplasia. In simple hyperplasia, the endometrial gland to stroma ratio is increased. Glands have varying size, but maintain simple architecture and have no cytological atypia (a). Complex atypical hyperplasia has marked glandular crowding and, compared with (a), a markedly increased gland to stroma ratio. The important clues to the correct diagnosis include architectural atypia (glands within glands) and the associated nuclear atypia (b).

Less common endometrial carcinoma histological subtypes include papillary serous carcinoma (3–10%) and clear cell carcinoma (0.8–5%). These patterns are histologically identical with their counterparts in the ovary and vagina/kidney, respectively. It is important to recognize these patterns as distinct entities because they tend to present at a more advanced stage and are associated with a more aggressive clinical course than endometrioid adenocarcinoma (Cirisano *et al*., 1999). Because these histological patterns have not been associated with a clear premalignant condition or excess oestrogen, have clearly more aggressive behaviour, and have also been shown to have distinctly different molecular alterations compared with endometrioid carcinomas (see below), it is hypothesized that these tumour types have divergent patterns of development. Consequently, endometrial tumours are divided into Type I carcinomas encompassing endometrioid/ oestrogen-dependent cancer and Type II carcinomas encompassing those histological subtypes not associated with oestrogen (Cirisano *et al*., 1999). **Figure 9** shows the histological features of Type II endometrial carcinomas.

Leiomyomas are the prototypical benign tumour of the uterine myometrium and are benign clonal neoplasms of smooth muscle. These tumours grossly appear as well-circumscribed, white, whorled nodules usually without haemorrhage or necrosis (**Figure 10**). Histologically, these tumours typically have uniform, bland spindle cells with few mitoses. This is in direct contrast to uterine sarcomas, which are usually large tumours with haemorrhage and necrosis displaying histological features of marked cellular pleomorphism and abundant mitoses. Uterine sarcomas represent only 5% of uterine malignancies. The malignant counterpart to leiomyoma is the leiomyosarcoma, which represent one third of uterine

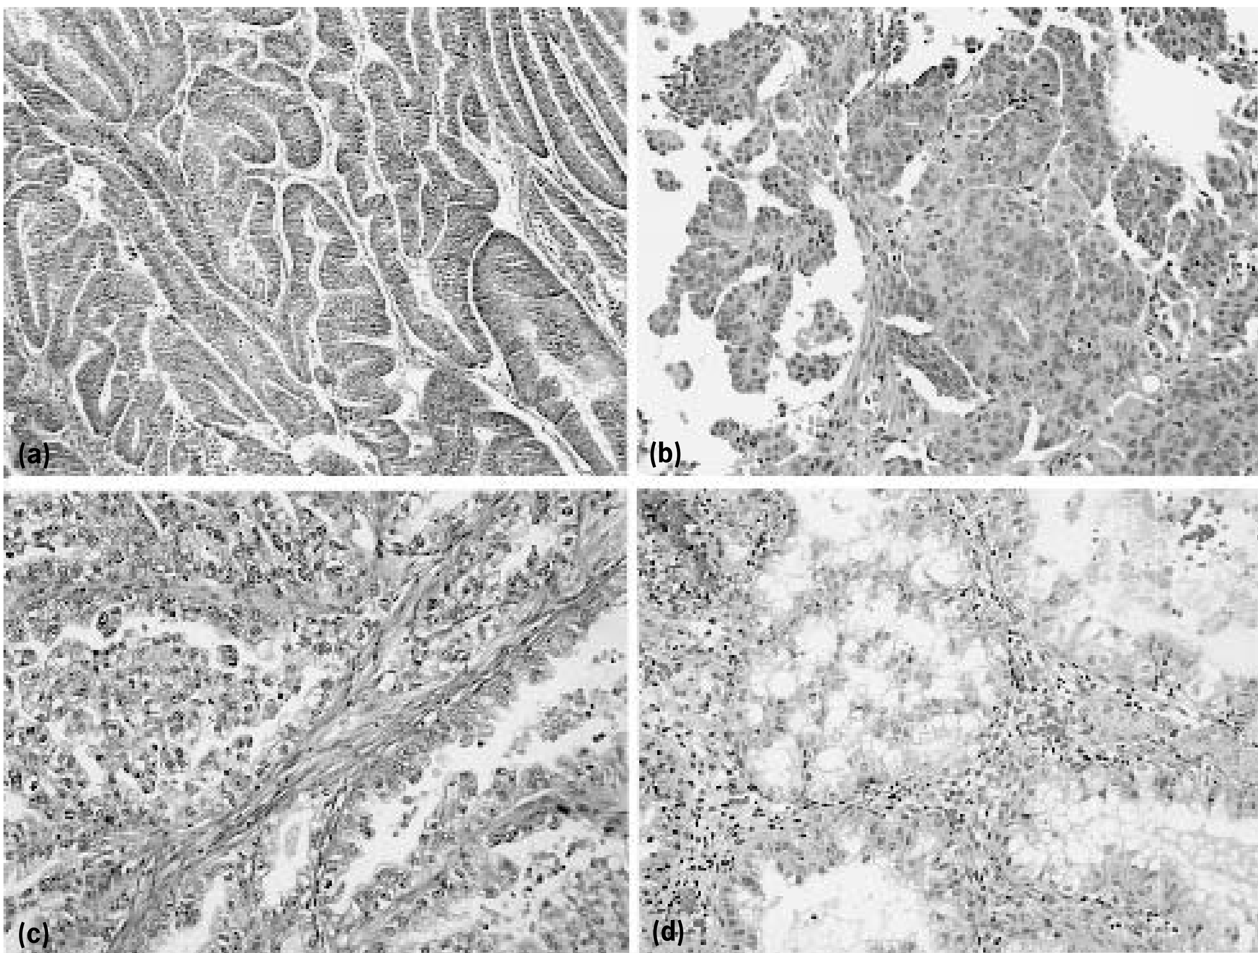

Figure 9 Histological appearance of endometrial adenocarcinoma. In well-differentiated endometrioid adenocarcinoma (grade FIGO I), the tumour is comprised of well-formed glands without solid growth (a). Panel (b) shows a rare and aggressive variant of endometrial carcinoma, papillary serous carcinoma; note the multiple small detached groups of cells characteristic of this entity. A clear-cell carcinoma has in some areas clearing of the cytoplasm with marked cellular atypia; note the 'hobnail' appearance of the nuclei (c). A mimic of clear-cell carcinoma is the Arias Stella reaction (d), characteristic of pregnancy. These cells lack the cytological atypia of clear-cell carcinoma and have larger vacuoles reflecting active secretion.

sarcomas (Levenback, 1996). Other types of uterine sarcoma include the mixed mullerian tumour (most common uterine sarcoma) and endometrial stromal sarcoma. The malignant mixed mullerian tumour (MMMT) is characterized by the presence of a sarcomatous element intimately admixed with a malignant glandular component. This sarcomatous component may be composed of elements normally found in the uterus such as smooth muscle or endometrial stroma (homologous elements), or it may contain elements not present in the uterus such as cartilage and bone (heterologous elements). **Figure 10** shows a comparison of benign and malignant myometrial tumours. Endometrial stromal sarcomas usually show a more bland appearance than leiomyosarcoma or MMMT; they are characterized by increased mitotic activity and invasion of the uterine wall.

Epidemiology and Aetiology

Because endometrial carcinoma, particularly the endometrioid subtype, is by far the most common malignancy of the uterus, the discussion on epidemiology and aetiology will pertain most directly to these tumours. Endometrial cancer is the most common gynaecological malignancy and represents the fourth most common malignancy overall in American women while being the eighth most common cause of cancer death (Burke *et al.*, 1996). The incidence of endometrial cancer peaks at 70–74 years of age, and the lifetime risk of developing endometrial cancer is estimated to be 2%. Into the mid-1980s, the incidence of endometrial carcinoma increased. This has been attributed to increased use of oestrogen replacement therapy; increasing age of the population may also be

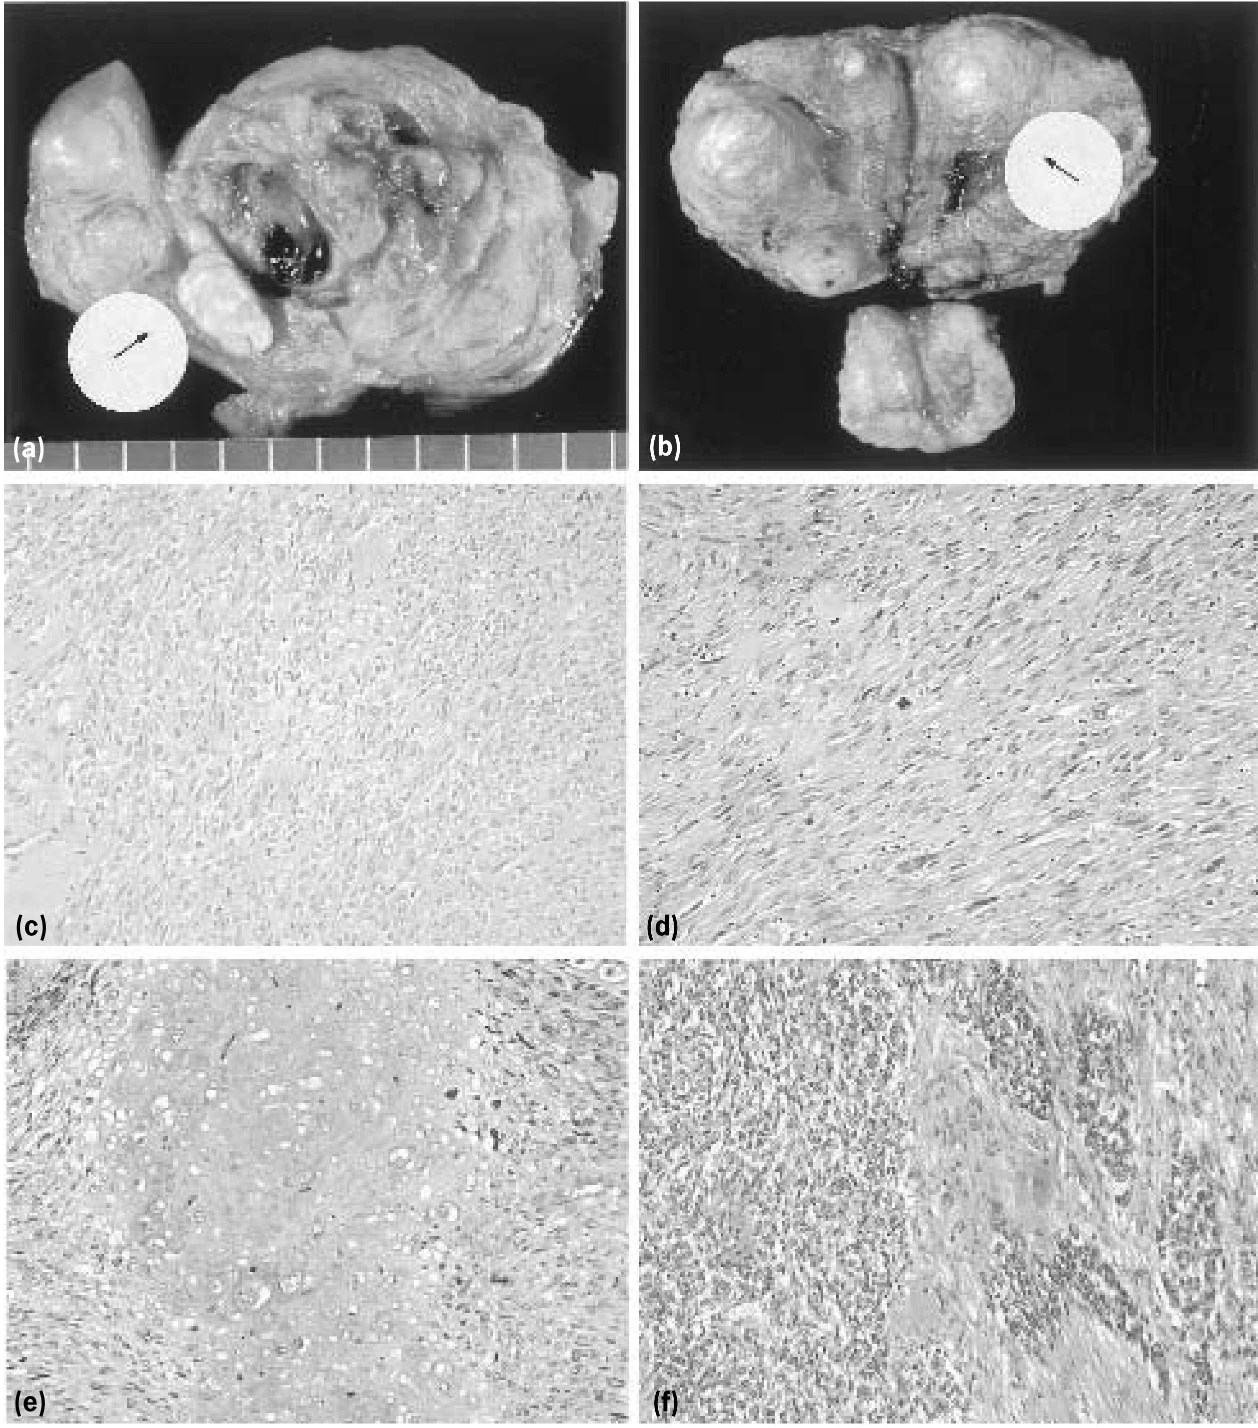

Figure 10 Stromal tumours of the endometrium. Panel (a) shows a benign leiomyoma with a smooth, well-defined tumour border. The cut surface is homogeneously white with a whorled texture (arrow). Panel (b) shows a leiomyosarcoma. In contrast, this tumour appears soft and friable with areas of haemorrhage and lacks a well-defined tumour border (arrow). The corresponding histology of the leiomyoma with bland spindled cells and no mitoses (c) is in contrast to the increased cellularity, marked cellular atypia, and the presence of mitoses of a leiomyosarcoma (d). A malignant mixed mullerian tumour with heterologous elements (cartilage) surrounded by malignant homologous stroma is shown in panel (e). Panel (f) shows an endometrial stromal sarcoma; such tumours usually show less cytological atypia than the other nonepithelial tumours of the endometrium.

related. More recently, a decline in incidence of endometrial carcinoma has been noted, which may be related to improved formulations in oral contraceptives with lower oestrogen content and to the addition of progesterone to menopausal hormonal replacement regimens (Burke *et al.*, 1996).

As previously discussed, a relationship between unopposed oestrogen and the development of endometrioid adenocarcinoma is well established. This was first suggested by the increased incidence of endometrial carcinoma with the advent of single-agent hormone replacement therapy with oestrogen. Other conditions that could expose the endometrium to unopposed oestrogen have been associated with an increased risk of developing endometrial cancer. Nulliparity is associated with the development of carcinoma, as are early menarche and late menopause. These three conditions allow for increased time of exposure of the endometrium to oestrogen. It is important to consider that nulliparity may be related to infertility due to anovulation. It is only after ovulation that progesterone impacts the endometrium. Therefore, anovulatory women have chronic overexposure to excess oestrogen. Obesity is a commonly cited risk factor and may be explained by an increased availability of unopposed oestrogen due to increased production of oestrone from androstenedione. Medical conditions such as diabetes and hypertension are also associated with increased cancer risk. It is not entirely clear whether they represent independent risk factors or whether their association with underlying morbid conditions such as obesity explains the association. A less common association with the development of endometrial cancer, secondary to the rarity of the tumour, is an oestrogen-secreting tumour such as a granulosa cell tumour of the ovary (Burke *et al.*, 1996). Finally, mention should be made of the association of tamoxifen with the development of endometrial carcinoma. Tamoxifen has an antioestrogenic effect in breast tissue and is therefore both a successful adjuvant therapy and a potential chemopreventive agent for breast cancer. In the uterus, however, tamoxifen is a partial oestrogen agonist leading to polyp formation, endometrial hyperplasia and carcinoma in some women (Nuovo, 1994).

Few risk modifiers have been described. Oral contraceptives with relative increased proportion of progestational agents may confer a decreased risk. Smoking has also been shown to decrease the risk of developing endometrial carcinoma and may be related to differences in oestrogen metabolism and earlier menopause (Burke *et al.*, 1996). It should be noted that the moderate decrease in endometrial cancer associated with smoking does not outweigh the risk of lung cancer, which is now the leading cause of cancer death in women in the United States.

The above discussion focused on endometrial cancers with Type I pathology. Cancers with Type II pathology do not have a relationship with unopposed oestrogen, and risk and lifestyle factors for these tumours have not been entirely elucidated. Precursor lesions to these cancer subtypes are currently being established, and certain oncogene mutations have been more strongly associated with the development of Type II than with Type I carcinomas. Family history with documented inherited predispositions to oncogene mutation is emerging as a risk factor for these tumour types.

Screening and Prevention

Although endometrial carcinoma is the most common gynaecological malignancy, no well-developed screening programme exists, as screening has not proven beneficial in the early detection of carcinoma. The majority of women present with postmenopausal bleeding or abnormal uterine bleeding if premenopausal and is subsequently discovered to have uterine carcinoma at an early stage (Burke *et al.*, 1996).

Some have attempted to detect preclinical disease in the asymptomatic patient and have suggested various screening options including the Pap smear, transvaginal ultrasound (TVUS) and endometrial biopsy (EMB). The sensitivity and specificity for the detection of endometrial carcinoma by Pap smear is low. In symptomatic patients, an abnormal Pap smear predicted correctly the presence of carcinoma in only 28% of patients (Nuovo, 1994). TVUS in the asymptomatic patient has no well established cutoffs for which a screen would be considered positive, although endometrial thickness <4 mm usually results in tissue insufficient for diagnosis on subsequent biopsy and is less likely to be associated with significant uterine pathology. Important, too, is the cost of the equipment and time involved (Burke *et al.*, 1996). Endometrial biopsy in the asymptomatic patient may be problematic as many elderly patients have cervical stenosis and an office pipelle biopsy may be technically impossible (Burke *et al.*, 1996). It has been suggested that endometrial biopsy in patients without postmenopausal bleeding be limited to patients on postmenopausal hormone replacement therapy or in those patients with endometrial cells or ASCUS on Pap smear or who are taking tamoxifen. Some advocate the use of tumour markers to detect preclinical disease. The most commonly used marker in gynaecological malignancies is CA-125. Unfortunately, CA-125 may be elevated in inflammatory states and also in benign gynaecological conditions such as endometriosis. It has been reported as a useful marker to detect early disease recurrence in patients who have elevated CA-125 prior to definitive treatment. This is particularly true of papillary serous carcinoma (Kurman *et al.*, 1995).

In patients who have symptoms, i.e. abnormal bleeding, TVUS can be a useful tool. An endometrial stripe thickness of >10 mm predicts the presence of significant uterine pathology in 10–20% of patients. When technically

possible, EMB is most frequently performed to evaluate abnormal bleeding. It has the advantage of being an office procedure, and although only 5% of the endometrium is sampled, EMB has a 97% sensitivity and an 83% specificity (Chen *et al*., 1999). The gold standard for the evaluation of symptomatic women remains hysteroscopy with D&C. However, this requires general anaesthesia. The advantage is that 60% of the endometrium is sampled and there is direct visualization of any polypoid lesions in the endometrial cavity (Chen *et al*., 1999).

Little is written about prevention. Maintenance of ideal body weight and addition of progestational agents in hormone replacement regimens appear to be practical methods of prevention based on currently understood risk factors.

Gross/Histology/Preinvasive/ Immunohistochemistry

The gross and histological features of uterine tumour pathology and preinvasive lesions have been discussed in a previous section. This part of the chapter will focus on ancillary techniques of tumour diagnosis and histological mimics of uterine tumours.

Immunohistochemistry has become a useful tool in detecting markers of cellular differentiation in order to assign a histological subtype when the answer is not obvious by usual microscopic examination. Expression of immunohistochemical markers may also be used as prognostic indicators for tumour behaviour. Because the endometrium is a hormonally modulated by oestrogen and progesterone, it is logical that receptors for these hormones would be present. Oestrogen and progesterone receptors are abundant in benign endometrium but show a decreased presence in endometrioid malignancies by immunohistochemical analysis. This makes sense because malignancies are not under the same regulatory influences as benign tissues. Well-differentiated cancers are more likely to be receptor positive; they more closely resemble their tissue of origin. It has been suggested that progesterone receptor positivity is associated with better-differentiated tumours with less aggressive biological behaviour. In theory, progesterone administration as adjuvant therapy for patients with progesterone positive tumours could be useful in counteracting the effects of oestrogen as in the normal endometrium (Kurman *et al*., 1995).

There are times when endometrial adenocarcinoma may be difficult to distinguish from endocervical adenocarcinoma, particularly when endometrial cancer extends into the cervix. In the past, some have used carcinoembryonic antigen (CEA) as a distinguishing tool, citing that there is positive staining in 80% of endocervical adenocarcinomas and 8% of endometrial carcinomas (Kurman *et al*., 1995). The distinction is important because, of the two, endometrial carcinoma has a better prognosis. Recently, because endocervical cancers have been associated with HPV (particularly subtype 18), studies have been made to determine whether there is a difference in HPV expression and determined that endometrial carcinoma is not associated with HPV, and is thus a more reliable way to differentiate endocervical from endometrial cancers, as discussed in detail above in the section on cervical cancer (Nuovo, 1994).

It is important to be aware of benign conditions that can simulate malignancy. The classical example is the Arias Stella reaction, which can look nearly identical with clear cell carcinoma (**Figure 9**). It is most commonly associated with pregnancy but has been reported to occur with use of certain medications (Kurman *et al*., 1995). A good history and the presence of progesterone-related endometrial stromal changes (decidualization) are invaluable in making this distinction; if the Arias Stella reaction is due to miscarriage, villi may be present.

Molecular Genetic Findings

The molecular aspects of endometrial carcinogenesis continue to be elucidated. Endometrioid tumours are influenced by oestrogen and progesterone, and the development of endometrial hyperplasia is directly related to excess oestrogen. These hormones have effects on cellular proliferation; therefore, it is possible that molecular disturbances in the cell cycle contribute to the development of carcinoma. How transformation from premalignant lesions to cancer at the cellular level is still not known.

p53 has been studied extensively in the endometrium. It is involved in many crucial cellular functions such as cell cycle regulation, DNA repair, cellular differentiation and apoptosis (programmed cell death). It has been shown that there are alterations in the function of p53 in Type II, or nonoestrogen-dependent tumours, probably due to gene mutation. Oestrogen-dependent tumours (Type I) and their precursors rarely demonstrate *p53* mutations. The functional alteration of p53 in Type II tumours along with their lack of association with unopposed oestrogen suggests the existence of an oestrogen-dependent pathway in endometrial tumorigenesis. In non-endometrial tumours, *p53* mutation is associated with poor differentiation, aggressive clinical course and poor prognosis. The fact that most Type II tumours have altered p53 function explains at the molecular level why this subset of endometrial cancer has a more aggressive clinical course than Type I tumours.

Prognostic Factors

Endometrial cancer is currently surgically staged as anatomical extent of disease is felt to be an important indicator of prognosis and in directing adjuvant therapy. **Table 4** shows the current FIGO staging system. Additional

Table 4 FIGO* surgical staging for endometrial carcinoma

I		Tumour limited to the uterine fundus
	IA	No myometrial invasion
	IB	Myometrial invasion $\leq 50\%$
	IC	Myometrial invasion $\geq 50\%$
II		Tumour extends to the cervix
	IIA	Superficial glandular spread
	IIB	Stromal invasion
III		Regional tumour spread to the pelvis
	IIIA	Involvement of the uterine serosa, adnexa or positive peritoneal cytology
	IIIB	Vaginal metastases

Simplified Staging for Ovarian Carcinoma

Stage I Growth limited to the ovary/ovaries

Stage II Growth involving one or both ovaries, but limited to the true pelvis

Stage III Extension of tumour beyond the true pelvis, and/or positive pelvic lymph nodes or implants outside the pelvis

Stage IV Distant metastases

* Federation of International Gynecologic Oncologists.

features in determining prognosis and risk of recurrence include histological grade, histological subtype and age.

Studies of survival based on surgical stage have shown that depth of myometrial invasion is important with a 97% survival in patients with tumours confined to the inner third of the myometrium, decreasing to 70% with outer third involvement. The incidence of lymph node metastasis increases with depth of muscle invasion. Involvement of the cervix (stage II), particularly the cervical stroma, decreases the 5-year survival to 50%, probably related to the increased incidence of para-aortic lymph node metastases in these patients. Grade III histology is a sensitive indicator for poorer prognosis with a higher percentage of pelvic lymph nodes involved in these patients (Ludwig, 1995).

When one considers Type I versus Type II tumours, stage becomes a less important indicator of prognosis. Tumours with Type II histology do worse stage for stage than those with Type I histology. This is reflected in overall survival rates of 33% and 92%, respectively. These patients tend to present with more advanced disease than is initially suspected. Even when disease is at a very early stage, these tumours have a higher recurrence risk (Ludwig, 1995).

Clinically, age is considered to be an indicator of prognosis. Younger women tend to fare better than older women. Younger women who develop endometrial carcinoma usually do so in the context of complex atypical hyperplasia secondary to oestrogen excess. These malignancies tend to be better differentiated and less aggressive. Older women more often have tumours with poor differentiation and are at increased risk for developing tumours with Type II histology (Ludwig, 1995).

Clinical Management

The current first-line therapy for endometrial carcinoma is an exploratory laparotomy with a simple total abdominal hysterectomy/bilateral salpingo-oophorectomy. A lymph node dissection may also be performed as part of the staging procedure based on whether lymph nodes appear enlarged or firm, if high-grade or high-risk histology is known to be present, and when there is $>50\%$ myometrial invasion (Chen *et al*., 1999). The need for adjuvant therapy is based upon final surgical stage. Current modalities include radiation and chemotherapy.

UTERINE STROMAL TUMOURS

The most common benign stromal tumour in the uterus is a leiomyoma. In fact, it is one of the most common tumours encountered in gynaecological pathology with an estimated incidence of 20–40%. These tumours are benign proliferations of smooth muscle. Clinically, they tend to be less important as at least 50% are asymptomatic. Abnormal uterine bleeding (from submucosal leiomyomas) is the most common symptom and can be seen in one third of patients, and one third of patients may have pelvic pain. Local symptoms such as genitourinary and gastrointestinal compression and pelvic pressure may be seen when tumours reach a large size. These tumours may be detected incidentally in hysterectomies for other reasons, or may be discovered on routine bimanual examination. Treatment is often not indicated, but abnormal uterine bleeding, severe pelvic pressure or pain, infertility/habitual abortion due to uterine cavity distortion and compromise of adjacent organs (i.e. hydronephrosis) are all indications for therapy (Barbieri, 1999). Current therapeutic options include hysterectomy or myomectomy (local resection of the leiomyoma). Because these tumours are sensitive to oestrogen and progesterone, drugs to block the actions of these hormones have also been used with some success in an effort to treat these tumours (Deligdisch, 2000).

Uterine sarcomas are the least common uterine malignancy. In general, these tumours represent less than 5% of corpus cancers and have a poorer prognosis. The gross and histological subtypes have been discussed previously. Most patients present with abnormal uterine bleeding, and the tumour may be seen protruding through the cervix (classical for MMMT). The incidence tends to increase with age, and sarcomas may be more common in African Americans. Few risk factors are clearly defined. The most common histological subtype is the malignant mixed mullerian tumour. It also has the worst prognosis with an overall survival of 20%. Leiomyosarcomas account for 30% of sarcomas. It is important to note that most arise independently, and it is now no longer believed that they arise from pre-existing leiomyomas. Survival for patients with disease confined to

the uterus approaches 30%. Endometrial stromal sarcomas are the least common subtype, but if the tumour is low-grade, the prognosis is good with 90% survival overall. The standard therapy for sarcomas is hysterectomy. The benefit of adjuvant therapy in extending survival has not been clearly proven (Levenback *et al*., 1996).

PATHOLOGY OF THE OVARY

Tumour Pathology

Primary tumours of the ovary can be divided into three major groups that are based upon their presumed cell of origin. Tumours derived from the mesothelial-like lining of the ovary comprise the common group of epithelial ovarian tumours, which show various types of epithelial differentiation. Tumours derived from the germ cell elements are referred to as germ cell tumours, and encompass a wide variety of histological types. Tumours derived from the supporting elements of the ovary, which includes granulosa, theca and fibrous cells of the stroma, make up the group of tumours referred to as sex-cord stromal tumours. These tumours generally have less histological variety than germ cell tumours and are noted for their potential for hormonal production. A fourth group of tumours can be included that make up a wide variety of tumour types, including metastatic tumours, pseudoneoplastic tumours or tumour-like conditions, and a rare group of tumours of uncertain cell origin. For the purpose of simplicity, this last group of rare tumours will not be discussed.

Although ovarian tumours encompass a wide variety of neoplasms with numerous histological types and diverse clinicopathological features, general principles can be established regarding their presentation and outcome. In the premenopausal patient ovarian tumours must be distinguished from benign ovarian processes, including various benign types of cysts, endometriosis and inflammatory lesions whose mode of clinical presentation will often be identical with that for ovarian tumours and include vague abdominal symptoms, pelvic pain, urinary symptoms or abdominal distension. Rarely does either group present as dysfunctional uterine bleeding.

The presentation of epithelial ovarian tumours can best be explained by examining their natural course of spread. Tumour dissemination of ovarian carcinomas generally occurs by penetration of the ovarian capsule and seeding of peritoneal surfaces and by lymphatic invasion and spread to contiguous lymph nodes in the pelvic region. Spread by haematogenous routes to distant sites is a late manifestation and signals an ominous prognosis. Implantation of peritoneal surfaces is generally associated with relatively noninvasive growth, but increasing tumour size causes mechanical interference with other vital structures and organs such as the bowel and ureters. Because of this predictable route of dissemination, staging and prognosis of epithelial ovarian tumours can be divided into tumours confined to the pelvis and tumours that have spread beyond the pelvis. In contrast, germ cell tumours frequently disseminate to distant sites by haematogenous and lymphatic routes. Sex-cord stromal tumours, even when of a malignant nature, tend to be localized to the ovary, with metastases to distant sites noted many years after their removal.

Epidemiology

The incidence of ovarian cancer has remained relatively stable over the last 25 years. Ovarian cancer is the sixth most common form of cancer in women, the fourth leading cause of cancer death among women and the leading cause of death among gynaecological malignancies. The overall lifetime risk of a woman dying from ovarian cancer is approximately 1.5%, with ovarian cancer being the cause of death in one of every 90 women. Most malignant ovarian tumours occur in women over the age of 45 years where an ovarian mass has an approximately 30–40% chance of being malignant. Conversely, in women less than 45 years old, or premenopausal women, an ovarian mass is most likely to be a benign with malignant tumours making up less than 15% of this group. Thus, an ovarian mass in a premenopausal woman is approached much differently from an ovarian mass in a postmenopausal woman.

Certain generalizations can be made regarding the incidence of specific tumour types in pre- and post-menopausal woman. The most common ovarian tumour accounting for approximately one quarter of all ovarian tumours and one third of all benign ovarian tumours is the benign dermoid cyst (mature cystic teratoma), which belongs to the group of germ cell tumours. Germ cell tumours as a group are much more common in the first two decades of life. Conversely, the common group of epithelial ovarian tumours are rare in the first two decades of life and become much more prevalent with the onset of reproductive age and in postmenopausal women. Within these two groups, malignant epithelial ovarian tumours (carcinomas) tend to occur after the age of 60 years, whereas benign ovarian tumours and tumours of low malignant potential (borderline tumours) tend to occur in the 40–60 year age group. Sex-cord stromal tumours are most common in women from 40 to 60 years of age.

Most epidemiolgical factors of ovarian cancer relate to the common group of epithelial tumours. This group of tumours is uncommon before the age of 40 years, and peaks in the seventh to eighth decades of life. Most tumours in this group, 70–80%, are of a benign nature with the incidence of malignant tumours being closely related to age. Factors that have been associated with a higher risk of epithelial ovarian cancer include infertility, nulliparity,

multiple miscarriages and the use of clomiphene (a fertility drug); factors associated with a lower risk include multiple pregnancies, breast feeding, tubal ligation and the use of oral contraceptives. Most of these factors can be explained by the hypothesis that ovulation induces an aberrant repair process, and factors which decrease ovulation decrease the incidence of this group of tumours. The use of oestrogen in postmenopausal women has not been shown to increase the risk of ovarian cancer.

Aetiology

Between 5 and 10% of women with ovarian cancer have a family history of ovarian cancer, and approximately half or less of this group have inherited disease. A woman with one affected first-degree relative has an approximately 5% lifetime risk of developing ovarian cancer, while two or more affected first-degree relatives confers a 30–50% lifetime risk of developing ovarian cancer. The most notable hereditary group is the breast–ovarian cancer group linked to *BRCA-1*, a probable tumour-suppressor gene. BRCA-linked ovarian cancer does not show distinct clinicopathological characteristics that distinguish it from sporadic ovarian tumours, although different studies have shown a significantly more favourable outcome. Owing to the much higher incidence of sporadic ovarian cancer versus inherited ovarian cancer, a routinely obtained family history is an unreliable way to identify patients who might be at high risk of developing ovarian cancer. Unlike *BRCA-1*, which confers a relatively high risk for breast and ovarian cancer, the incidence of ovarian cancer with *BRCA-2* appears to be much lower. Other inherited ovarian tumours are usually components of a multi-system genetic syndrome, and usually are not related to the common group of epithelial tumours. These syndromic complexes include Peutz–Jeghers syndrome (sex-cord stromal tumours), gonadal dysgenesis (gonadoblastomas), basal cell nevus syndrome (ovarian fibromas), ataxia telangiectesia, Muir–Torr syndrome, Li–Fraumeni syndrome and Cowden syndrome.

The effect of environmental factors on the incidence of ovarian cancer have been inconclusive with the exception of drugs used to enhance fertility or treat infertility, which generally increase the rate of epithelial malignancies. Factors which have shown conflicting results but may be possibly related to an increased rate of ovarian cancer include increased dietary fat, increased coffee consumption and the use of talc in the perineal area. The effect of oral contraceptive (OC) use has been extensively studied with results consistently showing a lower incidence of ovarian cancer in women who have used OCs for more than five consecutive years. A hypothetical analysis of the protective effect of OCs in nulliparous women with no family history of ovarian cancer has postulated that the risk of ovarian cancer in this group of women is reduced by more than 50% after 5 years of consecutive OC use and is less than the risk in parous women with a comparable family history and no history of OC use. (See also chapter *Inherited Predispositions to Cancer*.)

Screening and Prevention

Screening for ovarian cancer has primarily been directed towards the postmenopausal patient owing to the much higher incidence of malignant tumours in this group. Stage I ovarian carcinomas have a 90% cure rate, but only 25% of such tumours present as localized malignancies. Stage II ovarian carcinomas have an approximately 70% cure rate, while the prognosis for Stage III and IV carcinomas declines dramatically to 15–20%. Various screening tests that have been employed for the detection of ovarian cancer include tumour markers, ultrasound, rectovaginal or bimanual vaginal examination and Pap smears. All of these tests have various problems which has prompted many investigators to combine the various tests to increase sensitivity and specificity. Rectovaginal and bimanual vaginal examination is sensitive with experienced gynaecologists, but lacks specificity owing to the frequent occurrence of benign ovarian masses. Pap smears, although relatively specific, lack sensitivity as only 10–30% of ovarian cancers can be detected by this method (Nuovo, 1994).

Of the various tumour markers studied, including carcinoembryonic antigen, ovarian cyst adenocarcinoma antigen, lipid-associated sialic acid, NB/70K, TAG 72.3, CA 15-3 and CA 125, only the last has received widespread use. CA 125 is not specific for ovarian cancer and can be elevated in 5–40% of benign gynaecological masses including uterine leiomyomas and endometriosis. Other nongynaecological cancers, including those of the pancreas, stomach, colon, and breast, have been associated with elevated CA 125. Among gynaecological cancers other than ovarian cancers, elevated CA 125 has been reported in cervical and fallopian tube malignancies. Although rare, elevated CA 125 has been reported in up to 1% of healthy women with no evidence of cancer. Problems with sensitivity also exist with CA 125 and must be considered with regards to quantitative parameters. CA 125 is determined by radioimmunoassay methods and is reported in units per millilitre, with levels $>35\,\mathrm{U\,mL^{-1}}$ being considered abnormal and levels $>65\,\mathrm{U\,mL^{-1}}$ being indicative of malignancy. CA 125 will be elevated above normal levels in 80–85% of women with Stage III or IV ovarian cancer, but varies in different studies from 30 to 50% in women with Stage I or II ovarian cancer. Most certainly it can be said that CA 125 is much more sensitive and reliable at detecting higher-stage ovarian cancer, but the lack of elevated CA 125 must be regarded cautiously in early ovarian cancer.

Owing to the lack of sensitivity of pelvic examination and serum CA 125 in detecting ovarian cancer a

combination of these tests with ultrasonography has been advocated. A large study involving more than 22 000 postmenopausal women using a combination of CA 125 measurement and ultrasonography showed a specificity of greater than 99% for the detection of ovarian cancer but a positive predictive value of less than 30%. Others have advocated a more elaborate screening protocol first by transvaginal ultrasonography with abnormal results followed by pelvic examination, serum CA 125 determination, Doppler flow sonography and tumour morphological indexing by ultrasonography results. In these and numerous other studies the routine testing of asymptomatic women has shown limited utility in the prevention of ovarian cancer owing to the number of diagnostic laparotomies performed per cancer detected. It has been calculated that screening 100 000 asymptomatic women over the age of 45 years for ovarian cancer would detect 40 cases of ovarian cancer with 5398 false-positive results and 160 complications from diagnostic laparotomy. The NIH Consensus Development Panel in their most recent statement in 1995 concluded that there was no evidence to support routine screening in the general population and no convincing data even in high-risk patients.

Gross/Histopathology/Preinvasive Lesions/Ultrastructure/Immunohistochemistry

Among the three common groups of ovarian tumours, i.e. sex-cord stromal tumours, germ cell tumours and epithelial tumours, the last group accounts for over 90% of all malignant tumours of the ovary and approximately 60% of all ovarian tumours. The epithelial ovarian tumours are divided according to cell type and architectural pattern, with special reference given to any significant contribution by the surrounding ovarian stroma. If the tumour contains a prominent stromal component the suffix-fibroma is attached and the tumour is designated an adenofibroma rather than an adenoma, with this particular entity being almost invariably a benign proliferation. Architectural features are used in describing the location of the tumour as either on the surface or within the ovary, the degree of solid or cystic component, and are important in assessing the risk of benign or malignant behaviour. If the most prominent portion of the tumour is on the outer surface of the ovary, which almost invariably has papillary histological features, these are designated as surface papillary tumours. If the tumour contains a prominent cystic component the prefix cyst- is attached, such as cystadenoma, cystadenofibroma (**Figure 11**) and cystadenocarcinoma. A solid tumour with no cystic change would thus be called an adenoma, adenofibroma or adenocarcinoma. Adenofibromas and cystadenofibromas are generally solid tumours with the cystic component of cystadenofibromas only being recognized microscopically. The majority of ovarian tumours of the epithelial type are grossly cystic and their distinction into specific type or prediction of their biological behaviour is limited by the gross examination. Most ovarian tumours in general cannot be distinguished from each other by their gross pathologic examination and require histologic examination for their final classification.

Architectural features are especially important in predicting the biological behaviour of a given tumour which is generally divided into three main categories of benign, borderline or malignant. Benign architectural features generally imply a tumour, whether it be solid or cystic, has a simple morphological pattern and shows no invasion of the surrounding stroma. Malignant architectural features are the opposite extreme with a complex morphological pattern and obvious invasion of the surrounding stroma. In between are borderline tumours. Each specific tumour type has its own specific criteria for what defines a borderline tumour, but the general concept is that borderline tumours exhibit a morphological pattern between simple and complex and can show minimal invasion of the surrounding stroma. Cytological features are also evaluated in placing a given tumour into one of these three specific categories of biological behaviour and include nuclear atypia, number of mitoses and other parameters such as multinucleation and the amount of cytoplasm present.

The most specific categorization of the epithelial ovarian tumours relates to the type of cellular component present, with the five major groups being serous (resembles fallopian tube), mucinous (resembles cervix), endometrioid (resembles endometrium), clear cell (resembles kidney tumour) and transitional cell (Brenner tumours, resemble urinary bladder). Not infrequently epithelial tumours of the ovary will be associated with numerous small foci of tumour spread throughout the peritoneal lining, which can be either totally benign or malignant. These peritoneal implants generally recapitulate the primary ovarian tumour and their origin is generally considered to be an example of independent primary tumours in a low-grade tumour, while in high-grade tumours they may be either true metastases or independent primary tumours. It is important to realize that these implants do not necessarily indicate malignant behaviour of the primary ovarian tumour and are not an unexpected finding.

The most common of all of the epithelial tumours are tumours of the serous type, which account for over half of this group and from 30 to 50% of all ovarian tumours. Over 70% of serous ovarian tumours are benign, with borderline tumours being relatively rare and malignant types accounting for the remaining 20–25% of these tumours. Serous tumours are usually cystic, generally of moderate size (less than 10 cm) and lined by an epithelium that mimics that of the fallopian tube being ciliated cuboidal or columnar. Microscopic features of benign tumours are single or multiple cysts with simple papillae projecting into the lumen (usually comprising less than 10% of the total cyst wall) that are lined by a single layer of serous

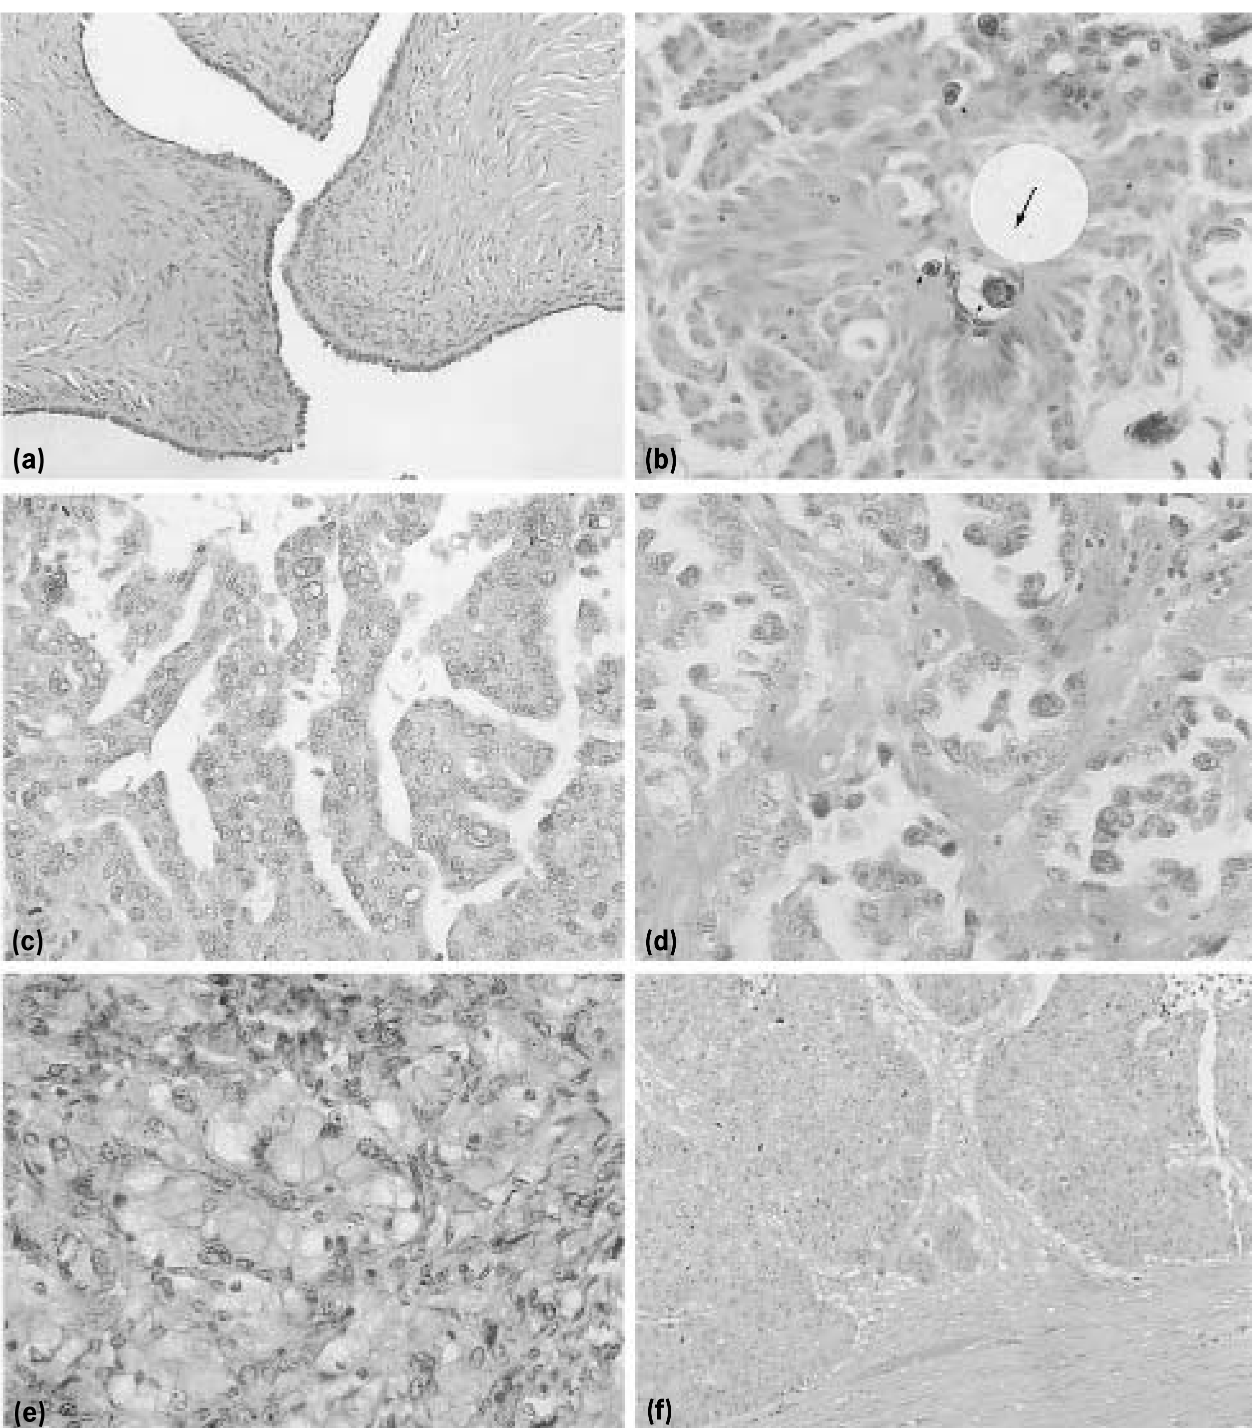

Figure 11 Epithelial tumours of the ovary. Panel (a) shows the large, broad papilla of a serous cystadenofibroma; the simple columnar lining indicates that this is a benign lesion. In panel (b), note that the papilla are more complex and that psammoma bodies are now evident (arrow); this is a serous cystadenoma of borderline malignant potential. In contrast, note the much more complex architecture of a serous cystadenocarcinoma (c). The other panels show other carcinomas of the ovary including clear cell carcinoma (d), note similarity to similar tumour of the endometrium), metastatic carcinoma from the stomach (Krukenberg tumour, where the malignant cells contain ample mucin (e)) and (f) endometrioid carcinoma of the ovary with its characteristic squamous metaplasia.

cells with no atypia. Borderline tumours show more complex papillae with a stratified layer of cells that usually show some atypia. Owing to the complex branching nature of the papillae and multiple layer of cells lining the papillae, histological sections will often show small clusters of cells that appear to be floating freely in the cystic space adjacent to the papillae. As these papillae become more complex they may become condensed into concentric concretions referred to as psammoma bodies, a characteristic feature of serous tumours (**Figure 11**). Some serous borderline tumours may show microinvasion of the surrounding stroma which has not been shown to have any prognostic significance. Serous borderline tumours frequently are associated with peritoneal implants that are generally of low grade and noninvasive. If these implants are benign they are often referred to as endosalpingiosis after their resemblance to fallopian tube epithelium.

Serous carcinomas are the most common malignant ovarian tumour and are most common in women after 65 years of age. They usually are grossly cystic but can appear solid owing to the greater degree of epithelial proliferation and their cystic nature is only recognized microscopically; when cystic most of their inner wall contains papillary structures. Serous carcinomas show more complex branching of the papillae and stratification of the epithelial lining to such a degree that crowding of the papillae results in a more solid appearing tumour with slit-like lumina (**Figure 11**) Areas of the tumour may show solid sheets of cells, making their distinction from endometrioid tumours difficult. Findings that may help in this instance are the presence of multinucleated cells and psammoma bodies and the absence of squamous differentiation and intracellular mucin, the latter two of which are often present in endometrioid carcinomas. Serous carcinomas show obvious stromal invasion and nuclear atypia.

Mucinous tumours represent approximately 25% of epithelial tumours and 15% of all ovarian tumours and are noted for the large size they commonly attain at presentation. Of all ovarian tumours, mucinous tumours are the type that can be most readily recognized grossly owing to their frequent multicystic appearance with prominent mucin production. The majority of mucinous tumours, (>75%), are benign with borderline tumours being extremely rare. As opposed to the fairly constant histological type seen in any given serous tumour, mucinous tumours are noted for histological variability. One histological section of a mucinous tumour may appear of borderline type, while an adjacent histological section shows invasive carcinoma. For this reason it is important to sample mucinous tumours well.

Mucinous tumours are lined by epithelium that resembles that of the endocervical canal and consists of mucin-filled columnar cells. Less often the epithelial lining resembles intestinal-type epithelium with prominent goblet cells. Low-grade mucinous tumours, or mucinous cystadenomas, are generally cystic tumours lined by a single layer of endocervical-type mucinous epithelium. The criteria for endocervical-type borderline mucinous tumours closely resemble those of serous borderline tumours. Mucinous carcinomas vary greatly in their microscopic appearance in any given tumour and are not divided into endocervical or intestinal type, both of which are frequently seen in a single example. Mucinous carcinomas vary from solid nodules to glands, often with scant stroma.

Endometrioid tumours are usually carcinomas, with benign and borderline examples being very uncommon. Although endometrioid tumours comprise less than 5% of all ovarian tumours, they account for 15–20% of malignant ovarian tumours. Endometrioid carcinomas may be cystic or solid and lack gross features that distinguish them from other ovarian tumours. They are lined by epithelium that mimics the endometrium and are associated with endometriosis in 5–10% of all cases and a synchronous carcinoma of the endometrium in approximately 25% of cases. Endometrioid carcinomas classically are characterized microscopically by tubular glands lined by mucin-free psuedostratified epithelium as well as squamous metaplasia. Another feature commonly seen in endometrioid carcinomas is focal squamous differentiation (**Figure 11f**). Owing to their glandular appearance their distinction from metastatic carcinoma, particularly colonic adenocarcinomas, can be difficult. In the case of adenocarcinomas of the colon immunohistochemical stains can help in this distinction. Epithelial tumours of the ovary as a group are positive for cytokeratin 7 and negative for cytokeratin 20 whereas intestinal adenocarcinomas generally show the opposite pattern of immunoreactivity. Another common distinction is from metastatic breast cancers and again immunohistochemical stains can be helpful, with ovarian carcinomas staining positively for CA 125 and metastatic breast cancer staining for gross cystic disease fluid protein 15.

Clear-cell carcinomas represent approximately, 5% of all ovarian carcinomas. Like endometrioid carcinomas they are frequently associated with endometriosis, and in some reports up to 50% of clear-cell carcinomas show such an association. Clear-cell carcinomas, unlike other ovarian carcinomas, more frequently present as Stage 1 tumours prompting earlier investigators to suggest a better prognosis for this class of ovarian carcinomas, but if adjusted for stage at presentation clear-cell carcinomas have a worse prognosis than other epithelial ovarian carcinomas. Grossly, clear-cell carcinomas may be solid or cystic and typically show numerous nodules of solid tumour protuding into cystic cavities. Microscopically clear-cell carcinomas usually show a solid nest of clear cells mixed with small cysts lined by cells with a hobnail appearance (**Figure 11**).

Transitional cell tumours of the ovary are relatively rare, making up less than 2–3% of all ovarian tumours, and of this group practically all are benign. Often referred to as

Brenner tumours, these tumours show urothelial differentiation similar to the lining of the urinary tract. Grossly, Brenner tumours are usually solid tumours but may show cystic change. Microscopically, Brenner tumours are composed of sharply demarcated nests of transitional cells, often with small cysts in their central portion, in an abundant fibromatous stroma. Up to half of Brenner tumours are incidental findings in ovaries removed for other reasons, and are frequently associated with mucinous cystadenomas.

The other common group of epithelial tumours seen in the ovary are metastatic tumours. Owing to the rich vascularity of the ovarian stroma, 10–20% of all tumours of the ovary are metastatic. The clinical history is very valuable in such instances, but other findings that may help in such instances are the presence of bilateral tumours, numerous separate nodules within a single ovary and the presence of tumour on the ovarian surface without peritoneal involvement. The presence of bilateral involvement should be approached cautiously as only 75% or less of metastatic ovarian tumours are bilateral and 10–20% of primary ovarian carcinomas will present as bilateral masses with primary serous tumours being bilateral 50–75% of the time. Up to one third of breast cancer patients and one quarter of colon cancer patients will have ovarian metastases during the course of their treatment. Among metastatic ovarian tumours, those derived from signet ring cell carcinomas of the stomach, i.e. Krukenburg tumours, have received the most attention. Although not the most frequent metastatic tumour to the ovary, Krukenburg tumours have received such attention because they often occur in middle-aged to younger patients without a known primary. Krukenburg tumours can closely mimic clear-cell carcinomas and germ cell tumours owing to their histological appearance (**Figure 11**).

Sex-cord stromal tumours are relatively uncommon tumours that make up approximately 5% of all ovarian tumours. As a general rule this group of tumours occur in a slightly younger population than epithelial tumours and examples in paediatric populations are not rare. Derived from the stroma of the ovary this group of tumours is noted for their response to and production of hormones as they recapitulate their normal role in reproduction. Most ovarian sex-cord stromal tumours are oestrogenic but up to one quarter may be androgenic. The most general histological characteristic of this group of tumours is the presence or absence of the accumulation of lipid in the tumour cells which imparts a particular histological appearance. The most common tumours in this group include fibromas, thecomas and granulosa cell tumours. Grossly they are generally solid tumours but may be cystic, especially in the case of granulosa cell tumours. These tumours can occur in a mixed pattern and are usually solid nests of cells that vary from spindle-shaped cells to round or oval cells. Fibromas and thecomas are generally solid tumours and a sharp distinction between the two is often difficult to distinguish as fibromas may undergo leutinization focally and are referred to as fibrothecomas. Whereas fibromas are generally spindle-shaped cells, thecomas undergo leutinization and classically have pale abundant cytoplasm (**Figure 12**). Granulosa cell tumours are divided into an adult and juvenile types, with the latter having a better prognosis, and both are characterized by round to oval cells with nuclear grooves surrounding small cystic spaces. In the case of adult granulosa cell tumours, these cystic spaces take on a microfollicular appearance classically referred to as Call–Exner bodies (**Figure 12**). Granulosa cell tumours generally present as Stage I tumours and have a 90% survival at 5 years, but are notorious for recurrence at distant metastatic sites 15–20 years later with a 50% mortality rate at this time. Other tumours in this group often referred to as steroid cell tumours, including Sertoli–Leydig cell tumours, are extremely rare.

Germ cell tumours account for approximately 30% of all ovarian tumours, and the dermoid cyst accounts for approximately 95% of this group of tumours. The remaining 5% of germ cell tumours are generally of a malignant tumour type and include dysgerminoma, yolk sac tumour, embryonal carcinoma, choriocarcinoma and immature teratoma. This latter group of tumours occurs almost exclusively in patients less than 20 years of age and as a group account for less than 1% of all ovarian tumours. Malignant germ cell tumours in general are most common in the paediatric population and young women. There are major differences between germ cell tumours occurring in very young female patients and those occurring in adolescents and adults. Germ cell tumours occurring in early childhood tend to be pure yolk sac tumours or teratomas, have no malignant non-neural epithelial components, are euploid or tetraploid and prior to puberty occur almost exclusively in extragonadal sites with primary germ cell tumours of the ovary being very rare. Germ cell tumours occurring in adolescents and adults are generally of mixed histological type or dysgerminomas, may have malignant epithelial components, commonly show isochromosome 12p and aneuploidy by cytogenetic studies and generally involve the ovary with extragonadal tumours being rare.

Germ cell tumours may be composed of a number of different tissue types or show a combination of different germ cell tumour types and are frequently complex histologically. It is the most malignant component present that determines the behaviour of these tumours. At one extreme of this complexity is the mature teratoma that contains tissue representing all three embryonic layers in a uniformly mature fashion. At the other end of the spectrum are immature teratomas and mixed malignant germ cell tumours which show a wide spectrum of histological types and degree of malignancy. In between these extremes of histological complexity are pure malignant germ cell tumours, with dysgerminoma being the most common example (**Figure 12**).

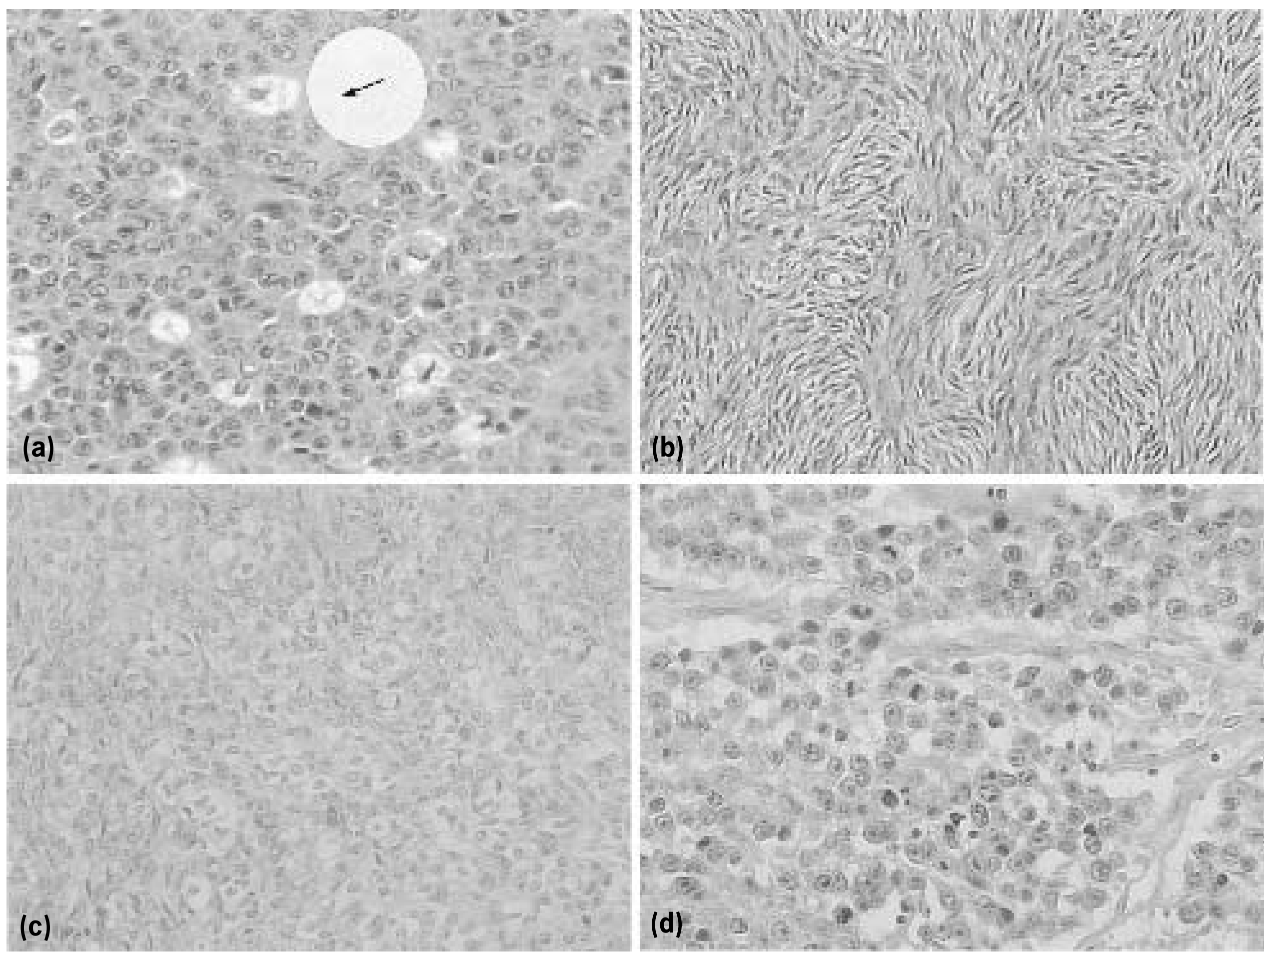

Figure 12 Stromal and germ cell tumours of the ovary. Panel (a) shows a granulosa cell tumour; note the nuclear grooves and the circular areas of degenerated material, called Call–Exner bodies (arrow). Panel (b) shows the interlacing fascicles of a fibroma whereas panel (c) demonstrates the prominent cytoplasm of a luteinized thecoma; this change often indicates hormonal production by the tumour. Panel (d) shows the large, polygonal cells of a dysgerminoma of the ovary; scattered lymphocytes are also characteristic of this tumour.

Molecular Genetic Findings

The most commonly identified gene conferring a high risk of epithelial ovarian cancer is *BRCA-1*, as discussed above. Among the sex-cord stromal tumours, molecular studies have generally been directed at adult-type granulosa cell tumours, where mutations have been identified in the G_I subunit of regulatory G proteins. Similar findings have been identified in individuals with the McCune–Albright syndrome, who show dysregulated ovarian function and isosexual precocity but no associated risk of ovarian cancer. Further studies are needed to identify the role of molecular alterations and the associated molecular genetic findings associated with regulatory G proteins.

The majority of molecular genetic findings in germ cell tumours have centred around cytogenetic findings with single gene mutations not being readily identified. The majority of mature teratomas have been shown to be karyotypically normal whereas immature teratomas show a high frequency of random nonrecurrent chromosomal abnormalities. Other adult germ cell tumours have frequently shown two copies of the short arm of chromosome 12, with this finding being rare in prepubertal patients with similiar tumours.

Prognostic Factors

The most reliable indicator of prognosis is stage at presentation. The overall 5-year survival rate for ovarian cancer confined to the ovary (Stage I) is approximately 75%. The rate declines to approximately 60% for pelvic extension of tumour beyond the ovary (Stage II) and 20% for metastatic disease (Stage III or IV). The size of the tumour in postmenopausal women has important prognostic implications, with tumours less than 5 cm usually being benign (95%), while tumours greater than 10 cm in size are often malignant (60%). Another prognostic factor at presentation is the presence or absence of ascites and the

volume of fluid present, with high-volume ascites having a worse prognosis. Levels of CA 125 both preoperatively and postoperatively have prognostic significance. Older age at presentation is associated with a worse prognosis, although other medical factors associated with the elderly patient make this parameter difficult to judge. A large volume of residual tumour after initial surgery and adjuvant chemotherapy portend a poor prognosis. Histological type among epithelial tumours is most important for clear-cell carcinomas, which usually have a higher recurrence rate and lower survival rate for Stage I tumours than other ovarian epithelial carcinomas. The grade (or cytological details) of an ovarian epithelial carcinoma is generally only important in Stage I tumours, as poorly differentiated tumours as opposed to well or moderately differentiated have a worse prognosis (and thus higher stage) and often prompt more aggressive treatment.

Overview of Present Clinical Management

The initial management of a patient with an adnexal mass is directly related to the age of the patient and the size of the mass. An initial mass greater than 10 cm in any patient regardless of age will usually result in laparoscopy or an exploratory laparotomy. At the other extreme an adnexal mass slightly increased over normal ovarian size, or less than 5 cm, is approached differently in pre- and post-menopausal patients. In women of reproductive age the high incidence of cystic enlargement of one or both ovaries due to the process of ovulation and formation of corpora lutea allows a much more cautious approach. These patients will usually be re-evaluated after two menstrual cycles and if the mass persists will then be evaluated by transvaginal ultrasonography and CA 125 measurement. In the postmenopausal patient any ovarian enlargement will prompt transvaginal ultrasonography and measurement of CA 125. In these patients any abnormal findings by ultrasonography other than a simple cyst will prompt an exploratory laparotomy.

In the event that a primary ovarian cancer is found, the most important parameter that will influence future treatment is accurate surgical staging. A simplified view of ovarian cancer staging determines three basic parameters that include whether or not the tumour is confined to the ovary or ovaries (Stage I) and, if not, then whether the cancer is limited to the true pelvis (Stage II) or extends beyond the true pelvis (Stage III or IV). Generally, ovarian epithelial cancers limited to the ovary do not require adjuvant chemotherapy or radiation and reproductive sparing surgery may be performed with the exception of tumours that are poorly differentiated and clear-cell carcinomas. All other stages of ovarian epithelial cancers require at least a total abdominal hysterectomy and some form of adjuvant chemotherapy and radiation. Of special note is that some borderline tumours, even if bilateral, can be treated with a reproductive sparing procedure.

Proper and accurate staging are particularly important in malignant germ cell tumours where reproductive sparing surgery is sufficent for Stage I tumours, which is the common presentation in this group. With the advent of multiagent chemotherapy, higher-stage germ cell tumours can be cured with a high rate of success (90%), and accurate staging can prevent significant morbidity and mortality in patients requiring such therapy, and just as importantly avoid undesirable side effects in those patients not requiring chemotherapy.

The management of sex-cord stromal tumours is not as well defined as for epithelial and germ cell tumours. Surgical treatment alone is often considered adequate treatment with the choice of adjuvant chemotherapy and/or radiation being of some debate. Historically, granulosa cell tumours have been treated with postsurgical radiation, but the recent recognition of their frequent recurrence 15–20 years later has prompted reconsideration of their treatment.

INTRODUCTION

A myriad of tumours affect the urinary tract, including numerous benign and malignant types. These tumours arise from the different tissues that comprise the structures of the urinary tract. The malignant tumours originating from the epithelium are referred to as carcinomas and are the most common malignant tumours of the urinary tract (**Figure 1**). Only the most common malignant tumours of the urinary tract are discussed in this chapter. Sarcomas, lymphomas and other assorted tumours affecting the urinary tract are rare and are beyond the scope of this text.

NORMAL DEVELOPMENT AND STRUCTURE OF URINARY TRACT

Normal Development

The urinary tract is almost entirely derived from the mesoderm, except for the most distal part of the urethra, which develops from the ectoderm. The kidney and ureter develop from the intermediate mesoderm, while the urinary bladder and urethra are derived from the urogenital sinus.

Structure

The kidneys are paired organs located in the retroperitoneum, extending from the level of the twelfth thoracic vertebra to the third lumbar vertebra. Each kidney is surrounded by abundant adipose tissue that is covered by the membranous perirenal fascia of Gerota. The renal parenchyma is enveloped by a fibroelastic capsule, which acts as a barrier to the spread of cancer. The kidney is divided into 8–18 (average 14) lobes that are fused together. Each lobe is constituted by the outer cortex and inner medullary pyramid. The nephron is the functional unit, which is composed of the glomerulus and tubule. The tubules empty into collecting ducts that coalesce to form the terminal ducts of Bellini; the latter number 10–25 in each lobe. The ducts of Bellini open at the tip of the papilla, which is the apex of the medullary pyramid. The renal sinus is a concave space at the medial aspect of the kidney where the renal pelvis and calyces, blood vessels and nerves enter the kidney. It is filled with fibroadipose tissue that is continuous with the perirenal adipose tissue and has numerous lymphatic channels and blood vessels.

The renal pelvis is located at the renal hilum and consists of two or three major calyces and 8–18 minor calyces. The minor calyces surround the renal papillae. The ureters arise from the renal pelves, and both are hollow structures with similar features. Their walls are composed of four layers, which from inside out are the urothelium (transitional epithelium) lined mucosa, lamina propria, muscularis propria and adventitia.

The urinary bladder is also a hollow organ that is located deep in the pelvis, behind the pubic bone. The ureters traverse the wall of the urinary bladder to open in the inferior part referred to as the trigone. The superior portion is the dome. The wall of the urinary bladder is composed of four layers, starting from the inside with the urothelium (transitional cell) lined mucosa, followed by the lamina propria, muscularis propria, adventitia and

(Figure courtesy of Dr J. A. Gomez.)

perivesical adipose tissue. The muscularis mucosae is an interrupted layer of smooth muscle in the lamina propria, which needs to be distinguished from the muscularis propria as the staging of urinary bladder tumours is dependent on the depth of invasion.

The urethra is continuous with the neck of the urinary bladder. The male urethra is divided into the prostatic, membranous, penile and bulbar segments. Except for the distal end, which is lined by squamous epithelium, the urethra is also lined by urothelium. The female urethra is shorter and is roughly divided into the proximal one-third, which is lined by urothelium, and distal two-thirds lined by squamous epithelium.

KIDNEY

A variety of different benign and malignant tumours involve the kidney in children and adults, which are listed in **Table 1**. These tumours arise from the different components that constitute the kidney. Malignant tumours arising from the epithelium of the kidney include nephroblastoma (Wilms' tumour), which is the most common renal tumour in children, and renal cell carcinoma, which is the most common renal cancer in adults. Urothelial carcinoma also affects the kidney, arising in the structures lined by urothelium, i.e. the renal pelvis. The discussion in this chapter will concentrate on the most common malignant tumours, i.e. nephroblastoma, renal cell carcinoma and urothelial carcinoma. The other less common tumours will not be described as they are beyond the scope of this text.

[a] Tumours predominantly or exclusively affecting children.

Nephroblastoma (Wilms' Tumour)

Tumour Pathology

Nephroblastoma (Wilms' tumour) is the most common primary renal tumour that affects children, accounting for more than of 80% of renal tumours in children. The eponym Wilms' tumour is used commonly in honour of Max Wilms, who reported seven tumours and reviewed the literature, although he was not the first to describe this tumour. The improvements in treatment and survival of nephroblastoma (Wilms' tumour) patients have in large part been due to the success of multidisciplinary cooperative

groups such as the National Wilms' Tumor Study (NWTS) and the Société Internationale d'Oncologie Pédiatrique (SIOP). A large part of our knowledge of this disease is based on the findings of the NWTS and SIOP studies (Boccon-Gibod, 1998; Neville and Ritchey, 2000).

More than 90% of these tumours develop in children with no other known problems, while the remainder affect children with specific malformations. The presence of an abdominal mass is the most common presenting feature. Other signs and symptoms include pain, haematuria, hypertension, intestinal obstruction and sometimes problems related to distant metastasis.

There are two staging systems for nephroblastoma (Wilms' tumour) based on the extent of spread of tumour; these are listed in **Table 2**. The NWTS and SIOP staging systems are very similar, but the fundamental difference is that in the former the tumour is staged prior to chemotherapy.

Epidemiology

Nephroblastoma (Wilms' tumour) affects one in 8000–10 000 children (0–15 years of age), with over 90% tumours occurring in children under 6 years of age, most commonly between the ages of 3 and 4 years. Patients with unilateral tumours present at a mean age of 41.5 months for males and 46.9 months for females. In contrast, patients with bilateral tumours present at a younger age, with a mean of 29.5 months for males and 32.6 months for females. This tumour is very rare in neonates (0.1% of all nephroblastomas) and rarely affects adults. Girls are affected more commonly than boys, with a male to female ratio of 0.92:1 for unilateral tumours and 0.60:1 for bilateral tumours. In the United States this tumour is most common in African-Americans and least common in Chinese-Americans.

Aetiology

Nephroblastoma (Wilms' tumour) is associated with at least three well-defined congenital syndromes. The WAGR syndrome (Wilms' tumour, Aniridia, Genital abnormalities and mental Retardation) is associated with a deletion in the *WT-1* gene located on chromosome 11p13. The Denys–Drash syndrome (glomerulonephritis, pseudohermaphroditism and nephroblastoma) is also associated with mutations of the *WT-1* gene. Patients with Beckwith–Weidemann syndrome (hemihypertrophy, renal medullary cysts, adrenal cytomegaly and nephroblastoma) have abnormalities of the *WT-2* gene located distal to the *WT-1* gene on chromosome 11p15.5. In up to 1% of patients the tumours are familial. Other possible associations include renal malformations, cutaneous naevi, trisomy 18, genital malformations and neurofibromatosis.

Screening and Prevention

The use of abdominal ultrasound is recommended for routine screening of patients at high risk of nephroblastoma (Wilms' tumour), such as children with the three above-mentioned syndromes. Recommendations for screening include ultrasound examination every 3 months until the age of 7 years, followed by physical examination every 6 months. However, the efficacy of screening programme remains to be determined.

Gross Features

Nephroblastoma usually presents as a solitary tumour that is well encapsulated from the adjacent normal renal parenchyma. The tumour size varies, but the majority are larger than 5 cm and some may exceed 10 cm in greatest dimension. According to data from the NWTS the median weight of these tumours is 550 g. The cut surface shows a mainly

Table 2 Staging systems for nephroblastoma (Wilms' tumour)

Stage	NWTS[a]	SIOP[b]
I	Tumour confined to the kidney and completely resected without rupture	Tumour limited to the kidney and completely excised
II	Tumour extends beyond the kidney (by direct invasion of capsule, extrarenal vascular invasion or tumour spillage without peritoneal contamination), but is completely resected (includes biopsied tumour)	Tumour extending outside kidney, but completely excised, with or without regional lymph node invasion
III	Gross residual tumour, and/or involved surgical margin, and/or tumour in regional lymph nodes	Incomplete surgical excision, without haematogenous metastases, but including biopsy before or at surgery, preoperative rupture, peritoneal implants or nodal metastasis beyond regional lymph nodes
IV	Any local stage with haematogenous metastasis	Distant metastases
V	Bilateral renal tumours at time of diagnosis (tumour in each kidney is separately substaged)	Bilateral renal tumours at time of diagnosis

[b]Société Internationale d'Oncologie Pédiatrique: tumour staged following surgery preceded by chemotherapy (unless metastases are present at time of presentation).

solid, uniform, soft, tan or grey tumour. Haemorrhagic and necrotic areas may be present. Cyst formation may be present, sometimes extensively involving the entire tumour.

Microscopic Features

Nephroblastoma (Wilms' tumour) has three components that are present in varying quantities, blastema, epithelium and stroma (**Figure 2, see colour plate section**). Blastema is composed of closely packed small cells without visible cell borders that are arranged as nodules, interconnecting cords or diffuse sheets (Schmidt and Beckwith, 1995). The epithelial component generally forms tubules, glands or glomeruloid structures. The stromal component is made of spindle cells that surround the blastema and epithelial components. The spindle cells may be set within a myxoid background resembling primitive mesenchyme or may have a fibroblastic appearance. The stromal cells may be differentiated into rhabdomyoblasts, bone, cartilage, adipose tissue, mature ganglion cells or neuroglia.

Anaplasia is one of the most important histological features that needs to be determined in every tumour. Anaplasia, which may be either focal or diffuse, is defined as the presence of multipolar mitotic figures and nuclei with increased chromatin that are at least three-fold larger than adjacent cells (Faria *et al*., 1996). Diffuse anaplasia is the presence of anaplasia in more than one portion of the tumour or if found in any extrarenal or metastatic site.

Immunohistochemistry

There are no specific immunohistochemical stains for making the diagnosis of nephroblastoma (Wilms' tumour). The blastema component does stain with vimentin immunohistochemical stain.

Prognostic Factors

Tumour histology and stage are the most important prognostic factors in nephroblastoma (Wilms' tumour). Tumours are divided into those with favourable histology and those with unfavourable histology, depending on the presence or absence of anaplasia. Tumours with unfavourable histology account for 5–6% of all cases. Patients who have tumours with unfavourable histology have a worse prognosis, e.g. nearly half of the patients in the second NWTS who died of disease had unfavourable histology, although they numbered only 12% of all cases. Other prognostic factors that have limited success in predicting prognosis and that are still under investigation include DNA content measured by flow cytometry, nuclear morphometry, serum renin and erythropoietin.

Overview of present Clinical Management

A multimodal approach is used for treating patients with nephroblastoma (Wilms' tumour), which varies in different parts of the world. In most of the United States and Canada the NWTS protocol is followed, which calls for radical nephrectomy (with rare exceptions) followed by chemotherapy and/or radiation therapy, based on the surgical and pathological findings. In most of Europe the SIOP protocols are followed, in which chemotherapy is given prior to nephrectomy.

Renal Cell Carcinoma

Tumour Pathology

Renal cell carcinoma is a malignant tumour that arises from the renal epithelium. The history of renal cell carcinoma is interesting in that it was not until 1960 that Oberling *et al*. laid to rest the controversy regarding the origin of renal cell carcinoma by providing conclusive electron microscopic evidence of its origin from renal tubular epithelium. Prior to the study by Oberling *et al*. there were certain schools of thought that considered renal cell carcinoma to be of adrenal origin. It was Grawitz in 1883 who put forth the theory of renal cell carcinoma originating from adrenal rests in the kidney, rather than from renal epithelium, because of its resemblance to the adrenal gland cortex. Therefore, in the past this tumour was referred to as Grawitz tumour or 'hypernephroma', the latter term being coined by Birch-Hirschfeld in 1892.

A number of renal cell carcinomas are detected incidentally when the patient is investigated for other medical conditions. The tumour may grow substantially before it induces any signs or symptoms. The so-called 'classical triad' of flank pain, flank mass and haematuria is now only seen with advanced-stage tumours, which occur rarely. In addition to the aforementioned, patients may have nonspecific complaints such as fever, weakness, malaise and weight loss. Renal cell carcinoma may also be associated with paraneoplastic syndromes such as polycythaemia, hypertension, Cushing syndrome and hypercalcaemia. In 25%–30% of patients metastasis may be the first indication of the presence of the cancer.

The classification of renal cell carcinoma has changed in the recent past to better embody our understanding of this disease. Two important workshops on the classification of renal tumours were held in 1996 and 1997. The first, entitled 'Impact of Molecular Genetics on the Classification of Renal Cell Tumours' was held in October 1996 in Heidelberg, Germany. The conclusions of this workshop are referred to as the Heidelberg classification of renal tumours (Kovacs *et al*., 1997). The second, entitled 'Diagnosis and Prognosis of Renal Cell Carcinoma: 1997 Workshop', organized by the American Joint Committee on Cancer (AJCC) and Union Internationale Contre le Cancer (UICC), was held in March 1997 (Störkel *et al*., 1997). These two classification systems are listed in **Table 3**. While these two classification systems at first glance may seem to be similar, and they are in the use of similar terms, the major difference is the Heidelberg

classification's emphasis on genetic correlation. Both of these classification schemes are based on the light microscopic appearance of the tumour but are in keeping with our prevailing knowledge of the genetics of these cancers. The diagnostic terminology used is practical, concise and reflective of the morphologic appearance of the tumour; however, some of these terms are not descriptive and do not encompass all the morphologic patterns of a given tumour. There are numerous older classification schemes for subtyping renal cell carcinoma that use different terminology, including terms such as chromophil carcinoma (for papillary renal cell carcinoma), nonpapillary renal cell carcinoma, etc. It is preferable to avoid use of these terms as they may cause confusion.

All renal cell carcinomas are graded according to Fuhrman's nuclear grading system, which is divided into four grades based on the nuclear size, nuclear irregularity and nucleolar prominence (**Table 4**). The grade is based on the highest grade within the entire tumour, and not the predominant grade. It is evaluated at 100× and 400× magnification using a light microscope.

The tumour, nodes and metastasis (TNM) system is the most widely used system for staging renal cell carcinoma (**Table 5**). The other system that is used sometimes is the Robson staging system (**Table 5**). The staging systems are partly based on the extent of invasion by the tumour, with the lower stage tumours (pT1 and pT2) being confined to the kidney, whereas the higher stage tumours (pT3 and pT4) extend beyond the confines of the organ.

Table 3 Classification of renal cell carcinoma

Heidelberg classification[a]	AJCC/UICC classification[b]
Benign tumours	*Benign tumours*
Papillary renal cell adenoma	Papillary adenoma
Renal oncocytoma	Renal oncocytoma
Metanephric adenoma	Metanephric adenoma

Malignant tumours	*Malignant tumours*
Common or conventional renal cell carcinoma	Conventional (clear) renal cell carcinoma
Papillary renal cell carcinoma	Papillary renal cell carcinoma
Chromophobe renal cell carcinoma	Chromophobe renal cell carcinoma
Collecting duct carcinoma	Collecting duct carcinoma
RCC, unclassified	Unclassified renal cell carcinoma

[a]Kovacs *et al.*, 1997.
[b]Störkel *et al.*, 1997.

Epidemiology

Renal cell carcinoma affects approximately 1–3% of all patients with cancer worldwide (McLaughlin and Lipworth, 2000). The highest incidence of renal cell carcinoma is recorded in Scandinavia followed by other parts of northern Europe, the United States and Canada. The lowest incidence rates have been recorded in Central and South America and in Asia. It is estimated that 30 800 new cases of renal cell carcinoma will be diagnosed in the United States in the year 2001, constituting the ninth most common tumour in that country. An estimated 12 100 persons are expected to die of the disease in the United States in the year 2001. The incidence of renal cell carcinoma has been increasing every year in the United States since the 1970s, with a greater increase being noted in the African-American population as compared with Caucasians. This cancer more commonly affects men than women, with a male to female ratio of 2 : 1. Patients of renal cell carcinoma are more likely to be in the late sixth and early seventh decades of life, although these cancers have been reported to occur in children. In addition to the sporadic forms of the cancer, a small percentage are familial, these include renal cell carcinoma associated with Von Hippel–Lindau (VHL) syndrome, familial conventional (clear cell) carcinoma and familial papillary renal cell carcinoma. These cancers usually occur in younger patients, and show autosomal dominant inheritance.

Aetiology

Numerous agents (**Table 6**) are associated with development of renal cell carcinoma (McLaughlin and Lipworth,

Table 4 Fuhrman's nuclear grading for renal cell carcinoma

Grade	Nucleus	Nucleolus
1	Small (10-μm diameter), round, uniform, resembling nucleus of mature lymphocyte	Inconspicuous or absent nucleoli (viewed at 400× magnification)
2	Larger nuclei (15-μm diameter), with slight nuclear irregularity	Small nucleoli (only visible at 400× magnification)
3	Large nuclei (20-μm diameter), with obvious nuclear irregularity	Large, prominent nucleoli (visible at 100× magnification)
4	Same as grade 3 but more bizarre with multilobation and large clumps of chromatin	Large, prominent nucleoli (visible at 100× magnification)

Table 5 1997 TNM staging systems for renal cell carcinoma

Primary tumour (T)	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Tumour 7.0 cm or less in greatest dimension, limited to the kidney
T2	Tumour > 7.0 cm in greatest dimension, limited to the kidney
T3	(a) Tumour invades adrenal gland or perinephric tissue, but not beyond Gerota's fascia

2000). Cigarette smoking is the most prominent aetiological factor associated with renal cell carcinoma; 20–30% of all renal cell carcinomas affecting men and 10–20% affecting women are attributed to cigarette smoking. There is a strong dose–response relationship associated with cigarette smoking; the relative risk for smokers ranges from 1.2 to 2.3, with a relative risk from 1.9 to 2.5 for heavy smokers. In the familial forms of renal cell carcinoma, genetic alterations play an important aetiological role. Germ-line mutations of chromosome 3p are associated with the VHL syndrome; mutations of chromosome 3p are also associated with familial conventional (clear cell) carcinoma. Germ-line mutations of the *MET* proto-oncogene, located on chromosome 7, are associated with the familial form of papillary renal cell carcinoma. In women, there is a positive association with obesity, which may be hormonally related. Long-term haemodialysis used in the treatment of renal disease leads to an increased incidence of acquired cystic disease, which in turn leads to increased risk of renal cell carcinoma. Although use of the drug phenacetin has been related to urothelial carcinoma of the renal pelvis, there is a less consistent association with renal cell carcinoma. Association with the drug acetaminophen has not been proved, except in one study. Other possible aetiological factors include hypertension, diet, and exposure to asbestos and petroleum products.

Gross Features

Renal cell carcinoma most often occurs as a single solid tumour often located at the periphery of the renal parenchyma (**Figure 3; see colour plate section**). However, collecting duct carcinoma is located more centrally in the medullary region. A bright yellow or light orange colour is most characteristic of conventional (clear cell) renal cell carcinoma, which is the most common type of renal cell carcinoma. In addition, there may be areas of haemorrhage and necrosis resulting in a mottled

Table 6 Aetiological and putative aetiological factors in urinary tract tumours

Renal cell carcinoma	Urothelial carcinoma of renal pelvis and ureter	Urothelial carcinoma of urinary bladder

		Bladder exstrophy
		Artificial sweeteners
		Human papillomavirus
		Gene mutation/deletions (*p15*, *p16*, *p53*, *ras*, *c-myc*)

appearance. Chromophobe renal cell carcinoma is relatively homogeneous with a light beige, tan–brown or brown colouration; however, higher grade tumours may have haemorrhage and necrosis. Papillary renal cell carcinoma is well circumscribed; it may have a similar colouration as the conventional (clear cell) type, or may be light tan to grey, depending on the number of foam cells in the stroma. Foci of necrosis, haemorrhage and cyst formation may be seen in any of the subtypes. Areas of sarcomatoid dedifferentiation are grey–white, more fleshy or firm. Pale yellow or pale tan firm areas of scar formation should not be confused for sarcomatoid dedifferentiation. Foci of calcification may also be present. The majority of the carcinomas are confined to the kidney, but some may show gross invasion into the perinephric adipose tissue or into the renal vein, rarely extending into the inferior vena cava and the right side of the heart.

Microscopic Features

Each of the different subtypes of renal cell carcinoma has distinct morphological features, which are detailed below.

Conventional (Clear Cell) Renal Cell Carcinoma

Conventional (clear cell) renal cell carcinoma is the most common subtype, representing 65–75% of renal cancer in most series. Tumour cells are arranged in sheets, nests, or tubules (**Figure 4; see colour plate section**). Uncommonly they may show a tubulocystic or, rarely, a papillary arrangement. Most tumour cells have clear cytoplasm; however, tumours can have a combination of cells with clear and granular eosinophilic cytoplasm. Tumours almost exclusively composed of cells with eosinophilic cytoplasm are rare. The clear cell appearance of conventional renal cell carcinoma is secondary to the lipid and glycogen content of the cells. The periodic acid Schiff (PAS) histochemical stain, with and without diastase, is the best method for demonstrating the cytoplasmic glycogen. One of the hallmark histological features is the delicate, interconnecting, sinusoidal-type of vasculature, sometimes likened to ‘chicken wire’ (**Figure 4**). This type of vascular pattern is generally not seen in the other subtypes of renal cell carcinoma and is a good clue to making the diagnosis of conventional renal cell carcinoma when cells with granular eosinophilic cytoplasm predominate. Thus, the diagnosis of conventional renal cell carcinoma is based on the architectural pattern and the vascular pattern, rather than the tinctorial properties of the cell cytoplasm.

Papillary Renal Cell Carcinoma

Papillary renal cell carcinoma accounts for about 10–15% of all renal carcinomas. Multifocal and bilateral tumours are more common in this subtype than any other subtype of renal cell carcinoma. Microscopically, it shows fibrovascular papillary cores lined by a single layer of low cuboidal epithelial cells that have scant pale cytoplasm and oval dark nuclei (**Figure 5; see colour plate section**). Some tumours have tall columnar pseudostratified cells with abundant eosinophilic cytoplasm. Tumour cells may have haemosiderin pigment within the cytoplasm. In addition to the papillae, tumour cells may form tubules, tubulopapillary structures and, rarely, solid nests. A characteristic feature, which may not be present in all tumours, is the presence of foamy macrophages within the fibrovascular stalks. Laminated calcifications (psammoma bodies) are also commonly present.

Chromophobe Renal Cell Carcinoma

Chromophobe renal cell carcinoma accounts for about 5% of all renal carcinomas and presents distinctive histological and ultrastructural features that clearly separate it from the other subtypes. There are two morphological variants, typical or classical chromophobe and the eosinophilic variant; this distinction is based on the tinctorial properties of the cytoplasm. These variants are not clinically important, but are important from the diagnosis point of view as the eosinophilic variant may be mistaken for renal oncocytoma, a benign tumour. Tumour cells are arranged in sheets, broad alveoli or nests. There are two types of cells, clear and eosinophilic (**Figure 6; see colour plate section**). Both types are usually present with one type predominating; if clear cells predominate, the tumour is referred to as typical or classical, and if the eosinophilic cells predominate, it is the eosinophilic variant. The clear cells have abundant clear cytoplasm with a frothy, vacuolated or bubbly appearance (soap bubble appearance) and prominent cell membranes, resembling plant cells. The cytoplasm typically forms a rim along the cell membrane that appears darker than the remainder of the cytoplasm. These cells also may have a perinuclear halo. The eosinophilic cells are smaller and have finely granular eosinophilic cytoplasm, with a variable degree of perinuclear clearing. The nuclei are hyperchromatic, frequently binucleate and have a wrinkled nuclear membrane. The nuclear features along with the perinuclear halo and the prominent cell membranes is referred to as ‘koilocytoid atypia,’ as it superficially resembles the changes seen in cells infected by the human papillomavirus. Hale’s colloidal iron stain is the histochemical stain of choice for confirming the diagnosis of chromophobe renal cell carcinoma; this stain shows diffuse, reticular staining.

Collecting Duct Carcinoma

Collecting duct carcinoma is rare, accounting for about 1% of all renal cell carcinomas. Microscopically, three features characterize this renal cancer; a tubulo-papillary arrangement of cells, desmoplastic reaction of the stroma and dysplastic changes in the adjacent collecting ducts. Dilated tubules or solid areas may also be present. In

general, before making a diagnosis of collecting duct carcinoma, metastasis to the kidney should be excluded. Renal medullary carcinoma is a distinctive type of collecting duct carcinoma with an aggressive clinical course, which arises in the renal medulla and is associated with sickle cell trait. In addition to the typical morphological features of collecting duct carcinoma, these cancers have reticular, microcystic areas, which resemble yolk sac tumour. Collecting duct carcinoma shows variable areas of mucin formation, which stain with histochemical stains for mucin, such as mucicarmine and Alcian blue.

Renal Cell Carcinoma, Unclassified

Unclassified renal cell carcinoma is not a distinctive subtype, but rather represents renal cancers that do not fit into one of the above-mentioned categories. Renal cancers in this category include, but are not limited to, those not conforming to any of the known histological subtypes, composites of recognizable subtypes, cancers with extensive necrosis and minimal viable tumour, mucin-producing tumours that are not collecting duct carcinoma and tumours with sarcomatoid dedifferentiation that do not have an epithelial element that can be readily assigned to one of the above categories (Störkel *et al*., 1997).

Renal Cell Carcinoma with Sarcomatoid Dedifferentiation

Sarcomatoid dedifferentiation is seen in approximately 1.5% of renal cell carcinomas. The term sarcomatoid dedifferentiation denotes anaplastic transformation of the renal cell carcinoma into a high-grade biphasic tumour that contains both malignant carcinomatous and mesenchymal elements. These tumours have been referred to in the past as carcinosarcoma or mixed mesodermal tumours. The incidence of sarcomatoid dedifferentiation, in our experience, varies amongst the different subtypes: 8% in conventional (clear cell), 3% in papillary renal cell carcinoma, 9% in chromophobe renal cell carcinoma, 27% in collecting duct carcinoma and 11% in renal cell carcinoma unclassified. The carcinoma component is usually high grade, at least a Fuhrman's nuclear grade 3, but may have any grade. The sarcomatous component may resemble pleomorphic malignant fibrous histiocytoma or an unclassified spindle cell sarcoma, or may show differentiation into bone, cartilage, skeletal muscle or blood vessels. It is important to differentiate a true sarcomatous component from benign spindle cells that are sometimes seen in renal cell carcinoma. The majority of these lesions are high stage at presentation and the prognosis is very poor. When reporting sarcomatoid dedifferentiation in renal cell carcinoma it is important to mention the percentage of the sarcomatoid component and the type of epithelial and sarcomatoid components. The percentage of the sarcomatoid component has been reported to be important for survival; patients with >50% sarcomatoid dedifferentiation in their cancer do poorly.

Immunohistochemistry

All renal cell carcinomas stain positive with immunohistochemical stains for cytokeratin cocktail (AE1/AE3 and CAM 5.2), low molecular weight cytokeratin and epithelial membrane antigen (EMA). Conventional (clear cell) and papillary renal cell carcinoma also stain with vimentin, which is an intermediate filament usually associated with mesenchymal structures. Chromophobe renal cell carcinoma, on the other hand, does not stain with vimentin, which may be utilized for distinguishing the eosinophilic variant of chromophobe renal cell carcinoma from conventional renal cell carcinoma with predominantly eosinophilic cells. Collecting duct carcinoma, however, has a unique staining pattern, reacting with both low and high molecular weight cytokeratins, peanut agglutinin, *Ulex europaeus* lectin and epithelial membrane antigen. This characteristic staining pattern is similar to that of the distal collecting tubule epithelium.

Electron Microscopy

Ultrastructurally, the cells of conventional (clear cell) renal cell carcinoma exhibit a brush border, tend to form microlumina and have a basal lamina that separates groups of cells from each other. Abundant glycogen and lipid are present in the cytoplasm. Chromophobe renal cell carcinoma has characteristic microvesicles, which are probably derived from the endoplasmic reticulum or from mitochondria. Mitochondria also impart the characteristic granularity to the cytoplasm seen by light microscopy.

Molecular Genetics

Sporadic conventional (clear cell) renal cell carcinoma typically (in approximately 80–90%) shows loss of genetic material from the short arm of chromosome 3, in the region 3p14–3p26 that harbours the *VHL* gene at 3p25.3. Mutations within the *VHL* gene region and inactivation of this gene by hypermethylation are common. Sporadic papillary renal cell carcinoma is characterized by trisomies, especially of chromosomes 7 and 17, and loss of the Y chromosome. Other chromosomes that may be involved include 3, 9, 11, 12, 16, and 20; some of these additional abnormalities are speculated to lead to progression to a more aggressive phenotype. Translocation between chromosomes X and 1 has also been reported, and is more common in children. As mentioned earlier, the familial cases of papillary renal cell carcinoma show germ-line mutations of the *MET* proto-oncogene. Chromophobe renal cell carcinomas are characterized by combined losses of multiple chromosomes including 1, 2, 6, 10, 12, 13, 14, 15 and 17. Polysomy of chromosome 7, trisomy 12, 16 and 19, telomeric associations and structural abnormalities of 11q have also been described in these cancers. Another important finding in chromophobe renal cell carcinoma is abnormalities of

mitochondrial DNA, a feature not seen in the other subtypes. Collecting duct carcinoma does not have any distinct genetic alterations. Monosomy of chromosomes 1, 6, 14, 15 and 22, deletions of 8p and13q, and loss of heterozygosity (LOH) in 1q have all been reported in this cancer.

Prognostic Factors

The prognosis of renal cell carcinoma is heavily dependent on the TNM stage of the tumour (Rini and Vogelzang, 2000). The 5-year survival rate of all patients with renal cell carcinoma is 70–75%. The overall 5-year survival rate is $\leq 10\%$ in patients with stage IV disease, 20–40% in patients with stage III tumours, 50–60% with stage II tumours and 60–90% with stage I tumours. The presence of sarcomatoid dedifferentiation also portends a poor prognosis, with disease-specific survival rates of 59 and 22% at 1 and 5 years, respectively. Fuhrman's nuclear grade has also been shown to have limited value in predicting prognosis. Up to 50% of patients with the VHL syndrome die of renal cell carcinoma. Newer markers that are under investigation for determining prognosis include DNA ploidy, proliferation marker MIB-1, p53, vascular endothelium growth factor (VEGF), *VHL* gene mutations, etc. None of these markers has so far been shown to be better at predicting tumour recurrence or death from disease, and all of these markers and molecular genetic alterations need to be studied further.

Overview of Present Clinical Management

Surgical resection in the form of radical nephrectomy remains the most effective treatment for clinically localized tumours. In recent years the use of nephron-sparing surgery has been gaining popularity for the treatment of small, localized tumours that can be easily resected (Wunderlich *et al*., 1998). Solitary metastasis of renal cell carcinoma may be resected, but with limited success. Immunotherapy using interferon and/or interleukin 2 (IL-2) has had partial success in treating metastatic disease, as it remains resistant to systemic chemotherapy. Newer therapies for metastatic renal cell carcinoma that are currently undergoing investigation include tumour-specific vaccines, angiogenesis inhibitors, monoclonal antibodies and dendritic cell therapy.

RENAL PELVIS AND URETER

Tumours of the renal pelvis and ureter are uncommon. Urothelial carcinoma accounts for 90% of the malignant tumours, but represents less than 5% of all tumours arising from the urothelium. The remaining 10% include squamous cell carcinoma and adenocarcinoma. Urothelial carcinomas of the renal pelvis and ureter have epidemiological, clinical, morphological and prognostic features similar to those arising in the urinary bladder (Steffens and Nagel, 1988). There are significantly different aetiological factors (**Table 6**) associated with these tumours including phenacetin abuse, thorium (radiographic contrast medium) exposure and Balkan nephropathy. Another characteristic feature is the association with urothelial tumours of the urinary bladder, which may occur synchronously or metachronously. Tumours arising in the ureter may fill the lumen, leading to obstruction and possibly hydronephrosis. All the different morphological variants of urothelial carcinoma reported in the urinary bladder have also been reported in the renal pelvis and ureter. The grading system is similar to that of the urinary bladder urothelial carcinomas. Also like the urinary bladder, the TNM staging system is based on the depth of invasion (**Table 7**).

Table 7 1997 TNM staging system for urothelial carcinoma of renal pelvis and ureter

Primary tumour (T)	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma *in situ*
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades the muscularis
T3	(For renal pelvis only): tumour invades beyond muscularis into peripelvic fat or the renal parenchyma
T3	(For ureter only): tumour invades beyond muscularis into periureteric fat
T4	Tumour invades adjacent organs, or through the kidney into the perinephric fat
Regional lymph nodes (N)[a]	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node more than 5 cm in greatest dimension
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

	Any T	Any N	M1

[a]Laterality does not affect the N classification.

Nephroureterectomy with a bladder cuff remains the treatment of choice for these cancers.

URINARY BLADDER

Up to 95% of urinary bladder tumours (**Table 8**) are of epithelial origin, of which 90% are urothelial neoplasms. The urothelium is a highly specialized epithelium that lines the entire urinary tract and has the ability to modify the number of layers forming it, depending on the level of distention of the organ wall. It has traditionally been referred to as the transitional cell epithelium, but urothelium is currently the preferred term (Epstein *et al*., 1998).

Other types of epithelial tumours arise in the urinary bladder, including squamous cell carcinomas and adenocarcinomas. These are usually diagnosed when the entire tumour is entirely composed of malignant squamous or glandular elements, as foci of squamous or glandular differentiation can be seen in otherwise typical urothelial carcinomas, more commonly in high-grade tumours. Small cell carcinoma and other neuroendocrine carcinomas of the urinary bladder have also been reported.

Table 8 Tumours of the urinary bladder

Benign tumours	Malignant tumours
Epithelial tumours	*Epithelial tumours*
Urothelial papilloma	Urothelial carcinoma (papillary noninvasive, papillary invasive, flat noninvasive, flat invasive, invasive NOS, micropapillary, lymphoepithelioma-like, nested)
Urothelial inverted papilloma	Squamous cell carcinoma
Villous adenoma	Adenocarcinoma
	Small cell carcinoma
	Undifferentiated carcinoma
Mesenchymal tumours	*Mesenchymal tumours*
Leiomyoma	Rhabdomyosarcoma
Neurofibroma	Leiomyosarcoma
Haemangioma	
Inflammatory myofibroblastic tumour	
	Miscellaneous neoplasms
	Lymphoma/leukaemia
	Plasmacytoma
	Malignant melanoma
	Paraganglioma
	Germ cell neoplasms
	Secondary involvement
	Direct extension from adjacent organs (rectum, bladder, uterus)
	Metastasis

Mesenchymal neoplasms, which range from benign proliferations to highly malignant and aggressive tumours, are much less common. The most common benign mesenchymal neoplasm is leiomyoma, while the most common sarcomas are rhabdomyosarcoma in children and leiomyosarcoma in adults. Lymphoma, plasmacytoma and infiltration by leukaemia rarely present in the urinary bladder without a previous history of the disease. Finally, secondary involvement of the urinary bladder by other tumours is rare, but when it occurs it is usually by direct extension from adjacent organs.

Urothelial Carcinoma

Tumour Pathology

Urothelial neoplasms arise by two distinct pathobiological pathways, resulting in the development of either papillary or nonpapillary tumours (see Molecular Genetics, below). Benign urothelial neoplasms, including exophytic and inverted urothelial papillomas, are much less frequent than carcinomas. Most urothelial carcinomas are preinvasive or early invasive papillary tumours. These tumours show a range of cytological and architectural atypia, which has been the basis for several proposed grading systems (see Microscopic Features, below). They are commonly multifocal, and may involve other sites along the urinary tract in addition to the urinary bladder. Papillary tumours tend to recur several times and eventually can invade the underlying lamina propria and muscularis propria. Less commonly, urinary bladder neoplasms start as nonpapillary or flat intraepithelial lesions, referred to as primary or *de novo* urothelial carcinoma *in situ*. These tumours also have the potential to invade the underlying wall. Up to 20% of urinary bladder neoplasms are diagnosed in an advanced stage, with invasion of the muscularis propria. When invasive, urothelial neoplasms have the potential to produce metastasis and death due to disease.

Epidemiology

It is estimated that 54 000 new cases of urinary bladder cancer will be diagnosed in the United States in the year 2001, constituting the fifth most common tumour in that country. Despite recent advances in treatment of both early and advanced urinary bladder tumours, an estimated 12 000 persons are expected to die of the disease in the United States in the year 2001. Urinary bladder cancer is more frequent in North America and Western Europe and uncommon in Japan. In the United States, it is twice as common in Caucasians as in African-Americans. It also has a 2.6-fold higher incidence in men than in women. Most tumours arise during late adulthood, with a median age at diagnosis of over 65 years.

Aetiology

Several aetiological factors have been associated with the development of urinary bladder cancer (Johansson and Cohen, 1997). This still growing list started in the nineteenth century when an increased incidence in urinary bladder tumours was noted among workers in the dye industry. Today, new data on the role of tumour-suppressor genes, oncogenes and other external influences have enhanced our knowledge of the pathogenesis of urinary bladder cancer (**Table 6**).

Tobacco

Approximately 33% of urinary bladder tumours (50–80% of tumours in men) are associated with smoking. The risk in smokers is increased 3–7-fold compared with nonsmokers, depending on the number of pack-years and smoking habits. Ex-smokers have a reduced risk, but the period of time necessary for them to return to the same risk level as nonsmokers is unknown.

Arylamines

Occupational exposure to arylamines, which are widely used in the aniline dye and rubber industry, has been associated with up to one-third of urinary bladder cancers. The risk is dependent on the intensity and duration of the exposure, and tumours usually appear 15–40 years after the first exposure. The insult to the urothelium results when the urinary enzyme glucuronidase splits the nontoxic glucuronate conjugate previously formed in the liver, releasing an electrophilic reactant. The process is highly specific to humans, as we are one of the few species to possess glucuronidase.

Radiation

There is an increased risk of developing urothelial carcinoma in women treated with radiation for cervical carcinoma. The tumours usually develop many years after exposure and are usually of high grade and high stage at presentation.

Cyclophosphamide

Cyclophosphamide, an alkylating agent used as an immunosuppressant, is associated with up to a 10.7% cumulative risk of developing urinary bladder cancer after 12 years of exposure.

Urinary Tract Infection

Chronic urinary tract infection also appears to confer a significant risk for urinary bladder neoplasia, especially in women. This mechanism also explains the higher incidence of urinary bladder neoplasms in paraplegic patients with indwelling catheters. Urinary bacteria increase the levels of volatile nitrosamines, believed to be mediators in the development of neoplasia.

Other Aetiological Factors

Phenacetin has been linked to the development of urothelial carcinoma of the renal pelvis. In urinary bladder tumours, however, only a weak association has been demonstrated, except when high cumulative doses have been used. Artificial sweeteners have been associated with urinary bladder tumours in animal studies. A single case-control study in humans reported a 1.6-fold increase in risk for men who use saccharin. These findings, however, have not been confirmed by other studies, and thus the aggregate data appear to show no significant risk of urinary bladder cancer for persons using artificial sweeteners. Similarly, some studies have suggested an increased risk in coffee and tea drinkers, but based on the aggregate data the risk level appears to be weak to nonexistent. Although still limited, the overall data also show little if any role for human papillomavirus in urinary bladder neoplasia.

Screening and Prevention

Screening for urothelial cancer is usually done in one of three settings: (1) screening individuals at high risk for urinary bladder cancer (i.e., exposure to known carcinogens), (2) screening individuals with microscopic haematuria or irritative voiding symptoms, and (3) monitoring patients following diagnosis and conservative local therapy of urothelial carcinoma (i.e., for detection of recurrences).

A variety of methods have recently been developed, most of which target molecules that are present more frequently in the urine of patients with urothelial carcinoma than in that of patients without urothelial carcinoma (**Table 9**). As yet, none of these methods has replaced urine cytology, which is inexpensive, noninvasive and still considered the 'gold standard' screening method (Brown, 2000).

Urine Cytology

Urine cytology is still the most common screening method for diagnosing urothelial carcinoma. Although it is primarily used for the follow-up of patients with a diagnosis of urothelial carcinoma, it has value in the screening of

Table 9 Screening and monitoring methods for urothelial carcinoma

Urine cytology

Nuclear matrix proteins
Fibrin/fibrinogen degradation products
Telomerase activity
Hyaluronic acid/hyaluronidase
Cystoscopy and biopsy
Cystogram and excretory urography

high-risk populations. The main limitations of urine cytology are its low sensitivity for low-grade lesions and that its accuracy is dependent on the experience of the pathologist reviewing the specimen. Sensitivity for low-grade tumours has ranged from 0 to 100%, with most studies reporting less than 50%. For high-grade tumours, including carcinoma *in situ*, sensitivity and specificity approach 90 and 100%, respectively.

Bladder Tumour Antigen

Urothelial neoplasms secrete enzymes that lyse the urothelial basement membrane, exposing antigens that can be detected in the urine by a latex agglutination reaction. Initial studies have suggested that this method has a higher sensitivity than urine cytology, but other studies have found conflicting results. Further, specificity is significantly reduced in patients who have urinary tract infections or urolithiasis or have undergone prior instrumentation.

Nuclear Matrix Proteins

Nuclear matrix proteins, the structural framework of the nucleus, are present at low levels in the urine of normal individuals and in increased quantity in patients with urothelial carcinoma. An immunoassay that quantifies the amount of nuclear matrix proteins has been developed. Its sensitivity and specificity are dependent on the cut-off value. An overall sensitivity of 66% has been reported. Specificity is significantly diminished in the presence of gross haematuria and prostate cancer, but even in optimal cases the test does not appear superior to urine cytology.

Fibrin/Fibrinogen Degradation Products

Increased vascular permeability induced by a urinary bladder tumour results in leakage of fibrinogen and plasminogen. The fibrinogen is converted into an extravascular fibrin clot but is degraded by plasmin, which is activated by the urinary enzyme urokinase. Thus, the presence of fibrin or fibrinogen degradation products is indicative of urinary bladder carcinoma. The currently available assay for detecting these products has an overall sensitivity in the range 48–68% and a specificity of around 80%, which is also diminished in patients with gross haematuria and prostate cancer.

Telomerase

Degradation of telomeres after several cell cycles is a cell death mechanism. Telomerase's primary function is to repair the telomeres at the end of each cell cycle, delaying their degradation. Thus, over-activity of telomerases, prolongs cell life and may turn cells immortal. The method for measuring telomerase activity has a sensitivity of 70% and a specificity of up to 99% for detecting urinary bladder cancer. However, the assay is not yet widely available and requires laboratories with well-established expertise. False-positive results may occur in patients with inflammatory conditions, and false negatives may occur in patients with gross haematuria.

Hyaluronic Acid/Hyaluronidase

High levels of hyaluronic acid in the urine of patients with urinary bladder cancer can be detected with a sensitivity and specificity of 92%. Further, patients with high-grade neoplasms have elevated urinary hyaluronidase activity that can be detected with a 100% specificity. These still rather preliminary data suggest that this assay could be used for the diagnosis of low-grade lesions and the early detection of tumour progression.

Cystoscopy and Biopsy

Cystoscopy allows the direct visualization of the urinary bladder mucosa and biopsy of suspicious lesions. Urinary bladder washings obtained at the time of cystoscopic examination also provide useful cytological material. Carcinoma *in situ* is not always identified by cystoscopic examination, and thus random urinary bladder biopsies are usually performed to identify this lesion.

Cystograms and Excretory Urography

These methods provide useful information regarding the presence of multifocal disease involving the upper urinary tract and the localization of large urinary bladder masses that produce filling defects.

Gross Features

Noninvasive papillary tumours are recognized by cystoscopy as exophytic papillary fronds in the mucosa, usually of varying size. Up to 40% of tumours may be multifocal. Tumours occur most often in the lateral and posterior walls of the urinary bladder and least often in the dome. Urothelial carcinoma *in situ* usually appears as an erythaematous area in the mucosa of the urinary bladder, but it can also be grossly inapparent. When invasive, urothelial carcinomas are usually bulging, nodular exophytic tumours, or ulcerated and indurated. A papillary component may still be present, albeit focally. Some tumours display diffuse infiltration of the urinary bladder wall with relatively unremarkable mucosa, analogous to the so-called linitis plastica of the stomach. Large, fleshy, polypoid tumours that fill the urinary bladder cavity usually exhibit sarcomatoid features.

Microscopic Features

Papillary urothelial neoplasms range from small and benign to large and aggressive tumours. The distinction is usually based on the degree of cytological and architectural atypia, which is the basis of the grading schemes used for these neoplasms. Recently, a new grading system, the one used in this discussion, was proposed by a conjoint effort of the World Health Organisation (WHO) and the

Table 10 World Health Organisation/International Society of Urologic Pathology grading scheme for urothelial neoplasia

Papillary lesions	Flat lesions
Papillary hyperplasia	Flat urothelial hyperplasia
Urothelial papilloma	Reactive atypia
Inverted papilloma	Atypia of unknown significance
Papillary urothelial neoplasm of low malignant potential	Dysplasia (low-grade intraurothelial neoplasia)
Papillary urothelial carcinoma, low grade	Carcinoma *in situ* (high-grade intraurothelial neoplasia
Papillary urothelial carcinoma, high grade	

International Society of Urologic Pathology (ISUP) (**Table 10**) (Epstein *et al*., 1998). In this system, benign papillary tumours are referred to as papillomas. They are usually small, delicate, papillary epithelial proliferations attached to the mucosa by a thin fibrovascular stalk. The urothelial lining is identical with that of the normal urinary bladder mucosa. Papillomas represent less than 1% of tumours and are usually seen in younger patients. These lesions can recur, although probably at a lower rate than other higher grade lesions. Tumours with slightly more complex architecture, of larger size and lined by cytologically normal or minimally abnormal urothelium are referred to as papillary urothelial neoplasms of low malignant potential. They have a tendency to recur but not invade or cause death. These tumours were previously referred to as transitional cell carcinomas, grade 1 (using the old WHO classification system). Papillary tumours containing cytologically malignant cells are currently classified as low-grade and high-grade papillary urothelial carcinomas (previously referred to as grade 2 and grade 3 transitional cell carcinomas, respectively). These tumours have a higher degree of nuclear pleomorphism and disorganisation of the epithelial cells, progressively losing their resemblance to normal urothelium (**Figure 7; see colour plate section**). High-grade tumours usually have less well-developed, blunt and fused papillae, with occasional solid areas.

Flat urothelial lesions also display a range of cytological changes, lesions at the lower end of the spectrum being referred to as urothelial dysplasia and at the higher end as carcinoma *in situ* (**Figure 8; see colour plate section**). As opposed to papillary lesions, however, only the high-grade lesions (i.e. carcinoma *in situ*) are known clinically significant, worthy of therapeutic intervention. As stated before, carcinoma *in situ* may be primary (i.e. arising *de novo*), or more commonly secondary (i.e. arising in association with previous or concurrent urothelial carcinoma). In the latter setting, its presence confers increased risk of progression to invasive disease.

Invasion into the underlying wall is most common in high-grade papillary tumours or in patients with carcinoma *in situ*. The extent of invasion ranges from microscopic foci of tumours invading the lamina propria to bulky tumours extending through the urinary bladder wall into the perivesical adipose tissue. The invasive components usually display high nuclear grade and may grow in nests, cords or trabeculae of neoplastic cells, which infiltrate the muscle bundles and adipose tissue (**Figure 9; see colour plate section**).

Sarcomatoid urothelial carcinoma is a high-grade neoplasm that has partially or totally lost its carcinomatous morphological phenotype and shows differentiation into spindle-cell mesenchymal elements. A well-defined malignant heterologous mesenchymal component, (e.g. leiomyosarcoma, osteosarcoma, rhabdomyosarcoma) may be present, but most often the mesenchymal component is relatively undifferentiated and high grade. Diagnosis of sarcomatoid carcinoma requires the presence of a focal, unequivocal, invasive or *in situ* epithelial component or evidence of epithelial differentiation either by immunohistochemistry (i.e. cytokeratin expression) or electron microscopy (i.e. presence of desmosomes or other epithelial elements). Differentiation between sarcomatoid carcinoma and sarcoma of the urinary bladder is clinically relevant, as the prognosis is significantly worse for sarcomatoid carcinomas.

Immunohistochemistry

The urothelium is a complex epithelium that expresses a wide variety of cytokeratin intermediate filaments. The urothelium and its neoplasms express both low and high molecular weight cytokeratin, and cytokeratin 7 and cytokeratin 20; however, up to 40% of high-grade urothelial cancers are negative for cytokeratin 20. Carcinoembryonic antigen (CEA) is expressed in approximately 60% of urothelial carcinomas, most frequently in those that show glandular differentiation. Cytokeratin 10 and 14 are frequently expressed in areas of squamous differentiation. The urothelium usually lacks vimentin expression. Expression of other epithelial markers, such as epithelial membrane antigen and Leu-M1, has also been reported. Uroplakin and thrombomodulin are newer markers that are also useful for staining urothelial tumours. Immunohistochemistry has also been used to identify a wide range of molecular markers, mostly for prognostic purposes (see Prognostic Factors, below, for a brief review of these markers).

Molecular Genetic Findings

The data from cytogenetic and molecular studies of urinary bladder carcinoma support the two-pathway mechanism seen morphologically (Cordon-Cardo *et al*., 1997; Lee and Droller, 2000). Most low-grade papillary neoplasms that have been studied have been associated with deletions

of chromosome 9, including monosomy of chromosome 9 and 9p and/or 9q deletions. Chromosome 9 deletions are the only genetic change consistently present in noninvasive and early invasive papillary tumours and are thus believed to be an initial step in the development of these neoplasms. The 9p deletions involve the tumour-suppressor genes *p15* and *p16*, which encode inhibitors of cyclin-dependent kinase. The 9q deletions also likely include multiple tumour-suppressor genes, most of which are yet to be identified. On the other hand, urothelial carcinoma *in situ* is usually associated with deletions of 14q and deletions of 17p or mutations of the *p53* gene. These alterations are rarely seen in noninvasive, low-grade papillary tumours. Invasive tumours are similarly associated with mutations of p53 and deletions of 13q, the site of the *RB* gene. Other alterations observed in invasive tumours, but seldom in papillary tumours, include deletions of 11p, 3p, 8p, 6q, 4p, and 5q and increased expression of Ras, c-Myc and epidermal growth factor receptors.

Hence, these data support two distinct molecular pathways for urothelial carcinoma. On one side, alterations of chromosome 9 induce the formation of papillary tumours, which have low potential for progressing. If additional molecular alterations are acquired (*p53* mutations, 17p−, 3p−, 5q−), the tumours progress to high-grade lesions and invasion. On the other hand, *p53* mutations, 14q deletions and possibly other mechanisms result in urothelial carcinoma *in situ* with a propensity for progressing and developing invasive disease upon acquisition of additional alterations. Molecular events correlating with development of advanced disease and metastasis are also likely to be identified in the future.

Prognostic Factors

Numerous factors are used for evaluating the prognosis of urothelial carcinoma (**Table 11**). The extent of disease is the most valuable prognostic information used for the management of urothelial carcinoma. When dealing with noninvasive or at most lamina propria-invasive tumours, management is focused on local control of the disease and parameters in this setting are those that can predict the frequency of tumour recurrence and likelihood of progression to muscle-invasive disease. Once the tumour has invaded the muscularis propria layer (**Figure 9**), aggressive management (usually cystectomy or radiation) is usually indicated, and useful prognostic parameters are those that can help predict development of distant metastasis or local recurrence. Thus, the main prognostic indicator for urothelial carcinoma, and the one on which others are dependent, is tumour stage (Mazzucchelli *et al*., 1994).

Table 11 Prognostic factors in urothelial carcinoma

Tumour Stage

Tumour stage is important not only because of the powerful prognostic information it conveys but also because it defines the management of the patient. The TNM system (**Table 12**) is the most commonly used staging system. Five-year survival for patients with T1 tumours is approximately 90% but drops to 70% for patients with T2 tumours and to 35% for those with T3 and T4 neoplasms (Mazzucchelli *et al*., 1994). Owing to the abrupt difference in clinical behaviour between tumours showing only lamina propria invasion and those showing muscularis propria invasion, there is a tendency to simplify the staging system into two categories: 'superficial' (i.e. pTa pTis, and pT1 tumours) and 'invasive' (i.e. pT2, pT3, and pT4 tumours). While this nomenclature identifies two subsets of urinary bladder cancer that are traditionally managed in substantially different fashion, it oversimplifies and diminishes the power of the staging system. Further, the inaccurate terminology is confusing and can lead to miscommunication between pathologists and clinicians.

Tumour grade

Prognostic significance of grading in urinary bladder tumours is mostly limited to noninvasive or early invasive papillary tumours. Carcinoma *in situ* is a high-grade lesion by definition, and flat lesions of lesser grade (i.e. dysplasia) imply urothelial instability, but do not warrant therapeutic intervention. In muscle-invasive disease, grade has not provided any more prognostic information than stage alone. However, grade has repeatedly been shown to predict tumour recurrence and progression in papillary neoplasia. Patients with papillary urothelial neoplasms of low malignant potential have a 98% 10-year survival, whereas high-grade tumours are associated with a 35% 10-year survival. High-grade tumours with invasion into the lamina propria account for 60% of tumours that progress to muscle invasion (Lapham *et al*., 1997).

Histological Tumour Type

The histological type of urinary bladder tumour has also been shown to have significant prognostic value.

Table 12 1997 TNM staging system for the urinary bladder

Primary tumour (T)	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma *in situ* 'flat tumour'
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T2a	Tumour invades superficial muscle (inner half)
T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue
T3a	Microscopically
T3b	Macroscpocially (extravesical mass)
T4	Tumour invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumour invades prostate, uterus, vagina
T4b	Tumour invades pelvic wall, abdominal wall
Regional lymph nodes (N)[a]	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node more than 5 cm in greatest dimension
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Stage groupings			
Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T4a	N0	M0
Stage IV	T4b	N0	M0
	Any T	Any N	M0
	Any T	Any N	M1

[a]Regional lymph nodes are those within the true pelvis; all others are distant lymph nodes.

Squamous and glandular differentiation have been associated with poor responses to radiotherapy and to chemotherapy, respectively. Both are associated with high-stage urinary bladder cancer. Certain histological types of carcinoma, such as sarcomatoid carcinoma, small cell carcinoma and the variant of urothelial carcinoma known as micropapillary carcinoma, usually present at an advanced tumour stage (Lapham *et al*., 1997). A variant known as lymphoepithelioma-like carcinoma of the urinary bladder may be amenable to chemotherapy alone.

Vascular invasion

Vascular invasion in tumours with limited lamina propria invasion has been associated with worse prognosis. However, data on the impact of vascular invasion in urothelial carcinoma are conflicting and difficult to interpret, owing mostly to the fact that in the urinary bladder, vascular invasion is difficult to recognize histologically, is easily over-diagnosed and confirmation usually requires use of immunohistochemical stains for endothelium (Lapham *et al*., 1997).

Multicentric Tumours and Tumour Size

Tumour size, as assessed at time of cystoscopy, is correlated with muscularis propria-invasive disease. Similarly, multicentric tumours (i.e. presence of multiple tumours at the time of cystoscopy) are more likely to both recur and progress (Lapham *et al*., 1997).

Adjacent Carcinoma In Situ

In cases of papillary bladder tumours, the presence of carcinoma *in situ* in the adjacent mucosa has been associated with a higher risk of recurrence and progression than in tumours without carcinoma *in situ*. Thus, it is common practice to randomly biopsy urothelium that appears normal at the time of resection of a papillary tumor (Lapham *et al*., 1997). Studies have also shown that dysplasia in the adjacent urothelium is associated with higher risk of recurrence and progression.

Biological Prognostic Factors

A growing list of biological/molecular prognostic markers has been studied in the literature (**Table 11**) (Stein *et al*., 1998). Most of them, however, have not provided significant or consistent predictive power beyond traditional pathological parameters. Several of these markers are currently being evaluated in a prospective and/or randomized manner, in order to determine their true clinical significance.

Lack of expression of blood group antigens, which are commonly expressed in normal urothelium, has been associated with tumour progression in patients with urinary bladder neoplasms. DNA ploidy has been shown to predict recurrence and progression in stage Ta and T1 tumours, and aneuploidy has been associated with a better response to radiation therapy. Proliferation indexes, whether derived by DNA flow cytometry, thymidine labelling, Ki-67 immunohistochemical staining or other methods, are correlated with tumour grade, disease progression and poor survival. As stated before, p53 mutations have also been associated with progression of urinary bladder tumours and possibly with initiation of cancer via the carcinoma *in situ* pathway. Current data suggest that p53 status is most useful in the management of locally advanced urinary bladder neoplasms, by helping to select patients who would benefit most from urinary bladder preservation or chemotherapy. Other molecular/biological prognostic indicators suggested

in urinary bladder cancer include mutations in oncogenes, epidermal growth factor receptors, growth factors, adhesion molecules, angiogenesis inhibitors, and other cell-cycle regulatory proteins, such as the gene products of the retinoblastoma tumour-suppressor gene and $p21^{WAF1}$. Analysis of these markers is beyond the scope of this discussion, but a recent comprehensive review is available (Stein *et al.*, 1998).

Overview of Present Clinical Management

As stated above, clinical management is highly dependent on the stage of disease and includes local resection of a surface tumour, intravesical therapy, radical resection, radiation therapy and systemic therapy.

Stage Ta tumours are treated mainly with transurethral resection and fulguration of visible tumours. Patients at high risk for recurrence or progression (i.e. those who have high-grade tumours, large tumours, associated carcinoma *in situ* or multiple tumours) also benefit from intravesical therapy, including immunotherapy (*Bacillus Calmette-Guérin*, interferon) and chemotherapy (thiotepa, mitomycin C, doxorubicin). These patients require close follow-up with repeat cystoscopy and urine or bladder-wash cytology every 3 months for 2 years, every 6 months for a further 2 years and subsequently every year for the rest of their lives. Stage Tis lesions are treated mainly with intravesical therapy and require close surveillance owing to the high rate of progression to invasive disease. Stage T1 tumours are most often treated conservatively with local resection and intravesical therapy, although some physicians advocate cystectomy for high-grade T1 tumours. Standard treatment for muscularis propria invasive tumours (i.e. stages T2, T3 and T4) is radical cystectomy or cystoprostatectomy. Radiation therapy is also an acceptable treatment and is standard therapy in some parts of the world. Local or distant metastatic disease is treated with adjuvant systemic chemotherapy; doxorubicin, cisplatin and methotrexate being the most commonly used agents.

Other Carcinomas of the Urinary Bladder

Squamous cell carcinoma accounts for up to 75% of urinary bladder cancers in areas where schistosomiasis is endemic. In the developed world they constitute less than 10% of all urinary bladder cancers. The mean age of presentation for these tumours is 46 years, almost 20 years younger than that for urothelial carcinomas in the Western world (Johansson and Cohen, 1997). Men are affected more often than women. Patients usually present with haematuria or irritative symptoms and most tumours are usually high stage at the time of presentation. Infection with *Schistosoma haematobium* is endemic to the Nile river valley in Egypt and other parts of Africa. Its eggs are deposited in the urinary bladder wall, eliciting a chronic granulomatous inflammatory response, fibrosis, calcification and squamous or glandular metaplasia of the urothelium. Tumours associated with schistosomiasis are mostly squamous cell carcinomas (75%), with a smaller proportion of adenocarcinomas (6%). Schistosomiasis appears to induce urinary bladder neoplasia by promoting increased cell proliferation as a result of inflammation, which in turn provides an increased risk of spontaneous genetic mutations. High levels of nitrosamines have also been found in patients with schistosomiasis, as in patients with chronic urinary tract infections. In countries where schistosomiasis is not endemic, squamous cell carcinoma usually arises secondary to chronic irritation caused by factors such as calculi, urinary retention, indwelling catheters, etc. These tumours tend to be large and bulky, often necrotic, sometimes filling most of the lumen of the urinary bladder. Squamous cell carcinomas display similar histology to those occurring at other sites and include tumour islands of squamous cells showing intercellular bridges and keratinization. Typical areas of urothelial carcinoma are not present. Squamous metaplasia of the adjacent urothelium is usually present. Verrucous carcinoma is a variant of squamous cell carcinoma that rarely affects the urinary bladder. They are graded according to the amount of keratinization and degree of nuclear pleomorphism. The TNM staging system for urinary bladder tumours (**Table 12**) is also used for these tumours and is the most useful prognostic indicator. Radical cystectomy or cystoprostatectomy with or without radiation therapy is the mainstay of therapy for this tumour.

Adenocarcinomas of the urinary bladder are rare, forming less than 1% of urinary bladder cancers. There is a significant association between urinary bladder exstrophy and the development of urinary bladder adenocarcinoma, although the mechanism by which this occurs remains unknown. Adenocarcinomas may be classified according to their location into urachal and non-urachal types. Both types show a variety of histological patterns, including enteric (i.e. mimicking colonic adenocarcinoma), signet ring, mucinous (colloid), clear cell, mixed and not otherwise specified (NOS).

URETHRA

Tumours of the urethra are distinctly rare. Owing to their significant anatomical and pathological differences, tumours arising in the female urethra are discussed separately from those arising in the male urethra (Grabstald, 1973; Ray *et al.*, 1977; Amin and Young, 1997). In both settings, most tumours are epithelial neoplasms (**Table 13**), with only leiomyoma and melanomas of the urethra being common enough to deserve mention.

Carcinomas of the Female Urethra

Urethral carcinomas typically occur in the postmenopausal period. Clinically patients present with one or more of

the following symptoms: vaginal or urethral bleeding, dysuria, urinary frequency, incontinence, urinary tract infection, perineal or introital mass or urinary obstruction. Associated aetiological factors include trauma and infection, human papillomavirus for squamous cell and urothelial carcinomas and urethral diverticula for clear cell adenocarcinomas.

The histological spectrum of urethral carcinomas is similar to that of the urinary bladder, although the histological type is highly dependent on the sites where they arise. Tumours involving the distal urethra and meatus (approximately 70% of tumours) are usually squamous cell carcinomas (**Figure 10; see colour plate section**). They are aggressive neoplasms that present at an advanced stage. Carcinomas of the proximal urethra are either urothelial carcinomas or adenocarcinomas. Urothelial carcinomas account for approximately 20% of tumours and exhibit the same diversity of histology as that seen in the urinary bladder, including papillary, flat, noninvasive and invasive tumours. Frequently, they are preceded by, followed by or occur concurrently with a urinary bladder urothelial carcinoma. Adenocarcinomas account for approximately 10% of female urethral carcinomas. Approximately 40% of adenocarcinomas are clear cell adenocarcinomas and the remaining show colloid, signet ring or NOS histology. Clear cell adenocarcinomas are pathologically and clinically distinctive. Histologically, they display papillary, tubulocystic, tubular or solid patterns. The tubules are usually hollow or contain eosinophilic secretions. The lining cells show characteristic hobnail shape and typically display clear to eosinophilic cytoplasm. Patients with clear cell adenocarcinomas appear to have a slightly better prognosis than those with nonclear cell adenocarcinomas, with between 30% and 40% of patients dying within 24 months; the survival is significantly lower for other types of adenocarcinomas.

Table 13 Histological classification of carcinomas of the urethra

1. Primary Tumors
- a. Transitional cell carcinoma
- b. Squamous cell carcinoma
- c. Adenocarcinoma
  - i. Clear cell carcinoma
  - ii. Colloid (mucinous) carcinoma
  - iii. Signet-ring cell carcinoma
  - iv. Adenocarcinoma, not otherwise specified
- d. Adenosquamous carcinoma
- e. Undifferentiated carcinoma

2. Secondary Tumors
- a. Direct extension from adjacent organs
- b. Metastatic

The prognosis of female urethral carcinomas is relatively poor. Location of the tumour and stage of the disease are the most important prognostic parameters. Between 18% and 50% of women will have metastasis at presentation. Tumours restricted to the anterior urethra are more amenable to local surgical excision and have a better outcome than those involving the posterior or entire urethra. In 1973, Grabstald proposed a staging system specific for female urethral carcinomas (Grabstald, 1973) (**Table 14**). Five-year survival when this system is used is roughly 45% for stage A, 40% for stage B, 25% for stage C, and 18% for stage D. The 1997 TNM staging system (**Table 15**) is applicable to both male and female urethral tumours.

Carcinomas of the Male Urethra

Tumours of the male urethra occur in the sixth and seventh decades and usually present with obstructive symptoms or

Table 14 Staging systems in urethral carcinoma

Female urethral tumours: Grabstald system	1997 UICC/AJCC TNM system	Male urethral tumours: Ray system

infection. Tumours of the posterior urethra are associated with haematuria, purulent discharge or urinary obstruction. Some patients present with a palpable mass. Other symptoms include painful priapism, penile erosion and impotence. Suggested aetiological factors include chronic irritation from strictures or infectious processes. Human papillomavirus has been documented in squamous and urothelial carcinomas.

Grossly, tumours appear as ulcerative, nodular, papillary, cauliflower-like or firm solid masses. About 75% of tumours are squamous cell carcinomas, with the remainder being urothelial carcinomas, adenocarcinomas or undifferentiated carcinomas. Squamous cell carcinomas arise in a background of metaplasia. Urothelial carcinomas are seen most frequently in the prostatic urethra but may also occur in the membranous or penile urethra. They display the same histological spectrum as those arising in the urinary bladder. As in the female urethra, there may be a synchronous or metachronous urinary bladder tumour. Adenocarcinomas are less common in the male than in the female urethra, and clear cell adenocarcinoma is an oddity in the male urethra.

Prognosis is similarly dependent on location and extent of the disease. A staging system specific for male urethral cancer was proposed in 1977 by Ray *et al*. (Ray *et al*., 1977) (**Table 14**), but the TNM system (**Table 15**) is also applicable. Anterior tumours have a significantly better outcome than posterior tumours, as they can be managed successfully by surgery. Tumours of the anterior urethra generally metastasize to inguinal and external iliac lymph nodes, whereas posterior urethral tumours spread to internal iliac and hypogastric lymph nodes. Most often, the sign of treatment failure is patient's local recurrence, rather than distant metastasis.

Both male and female urethral tumours are initially treated for local excision if possible, including lymphadenectomy. Radiation therapy is indicated in cases that recur or in those not amenable to surgical excision. Adjuvant systemic therapy is indicated in metastatic disease.

PROSTATE

Normal Development and Anatomy

The prostate gland develops as outgrowths of epithelium from the urogenital sinus that are surrounded by primitive mesenchyme. This epithelial component forms the ducts and acini of the peripheral and transition zones of the prostate, and the mesenchyme differentiates into its fibromuscular stroma. The distal prostatic urethra, formed from the urogenital sinus, is thus in continuity with the prostatic ducts. The central zone glands and ducts may derive from mesonephric duct remnants, similar to the development of the proximal prostatic urethra.

The prostate gland in young men weighs about 20 g and is shaped like a truncated cone with its base along the neck of the urinary bladder and its blunt apex at the urogenital diaphragm. The prostatic urethra courses through the gland with an angulation occurring at its approximate mid-portion at the level of the verumontanum, a mound-like elevation on the posterior urethral surface. The two ejaculatory ducts penetrate the base of the prostate and run in an anteroinferior direction through the gland to empty into the prostatic urethra, just lateral to either side of the verumontanum.

The prostate gland is currently described in terms of its zonal anatomy according to the McNeal model (McNeal, 1981). In this model, there are three major prostatic zones (**Figure 1**). The central zone accounts for about 25% of the prostatic volume and occupies a pyramidal-shaped region with its base at the bladder neck and apex at the point of angulation of the prostatic urethra. The transition zone represents only about 5% of the prostatic volume and consists of two small lobes just lateral to the proximal prostatic urethra. The remainder of the glandular prostate (approximately 70%) is represented by the peripheral zone, which surrounds both the central and transition zones in the basal aspect of the gland and constitutes essentially all of the glandular prostatic tissue distal to the urethral angulation. The prostate is surrounded by a condensation of stroma along its peripheral and lateral aspects that blends, anteriorly, with the anterior fibromuscular stroma. No true capsule is present at the apex and bladder neck aspects of the gland.

The major blood supply to the prostate derives from the branches of the internal iliac arteries. These branches enter the gland with the major neurovascular pedicles at either superolateral aspect of the gland (**Figure 2**). Venous drainage occurs through a plexus of veins in the capsular region and into the internal iliac veins. The prostatic lymphatics mainly drain into the lymph nodes along the internal iliac vessels, but direct drainage into the external iliac nodes may also occur.

Tumour Pathology

A diverse number of different types of neoplasm may occur in the prostate gland, but the overwhelming majority (>95%) of malignant tumours of the prostate are adenocarcinomas. With the elaboration of the McNeal model of prostatic anatomy (see above), it has become clear that different zones of the prostate have different propensities to develop adenocarcinoma. Accordingly, about 75% of adenocarcinomas develop in the peripheral zone, about 15% in the transition zone and the residual cases in the central zone (McNeal *et al*., 1988). Because much of the peripheral zone abuts the anterior wall of the rectum, some prostate carcinomas, when sufficiently large, may present palpable abnormalities on digital rectal examination (DRE). However, DRE is not an especially sensitive or specific method for detection; it identified only 56% of patients who were ultimately diagnosed with prostate cancer in a screening programme and had a positive predictive value of 21% (Catalona *et al*., 1994).

Prostatic adenocarcinoma may not be grossly apparent. In one series that examined radical prostatectomy specimens, 63% of tumours were correctly recognized on gross examination; no tumour was apparent in 22% of cases, and tumour was falsely identified in 19% of the cases (Renshaw, 1998). When they are recognizable, the tumours often have a yellow to grey solid character that contrasts with the frequently spongy appearance of the adjacent non-neoplastic prostatic parenchyma (**Figure 3**). Those tumours that develop in the transition zone may sometimes be grossly recognizable in prostate chips that have a tan to yellow discoloration.

Prostatic adenocarcinoma is recognized microscopically through a combination of architectural and cytological features. Typically, the malignant glands are smaller in size than the associated benign acini, and often, but not always, tend to be arranged in haphazard or infiltrative patterns that contrast with the more organized, lobular arrangement of benign glands and patterns that tend to be produced by benign pathological processes.

The grading of prostatic adenocarcinomas may be performed by utilization of a variety of schemes, but the one in most widespread usage is the Gleason method (Gleason, 1966; Gleason and Mellinger, 1974) that has been shown to be of significant prognostic value in a variety of studies (Thomas *et al*., 1982; Gleason, 1992; Albertsen *et al*., 1999). This system relies on the architectural assessment of tumour growth according to five histological grades (**Figure 4**). Those tumours whose growth is a well-circumscribed collection of uniform small glands are assigned a grade of 1 (**Figure 5**) and, on the other end of the scale, grade 5 tumours are those having a diffuse sheet-like arrangement of malignant cells, isolated single cells infiltrating the stroma (**Figure 6**), and/or nests with central necrosis (**Figure 7**). Tumours with features intermediate between these two extremes receive an intermediate grade. Since many prostatic adenocarcinomas are heterogeneous with respect to their growth patterns, the Gleason method furthermore sums the grades of the two most prominent patterns to arrive at a 'pattern score' that varies from 2 to 10. When there are two patterns of close to equal proportions that are in competition for the second grade, the one with the higher grade is chosen. If only one grade is present, its value is doubled to determine the pattern score. Recent research also demonstrates that even small amounts of grade 4 or grade 5 tumours are prognostically important, and there may be a role for the assessment of so-called 'tertiary grades' in prostate cancer (Pan *et al*., 2000).

The Gleason method, in prostatectomy specimens, correlates with disease-free survival and overall survival

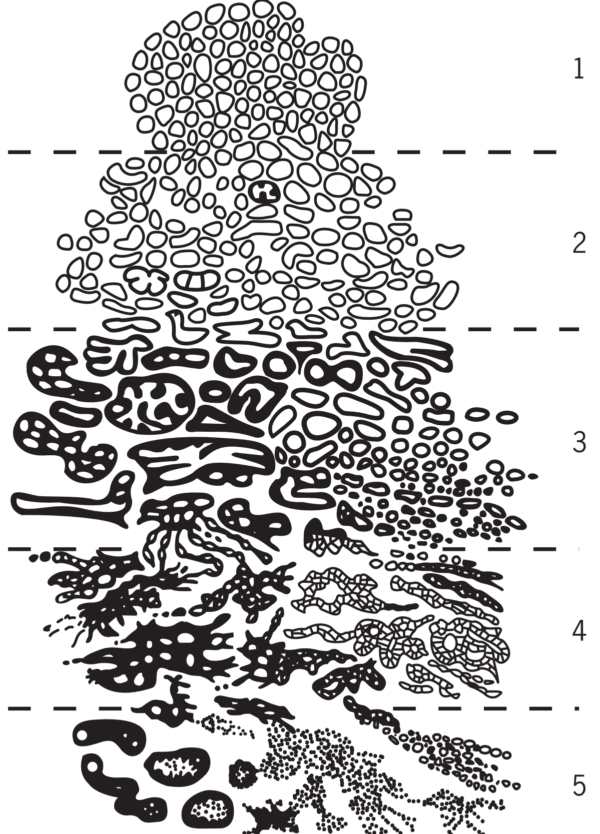

Figure 4 The Gleason grading system of prostate carcinoma. There are five grades based on the architectural pattern of tumour growth. (Adapted from Gleason, 1992.)

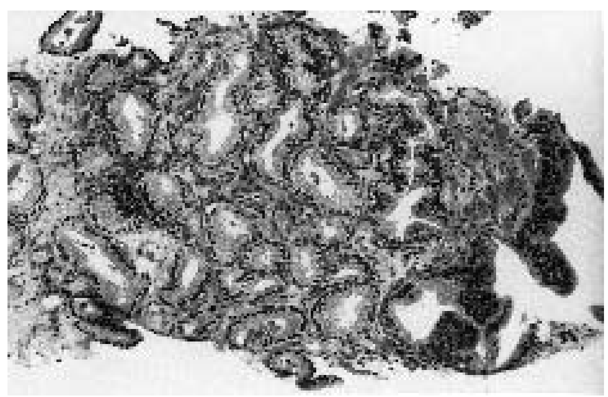

Figure 5 This well-circumscribed collection of relatively uniform-sized glands represents a Gleason grade 1 or grade 2 adenocarcinoma of the prostate.

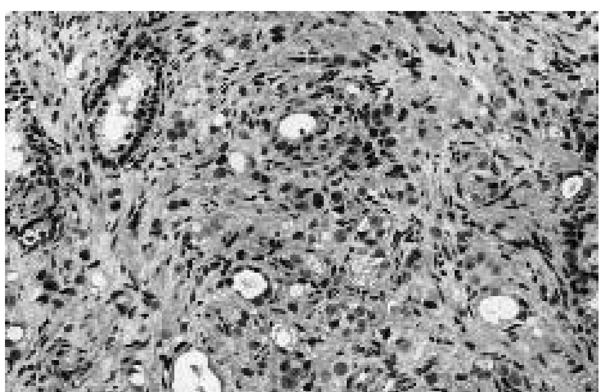

Figure 6 Atypical cells that infiltrate the stroma as irregular cords and single cells represent a grade 5 adenocarcinoma of the prostate. Note invasion between residual benign glands (left).

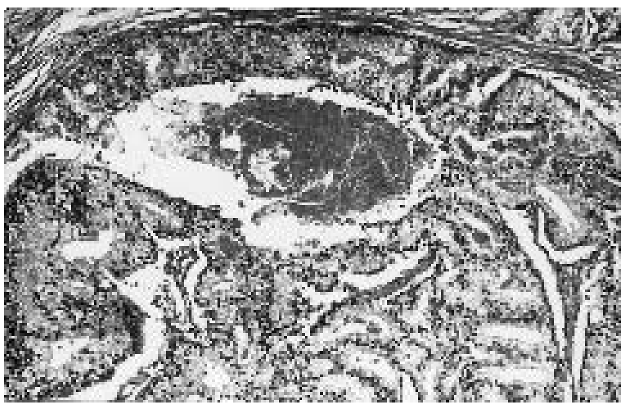

Figure 7 A cribriform pattern of adenocarcinoma of the prostate with zones of necrosis, a Gleason grade 5 tumour.

(**Figure 8**). Because of sampling problems, needle biopsy specimens are subject to grading disparity with respect to prostatectomy specimens, most commonly undergrading secondary to failure to sample a high-grade component. Such undergrading occurs in approximately 40% of the cases and most typically is a problem with small amounts of low-grade tumour on needle biopsy. Nevertheless, Gleason grading of needle biopsies and transurethral resectates does correlate with the final Gleason grade in prostatectomy specimens and also correlates with disease-free and overall survival.

In addition to the architectural patterns that are the initial basis for concern and that provide the Gleason pattern score, the diagnosis of cancer must be confirmed on cytological grounds. This is necessary because of several benign entities, such as atypical adenomatous hyperplasia (adenosis), sclerosing adenosis, prostatic extension of nephrogenic adenoma (nephrogenic metaplasia), mesonephric remnant hyperplasia and verumontanum mucosal gland hyperplasia, that may mimic prostatic adenocarcinoma on architectural grounds, particularly in small tissue specimens. There are several cytological features that, together, provide strong reassurance concerning the diagnosis of carcinoma (**Figure 9**). These include nucleolar prominence (usually considered in excess of 1.5 μm in

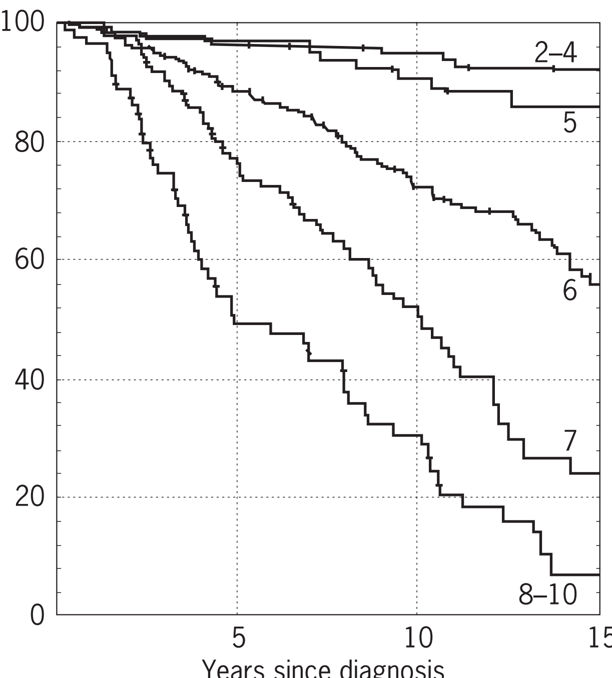

Figure 8 The relationship of Gleason pattern score to disease-specific survival in prostate adenocarcinoma. (Adapted from Albertsen *et al.*, 1999.)

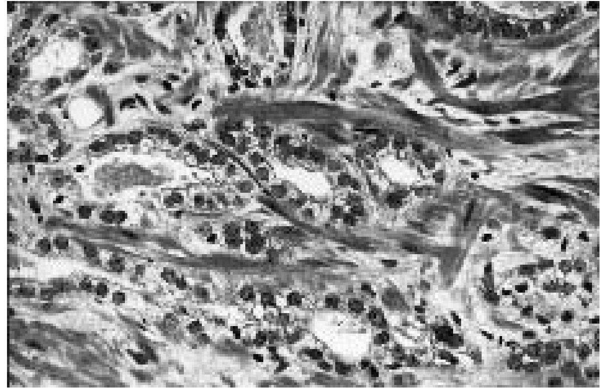

Figure 9 This adenocarcinoma of the prostate shows nuclear enlargement, hyperchromasia, prominent nucleoli and absence of a basal cell layer. The neoplastic glands intercalate between bundles of stromal collagen.

diameter), nuclear enlargement (compared with adjacent benign glands), nuclear hyperchromasia and irregularity, glands with an absence of basal cells and amphophilic cytoplasm (in contrast to the more pale cytoplasm of benign glands). Ancillary features that support a diagnosis of adenocarcinoma, but that are by no means specific for it,

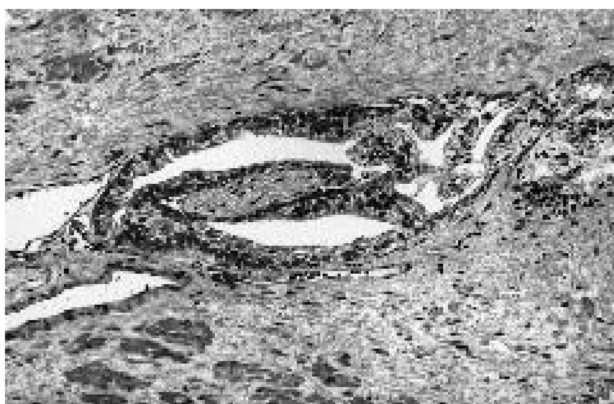

Figure 10 Circumferential perineural invasion in prostate adenocarcinoma, a finding considered pathognomonic of cancer.

include the presence of intraluminal acid mucins (usually visible as wispy, slightly basophilic intraluminal material on haematoxylin and eosin-stained sections) and the occurrence of intraluminal, eosinophilic, rod-shaped or polygonal crystalloids.

Only a few features are considered pathognomonic of carcinoma; these include huge nucleoli ($>3\,\mu m$), mucinous fibroplasia (also termed 'collagenous micronodules'), the occurrence of sieve-like, cribriform architectural patterns (**Figure 7**), and circumferential perineural invasion (**Figure 10**). The occurrence of any of these 'pathognomonic' features in biopsy material is rare, so the diagnosis of adenocarcinoma usually rests upon a constellation of features that vary in significance but that together permit its accurate and reproducible recognition.

There are two putative precursors for prostatic adenocarcinoma, one well established and the second of doubtful premalignant potential. The well-established precursor is now termed 'high-grade prostatic intraepithelial neoplasia' (PIN) (Bostwick and Brawer, 1987), although it has also been termed 'atypical hyperplasia' and 'intraductal dysplasia.' The poorly established possible precursor is known most commonly as either 'atypical adenomatous hyperplasia' or 'adenosis'.

PIN is considered a spectrum of atypical prostatic epithelial change that develops in pre-existing ducts and acini (**Figure 11**). Changes that include mild nuclear enlargement and stratification without nucleolar prominence characterize 'low-grade PIN,' a purely descriptive term that is not considered a diagnostic entity because of its unclear clinical significance and its poorly reproducible recognition. Cells resembling those of adenocarcinoma characterize high-grade PIN. Thus, on scanning magnification, one can appreciate the presence of a greater degree of basophilia in glands affected by high grade PIN than in normal glands (**Figure 12**). This reflects the cellular crowding, stratification, nuclear enlargement and nuclear hyperchromasia in these glands (**Figure 13**). As in

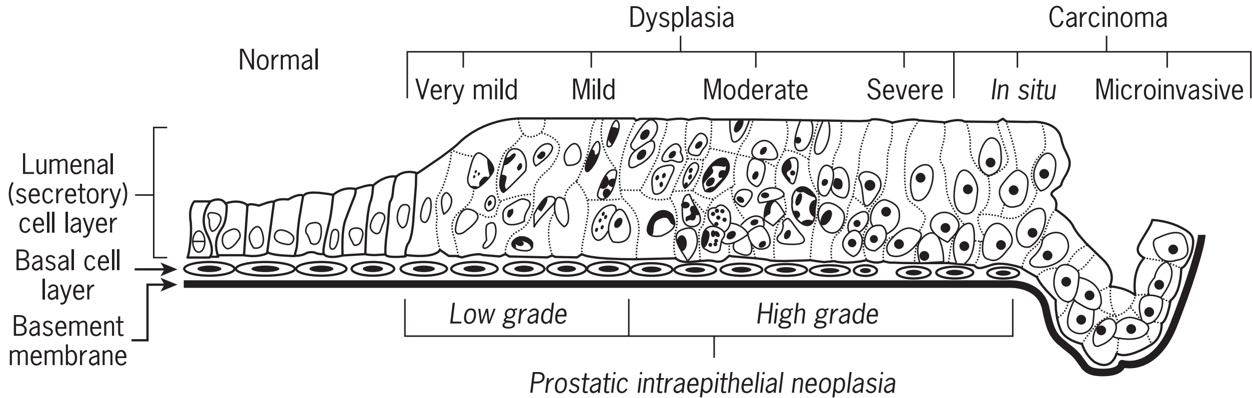

Figure 11 Drawing showing the spectrum of atypical epithelial changes in prostatic intraepithelial neoplasia (PIN), with final progression to invasive carcinoma. Cellular stratification and nucleolar prominence characterize high grade PIN. (Adapted from Bostwick, 1997.)

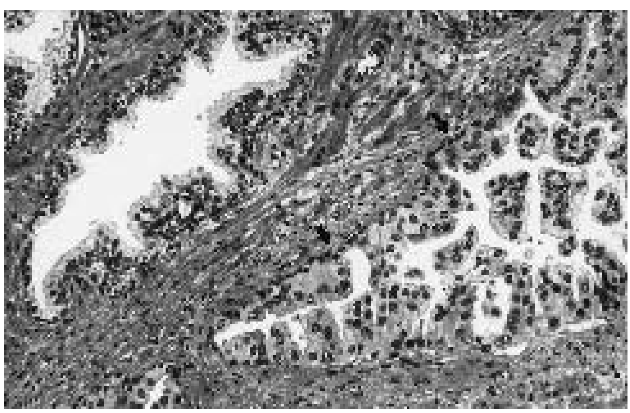

Figure 12 A normal prostate gland (left) contrasts with one having a papillary configuration of high grade PIN (right). The latter shows nuclear enlargement and cellular stratification, but there remains a basal cell layer (arrows).

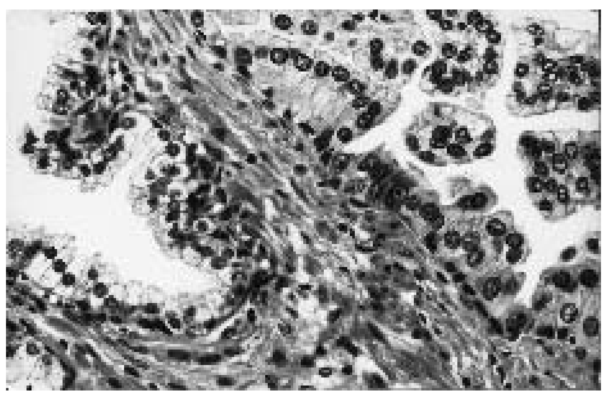

Figure 13 The nuclei in a gland with high-grade PIN (right) are focally stratified, have prominent nucleoli and are larger than those in an adjacent, normal gland (left). The gland with PIN still has an identifiable basal cell layer.

prostatic adenocarcinoma, nucleolar prominence is a key finding in high-grade PIN. In contrast to the acini of prostatic adenocarcinoma, the glandular structures of high-grade PIN have a residual basal cell layer, although it may be attenuated or focally absent. In the differential diagnosis of adenocarcinoma versus high-grade PIN, the absence or presence of a residual basal cell layer is thus a key finding. Several architectural patterns of high-grade PIN are common, caused by the piling up of increased numbers of epithelial cells in pre-existing duct/acinar units. Thus, tufted, papillary, cribriform and flat patterns occur, usually two or more together. Some authors have argued that the cribriform pattern of PIN is not a precursor to invasive adenocarcinoma, but reflects the growth of invasive adenocarcinoma into the duct/acinar system of the prostate, even though the invasive component may not be apparent in the available specimen (McNeal and Yemoto, 1996). This conclusion is based on the rare finding of cribriform 'PIN' in cancer-bearing prostates at sites remote from the tumour, whereas other patterns of 'PIN' are common at such foci.

There are numerous pieces of evidence that link high grade PIN with adenocarcinoma (**Table 1**). These include similar ploidy values, genetic and cytogenetic changes in high-grade PIN and the associated adenocarcinoma, the similar cytological appearance of both processes (as mentioned above), similar ultrastructure, morphometric values, topographical distribution in the prostate (i.e. almost always in the peripheral zone), lectin binding patterns and the occurrence of so-called transitive glands. The latter are adenocarcinomatous glands that appear to 'bud' from foci of high-grade PIN. There is a much higher frequency of high-grade PIN in prostates with cancer than in those without cancer (McNeal and Bostwick, 1986; Bostwick and Brawer, 1987). Most importantly, there is a significant risk for the subsequent identification of adenocarcinoma of the prostate in a patient who has

Table 1 Evidence for the association of high-grade prostatic intraepithelial neoplasia (PIN) and prostatic carcinoma. (Adapted from Bostwick, 1997.)

Histology	Immunophenotype (continued)
Similar architectural and cytological features	For some biomarkers there is progressive increase in expression with increasing grades of PIN and cancer, including type IV collagenase, TGF-alpha, EGF, EGFR, Lewis Y antigen and *c-erb-2* oncogene
Location	Morphometery
Both are located chiefly in the peripheral zone and are multicentric	High-grade PIN and cancer have similar nuclear area, chromatin content and distribution, nuclear perimeter, nuclear diameter and nuclear roundness.
Close spatial association of PIN and cancer	High-grade PIN and cancer have similar nucleolar number, size and location
Correlation with cell proliferation and death (apoptosis)	DNA content
Growth fraction of PIN is similar to cancer	High-grade PIN and cancer have similar frequency of aneuploidy
Number of apoptotic bodies in PIN is similar to cancer	Genetic instability
Apoptosis-suppressing oncoprotein bcl-2 expression is increased in PIN and cancer	High-grade PIN and cancer have similar frequency of allelic loss
Loss of basal cell layer	High-grade PIN and cancer have similar foci of allelic loss
The highest grade of PIN has loss of basal cell layer, similar to cancer	Microvessel density
Increased frequency of PIN in the presence of cancer	Progressive increase in microvessel density from PIN to cancer
Increased extent of PIN in the presence of cancer	Origin
Increased severity of PIN in the presence of cancer	Cancer found to arise in foci of PIN
Immunophenotype	Age
PIN is more closely related to cancer than benign epithelium	Age incidence peak of PIN precedes cancer
For some biomarkers there is progressive loss of expression with increasing grade of PIN and cancer, including prostrate-specific antigen, neuroendocrine cells, cytoskeletal proteins and secretory proteins	Predictive value of high-grade PIN
	PIN on biopsy has high predictive value for cancer on subsequent biopsy

high-grade PIN identified on needle biopsy. Several studies have shown up to a 50% frequency of invasive adenocarcinoma in second biopsy procedures of patients whose initial biopsy showed high-grade PIN. Whereas high-grade PIN and conventional acinar adenocarcinoma both occur disproportionately in the peripheral zone of the prostate, the other putative precursor for adenocarcinoma, atypical adenomatous hyperplasia (AAH), is usually seen in the transition zone. Hence AAH is sampled most commonly in transurethral resections specimens and is uncommon in needle biopsy material.

AAH is an architecturally worrisome lesion that consists of a circumscribed proliferation of tightly packed, relatively small glands, usually having abundant pale cytoplasm (**Figure 14**). Hence it is most likely to be confused with a Gleason grade 1 or grade 2 adenocarcinoma. Careful inspection, however, usually discloses that there is a greater variation in gland size and shape than in the typical low-grade adenocarcinoma, and many of the glands of AAH have an undulating border that contrasts with the straight luminal edges of adenocarcinoma. Most importantly, AAH lacks the cytological features of carcinoma, and basal cells are present, although frequently inconspicuous, often requiring high molecular weight cytokeratin immunostains for their demonstration.

Unlike high-grade PIN, the evidence linking AAH to adenocarcinoma is scant. One study identified a higher rate of subsequent carcinoma in patients who were initially diagnosed with 'adenosis' (Brawn, 1982), but that study has been criticized for misinterpreting some cases of low-grade adenocarcinoma for 'adenosis.' There

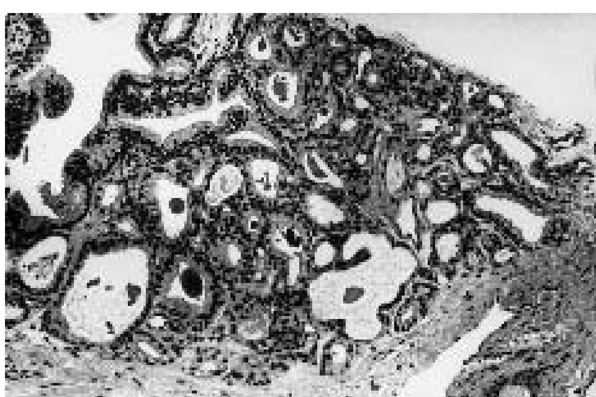

Figure 14 Atypical adenomatous hyperplasia consists of a collection of small glands that mimics the architectural features of a Gleason grade 1 or grade 2 adenocarcinoma. The close relationship to a 'parent' duct is a helpful distinguishing feature. At high magnification, these glands lacked the cytological features of adenocarcinoma.

is unquestionably a degree of morphological similarity between AAH and the typically low-grade adenocarcinomas that tend to occur in the transition zone of the prostate. Additionally, AAH, on average, tends to occur in patients who are 5–10 years younger than those with adenocarcinoma (Srigley, 1988; Amin *et al.*, 1993), supporting the evolution of the latter from the former. In addition, AAH has proliferation rates intermediate between those of normal prostate and adenocarcinoma. Disparate results have been obtained concerning cytogenetic abnormalities in AAH. One study found loss of heterozygosity (LOH) in 47% of cases by utilizing polymorphic microsatellite probes to chromosomes 7q, 8p, 8q and 18q (Cheng *et al.*, 1998). Another study, however, using probes to 1q, 6q, 7q, 8p, 10q, 13q, 16q, 17p, 17q and 18q, identified LOH that was confined to chromosome 8p in only 12% of AAH cases (Doll *et al.*, 1999). The former provided support for AAH as a neoplastic precursor but the latter questioned its neoplastic potential.

Immunohistochemistry may assist in the evaluation of prostatic adenocarcinoma. The secretory cells of the non-neoplastic prostate stain positively for prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP), and these substances are also identified in all but a very small percentage of poorly differentiated adenocarcinomas of the prostate, although the staining can be focal in many tumours. Immunostains for PSA and PAP may therefore be of help in distinguishing prostatic carcinoma from transitional cell carcinoma that has extended from the bladder. In addition, certain mimics of adenocarcinoma, such as nephrogenic adenoma (nephrogenic metaplasia), hyperplasia of mesonephric remnants, adenotic seminal vesicle and prostatic xanthoma, are negative for PSA and PAP, so immunostaining can help in their differentiation from prostatic adenocarcinoma. Also helpful are immunostains using antibodies directed against high molecular weight cytokeratins, including the most commonly used one, clone 34βE12. Such stains highlight the basal cells that are present in non-neoplastic glands but that are absent in adenocarcinoma. In a worrisome lesion that is suspicious for adenocarcinoma by routine light microscopy, the absence of high molecular weight cytokeratin in the worrisome focus may provide sufficient additional evidence to permit the diagnosis of adenocarcinoma (**Figure 15**). Conversely, the presence of high molecular weight positive basal cells in the worrisome lesion is strong evidence that it does not represent invasive adenocarcinoma.

In addition to the usual form of adenocarcinoma, a number of specialized forms of prostatic carcinoma exist. One such type is the small cell carcinoma that, pathologically, resembles the much more common form of lung cancer. Unlike conventional adenocarcinoma, small cell carcinoma may not be associated with PSA elevations. For patients who have *de novo* small cell

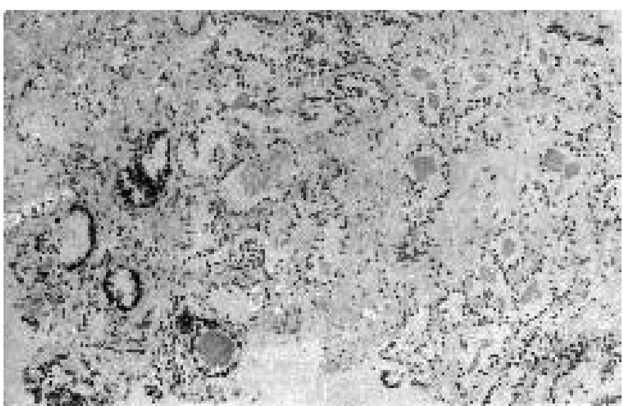

Figure 15 A high molecular weight cytokeratin immunostain is negative in a small acinar proliferation in the prostate, supporting that it is adenocarcinoma. A few non-neoplastic glands (left) show positively staining basal cells.

carcinoma, most have advanced stage disease at presentation. About half of small cell carcinomas are seen in patients who had a conventional acinar adenocarcinoma that failed hormonal or chemotherapeutic management, suggesting that many cases derive from therapy-resistant clones as a treatment selection phenomenon. The neuroendocrine nature of this tumour can be demonstrated with immunohistochemical markers, such as synaptophysin and chromogranin. Other types of prostatic carcinoma include prostatic duct, mucinous, signet-ring cell, adenosquamous, squamous, basaloid/adenoid cystic and transitional cell (i.e. of prostatic urethral or periurethral duct origin) types. It is controversial if the prostatic duct type of carcinoma merits separate classification since it is considered by some authorities to represent a conventional acinar adenocarcinoma with an unusual growth pattern caused by its extension into large periurethral ducts. Most continue to classify it separately but grade it using the Gleason method. In support of this approach, the clinical presentation is sometimes completely different from conventional adenocarcinoma. Patients with prostatic duct carcinoma may present with haematuria and, on cystoscopic examination, a mass may be seen protruding into the prostatic urethra. These features would not be expected with a conventional adenocarcinoma. The prior notion that prostatic duct carcinoma is derived from Mullerian tissues of the prostatic utricle (hence 'endometrioid' carcinoma of the prostate) is largely discredited on the basis of its positive staining with both of the usual markers of prostatic differentiation, PSA and PAP.

In addition to carcinomas, the prostate is also subject to much rarer mesenchymal tumours. Although virtually any form of sarcoma may be encountered in the prostate on occasion, only a select few merit special mention. Embryonal rhabdomyosarcoma of the prostate has an appearance similar to that seen in the soft tissues and

tends to occur in children and young adult patients, but it may rarely be seen in older adults. There also occur mixed epithelial–stromal tumours of prostatic origin that have a histological appearance and spectrum similar to the much more common phyllodes tumours of the breast (Gaudin *et al*., 1998) and the very rare, similarly named tumour of the seminal vesicle (see **Figure 23**). At the benign end of the spectrum, glands lined by bland epithelium are embedded in a cellular stroma, often with abundant stromal mucopolysaccharide. Cellularity, cytologic atypia and mitotic rate remain low. Malignant epithelial–stromal tumours of the prostate are characterized by increased stromal cellularity, stromal atypia and mitotic figures. Overgrowth of atypical stroma, to the exclusion of glands, remains an important malignant criterion. Between these two ends of the spectrum, there are tumours having intermediate features that are placed in a category of uncertain malignant potential. Benign tumours may recur locally, but do not metastasize, and this seems also to be the case with tumours thus far categorized as 'uncertain malignant potential,' although recurrence is more common than with unequivocally benign lesions. Malignant tumours are reported to metastasize.

Epidemiology and Aetiology

Apart from carcinomas of skin, prostate cancer is the most common malignant tumour of men. There is an estimated overall prevalence of 30% in men over 50 years of age, but the prevalence increases with age so that about 80% of men over 80 years old have prostate cancer based on autopsy studies. The apparent incidence of prostate cancer in the USA underwent a twofold increase from 1976 to 1994, but this observation may largely be attributable to better detection methods, including measurement of serum PSA levels and imaging the prostate with transrectal ultrasound (TRUS) (see chapter on *Ultrasound*). This viewpoint is supported by a decline in prostate cancer mortality rates by 0.5% per year between 1990 and 1994 that followed an increasing mortality rate from 1976 to 90. Nonetheless, prostate cancer currently ranks second only to lung cancer as a cause of cancer mortality in men in the USA. It therefore represents a major public health problem.

Epidemiological studies (see chapter on *Identifying Cancer Causes through Epidemiology*) demonstrate wide variations in the clinical incidence and mortality rates from prostate cancer in different countries. Low rates are seen in the Far East and many third-world countries, whereas there is a high incidence in Northern Europe, the USA, and Canada. Since migrated populations tend to acquire the prostate cancer rate of the new country of residence, environmental factors appear to have a major impact on prostate cancer incidence. Despite marked differences in the incidence of clinical carcinoma of the prostate in different geographic locations, the frequency of detectable prostate cancer at autopsy in these different areas is similar. These observations suggest that in countries with a high rate of clinical carcinoma, there is an increased rate of conversion of 'latent' carcinoma to clinical carcinoma.

Ethnic factors also appear important in determining prostate cancer risk. In the USA, there is a significantly higher mortality rate among African Americans than in Caucasians, and Jewish populations have a lower mortality rate compared with non-Jewish men. It is often not clear if genetic factors account for such differences or if differences in cultural habits are largely responsible. Some have suggested that the higher incidence of clinical prostate cancer in African Americans can be at least partially attributed to their higher levels of serum testosterone compared with other ethnic groups. It is clear that androgen exposure is necessary for the development of prostate cancer since prepubertal castrates do not develop prostatic carcinoma.

Among the environmental factors that have been linked to prostatic carcinoma, high fat intake has one of the more consistent associations. Intake of saturated fat, rather than monounsaturated or polyunsaturated forms, largely correlates with this increased risk and may account for at least some of the difference in prostate cancer incidence between Western and Far Eastern countries. Other factors that have been linked to an increased risk of prostatic carcinoma include vitamin D deficiency (partially based on the higher incidence in northern latitudes and among darkly pigmented persons), exposure to cadmium, employment in the textile, rubber, drug, chemical and atomic energy industries, large body mass and high plasma levels of insulin-like growth factor 1. Decreased risk has been associated with high soy protein intake (perhaps related to the phyto-oestrogens that are present in soy), high selenium intake, increased serum levels of lycopene (a carotenoid found in tomatoes) and increased intake of α-tocopherol.

It is now clear that prostate cancer has a genetic component (see chapter on *Inherited Predispositions to Cancer*), but cases with a clear familial component represent a small minority of prostate cancers. In men who have a single first-degree relative (father or brother) with prostate cancer, there is a calculated twofold increased risk, whereas having two or more affected first-degree relatives has been associated with an increased risk of 5–11-fold. Younger age (<50 years) of onset in a first-degree relative also appears to convey an increased risk beyond that seen with an older first-degree relative having had prostate cancer. A putative prostate cancer susceptibility gene has been identified on the long arm of chromosome 1.

Despite these numerous observations concerning factors conveying increased or decreased risk of prostate cancer, the cause or causes of carcinoma of the prostate

remain unknown. It is likely that environmental factors make certain important genetic mutations either more or less likely to occur in prostatic epithelial stem cells. One or more such mutations must be required for malignant transformation. It also seems likely that cases with a familial component represent tumours developing in patients with a germline mutation in one of the important genes for at least one of the pathways to malignant transformation. More specific information, however, is lacking at this time.

Screening and Prevention

The early detection of prostate cancer provides the best hope for its cure. The current screening recommendations are for men 50 years of age or older to have annual DRE and serum PSA measurements. Abnormal findings are typically followed by TRUS and, in some cases, biopsy. For men with a positive family history, it is recommended that screening begin earlier, at age 40 years. Unfortunately, neither PSA measurement nor DRE is entirely specific or sensitive. Benign prostatic hyperplasia and prostatitis can cause PSA elevations and abnormal DRE. The 'normal' PSA value is usually considered $<4\,\mathrm{ng\,mL^{-1}}$, and the positive predictive value of a PSA level exceeding $10\,\mathrm{ng\,mL^{-1}}$, is about 66%. A level of $4{-}10\,\mathrm{ng\,mL^{-1}}$, however, has one of only 22–35%. Furthermore, 22% of men with PSA values of $2.5{-}4.0\,\mathrm{ng\,mL^{-1}}$, generally considered in the 'normal' range, were found to have adenocarcinoma on prostate biopsy in one study (Catalona *et al*., 1997). A positive DRE has a positive predictive value of 21–39%.

In an effort to improve the specificity and sensitivity of PSA measurements, additional PSA measurements have been employed. Thus, the PSA density (total serum PSA per cubic centimetre of prostatic volume as determined by TRUS), PSA velocity (change in PSA value over time) and percentage of free (non-protein-bound) PSA improve the sensitivity and specificity for the detection of carcinoma and permit the avoidance of biopsy in some cases.

There have been no controlled trials to date that have documented a successful method of prostate cancer prevention. Potentially successful means might include drugs to decrease serum androgens or inhibit their tissue effects, a reduction in saturated fats in the diet and dietary supplements to provide increased amounts of phyto-oestrogens, vitamin E, selenium and/or lycopene. In one ongoing study looking at prostate cancer prevention with the 5-α-reductase inhibitor finasteride (which prevents the conversion of testosterone to its active metabolite, dihydrotestosterone), preliminary results showed no decrease in high-grade PIN among those receiving the drug, casting some doubt on its ultimate efficacy as a preventive measure.

Molecular Genetic Findings

A heterogeneous mixture of genetic alterations characterizes prostate cancers. Some of the most common abnormalities include loss of heterozygosity corresponding to loci on 7q, 8p, 10q, 13q, 16q and 18q. Loss of genetic material at these locations may well correspond to deletions of tumour suppressor genes that normally restrict cellular growth.

The association of prostate cancer with vitamin D deficiency has prompted the investigation of the role of genetic variation of the vitamin D receptor gene in prostate cancer. In one study of Japanese men with and without prostate cancer, one of three polymorphisms of the vitamin D receptor gene was associated with one-third the risk of prostatic cancer (Habuchi *et al*., 2000).

Because of the relationship of prostate cancer to androgen, studies of a gene (*CYP3A4*) that is normally involved in the deactivation of testosterone have been conducted and shown interesting results. A CYP3A4 variant has been linked to a higher frequency of prostate cancer and, more recently, this variant was found in a much higher proportion of African Americans, a group known to be at relatively high risk for prostatic carcinoma. Furthermore, African Americans with prostate cancer were homozygous for the variant gene significantly more frequently (46%) compared with a control group (28%) who did not have prostate cancer (Paris *et al*., 1999). Along similar lines, a missense mutation in the 5-α-reductase gene that is responsible for coding the protein that converts testosterone to its active metabolite was found to be associated with a much higher enzyme activity and was identified seven times more frequently in African Americans with prostate cancer compared with a healthy control population of African Americans (Makridakis *et al*., 1999).

A novel DNA transcript, designated *DD3* and mapping to chromosome 9q, was recently shown to be overexpressed in 53 of 56 prostate tumours, but it was not identified in other tumours or non-neoplastic tissues other than prostate (Bussemakers *et al*., 1999). Another gene that appears important in prostate cancer progression is the androgen receptor gene located on Xq-12, which is amplified in one-third of hormone refractory prostate cancers (Nupponen and Visakorpi, 1999).

Prognostic Factors

A number of features impact on the prognosis of prostate cancer. Initial stage remains of paramount importance. Clinical stage correlates with overall survival (**Figure 16**) and pathological stage, as determined from the examination of the radical prostatectomy specimen, provides a stronger assessment of the prognosis (**Figure 17**). Patients with incidentally identified

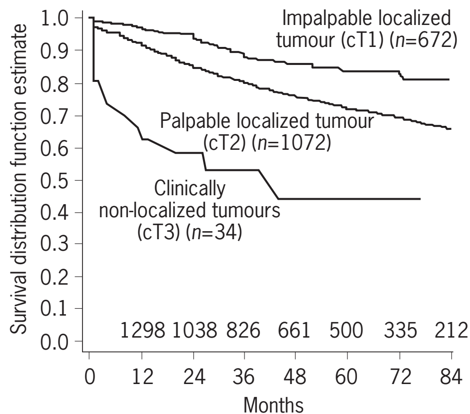

Figure 16 There is a decline in the survival of patients with prostate cancer treated by prostatectomy with advancing tumour stage as determined by clinical assessment. (Adapted from Catalona and Smith, 1998.)

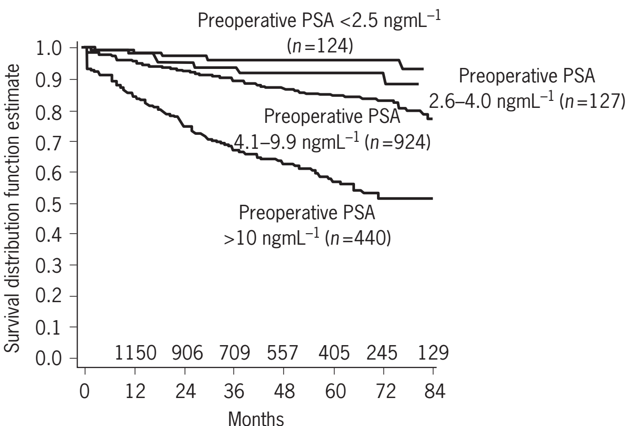

Figure 18 There is a decline in the survival of patients with prostate cancer treated by prostatectomy with increasing levels of serum PSA determined preoperatively. (Adapted from Catalona and Smith, 1998.)

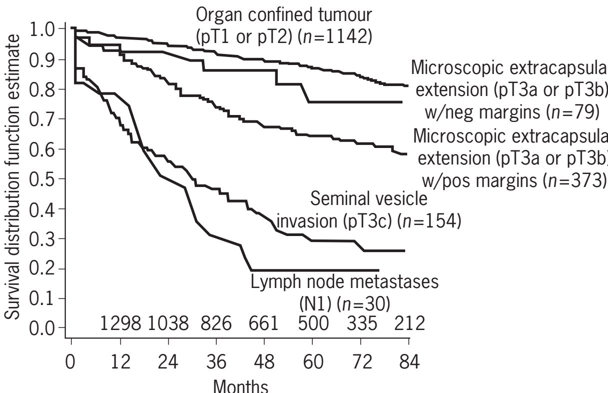

Figure 17 There is a decline in the survival of patients with prostate cancer treated by prostatectomy with advancing tumour stage as determined by pathological examination of the prostatectomy specimen and regional lymph nodes. (Adapted from Catalona and Smith, 1998.)

tumours in transurethral resectates (stage T1a) have a 95% 10-year survival, but there is a progressive decline in 10-year cancer-specific survival with advancing tumour stage; patients with T1b–T2 tumours have about an 80% 10-year cancer-specific survival, and those with T3–T4 tumours have a 60% 10-year cancer-specific survival. Patients who have nodal involvement at operation are rarely cured, but may have a prolonged survival, with a ten-year cancer-specific survival of about 40%.

In addition to stage, significant prognostic factors include pretreatment PSA levels (**Figure 18**), Gleason score (**Figure 8**) and, in patients treated by prostatectomy, tumour volume, margin status, the presence of perineural invasion and tumour ploidy in the prostatectomy specimen. These factors are not necessarily independent; some investigators, for instance, maintain that tumour volume provides no further prognostic information once Gleason score and margin status are determined.

Overview of Present Clinical Management

There are several treatment options for patients with carcinoma of the prostate. These include radical prostatectomy, radiation treatment by either external beam or radioactive seed implants (brachytherapy), anti-androgen treatment (orchiectomy or drug-induced androgen blockade) and so-called 'watchful waiting.' Patients with localized disease (T1–T2) are the best candidates for radical prostatectomy. Advanced prostate cancers (T3 and T4) are usually treated locally by radiation, whereas the primary approach for patients with metastatic disease is with androgen deprivation. Because many prostate cancers have an indolent course and do not affect the longevity of the patient, some have advocated no specific treatment for those with localized tumours. These patients receive periodic follow-up and may be treated if there is evidence of disease progression beyond a certain point. One problem with this approach is the reliable identification of those patients who will have a slowly progressive course versus those who are likely to experience rapid progression. For older patients with low-grade tumours that are predicted to be of small volume (based on TRUS and needle biopsy estimates), this may be a rational approach. T1a tumours (incidentally discovered in transurethral resectates) may be particularly amenable to this approach since they are often low-grade, low-volume lesions. Nonetheless, progression of the T1a tumours to high-stage lesions has been documented in up to 37% of patients who are followed beyond 10 years (Epstein *et al*., 1986). In one Swedish study there was no difference in cancer-specific survival comparing

treated versus untreated patients with localized tumours who had been followed for up to 15 years (**Figure 19**) (Johansson *et al*., 1997).

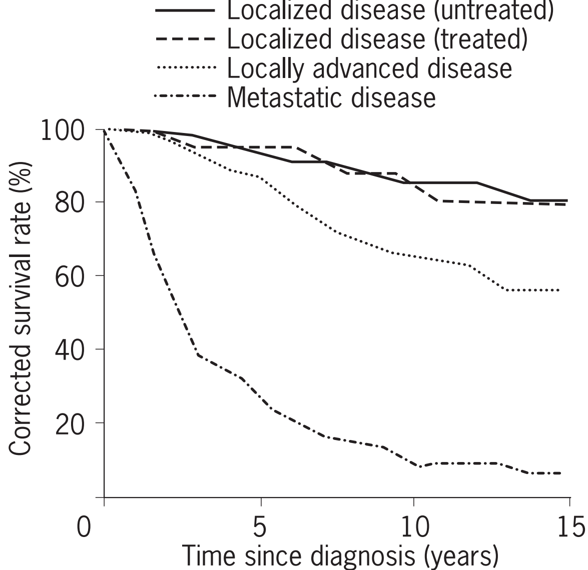

Figure 19 In this study there was no difference in the survival of patients with localized prostate cancer who received no treatment as compared to those who were treated. (Adapted from Johansson *et al*., 1997.)

PENIS

Normal Development and Structure

The penis develops from the genital tubercle, a swelling at the superior aspect of the cloacal folds. Such development is dependent on stimulation by androgenic hormones of testicular origin *in utero*. The superior portion of the cloacal folds is segregated from the inferior and become the urethral folds, which become incorporated into the penis to form the urethra. The genital tubercle, with androgenic stimulation, enlarges and elongates to form the phallus. A plaque of ectoderm at the distal aspect of the phallus forms the glans and distal most portion of the urethra.

The distal penis consists of the glans, the coronal sulcus and foreskin (prepuce) (**Figure 20**). The glans consists of a layer of stratified squamous epithelium, a thin lamina propria and the erectile tissue of the corpus spongiosum that surrounds the distal most portion of the urethra. The body or shaft represents the majority of the penis. The shaft is composed of three cylinders of erectile tissue, the paired corpora cavernosa and the ventralmost corpus spongiosum that contains the urethra. Each of these structures is covered by the tunica albuginea, a dense layer of connective tissue, and is encased in a layer of fascia (Buck's fascia). The most proximal portion of the penis, the root, is located in the perineum. Here, the paired corpora cavernosa form the penile crura, which have ligamentous insertions on the ischial bones. The central corpus spongiosum is expanded into the penile bulb, which is penetrated by the membranous urethra.

The arterial supply to the penis is derived from the pudendal branches of the internal iliac arteries. These give

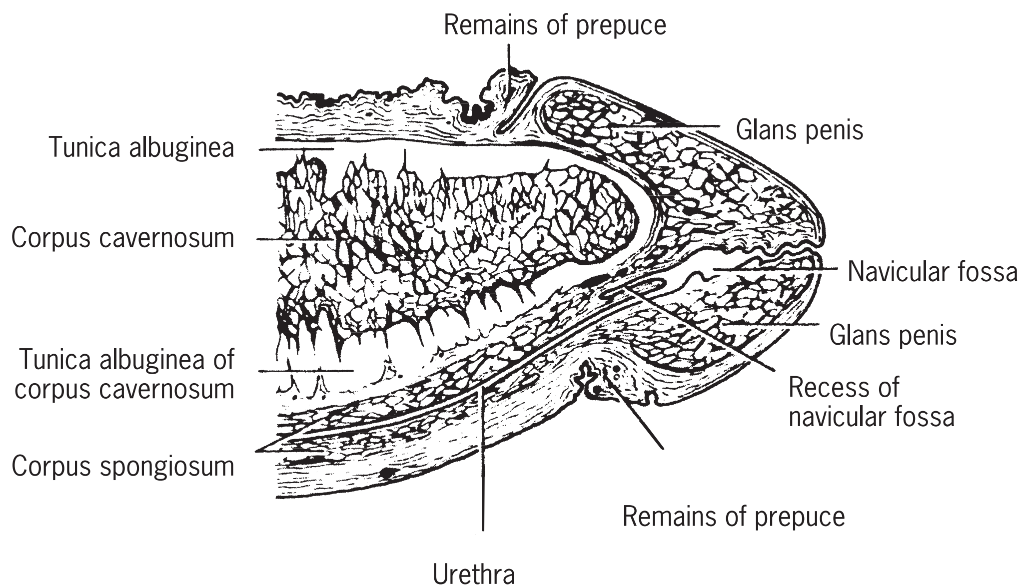

Figure 20 Sagittal section of distal penis, with foreskin removed. (Adapted from Romanes, 1986.)

rise to branches that run on the dorsal aspect, deep aspect, and bulb of the penis. The dorsal vein of the penis splits into two branches and drains into the prostatic plexus. The lymphatics that drain the glans and corpora cavernosa empty into superficial and deep inguinal nodes, whereas the skin of the shaft and foreskin empty into superficial inguinal lymph nodes.

Tumour Pathology

The overwhelming majority of penile cancers are squamous cell carcinomas. Most cases occur in older men (mean age, 58 years), but occasional younger patients may also be affected. The portions of penis that are most commonly affected are the glans (80%), foreskin mucosa (15%) and coronal sulcus (5%), but spread of tumours that originate in one of these locations to other penile components is common (Young *et al*., 2000).

Several subtypes of penile squamous cell carcinoma are described based on both the gross and histological appearances of these tumours. Young *et al*. (2000) have divided them into three major categories based on their grossly recognizable growth patterns: superficial spreading (35%), verruciform (25%) and vertical growth (20%), with the remainder having mixed patterns. The superficial spreading variant usually shows a plaque-like growth of white granular tissue that often spreads over large areas of the glans and foreskin. Verruciform tumours have an exophytic growth of white to grey tumour, typically with well-defined, circumscribed margins on cut surface. The vertical growth tumours are often ulcerated, deeply penetrating lesions with foci of haemorrhage, necrosis and cystic change.

Histologically, most tumours fall into the 'usual-type' squamous cell carcinoma category and are typically well differentiated and rarely poorly differentiated or sarcomatoid in type, with a spindle cell growth pattern. Other variants of squamous cell carcinoma include basaloid carcinoma (10%) (strongly associated with human papilloma virus (HPV; see chapter on *Infectious Agents and Cancer*)), papillary carcinoma (8%), which has a verruciform gross pattern but tends to have a jagged base composed of infiltrating nests of squamous cell carcinoma, warty carcinoma (6%) (**Figure 21**), which usually has a verruciform gross appearance and shows features related to HPV, and verrucous carcinoma (3%), which also has a verruciform appearance and pushing borders but lacks HPV-related features.

Preinvasive lesions of penile squamous carcinoma demonstrate the same spectrum of squamous cell dysplasia as is more commonly seen in the uterine cervix. For the high-grade dysplastic lesions, those affecting the glans may produce a diffusely erythematous clinical appearance, so-called 'erythroplasia of Queyrat.' 'Bowen disease' is the clinical term applied to high-grade squamous dysplasia that affects the penile shaft, producing a red or white elevated lesion. A third lesion, Bowenoid papulosis, typically affects the shaft as small, multiple papules in younger patients (mean age 30 years) than those with erythroplasia of Queyrat or Bowen disease (mean age in the sixth decade). Most commonly, the lesions of Bowenoid papulosis undergo spontaneous regression, whereas those of erythroplasia of Queyrat or Bowen disease persist and occasionally progress to invasive carcinoma.

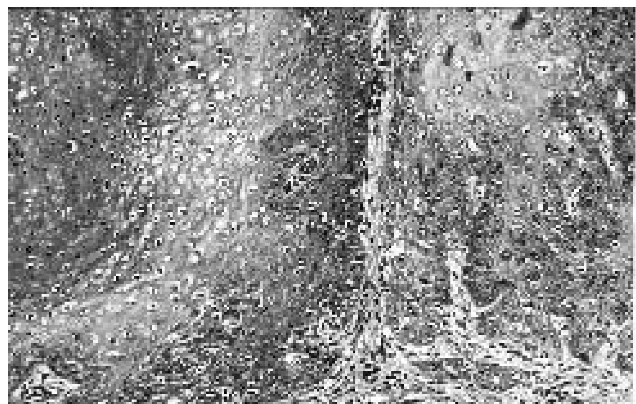

Figure 21 A portion of a 'warty' squamous cell carcinoma shows the nuclear enlargement and perinuclear clearing associated with the human papillomavirus (left) and an invasive growth of malignant-appearing squamous cells (right).

In addition to these variants of squamous cell carcinoma, some much more rare primary malignant tumours of the penis may also be seen. These include adenosquamous carcinoma, basal cell carcinoma, malignant melanoma, Paget disease, and various sarcomas. Of the sarcomas, those showing vascular differentiation are most common and include angiosarcoma, epithelioid hemangioendothelioma and Kaposi's sarcoma, the latter often occurring in patients with the acquired immunodeficiency syndrome. Other sarcomas include leiomyosarcoma, epithelioid sarcoma, malignant fibrous histiocytoma and embryonal rhabdomyosarcoma. Lymphoma may also rarely occur. Occasionally, metastatic tumours involve the penis, usually in patients with known advanced stage disease. The urinary bladder, prostate and kidney are the most common sources.

Epidemiology and Aetiology

The incidence of squamous cell carcinoma of the penis varies markedly around the world. It is common in Africa, Latin America and much of Asia, but rare in Europe and North America. Poor hygiene and phimosis are strongly associated with its development. Other features that are significantly associated with penile cancer include a history of HPV-related lesions, such as condylomata, and the absence of circumcision. It is likely that some forms are, like carcinoma of the uterine cervix, related to HPV infection given that HPV types can be identified in some

tumours and there is an increased frequency of penile cancer in the sexual partners of women with cervical dysplasia and carcinoma. It seems likely that absence of circumcision may permit carcinogenic substances or agents to accumulate in smegma to initiate tumour development. This hypothesis is also consistent with the anatomical distribution of penile cancer, with a marked predominance on the glans, mucosa of foreskin and coronal sulcus. Perhaps, in addition, the development of a thickened keratin layer that follows circumcision is a protective factor.

Screening and Prevention

Because of the rarity of penile carcinoma in Europe and North America, no experience with screening programmes is available. It is likely that simple inspection of high-risk patients would suffice to identify early lesions at a curable stage. In theory, precursor lesions could likely be detected by cytological preparations similar to those employed for the uterine cervix.

Circumcision in the neonatal period is considered a simple and effective method for the prevention of penile cancer. Schoen (1997) reported that the incidence of penile cancer among circumcised men in the USA is essentially zero, whereas it is 2.2/100 000 among uncircumcised men. Among a historical series of more than 1600 penile cancers that occurred in the last 60 years in the USA, none of the patients had been circumcised in infancy (Schoen, 1991).

Molecular Genetic Findings

Because of the rarity of penile cancer in Europe and North America, relatively little information is available concerning the molecular genetic events in these tumours. In one study of 64 penile cancers, HPV DNA was found in 36 cases (56%) (most commonly HPV 16), and 26% had evidence of *p53* mutations (Levi *et al*., 1998). An additional study identified c-Ha-*RAS* mutations in a metastasis of a penile squamous cell carcinoma that contained HPV 18 DNA. This mutation was not identified in the primary tumour or in an earlier metastasis, suggesting it was a late event involved in tumour progression (Leis *et al*., 1998).

Prognostic Factors

A number of features of penile carcinoma have prognostic significance regarding the occurrence of metastasis. Tumours with a verruciform growth pattern (Cubilla *et al*., 2000) have a better prognosis than those with a superficial spreading pattern which are, in turn, associated with a better outcome that those with vertical growth. Among the histological types, verrucous carcinoma has the best prognosis, warty and papillary squamous carcinomas have a good prognosis, but somewhat worse than the pure verrucous carcinomas, squamous cell carcinomas of the usual type have an intermediate prognosis and the most aggressive tumours are the basaloid (Cubilla *et al*., 1998) and sarcomatoid variants. A further refinement in outcome can be obtained by defining the degree of tumour differentiation, although this seems to have been applied mostly for the 'usual' type of squamous cell carcinoma rather than the less common variants (Horenblas and van Tinteren, 1994). Maiche *et al*. (1991) have further refined the grading methodology by developing a scoring system that factors the degree of keratinization, mitotic rate, cytological atypia and inflammatory response. Young *et al*. (2000) found a good correlation between a prognostic index (based on the tumour grade and anatomical level of invasion) and subsequent metastasis and tumour-related death. This is in line with the work of McDougal (1995) regarding the importance of the depth of tumour invasion and metastasis.

Overview of Present Clinical Management

The mainstay of treatment for penile carcinoma is surgical excision with lymph node dissection. For tumours of the foreskin, circumcision without penectomy may be adequate if frozen section evaluation of the margins is negative. For cases involving the glans, partial penectomy is required. In some cases with extensive areas of involvement, total penectomy may be necessary. In some cases, sentinel lymph node sampling, if negative, may permit the avoidance of more extensive inguinal lymph node dissection, but occasional cases of 'skip' metastases do occur.

SEMINAL VESICLE

Normal Development and Structure

The seminal vesicles develop from outpouchings of the mesonephric ducts, which also form the vasa deferentia. They are normally located along the posterolateral aspect of the urinary bladder and superior to the prostate, although they are occasionally embedded within the prostatic capsule. The excretory ducts of the seminal vesicles empty into the vasa deferentia, with the resultant conjoined structure known as the ejaculatory duct. Each seminal vesicle consists of numerous branching ducts embedded in a smooth muscle stroma.

Tumour Pathology

Primary cancers of the seminal vesicle are extraordinarily rare and hence have no known epidemiological features. Most have occurred in older men, with a mean age of 62 years, but occurrence in the third decade is also reported. Patients typically present with symptoms of urinary

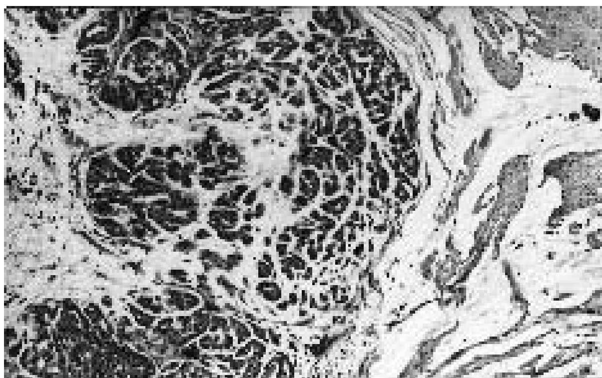

Figure 22 A mucinous carcinoma of the seminal vesicle has nests and cords of malignant epithelial cells in pools of extracellular mucinous secretion.

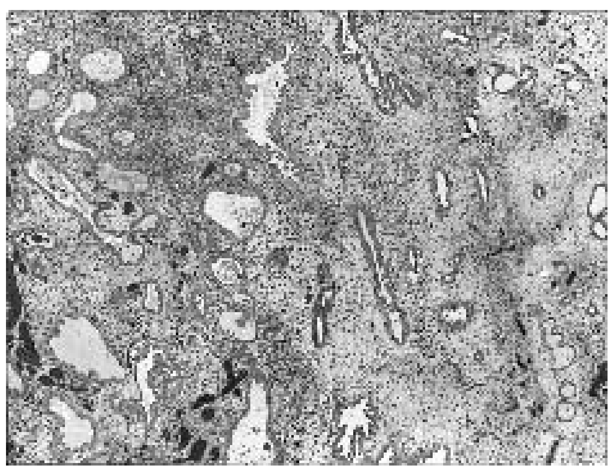

Figure 23 Epithelial–stromal tumour of the seminal vesicle. A cellular, neoplastic stroma surrounds numerous glands, some having a tufted epithelial lining. [From Young *et al.*, 2000, *Tumours of the Prostate, Seminal Vesicles, Urethra, and Penis*. 354 (Armed Forces Institute of Pathology, Washington, DC), by permission.]

obstruction, although haematuria and haemospermia also may occur. A palpable mass is present on digital rectal examination.

The tumours are usually multinodular, solid masses of grey–tan tissue. Microscopically, they are typically poorly differentiated adenocarcinomas. Papillary patterns are common, and clear cell carcinoma, similar to the tumour seen in the female genital tract, and mucinous carcinoma may also occur (**Figure 22**).

On immunohistochemical study, the primary carcinomas of the seminal vesicle are negative for PSA and PAP, assisting with the differential diagnosis of secondary involvement of the seminal vesicle by prostatic carcinoma, a much more common occurrence. In addition, seminal vesicle carcinomas may stain for carcinoembryonic antigen, CA-125 and cytokeratin 7, but are negative for cytokeratin 20 (Ormsby *et al.*, 2000).

In addition to the very rare primary carcinomas of the seminal vesicle, even more rare epithelial–stromal tumours also occur that are similar in appearance to those of prostatic origin. They typically occur in middle-aged to older patients who present with urinary retention. On gross examination, they are multicystic and may have solid foci. On microscopic examination, glandular structures, sometimes cystically dilated, are lined by cytologically benign cuboidal to columnar epithelium and surrounded by a variably cellular and atypical stroma that may show mitotic activity (**Figure 23**). Classification of the neoplasm as low or high grade depends on the stromal cellularity, atypia, mitotic activity and extent of stromal overgrowth. Immunostains for PSA and PAP are negative in the epithelial component, unlike the epithelial–stromal tumours of prostatic origin.

Rare sarcomas of the seminal vesicle origin are reported and include leiomyosarcoma, fibrosarcoma, malignant fibrous histiocytoma, liposarcoma and angiosarcoma.

Secondary spread of malignant tumours to the seminal vesicle is common. Overwhelmingly, these represent prostatic carcinoma or, less commonly, urothelial carcinoma from the bladder. Others include colorectal carcinoma, germ cell tumour and carcinoid. There is a significant decline in prognosis with secondary spread of prostatic carcinoma to the seminal vesicle as compared with otherwise similar tumours lacking such spread (**Figure 17**).

Prognostic Factors

Seminal vesicle carcinoma has a poor prognosis. Most of the reported patients have metastatic disease at the time of diagnosis; 95% of the patients with follow-up have survived less than 3 years. Of the few patients with survival of more than 1.5 years, all were treated with surgical excision (often requiring cystoprostatectomy) and anti-androgenic therapy, either with oestrogen, orchiectomy, or androgen inhibitors.

TESTIS

Normal Development and Structure

The testes develop initially as undifferentiated gonads represented by bilateral thickenings of mesenchyme between the mesenteric root and the mesonephros. The coelomic epithelium overlying these genital ridges proliferates and subsequently grows into the mesenchyme to form the primitive sex cords (**Figure 24**). The germ cells develop in the yolk sac but migrate along the midline to take residence in the gonads. The sex cord cells form the Sertoli cell component of the seminiferous tubules, which are also populated by the migrated germ cells. The Leydig cells differentiate from the primitive mesenchyme of the

interstitium. Gradually the testis assumes its adult shape as a distinct ovoid structure and migrates caudally, eventually to descend into the scrotal sacs in association with a small tongue of pelvic peritoneum, the tunica vaginalis. The seminiferous tubules anastomose with mesonephric tubules that form the ductular system of the testis and which empty into the mesonephric duct, the precursor of the vas deferens.

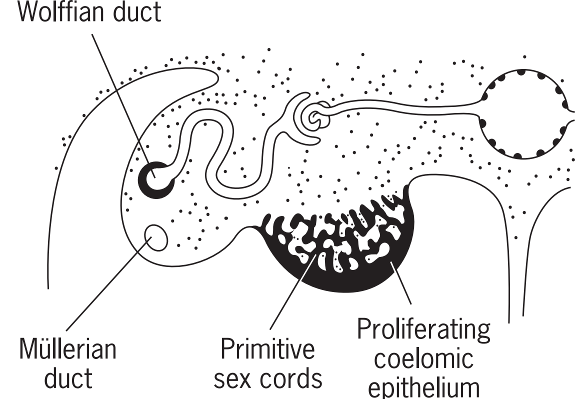

Figure 24 The primitive sex cords of the testis form from the proliferation of the coelomic epithelium that overlies the embryonic gonadal ridge. (Adapted from Langman, 1969.)

The ovoid testis is composed of numerous seminiferous tubules that anastomose with those of the rete testis and that, in turn, empty into the efferent ductules, which form the head of the epididymis, a structure closely applied to the external testicular surface (**Figure 25**). The testis is surrounded by a thick fibrous coating, the tunica albuginea, with a layer of mesothelium on its external aspect derived from the visceral layer of the tunica vaginalis.

The arterial supply to the testis and epididymis is from the testicular artery, usually a branch of the aorta, and from the artery of the vas deferens that derives from the superior vesical artery. The venous drainage exits the testis as a group of four to eight small veins at the hilum that invest the testicular artery in the spermatic cord as the pampiniform plexus. The lymphatics empty into the retroperitoneal lymph nodes.

Tumour Pathology

Although testicular germ cell tumours can be divided into two main categories that are often treated differently – seminomas and non-seminomatous germ cell tumours – both tumour types are derived from a common precursor malignant germ cell. This cell resembles those of

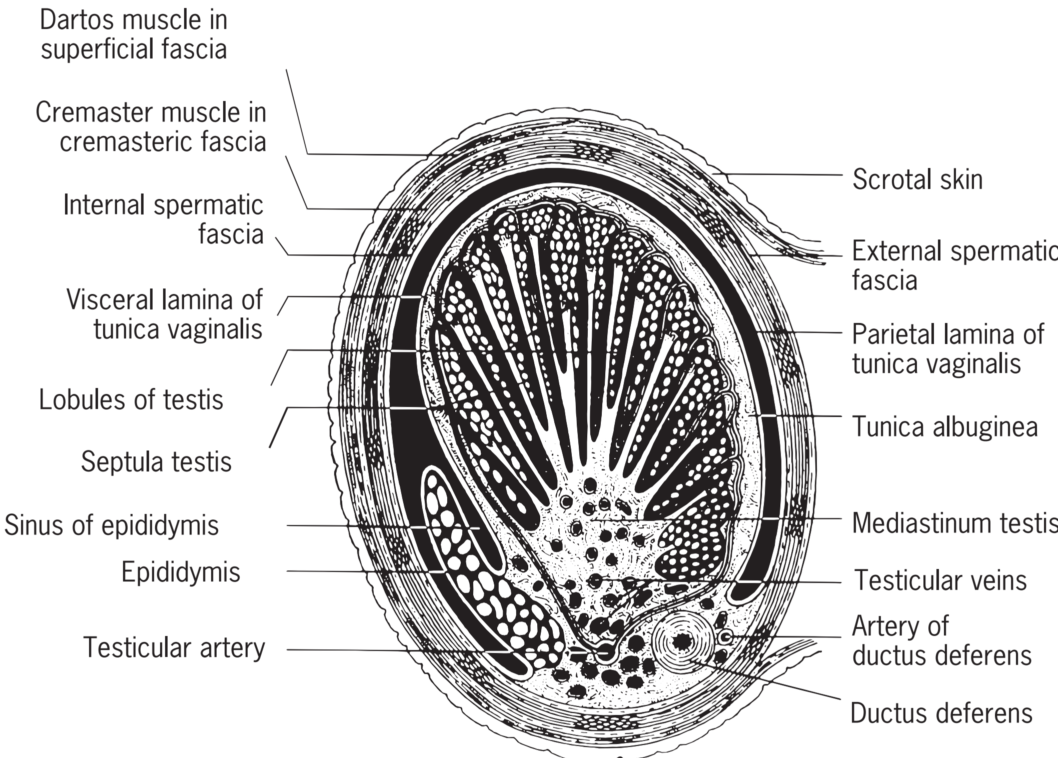

Figure 25 Cross-section of the testis and surrounding scrotum. (Adapted from Romanes, 1981.)

seminoma but also has the capacity to form non-seminomatous germ cell tumours. Such cells characteristically occur in the basal portion of seminiferous tubules that show decreased or absent spermatogenesis and have been termed 'carcinoma-*in-situ*' (**Figure 26**). However, since they can give rise to tumours that are not strictly 'carcinomas,' the term that a committee of pathologists recommended for this lesion is 'intratubular germ cell neoplasia, unclassified type' (IGCNU). Follow-up studies of patients who have had IGCNU identified on testicular biopsy verify a high rate of progression to an invasive germ cell tumour of either seminomatous or non-seminomatous type. The estimated rate of progression is 50% at 5 years, but some experts feel that all cases of IGCNU will eventually progress to an invasive tumour if sufficient time is allowed. Occasional cases of invasive testicular germ cell tumour have been reported in patients 15–20 years after a biopsy showing IGCNU.

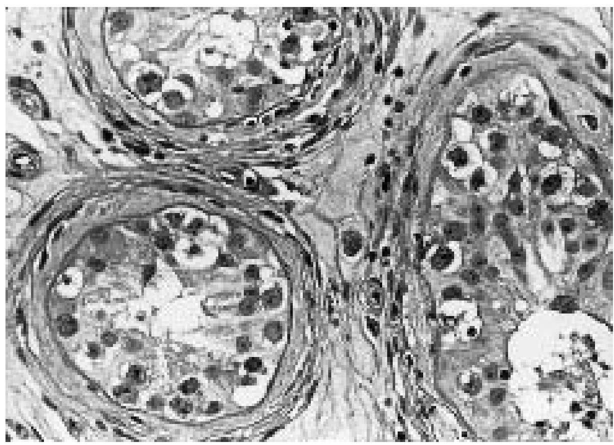

Figure 26 Intratubular germ cell neoplasia, unclassified type (also termed 'carcinoma-*in-situ*'). Note the basal proliferation of seminoma-like cells with clear cytoplasm and enlarged nuclei with prominent nucleoli in seminiferous tubules that lack spermatogenesis.

The evidence that IGCNU gives rise to testicular germ cell tumours is strong. Apart from the follow-up studies already mentioned, IGCNU is identified in the great majority of adult testes harbouring germ cell tumours (but, interestingly, not in prepubertal boys with testicular germ cell tumours). It also has the same immunohistochemical, ultrastructural and cytogenetic findings as are seen in seminomas, and it occurs with high frequency in patients who are known to be at increased risk for testicular germ cell tumours (see below).

Seminoma is the most common form of testicular germ cell tumour and occurs at an average age of 40 years. Most patients present with a testicular mass, but occasional patients present with metastatic tumour, most commonly manifest as vague abdominal or back pain because of retroperitoneal spread. A small group of patients actually have smaller than normal testes, reflecting pre-existing atrophy.

On gross examination, seminoma tends to have a fairly uniform, solid, white/grey to tan cut surface and a lobular outline (**Figure 27**). Some tumours, however, may diffusely replace the testis or show foci of haemorrhage or necrosis that produce a more variegated appearance.

On microscopic examination, the tumour cells are typically arranged in diffuse sheets in an overall lobulated configuration. The sheets are usually subdivided by fibrous septa that contain a lymphocytic infiltrate with occasional plasma cells (**Figure 28**). Some tumours may have a cord-like pattern of growth, especially at the tumour periphery.

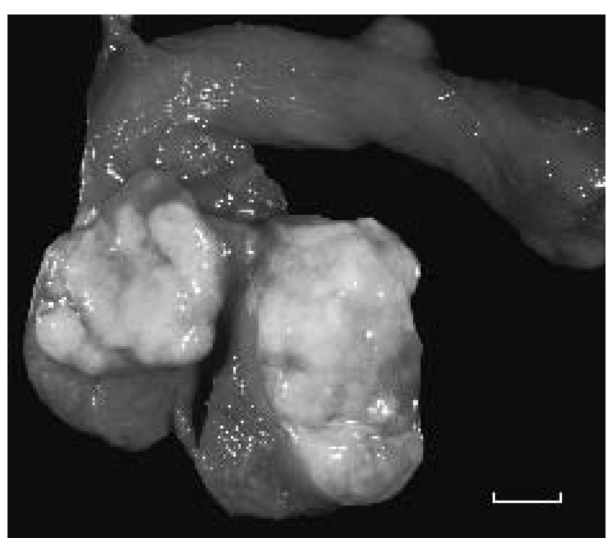

Figure 27 Cut surface of a testis with seminoma showing a solid, lobulated tumour with the typical, homogeneous, cream-coloured to light tan appearance. Bar, 1 cm.

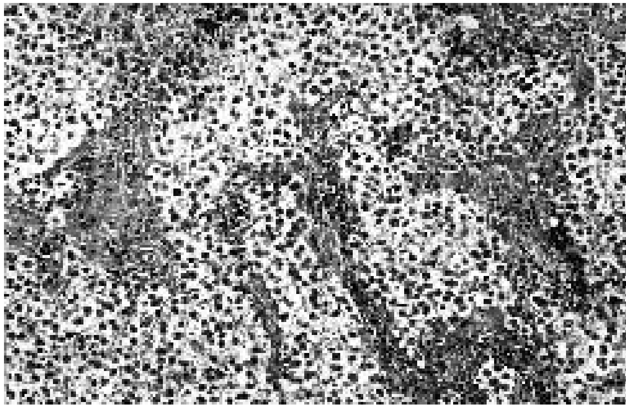

Figure 28 Typical seminoma, showing a sheet-like arrangement of cells with clear cytoplasm that is interrupted by fibrovascular septa with a lymphocytic infiltrate.

Occasional seminomas have a prominent interstitial growth pattern.

The tumour cells have round, often vesicular nuclei, with occasional flattened edges and one or more prominent nucleoli. They have polygonal shapes and generally abundant clear cytoplasm with well-defined cell membranes, although sometimes the cytoplasm is more dense and the nuclei more pleomorphic. The mitotic rate is usually brisk.

Small collections of epithelioid histiocytes occur in about 50% of seminomas, and rarely a similar granulomatous reaction may efface most of the tumour, making careful search for residual tumour cells necessary. Syncytiotrophoblast cells, usually multinucleated with eosinophilic cytoplasm, can be identified in about 10% of seminomas by light microscopy, but are more common if an immunohistochemical stain for human chorionic gonadotropin (hCG) is employed. They are often associated with small foci of haemorrhage, and their presence correlates with elevated levels of serum hCG.

Seminomas, like many other forms of testicular germ cell tumour, are cellular and friable, making artifactual tumour implants common on tissue surfaces and in vessels. Since these may lead to a false-positive diagnosis of extratesticular extension or lymphatic involvement, it is important to distinguish this phenomenon from legitimate examples of these processes. Artifactual implants on tissue surfaces occur at the periphery of tissue sections and in isolated tissue spaces that are discontinuous from clearly invasive tumour. The cells tend to have a poorly cohesive ‘floating’ arrangement and incite no tissue reaction. This is also true for artifactual vascular invasion, whereas true vascular invasion shows more cohesive cellular nests that conform to the shape of the vessel and may be attached to its wall and have an associated thrombus.

Spermatocytic seminoma is an entirely different entity from classic seminoma. It usually occurs in older men, with a mean age in the sixth decade, who present with testicular masses. Although it rarely ‘dedifferentiates’ into a sarcoma that behaves aggressively, the usual spermatocytic seminoma virtually never metastasizes; hence radical orchiectomy alone is adequate treatment. On gross examination, the tumours are often large, grey to haemorrhagic, multinodular, solid and cystic, and have a myxoid quality. Microscopically, the tumour cells are most typically arranged in sheets that are interrupted by oedema and have a paucity of lymphocytes and granulomas. The tumour cells vary in size from small, round, lymphocyte-like cells to intermediate-sized cells to giant cells that may be multinucleated. Despite the almost invariably benign biology of these cases, numerous mitotic figures, including abnormal forms, may be seen.

There are several types of non-seminomatous germ cell tumour; a detailed description of these tumours, however, is beyond the scope of this chapter and can be obtained from other sources (Ulbright *et al*., 1999). In general, the gross appearances of the non-seminomatous tumours are more heterogeneous than those of seminomas (**Figure 29**), reflecting the more common occurrence of haemorrhage, necrosis and cystic degeneration in the former.

Embryonal carcinoma, like the other forms of non-seminomatous germ cell tumour, tends to occur in patients who average 30 years of age. Although, like patients with seminoma, most present with testicular masses, a higher proportion have symptoms secondary to metastatic spread at presentation, reflecting the greater degree of aggressiveness of embryonal carcinoma. The tumour cells may be arranged in solid, glandular, and/or papillary patterns (**Figure 30**). They have large, pleomorphic, often irregularly shaped nuclei that appear crowded, with adjacent nuclei seeming to touch or even overlap. The

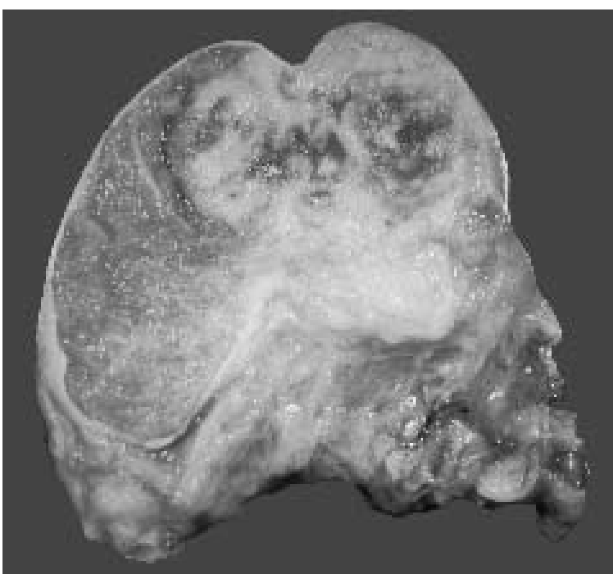

Figure 29 An embryonal carcinoma with a variegated, haemorrhagic appearance.

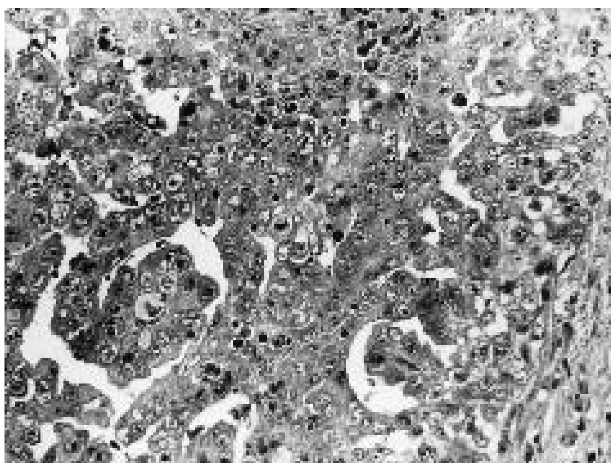

Figure 30 Papillary pattern of embryonal carcinoma. Note the crowded nuclei and indistinct cell borders.

cytoplasm is usually denser that that of seminoma cells and the cytoplasmic borders are ill-defined. The mitotic rate is brisk, and necrosis is frequent and often extensive. Intratubular embryonal carcinoma is often seen in the adjacent parenchyma and may be confused with intravascular tumour, although the more uniform size and shape of the rounded intratubular tumour and frequent comedo-type necrosis contrast with the features of intravascular tumour.

Yolk sac tumour is an uncommon form of pure non-seminomatous germ cell tumour in adult patients, but it represents about 70% of testicular germ cell tumours in children in whom it presents at an average age of 1.5 years. It is a common component of mixed germ cell tumours in postpubertal patients. Yolk sac tumour is the form of germ cell tumour that most consistently produces α-foetoprotein (AFP), which therefore serves as an extremely useful tumour marker. There are numerous yolk sac tumour patterns, and most tumours show several of them. The most common one is a microcystic arrangement wherein vacuolated tumour cells interconnect (**Figure 31**). Solid, myxoid, glandular, papillary, endodermal sinus-like (resembling structures normally identified in the placenta of rodents), macrocystic, hepatoid, sarcomatoid, polyvesicular vitelline, and parietal (basement membrane-rich) patterns also occur. In general, the neoplastic cells are less pleomorphic and atypical than those seen in embryonal carcinoma. The presence of hyaline, eosinophilic globules (**Figure 31**) and bands of basement membrane are helpful ancillary features for the recognition of yolk sac tumour.

Choriocarcinoma, as a pure tumour, is extremely rare and is even unusual as a component of mixed germ cell tumours. Unlike other forms of germ cell tumour, patients with choriocarcinoma usually present with metastatic tumour rather than a palpable mass. Even with known metastatic choriocarcinoma, careful clinical examination of the testes may fail to identify any testicular abnormality. This is because choriocarcinoma is the most common tumour to undergo regression in the testis, so that only foci of scarring with haemosiderin deposits may be present as evidence of pre-existing tumour. Choriocarcinoma is consistently associated with very high levels of hCG, and this can lead to gynaecomastia and thyrotoxicosis, which may therefore be presenting features. On gross examination, a haemorrhagic nodule is typical. Microscopically, syncytiotrophoblast cells and cytotrophoblast cells are intermixed, almost always with associated haemorrhage. Angioinvasion is frequent.

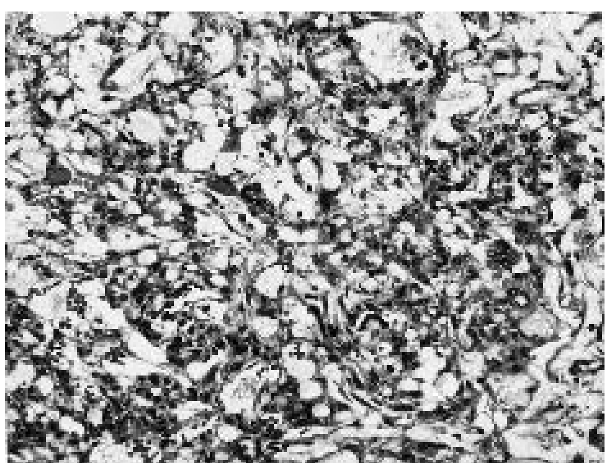

Figure 31 Typical microcystic pattern of yolk sac tumour. There are numerous hyaline globules.

Teratoma is uncommon as a pure tumour in adult patients, but it is the second type of germ cell tumour (in addition to yolk sac tumour) that occurs in children, representing about 30% of the total in paediatric patients. In children it is benign, but in adults it may be associated with metastases of either teratomatous or non-teratomatous germ cell tumours. The reason for this unexpected occurrence is that in postpubertal patients teratoma develops through a process of differentiation from an invasive malignant germ cell tumour, probably embryonal carcinoma most commonly. In postpubertal patients, therefore, teratoma has an aneuploid DNA content and cytogenetic abnormalities similar to those of other testicular germ cell tumours, whereas in prepubertal patients, it is diploid with a normal karyotype.

On gross examination, the tumours may be either solid or cystic. Microscopically, a large variety of tissues may be seen. Cartilage is common, as are enteric-type glands, squamous nests, and smooth muscle stroma. Immaturity is usually manifest as a cellular, mitotically active stroma or islands of neuroepithelium, but it is prognostically irrelevant, given the derivation of teratoma in postpubertal patients from an invasive malignant germ cell tumour and the benign outcome in prepubertal patients. Occasional overgrowth of primitive neuroepithelium or embryonic-appearing skeletal muscle is justification for a diagnosis of teratoma with a secondary malignant component (primitive neuroectodermal tumour or embryonal rhabdomyosarcoma, respectively).

Mixed germ cell tumours are fairly common and, by definition, represent those neoplasms having more than one of the types of tumours already discussed. Those cases with both seminoma and a non-seminomatous component are considered to be non-seminomatous in type because the latter component is most important in determining its behaviour.

Sex cord–stromal tumours of the testis are uncommon, representing about 5% of testicular tumours. They include Leydig cell tumour, Sertoli cell tumour, fibroma, granulosa cell tumour, mixed sex cord–stromal tumour, and unclassified variants. Most patients present with testicular masses, but some develop hormonal symptoms, which may be the presenting feature. This is particularly true for children who may develop pseudoprecocity or gynaecomastia. These tumours occur over a wide age range.

Grossly, sex cord–stromal tumours are usually solid, although cystic degeneration may be present. The colour

varies from grey/white to tan to yellow. Microscopically, a variety of patterns may occur. Leydig cell tumours most commonly have a diffuse arrangement of cells with abundant eosinophilic cytoplasm and sometimes have intracytoplasmic crystals (crystals of Reinke). The hallmark of Sertoli cell tumours is tubule formation. The granulosa cell tumours may have the range of patterns as seen in the more common ovarian counterpart, including microfollicular, trabecular, diffuse and gyriform. Fibromatous tumours again resemble the much more common ovarian lesions composed of gonadal stromal cells arranged in short fascicles and storiform patterns. Those showing substantial amounts of two or more well-recognized lines of differentiation are placed in the mixed category, whereas those with poorly formed elements such that much of the tumour can no longer be recognized in a reliable fashion as having a particular line of differentiation are placed in the unclassified category.

Malignant behaviour can occur with tumours in the sex cord–stromal category and generally correlates with a number of features, including large tumour size (>4–5 m), elevated mitotic rates, tumour necrosis, lymphovascular space invasion, significant cytological atypia and extratesticular growth. In general, about 10% of sex cord–stromal tumours are malignant.

A number of other malignant tumours may occur in the testis, but a detailed description of them is beyond the scope of this work, and most are similar to those occurring more commonly at other sites. These include malignant lymphoma, plasmacytoma, granulocytic sarcoma, leukaemic infiltrates, metastatic carcinoma and melanoma, malignant mesothelioma derived from the mesothelium of the tunica vaginalis, ovarian-type epithelial tumours of either 'borderline' or frankly malignant nature, the recently described desmoplastic round cell tumour and a variety of soft tissue sarcomas of paratesticular origin, including embryonal rhabdomyosarcoma in children.

Immunohistochemical stains are helpful in the evaluation of testicular tumours. Stains for placental alkaline phosphatase (PLAP) highlight the cytoplasmic membranes of most seminomas and are frequently positive in the other germ cell tumour types, with the exception of spermatocytic seminoma, although typically more focally. CD30 (BerH2) is a useful marker for embryonal carcinoma, but is virtually absent in other types. Epithelial membrane antigen is typically absent in germ cell tumours, with the exception of choriocarcinoma and teratoma. AFP is positive in yolk sac tumour and occasionally seen in embryonal carcinoma and teratoma, but it is absent in other types of germ cell tumours. hCG is present in syncytiotrophoblast cells, whether in choriocarcinoma or other types of germ cell tumour. Inhibin is a very useful marker for tumours in the sex cord–stromal category, typically staining most Leydig cell tumours diffusely and somewhat more than half of Sertoli cell tumours focally.

Epidemiology and Aetiology

Testicular cancer is overwhelmingly of germ cell origin and occurs predominantly in young men with a mean age of about 30 years (**Figure 32**). It is a disease that is most common in highly industrialized countries and in the Caucasian population. The highest incidence is reported from Denmark, Switzerland and Germany. Testicular cancer has increased in incidence over much of the twentieth century in those countries where it is common (**Figure 32**).

There are several well-recognized risk factors for testicular cancer (**Table 2**). Cryptorchidism remains one of the strongest associations. Some of the more recent studies suggest that patients with cryptorchidism have about a four times increased risk of testicular cancer that is not alleviated by orchiopexy, and that an elevated risk also applies to the non-cryptorchid testis. This risk, however, does not manifest until late adolescence. Swerdlow *et al*. (1997) presented data showing a higher relative risk, although the small number of abdominal testes in that study did not

allow an accurate assessment of their potential for malignant change (**Table 3**).

Patients with certain intersex syndromes have a remarkably high incidence of gonadal germ cell tumours. These syndromes include two main types: gonadal dysgenesis in patients with a Y-chromosome and androgen insensitivity syndrome. Patients with the former often have ambiguous external genitalia and gonads with 'streak' morphology or containing mixtures of ovarian-type stroma and immature-appearing seminiferous tubules. They often develop germ cell tumours in childhood or adolescence; hence, gonadectomy is indicated shortly after the diagnosis is established. Patients with androgen insensitivity syndrome are phenotypic females but genetic males. They have maldescended testes that are at high risk of germ cell tumours after puberty. One study reported that 22% of patients with androgen insensitivity syndrome who were over 30 years of age had developed a germ cell tumour (Morris and Mahesh, 1963).

Patients with a history of testicular germ cell tumour have an increased risk of a second germ cell tumour in the remaining testis, especially if that testis is atrophic. Overall, about 5% of patients develop bilateral neoplasia (Dieckmann and Loy, 1998), but the frequency of contralateral neoplasia increases to about 20% if the remaining testis is atrophic. A similar frequency of contralateral neoplasia is also seen in patients who have a positive family history (see below). At minimum, therefore, continued follow-up of the contralateral testis is indicated for testicular cancer patients.

Males with a family history of testicular cancer are at increased risk (see chapter on *Inherited Predispositions to Cancer*). The risk is greater if the relative is a brother rather than a father. Overall, there is a 2.2% frequency of testicular cancer in the first-degree male relatives of patients with testicular cancer (Tollerud *et al.*, 1985). As mentioned above, a family history also increases the risk of bilateral involvement. A recent study of a large group of testicular cancer families has, through linkage analysis, implicated a testicular cancer gene with a dominant pattern of inheritance that is present on the X-chromosome (Rapley *et al.*, 2000).

Despite these strong associations with testicular cancer, most cases do not occur in patients with well-recognized risk factors. Numerous epidemiological studies have found only weak associations with certain occupations or industrial exposures (see chapter on *Identifying Cancer Causes through Epidemiology*). More recently, a number of studies have implicated *in utero* exposure to high levels of circulating oestrogens as a significant factor for testicular carcinogenesis. Hence, there is increased risk in males born from first pregnancies, in those whose mothers had gestational hyperemesis and in those with a history of neonatal jaundice – all conditions associated with high oestrogen levels during foetal life. In addition, there are numerous factors that likely increase environmental oestrogen exposure, including the increased therapeutic use of oestrogenic substances, the oestrogenic supplementation of livestock and oestrogenic activity of some pesticides.

Molecular Genetic Findings

Most testicular germ cell tumours have a hyperdiploid to hypotriploid DNA content and, on cytogenetic study, they frequently have one or more copies of an isochromosome derived from the short arms of chromosome 12 (i (12p)). This distinctive marker chromosome is considered specific for germ cell tumours and can be used to establish a germ cell tumour diagnosis in problematic cases. Even in those germ cell tumours lacking i (12p), there is an increased amount of DNA derived from 12p, so this region of the genome appears to play a key role in the pathogenesis of germ cell tumours.

In addition to gain of 12p DNA, there are other nonrandom chromosomal changes. These include loss from 11p, 12q, 13, 18 and Y and gain of 7, 8, 21 and X. It has been noted that the DNA content of seminomas is greater

than that of non-seminomatous tumours, and it has been hypothesized that the non-seminomatous tumours derive from seminomas as a consequence of gene loss. As mentioned in the discussion of familial testicular cancer, a putative testis cancer gene has recently been localized to the X-chromosome through linkage analysis (Rapley *et al*., 2000).

Prognostic Factors

The great majority of testicular germ cell tumours are now curable through a combination of surgery, chemotherapy and/or radiation. Prior to the development of effective chemotherapy, many patients with metastatic seminoma could be effectively treated with radiation, but those with metastatic non-seminomatous tumours had a poor prognosis. Now, however, more than 80% of patients with metastatic non-seminomatous tumours are cured.

Stage remains of paramount prognostic importance. Patients with early stage tumours are almost uniformly cured, whereas those with bulky retroperitoneal disease experience about a 20% overall mortality. There are prognostic models to help divide patients into different categories that factor in features such as the levels of serum hCG and AFP, sites of involvement and size of metastatic lesions.

Occasional patients with early stage disease have an unexpectedly aggressive course or fail initial therapy for unclear reasons. It would be of great interest to identify such cases prospectively, but this goal has not yet been achieved.

Several investigators have attempted to define groups of testicular cancer patients who are at high or low risk for metastatic disease after an orchiectomy for clinical stage I tumour (i.e. having no clinical evidence of metastatic tumour after thorough staging, including radiographic evaluation of the retroperitoneum and chest and serum marker studies). Based on either follow-up studies or the results of retroperitoneal lymph node dissections, it is known that about 30% of such patients have occult retroperitoneal metastases. A successful division would permit simple follow-up for those patients at low risk, whereas high-risk patients could be recommended for staging retroperitoneal lymph node dissection (non-seminomatous patients) or adjuvant radiation (seminoma patients). Thorough pathological evaluation of the primary tumour for features such as lymphovascular invasion, extratesticular extension, percentage or volume of embryonal carcinoma and tumour size have shown strong correlations with either pathologically confirmed metastatic tumour or relapse. Alternative methods of evaluation, including flow cytometric studies for tumour S-phase and ploidy, and immunohistochemical staining for determination of proliferative fraction have also been applied with varying results.

Overview of Present Clinical Management

Patients with a clinical diagnosis of a testicular neoplasm receive radical orchiectomy. For those with seminoma, most receive adjuvant radiation to the retroperitoneum, although there is some interest in surveillance management (i.e. close follow-up but no adjuvant therapy) for clinical stage I patients with favourable pathological features. Radiation is usually given for those seminoma patients with small volume, retroperitoneal metastases, but cisplatin-based chemotherapy is used for those with bulkier disease or supradiaphragmatic spread. Patients with non-seminomatous tumours who are clinical stage I may either be placed on surveillance management or receive limited, nerve-sparing retroperitoneal lymph node dissection, again depending in part on pathological features. For those with known metastatic tumour, cisplatin-based chemotherapy is the mainstay followed by surgical excision of residual masses, if necessary. A patient with a teratomatous component in the testicular primary appears to be at higher risk of requiring post-chemotherapy resection because of the increased likelihood of teratomatous metastases and the non-responsiveness of teratoma to chemotherapy.

Patients who have sex cord–stromal tumours and who are clinical stage I may receive either surveillance management or retroperitoneal lymphadenectomy. It is sensible to manage patients whose tumours lack the features associated with malignant behaviour by surveillance and to reserve nodal dissection for those clinical stage I patients who have tumours with one or more of the pathological features that are associated with metastases. For patients with sex cord–stromal tumours that have metastasized, surgical excision by retroperitoneal lymphadenectomy or other procedures provides the best current approach. Chemotherapy and radiation have not proved effective for this situation.

Chapter 46

Lymph Nodes

Hans Konrad Müller-Hermelink and German Ott
University of Würzburg, Würzburg, Germany

CONTENTS

- The Anatomical Structure of the Lymph Node
- A Functional Approach to the Recognition of Reactive and Neoplastic Lymph Node Patterns
- Reactive Patterns of the Lymph Node
- Ancillary Methods Necessary for the Definition of Malignant Lymphomas
- Genotypic Studies
- Lymphoma Classification
- Lymphomas of B Cell Lineage
- Peripheral B Cell Lymphomas
- Lymphomas of T Cell Lineage
- Predominantly Leukaemic (Disseminated) Peripheral T and T/NK Cell Neoplasms
- Predominantly Extranodal T/NK Cell Lymphomas
- Hodgkin Lymphoma

THE ANATOMICAL STRUCTURE OF THE LYMPH NODE

Lymph nodes are organs with highly organized compartments, the knowledge of which is a prerequisite for the recognition of reactive and neoplastic lymph node processes.

They are surrounded by a fibrous capsule, where afferent lymphatics penetrate and reach the subcapsular (marginal) sinus. Within the lymph node parenchyma, the cortex contains the B cell follicles, which are embedded in the interfollicular paracortex, organized into the T cell areas and the perisinusoidal and vascular zones. The vascular hilus, where arterial branches reach and efferent lymphatic and venous vessels leave the lymph node, is the localization of the central medulla containing collecting sinuses and the perisinusoidal pulp cords.

The **primary B cell follicle** is composed either of small lymphocytes of mantle zone type, in older patients (or in inactive conditions) or sometimes marginal zone lymphocytes (marginal zone cell nodules). When confronted with antigenic stimulation, germinal centres develop within the primary follicles at the interface of paracortical T cell areas, then called **secondary follicles**. They are surrounded by small lymphocytes of the follicular mantle zone. The germinal centres are usually sharply demarcated, and are composed of a network of follicular dendritic reticulum (FDC) cells, the professional antigen presenting cells of the B cell follicle. The B cells within the germinal centres have the appearance of either large transformed cells, the so-called centroblasts, and smaller to intermediate-sized cleaved cells, the centrocytes. Characteristically, centroblasts and centrocytes are not haphazardly distributed, but display a zonation phenomenon with the appearance of a ‘dark’ zone predominantly composed of centroblasts (the proliferative compartment of the germinal centre), and a ‘light’ zone containing centrocytes (which is normally oriented towards the marginal sinus). Within the dark zone, multiple mitotic figures are found, and there may be a prominent admixture of large histiocytes with pale cytoplasm, thus creating a ‘starry sky’ appearance. These macrophages may be densely packed with pyknotic nuclear debris (‘tingible body macrophages’). Furthermore, a specific type of T cell is contained in germinal centres (the CD4 +, CD57+ T cell).

Reactive germinal centres, as a rule, are surrounded by the **follicular mantle zone**, composed of small lymphocytes with small cytoplasm and round inconspicuous nuclei. In some localizations, predominantly in abdominal (mesenteric) lymph nodes, and rarely also in superficial nodes after antigenic stimulation, another structural component of the follicular zone, termed the so-called **marginal zone** is present. This outermost part of the perifollicular B cell area may occasionally become apparent, but usually cannot be seen in all lymph nodes. Marginal zones, however, can be readily detected and form a characteristic part of the follicular B cell areas in the spleen. By morphology, the marginal zone, as compared with the ‘dark’ lymphocytes of the mantle zone, which are derived from germinal centre precursors or naive B lymphocytes, is composed of slightly larger cells with a broad

pale cytoplasm, which represent different populations of memory B cells.

On immunohistochemistry, all these different components of the follicle are composed of B cells, and therefore stain strongly positive for B cell-associated antigens (see **Table 2**), but may be distinguished by their different phenotypes.

The **nodal paracortex** is composed of T cells areas (or nodules) and the perivascular (perisinusoidal) cortical pulp areas. The paracortical T zone, which may become a nodular structure after chronic (antigenic) stimulation, is composed of small T lymphocytes and intermingled, frequently pale-appearing, interdigitating reticulum cells (the professional antigen presenting cells for T cell activation). In the paracortical pulp, post-capillary high endothelial venules and some transformed (blastic) cells are found which are a mixture of T and B cells or plasma cell precursors. In the paracortex, CD4+ T cells normally are more numerous than CD8+ T cells.

The central portion of the lymph nodes, the **medulla**, contains the collecting sinuses, which are often filled with histiocytes and a special type of endothelial cells, the sinus lining cells. The perisinusoidal pulp cords contain the plasma cells, some T cells and macrophages.

A FUNCTIONAL APPROACH TO THE RECOGNITION OF REACTIVE AND NEOPLASTIC LYMPH NODE PATTERNS

Lymph nodes are filter organs of interstitial fluids and lymph, where circulating molecules, particles, cells and microorganisms are subjected to cognate cells and interaction with the phagocytic and immune systems, and major effector functions of these systems are initiated. In particular, immune stimulation and acceleration, where complex interactions of highly specialized cell types are needed to generate and regulate potentially dangerous effector functions, usually take place in the organized structures of the lymphoid organs (tonsils, Peyer's patches, lymph nodes, spleen). The lymph reaches the lymph nodes via afferent lymph vessels by the marginal sinus which acts like a sieve – there are only few shunts to the collecting ducts, so that everything has to pass through the meshwork of the interstitial reticular tissue and re-enter the collecting sinus. Macrophages take up particles or macromolecular constituents by pinocytosis. Dendritic cells and possibly also sinus lining cells may transport and present antigens to the organized T and B cell areas for further immune reactions.

The blood arteries enter the lymph node at the opposite medullary hilus and branch via lobular vessels to the capillary bed of the cortical lymphoid follicle, where fenestrated capillaries allow plasma proteins including antibodies to leave the circulation and attach to the follicular dendritic cells. Migrating lymphocytes leave the blood stream after specific attachment to the high endothelial vessels penetrating the T and B cell areas and leave the lymph nodes via the collecting sinuses at the hilus through efferent lymph vessels, together with the veins.

Specific antigenic stimulation of naive reactive T and B cells takes place in the highly organized microenvironment of T and B cell areas by professional antigen presenting cells, the interdigitating cells of the T cell area and the follicular dendritic cells of the B cell follicle.

Within the germinal centre of the B cell follicle, antigenic stimulation of naive B cells leads to transformation of these resting B cells into highly proliferating centroblasts that mature into centrocytes. By antigen-dependent selection and somatic mutation of immunoglobulin receptor genes, cells with high receptor affinity become selected, whereas cells with low antigen reactivity die by apoptosis and become phagocytosed by the so-called starry sky macrophages. Selected B cells leave the germinal centre as memory B cells or plasma cell precursors. The T cell influence through different cytokines is crucial for these precursors. Somatic mutation is confined to the germinal centres, and stops in the emigrant cell population.

In the T cell areas, naive T cells become activated and either cooperate with B cells at the interface of T cell areas and B follicles to induce the germinal centre reaction by TH_2 cytokines, or T effector functions by TH_1 mediated macrophages and granulomatous reactions or MHC Class I restricted cytotoxic T cell responses. Effector T cells will leave the lymph node collecting medullary sinuses and form the recirculating lymphocyte pool.

REACTIVE PATTERNS OF THE LYMPH NODE

Table 1 gives an overview on major reactive patterns in lymph nodes. Some of them are described in greater detail, since they represent important differential diagnoses to malignant lymphomas.

Progressive transformation of germinal centres is a relatively rare, but distinct, condition in which in the background of reactive follicular hyperplasia few or many follicles are greatly enlarged. They are characterized by a prominent mantle zone and ill-defined germinal centres, mainly consisting of small lymphocytes. Remnants of germinal centre cells may be found, and are difficult to recognize. In some instances, epithelioid histiocytes are interspersed. This condition sometimes bears a close resemblance to nodular paragranuloma, but no lymphocytic and histiocytic (L&H) cells are present.

Castleman's disease of hyaline vascular type: in contrast to the lesions described above, Castleman disease (CD) represents a distinct clinicopathological entity.

Table 1 Reactive hyperplasias and reactions in different compartments in chronic lymphadenitis

B cell compartment
Follicular hyperplasia
Sinusoidal B cell reaction (immature sinus histiocytosis)
Marginal cell reaction/nodules
Plasmacytosis
Progressive transformation of germinal centres
T cell compartment
Paracortical nodular T zone hyperplasia
Diffuse cortical hyperplasia
Plasmacytoid monocyte reaction
Sinus reactions
Sinus histiocytosis
Foreign body reaction
Mastocytosis
Sinus lymphocytosis
Macrophage reactions
Foreign body reactions
Epithelioid cell reaction
Histiocytic-suppurative granulomas

Usually, this type of CD presents as a solitary lesion, most commonly found in the mediastinum, abdomen or cervical lymph nodes.

The morphological hallmarks of CD are regressively changed small follicles, increased vascularity in the interfollicular area and the presence of plasmacytoid monocytes. In addition, sinuses are lacking. Follicular centres frequently are 'onion skin' shaped with a predominance of follicular dendritic cells and few lymphocytes, and the mantle zone is prominent, sometimes exhibiting a curious 'Indian file' pattern with small lymphocytes being arranged in concentric circles. In the interfollicular areas, postcapillary venules of the high endothelial cell type are numerous, and sometimes one or more of these vessels are seen penetrating into the regressive germinal center. Usually, there is a mixture of lymphoid cells, histiocytes and few plasma cells present, and the so-called plasmacytoid monocytes are diffusely interspersed or may be recognized as small cell nests. They are of medium size and have round to oval nuclei with fine chromatin distribution and pale eccentric cytoplasm, reminiscent of plasma cells. On immunohistochemistry, they stain positive for CD68 and CD43.

In contrast, **multicentric Castleman's disease**, also called multicentric angiofollicular lymphoid hyperplasia, or plasma cell-rich variant of Castleman disease, consistently involves multiple peripheral lymph nodes and may also manifest in the bone marrow, liver, kidney and CNS. The germinal centres may be expanded, or regressively changed as in the hyaline-vascular variant. High endothelial venules are a prominent feature in the interfollicular tissues, as is an enormous proliferation of plasma cells. In most cases, these plasma cells are polyclonal; however, they may be monoclonal in HIV-infected individuals in which the disease is associated with human herpes virus type 8 (HHV-8) infection.

In some patients, the so-called 'POEMS' syndrome may be diagnosed, the acronym summarizing the principal disease features of polyneuropathy, organomegaly, endocrinopathy, M proteins and skin lesions (Rosati and Frizzera, 1997).

ANCILLARY METHODS NECESSARY FOR THE DEFINITION OF MALIGNANT LYMPHOMAS

Immunophenotypic Studies

Immunohistochemistry has gained particular importance both with respect to the differentiation of the various subtypes of malignant lymphomas and in the differentiation of reactive versus neoplastic lymphoproliferative disorders. Immunophenotypic studies have also become accepted as a valuable help in the recognition of lymphoma entities, and have also contributed substantially to our understanding of the histogenesis and pathogenesis of haematopoietic neoplasms in general.

They are not only useful in the primary distinction of a neoplastic versus a benign lymphoid infiltrate, but are also important in the revelation of a preserved or destroyed normal architectural pattern. With the use of antibodies to kappa and lambda immunoglobulin light chains, and the determination of the light chain ratio, plasma cells or other immunoglobulin-producing lymphoid cells can be judged as polyclonal or monoclonal, the latter at least documenting a monoclonal expansion of a B cell population, if not its malignant nature.

By the application of other antibodies, certain biological features (e.g. the Ki67 antigen reflecting the proliferative index of a neoplasm) or prognostic features such as the atypical expression of tumour-suppressor genes (e.g. a mutated *p53* gene) or the formation of a fusion gene (e.g. *NPM-ALK*) may be determined.

Table 2 gives an overview of antibodies useful in the daily diagnostic practice of lymphoid neoplasms. This table lists antibodies to CD antigens and other antibodies reliably working on paraffin sections provided that antigen retrieval is performed. The specificity indicated represents only basic reactivity. Some of the antibodies, therefore, may have a broader spectrum of reactions.

It should be strictly kept in mind, however, that immunophenotypic studies can only be an adjunct to morphological diagnosis. For example, aberrant monoclonal B cell populations may be identified in non-neoplastic disorders, e.g. in certain autoimmune diseases. Therefore, 'monoclonality' by no means equates with 'malignancy'.

Table 2 Overview of antibodies useful in diagnosis of lymphoid neoplasms

Antigen	**Specificity**
CD2	T cells
CD3	T cells
CD4	Helper T cells
CD5	T cells, B cell subpopulation
CD8	Cytotoxic T cells
CD10	Germinal centre B cells
CD15	Neutrophils, Hodgkin and Reed–Sternberg cells
CD20	B cells
CD21	B cell subpopulation, follicular dendritic cells
CD23	Follicular mantle cells, follicular dendritic cells
CD30	Activated B and T cells, Hodgkin and Reed–Sternberg cells
CD34	Precursor myeloid and lymphoid cells
CD43	T cells, B cell subpopulation, myelomonocytic cells
CD45	Leukocyte common antigen
CD45R0	T cells
CD56	T/NK cells, NK cells
CD57	NK cells
CD68	Monocytes, macrophages
CD79a	B cells, plasma cells
CD138	Plasma cells
Others	**Specificity**
TdT	Precursor B and T cells
TIA 1, granzyme B	Cytolytic/cytotoxic cells
DBA44	Hairy cells
Bcl-2	Proto-oncogene product
p53	Suppressor gene product
p27	Cdk inhibitor
p21	Cdk inhibitor
Cyclin D1	Cdk activator
VS38c	Plasma cells

GENOTYPIC STUDIES

The detection of a clonal population of B or T cells refers to the capability of these cells to rearrange physically either their immunoglobulin heavy (IgH) and light (IgL) chain genes or their T cell receptor genes. Some other gene rearrangements, such as in chromosomal translocations, also alter the spatial arrangement of the DNA in the nucleus, thus being accessible to DNA rearrangement studies. The Southern blot technique as a means of determining clonality in a lymphocytic proliferation may detect clonal populations as low as 1–5% of cells relative to the total number of cells in a (fresh) specimen, thus clearly exceeding the threshold of pure morphological analysis. In addition to the detection of a clonal cell population represented by a non-germline band (or bands), the technique may also be used for distinguishing T or B lineage neoplasms.

The most important shortcoming of this technique, the requirement for fresh material, can be overcome by the use of the polymerase chain reaction (PCR) technique. The PCR, in its basic principle, represents a technique in which small amounts of DNA can be amplified *in vitro*, provided that the DNA sequences flanking the regions looked for are known. Because of the requirement of only minimal amounts of DNA (or small degraded DNA particles), this technique can be used for the detection of clonal cell populations or DNA rearrangements also in paraffin-embedded formalin-fixed material (in which the DNA normally is largely degraded). Because of this inherent advantage, the PCR may also be used in the monitoring of minimal residual disease, especially if clonotypic primers are used.

By DNA sequence analysis of Ig receptor genes, non-mutated (naive) prefollicular and mutated (memory) postfollicular B cells may be distinguished. In follicular cell populations, and some of their descendants, various 'ongoing' somatic mutations show a micropolymorphism of the B cell receptor repertoire. The detailed analysis of Ig receptor genes, therefore, permits conclusions on the status of antigen-dependent selection and mutation as well as the V_H gene repertoire.

Karyotypic Studies

Malignant lymphomas, especially the non-Hodgkin lymphomas of B type, are fairly well characterized – at least with respect to their primary genetic alterations – on the cytogenetic level. Mitelman's catalog of 'Chromosome aberrations in cancer' lists over 2000 lymphoid neoplasms on which conventional cytogenetic (banding) studies have been performed. Apart from proving the neoplastic nature of a lymphoid cell proliferation, the description of characteristic cytogenetic aberrations in certain types of malignant lymphomas has greatly added to our understanding of the biology of malignant lymphomas and has also influenced taxonomy, as may best be exemplified by the close association of mantle cell lymphoma to the translocation t(11;14)(q13;q32), the recognition of which ultimately led to the worldwide acceptance of mantle cell lymphoma as an entity on its own.

Table 3 lists the most common and characteristic chromosome aberrations in malignant lymphoma.

At present, malignant lymphoid tumours can not be classified according to their primary genetic aberrations alone, because (1) in some entities, no characteristic aberrations have been detected so far, and (2) because a recurring chromosomal translocation may be encountered in different lymphoma entities, e.g. the t(14;18)(q32;q21) in follicular lymphoma and diffuse large B cell lymphoma. In addition, cytogenetically detectable alterations are recognized only in a fraction of a given lymphoma entity.

More recently, the use of fluorescent dye-conjugated DNA probes in *in situ* hybridization has overcome some

Table 3 Characteristic chromosome aberrations in malignant lymphoma

Diagnosis	Chromosome aberration	Genes involved
Precurser B cell lymphoblastic lymphoma/leukaemia	t(1;19)(q23;p13)	c-*ski* (1q23)
	t(4,11)(q21;q23) del(6q)	c-*ets1* (11q23-24)

limitations of conventional cytogenetics, i.e. the need for viable dividing cells. With the use of the fluorescence *in situ* hybridization (FISH) technique, cytogenetic investigations can today also be performed on interphase cells, thus allowing for the recognition of amplifications, deletions or even translocations without the need to cultivate cells. This technique is sometimes also referred to as 'molecular cytogenetics'. With the aid of the FISH technique, it has been possible to define independent prognostic parameters in certain lymphoma entities which, in some cases, may be equivalent to the items of the International Prognostic Index. *ATM* or *p53* deletions in B cell chronic lymphocytic leukaemia, for example, are strong negative prognostic indicators.

The comparative genomic hybridization (CGH) technique allows for an overview of genetic imbalances (overrepresentations and deletions) in malignant tumours and may be used to calculate the overall genomic instability, which appears to constitute a new important prognostic feature.

LYMPHOMA CLASSIFICATION

History

The history of the recognition and classification of tumours that today are called malignant lymphomas is long, controversial and complicated. In 1832, Sir Thomas Hodgkin first identified malignant tumours of lymph nodes. Among those were cases that we would now classify as Hodgkin lymphoma. The definition of 'leukaemia' followed in 1845 by Rudolf Virchow and in 1863 he laid down the concepts of lymphosarcoma and lymphoma. At the turn of the nineteenth century, Sternberg and Reed, in 1898 and 1902, defined morphologically the tumour cells of Hodgkin disease. About 25 years later, Brill and Symmers described follicular lymphoma and in 1948 Burkitt and in 1960 O'Connor and Davis described African lymphoma, now called Burkitt lymphoma. Within this short list, of course, only historical milestones have been cited, constituting only those steps that still remain valuable in the twenty-first century.

Since 1960, modern immunology has greatly influenced our knowledge of lymphoid tumours. The biology of lymphoma cells, reflecting the immunological activities of their normal counterparts, has been clarified to a great extent and has allowed the establishment of a biological basis for new and more comprehensive classification systems of malignant lymphomas. Two classification systems have been widely used until recently, the Kiel Classification of Non-Hodgkin Lymphomas (Stansfeld *et al.*, 1988; Lennert and Feller, 1992) and the Working Formulation for Clinical Usage (Non-Hodgkin's Lymphoma Pathologic Classification Project, 1982). The Kiel classification was based on the exact morphological description and immunological identification of the normal cellular counterparts of tumour cells and was updated several times, introducing

new findings and more comprehensive knowledge. The so-called Working Formulation, on the other hand, was based on historical clinical survival data and, therefore, was not updated, although its usage was also adapted to modern findings. Of importance, there was a geographic split of categories in the diagnosis of lymphoid tumours, the Kiel classification in Europe and the Working Formulation in the USA.

An international group of experienced haematopathologists, the International Lymphoma Study Group (ILSG) formulated a new proposal for a modern lymphoma classification and published it as the so-called Revised European American Lymphoma (REAL) Classification (Harris *et al*., 1994). In the following years, this proposal was tested for its applicability and reliability and then accepted worldwide. It is, therefore, largely identical (with some minor corrections and additions) with the now proposed WHO classification.

Basic Taxonomic Principles

The taxonomic unit of the new WHO classification is the **disease entity**. Distinct entities in malignant lymphomas can be recognized by pathologists and, ideally, are of clinical relevance. For each disease entity, a combination of morphological, immunophenotypic, genetic and clinical features is needed for its definition. The relative value of each of these features may vary among different disease entities. Variations in grade and aggressiveness, that may exist within a given disease entity, and may be related to patients' survival and treatment response, must be distinguished from 'different diseases' (Jaffe *et al*., 1998; Harris *et al*., 1999, 2000).

The basic rules for the definition of disease entities in this proposal are comparable to the general rules of tumour classification as used in many other organs and organ systems. A given lymphoma entity is defined in first line by recognition of the predominant differentiated cell type using morphological and immunological features, a principle that follows the rules of the Kiel classification. In addition, the importance of the primary site of involvement, which is not only a feature of staging, but also an easy, clinically relevant and important biological distinction, has been explicitly stated.

Second-line principles of classification are important for some entities. These are **aetiological features,** such as the association of certain infectious agents, like the Epstein–Barr virus, Helicobacter pylori or HTLV I, **primary cytogenetic abnormalities** or **specific clinical features**. Daily clinical and pathological experience shows minor or more evident exceptions to the proposed rules, leading to the well-recognized heterogeneity of each type of lymphoid neoplasia. Therefore, within many entities, specific morphological or clinical subtypes are mentioned which are of clinical importance. Morphological variants reflect the diagnostic spectrum of a disease, which is important to recognize in order to establish a correct differential diagnosis.

Table 4 lists the recent WHO classification of B and T cell lymphomas and of Hodgkin lymphoma.

The non-Hodgkin lymphomas are divided primarily into those of the B and the T cell system. In both lineages, there is a primary distinction of lymphomas that arise from precursor cells (the lymphoblastic lymphomas or acute lymphoid leukaemias) and from peripheral cells.

Clinical Relevance

The clinical relevance of the WHO proposal was intriguingly confirmed by the results of the Non-Hodgkin's Lymphoma Classification Project (1997), which involved the pathomorphological and immunophenotypic investigation of 1403 lymphomas in eight different sites around the world. These cases were taken from the years 1988–1990, and were reviewed by experienced haematopathologists attempting to compare different classification systems, the recognition of epidemiological variations in the occurrence of lymphomas and the correlation of treatment results with histological diagnoses. The results of this study clearly established that the criteria formulated in the REAL classification and applied in the WHO classification resulted in a high inter-observer accuracy and were of significant prognostic value for the recognition of diseases with different clinical courses and behaviour. It turned out that immunophenotyping was less important in some of the diseases (e.g. in follicular lymphoma), but absolutely essential in others (mantle cell lymphoma, T cell lymphomas). Some diseases were only reliably diagnosed if clinical data were available (e.g. mediastinal B cell lymphoma). In other cases, the differential diagnosis was at least greatly improved by the knowledge of clinical features and presentation (Armitage and Weisenburger, 1998).

For some disease entities and variants, however, diagnostic accuracy was less satisfactory. In particular, the distinction of Burkitt lymphoma and 'Burkitt-like' non-Hodgkin lymphoma involved a high inter-observer disagreement of more than 40%, clearly establishing that additional and better criteria will have to be proposed for the definition of certain disease entities. Similarly, the subclassification of peripheral T cell lymphomas showed high inter-observer variability.

Prognostic Factors

As was clearly shown by the international Non-Hodgkin's Lymphoma Classification Project (1997) and many other multicentre trials published in recent years, the most important prognostic factor today is the definition of the disease entity, that is, the exact type of non-Hodgkin lymphoma. Within these individual diseases, prognostic

Table 4 The WHO classification of lymphoid neoplasms

B cell neoplasms

Precursor B cell lymphoblastic leukaemia/lymphoma (Precursor B cell acute lymphoblastic leukaemia)

Peripheral B cell neoplasms
B cell lymphocytic leukaemia/small lymphocytic lymphoma
B cell prolymphocytic leukaemia
Lymphoplasmacytic lymphoma
Mantle cell lymphoma
Follicular lymphoma
Cutaneous follicle centre lymphoma
Marginal zone B cell lymphoma of mucosa-associated lymphoid tissue (MALT type)
Nodal marginal zone B cell lymphoma ($\pm$ monocytoid B cells)
Splenic marginal zone B cell lymphoma ($\pm$ villous lymphocytes)
Hairy cell leukaemia
Diffuse large B cell lymphoma
Variants: Centroblastic
Immunoblastic
T cell or histiocyte-rich
Anaplastic large B cell
Subtypes: Mediastinal (thymic) large B cell lymphoma
Intravascular large B cell lymphoma
Primary effusion lymphoma
Burkitt lymphoma
Plasmacytoma
Plasma cell myeloma

T cell neoplasms

Precursor T cell lymphoblastic leukaemia/lymphoma (Precursor T cell acute lymphoblastic leukaemia)

Peripheral T cell and NK cell neoplasms
T cell prolymphocytic leukaemia
T cell large granular lymphocytic leukaemia
Aggressive NK cell leukaemia
NK/T cell lymphoma, nasal and nasal type
Sezary syndrome
Mycosis fungoides
Angioimmunoblastic T cell lymphoma
Peripheral T cell lymphoma (unspecified)
Adult T cell leukaemia/lymphoma (HTLV 1+)
Anaplastic large cell lymphoma (T and null cell types)
Primary cutaneous CD30 positive T cell lymphoproliferative disorders
Variants: Lymphomatoid papulosis (Type A and B)
Primary cutaneous ALCL
Borderline lesions
Subcutaneous panniculitis-like T cell lymphoma
Enteropathy-type T cell lymphoma
Hepatosplenic γ/λ T cell lymphoma

Hodgkin lymphoma (Hodgkin disease)

Nodular lymphocyte predominance Hodgkin lymphoma

Classical Hodgkin lymphoma
Hodgkin lymphoma, nodular sclerosis
Classical Hodgkin lymphoma, lymphocyte-rich
Hodgkin lymphoma, mixed cellularity
Hodgkin lymphoma, lymphocyte depletion

factors may influence clinical outcome (Shipp *et al.*, 1993). Prognostic factors and variations in grades within diseases should be distinguished from different diseases. They may be histological, biological or clinical in nature, such as stage or the International Prognostic Index. Histological grading is one method to define types of prognostic factors. Usual approaches include the determination of cell size, nuclear features, mitotic rates and growth pattern. In recent years, biological markers, such as genetic features, have turned out to be important prognostic factors and may even be more powerful than clinical or morphological features. Some of them may be recognized today by interphase cytogenetics (such as *p53* and *ATM* deletions in B-CLL), or by immunohistochemistry (such as the presence of the t(2;5/ALK) rearrangement in anaplastic large-cell lymphomas of T and O cell types, or the determination of the proliferative index in mantle cell lymphomas using the Ki67 antibody). More recently, exciting new data have become available taking into account mutated or unmutated IgVH genes in B-CLL or the subdivision of diffuse large B cell lymphomas according to their mRNA expression profiles.

These examples show how dependent a given classification is on new facts and findings that may be used for the definition of diseases in the borderline and grey zone of different diseases. It does not need great fantasy to predict that the new approaches of molecular biology will further modify our concepts of the biology of malignant lymphoma, and that in the not too distant future our concepts of lymphoma classification will be stepwise modified and possibly reverted to a molecular definition of neoplastic processes in different lymphoma entities (Alizadeh *et al.*, 2000).

LYMPHOMAS OF B CELL LINEAGE

Precursor B Cell Lymphoblastic Leukaemia/Lymphoma (Precursor B Cell Acute Lymphoblastic Leukaemia)

Clinical Features

The peak incidence of lymphoblastic lymphomas, irrespective of B or T cell lineage, is in the second and third decades, and the male gender is over-represented in the range 2–10:1. The majority of patients are diagnosed with advanced disease stages, and central nervous system involvement is common. About 60% of patients with no obvious bone marrow infiltration at presentation are reported to develop marrow infiltration and leukaemic conversion. Only 20% of the so-called lymphoblastic lymphomas are of B cell lineage, in contrast to 80% of acute lymphoblastic leukaemias.

Morphology

Precursor B cell neoplasias, in most cases, show a diffuse infiltration and destruction of the normal tissue structure. The tumour cells are medium-sized with a scant cytoplasm and round to oval or convoluted nuclei, often with distinct nuclear membranes, a finely dispersed, sometimes 'dust'-like chromatin and inconspicuous nucleoli. In some cases, a 'starry sky' pattern may be seen due to the presence of tingible body macrophages. Usually, numerous mitotic figures are encountered with numbers of 10–20 per high-power field (HPF). Owing to their aggressive nature, they often infiltrate the lymph node capsule and invade the surrounding perinodal fatty or fibrous tissues.

Immunophenotype

The majority of precursor B cell lymphoblastic lymphomas express B cell antigens similar to or identical with B cell acute lymphatic leukaemia. They express HLA-DR antigens and B cell-associated antigens CD19 and/or CD22 and may be positive for IgM and Ig light chains. In paraffin sections, most of them are positive for CD20 and CD34, as well as for CD10 (cALLA). Of pivotal importance in the diagnosis of precursor B (and T) cell neoplasias is the detection of nuclear expression of the terminal deoxynucleotidyl transferase (TdT), thereby clearly differentiating these neoplasms both from chronic lymphocytic leukaemia/small lymphocytic lymphomas and diffuse large cell lymphomas.

Genetic Features

The majority of precursor B cell neoplasms express clonal IgH or IgL gene rearrangements. Characteristic cytogenetic abnormalities in precursor B cell neoplasias are numerical chromosome changes (hyperploidy), t(1;19)(q23;p13) involving c-*ski*, t(4;11)(q21;q23) involving c-*ets1*, del(6q), del(12p) and t(9;22)(q34;q11) involving *bcr-abl*.

PERIPHERAL B CELL LYMPHOMAS

Chronic Lymphocytic Leukaemia of B Type (B-CLL)/Small Lymphocytic Lymphoma (B-SLL)

Clinical Features

B-CLL comprises 90% of chronic lymphoid leukaemias in Europe and the USA. Most patients will present with generalized lymphadenopathy, bone marrow and blood involvement and enlarged spleen. Hepatomegaly is frequent. A minority of patients initially present with a leukaemic nodal involvement.

Morphology

Lymph nodes in patients with B-CLL show a characteristic infiltration pattern in roughly 90% of cases which may be recognized at low-power magnification. In most B-CLL, there is a so-called 'pseudo-follicular' growth pattern. In these pseudo-follicles (also termed proliferation centres), slightly larger lymphocytes (prolymphocytes and paraimmunoblasts) are found in contrast to the majority of the infiltrate which consists of small lymphoid cells with scant cytoplasm and slightly clumped chromatin. In the proliferation centres, which only very occasionally show some remnants of follicular dendritic cells, the larger cells possess a small cytoplasmic rim and a lighter nuclear chromatin, so that these pseudo-follicles stand out, imparting 'light zones' to the infiltrate (**Figure 1**). Only about 10% of B-CLL/SLL are characterized by a diffuse infiltration without pseudo-follicles, and this represents the predominant pattern in extranodal infiltrates of the disease.

Variants include cases with a larger number of prolymphocytes and/or paraimmunoblasts (B-CLL/PL), tumours in which a sometimes marked nuclear irregularity can be seen (and which may be difficult to differentiate from mantle cell lymphomas), and cases with a secretory differentiation (monotypic cytoplasmic light-chain expression) corresponding to the lymphoplasmacytoid immunocytoma of the Kiel classification system.

Immunophenotype

The tumour cells of B-CLL are characteristically positive for B cell-associated antigens (CD19, CD20 (weak), CD79a) and IgM ± IgD, and express CD5, CD23, and CD43. Recognition of CD23 expression is important in the differential diagnosis of mantle cell lymphoma, in which CD23 (on paraffin or frozen sections) is not expressed. In B-CLL, CD23 expression may be pronounced in the proliferation centres, and it is also more often preserved than CD5 in transformed large B cell lymphomas having evolved from B-CLL.

Genetic Features

Ig heavy- and light-chain genes are rearranged. Of importance, recent studies have shown that, by the analysis of somatic mutations in IgVH genes, B-CLL is not a homogeneous disease, but may contain at least two important subentities. In roughly 50% of cases, the tumour cells do not display somatic mutations and hence may be referred to as derived from naive or virgin B cells. In the other 50% of cases, somatic mutations have occurred, indicating a germinal centre passage of the tumour cells. As judging from clinical data available to date, the mutated form of B-CLL may have a better prognosis.

In contrast to many other non-Hodgkin lymphomas, B-CLL is not characterized by a reciprocal chromosome

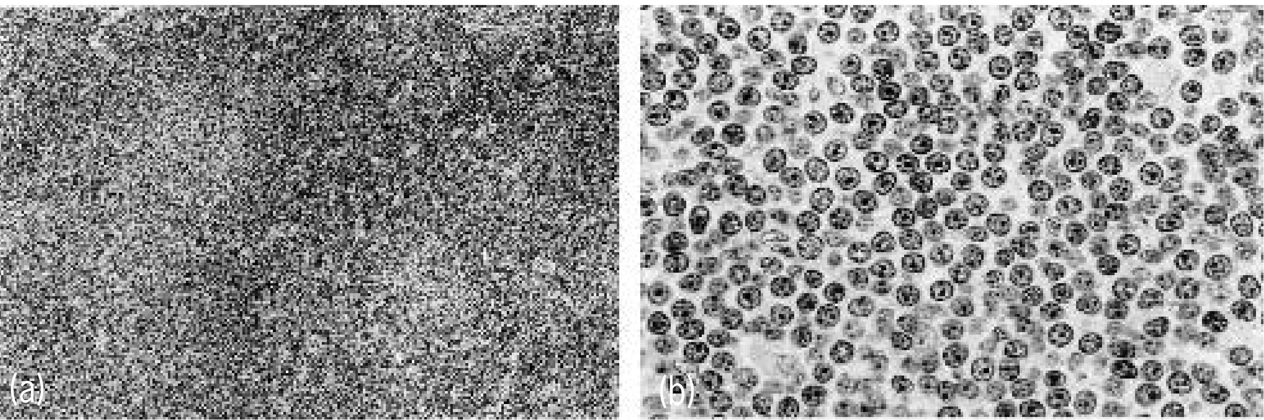

Figure 1 B cell chronic lymphocytic leukaemia. (a) The normal lymph node architecture is replaced by a pseudo-follicular infiltrate. (b) The infiltrate consists of small cells with round nuclei and few prolymphocytes.

translocation. The most common cytogenetic/molecular cytogenetic aberration is a deletion in chromosomal band 13q14 encountered in up to 40% of cases. Other recurring aberrations include trisomy 12, 6q deletions and deletions/mutations in 17p13 and 11q22/23. Deletions in 17p frequently target the *p53* gene and 11q deletions commonly result in the loss of one copy of the *ATM* (mutated in Ataxia telangiectasia) gene. Both aberrations have been shown to be prognostically relevant in defining patient subgroups with inferior prognosis.

In B-CLL, prolymphocytoid transformation or transformation to large B cell lymphomas (Richter syndrome) may occur. Transformation to Hodgkin disease was also observed and should be distinguished – by the appropriate background infiltrate and the characteristic immunophenotype of Hodgkin and Reed–Sternberg cells – from the occasional occurrence of Hodgkin- and Reed–Sternberg-like cells in B-CLL.

B Cell Prolymphocytic Leukaemia (B-PLL)

Clinical Features

B-PLL is a rare disease, occurring in older patients over 60 years of age with a marked male predominance presenting with massive splenomegaly, bone marrow infiltration and marked lymphocytosis in the peripheral blood (>55% prolymphocytes). Lymph nodes are rarely involved. Anaemia and thrombocytopenia are frequent.

Morphology

The infiltrate in the bone marrow consists of diffusely infiltrating medium-sized prolymphocytic or paraimmunoblastic cells with a small rim of slightly basophilic or pale cytoplasm, round to oval nuclei and a central prominent eosinophilic nucleolus. No pseudo-follicles are seen.

Immunophenotype

The tumour cells in B-PLL express pan B cell markers, IgM $\pm$ IgD and CD5 in a proportion of cases. CD23 usually is negative.

Genetic Features

Clonal rearrangements of IgH and IgL chain genes are found. Most of the tumours have been shown to carry somatic mutations. The occurrence of cases with t(11;14)(q13;q32) points to an overlap with mantle cell lymphoma ('mantle cell leukaemia').

Mantle Cell Lymphoma (MCL)

Clinical Features

MCL is a disease of middle-aged to older persons. Most patients present in stages III and IV. The tumour tends to involve lymph nodes and Waldeyer's ring. The bone marrow is often infiltrated, and a proportion of patients have prominent splenomegaly and peripheral blood involvement. The gastrointestinal tract is often infiltrated (lymphomatous polyposis). Sometimes, a high peripheral leukocyte count is found (mantle cell leukaemia). Blastic transformation may occur (blastoid MCL).

Morphology

Mantle cell lymphoma, in most cases, presents with diffuse lymph node infiltrates of monomorphic small to medium-sized cells with scant, barely recognizable cytoplasm and irregular or cleaved nuclei. The chromatin is slightly dispersed and inconspicuous nucleoli are found. In rare cases, the cells are nearly round, rendering a differential diagnosis to B-CLL. Two blastoid variants have been described, one with medium-sized nuclei with a more dispersed chromatin resembling lymphoblasts and a high proliferative index

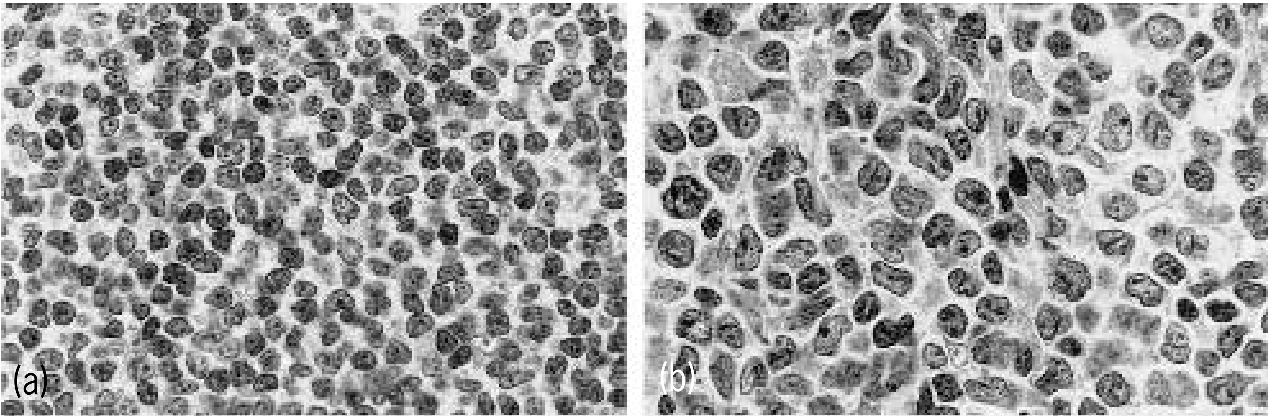

Figure 2 Mantle cell lymphoma. (a) In the classical variant, small- to medium-sized cells are seen, with small cytoplasm and irregular nuclei. (b) Pleomorphic variant of MCL. Cells are considerably larger and nuclei are deeply indented. The chromatin distribution is coarse.

(blastoid or lymphoblastoid type). Another variant variously termed as 'anaplastic,' 'large cell' or 'pleomorphic' is characterized by rather large cleaved cells with sometimes light or slightly basophilic cytoplasm and coarse chromatin distribution. This type obviously had been included in the Kiel classification as the 'centrocytoid' variant of centroblastic lymphoma (**Figure 2**).

In some cases, the infiltrate in mantle cell lymphoma may be found predominantly surrounding (partially) preserved germinal centres giving the impression of a 'mantle zone' pattern or may form sometimes vaguely circumscribed nodules.

Immunophenotype

The tumour cells of MCL are characterized by the expression, next to B cell antigens, of CD5 and CD43 in the absence of CD10 and CD23. Notably, the characteristic overexpression of Cyclin D1 can be recognized by suitable antibodies. Recently, it has been shown that the classical variant of MCL displays – in contrast to other non-Hodgkin lymphomas with comparably low proliferative indices – a marked down-regulation of nuclear p27 expression, a feature which is highly characteristic of and favours mantle cell lymphoma. Staining for follicular dendritic cells (using anti-CD21 or -CD23 antibodies) may show, especially in the cases with a nodular growth pattern, dispersed and disorganized meshworks of these cells.

Genetic Features

The cytogenetic hallmark of MCL is the chromosomal translocation t(11;14)(q13;q32), joining the Ig heavy-chain locus and the *BCL-1* locus and resulting in the overexpression of the cell-cycle protein Cyclin D1. It should be noted, however, that the t(11;14)/Cyclin D1 deregulation is not absolutely specific for mantle cell lymphomas, having also been described in plasmacytoma/multiple myeloma. Mantle cell lymphomas, in addition, show characteristic secondary aberrations, many of them targeting other cell cycle-related genes such as *p16*, *p53* and the *ATM* gene. Blastoid MCL of the pleomorphic type frequently are characterized by tetraploid chromosome clones.

Follicular Lymphoma (FL)

Clinical Features

Follicular lymphomas represent, together with diffuse large B cell lymphomas, the most frequent type of B cell lymphoma in Western countries. Both genders are equally affected. Systemic disease at presentation is common, including involvement of lymph nodes, spleen, bone marrow and, rarely, extranodal sites. PB involvement is rare and tends to occur only in final stages. The disease follows an indolent course.

Morphology

In the most common type with an almost exclusive follicular growth pattern, neoplastic follicular structures are found throughout the lymph node and also frequently penetrate the capsule and invade the perinodal fatty tissue. In contrast to reactive follicles, they are uniform in size and lack a well-defined mantle zone. Cytologically, they are composed of centrocytes and centroblasts. Centrocytes represent medium-sized cells with a small, barely recognizable cytoplasm and irregular contoured and indented nuclei. The chromatin is irregular, and small inconspicuous nucleoli are present. In contrast, centroblasts are large cells with a usually small, moderately basophilic cytoplasm, and round nuclei with vesicular chromatin and 1–3 nucleoli commonly found adjacent to the nuclear membrane. Centrocytes and centroblasts are arranged haphazardly, and a well-formed dark and light zone as seen in reactive germinal centres structures is not found (**Figure 3**). Likewise, in most cases, no tingible body

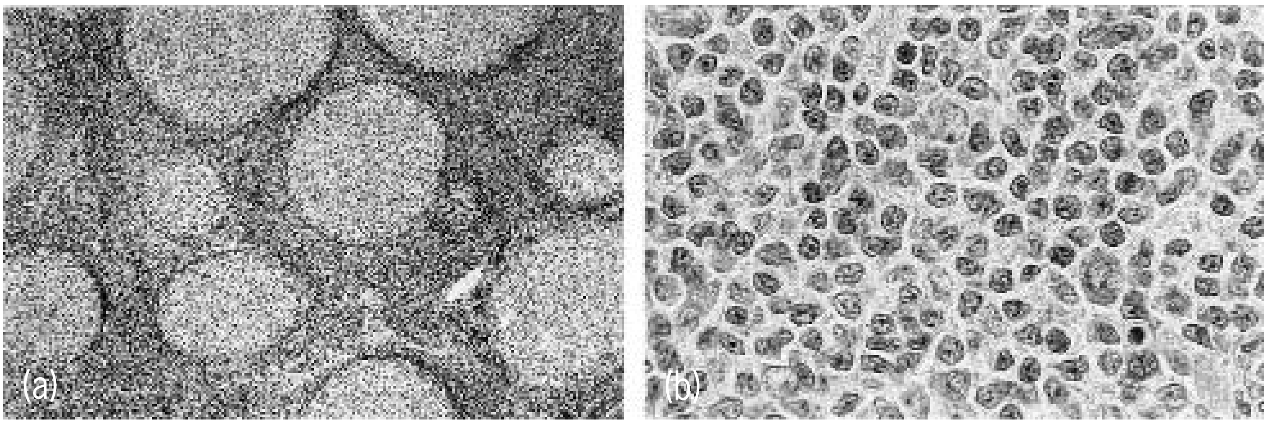

Figure 3 Follicular lymphoma. (a) The lymph node parenchyma shows an infiltration of atypical follicular structures. (b) On higher magnification, the neoplastic follicles are composed of small cleaved cells (centrocytes) with few interspersed blasts (centroblasts).

macrophages are present and the number of mitotic figures is low. Diffuse areas may be present in addition, and tumours may be classified as predominantly follicular (>75% follicular), follicular and diffuse (25–75% follicular) or predominantly diffuse (<25% follicular). Entirely diffuse follicular lymphomas, composed of centrocytes and centroblasts, are very rare neoplasms and caution has to be exerted in differentiating them from mantle cell lymphomas.

The WHO classification proposes a grading scheme for follicular lymphomas according to the content of centroblasts. Therefore, tumours with 0–50 centroblasts per 10 high-power fields (HPF) are grade 1, tumours with 50–150 centroblasts per 10 HPF are grade II and lymphomas with more than 150 centroblasts/10 HPF are grade III. Lymphomas with an exclusively follicular growth pattern and consisting entirely of centroblasts are very rare. They are more commonly found in association with a diffuse large B cell lymphoma and should be diagnosed as 'follicular lymphomas grade III with diffuse large B cell lymphoma'. There are some indications, however, that these tumours, on a genetic basis, are different from follicular lymphomas with varying centroblast content, but preserved maturation to centrocytes, being t(14;18) negative in 80% of the cases and more closely related to a 'follicular' variant of diffuse large B cell lymphomas. Follicular lymphomas grades I or II associated with a diffuse large cell component, in most cases, should be regarded as 'transformed' follicular neoplasias.

Some follicular lymphomas may show a more or less prominent 'marginal zone' differentiation, implying the occurrence of tumour cells slightly rounder than centrocytes and with a broad pale-staining cytoplasm reminiscent of monocytoid B cells. In most cases, these cells are accentuated in the outermost parts of the follicles, giving the impression of a marginal zone pattern. A differentiation to plasma cells (secretory differentiation) may be rarely seen in follicular lymphomas.

Immunophenotype

Most follicular lymphomas grades I and II express CD10 and show a nuclear reactivity for BCL-6, but lack CD5 and CD43 reactivity. In some tumours, CD23 may be expressed, and these lymphomas are frequently CD10-negative. One intriguing immunohistochemical finding in follicular lymphomas, and strongly suggesting a neoplastic process (in the differential diagnosis to reactive follicular hyperplasia), is the presence of CD10+ B cells in the interfollicular region. About 80–90% of follicular lymphomas express BCL2, a feature clearly differentiating them from reactive follicles which are always BCL2-negative. By staining of follicular dendritic cells using CD21 and/or CD23, FDC meshworks are usually dense and sharply demarcated. In BCL2-negative lymphomas, the diagnosis may require gene rearrangement studies.

Genetic Features

Apart from clonal rearrangements of (extensively hypermutated) IgH and IgL chain genes, follicular lymphomas are characterized by 'ongoing' somatic mutations, creating an intraclonal diversity. The cytogenetic hallmark of follicular lymphomas is the t(14;18)(q32;q21) chromosome translocation, that is found in 80–90% of grade I and II tumours. As already pointed out, follicular lymphomas grade III are t(14;18)-positive in only 50% of cases, and especially grade III lymphomas that are composed of centroblasts exclusively in the majority of cases are t(14;18) negative. On the molecular genetic level, the t(14;18) leads to the juxtaposition of the *BCL2* oncogene to the IgH chain gene promoter region, thus overexpressing *BCL2*, which is, as already mentioned, not expressed in centroblasts and centrocytes of reactive follicles. Secondary chromosome aberrations are common and well-defined in follicular lymphomas. Especially trisomies for chromosomes 1q, 7, 12, 18 and X are found, while deletions are encountered in chromosome regions 1p and 6q.

Transformed follicular lymphomas frequently are characterized by deletions in the short arm of chromosome 17, the site of the *p53* tumour suppressor gene. The retained allele has been found to be mutated in a fairly large number of transformed follicular lymphomas.

Marginal Zone B Cell Lymphomas (MZBL)

Marginal zone B cell lymphomas (MZBL) are B cell neoplasias with a presumed origin from the marginal zone cells of the B cell follicle. Three variants are discerned: extranodal MZBL of MALT type, splenic and nodal MZBL. Whereas the REAL classification regarded nodal and splenic MZBL as provisional entities, the WHO classification, taking into account the immunophenotypic and genetic differences in MZBL, regards them as true lymphoma entities.

Extranodal MZBL of MALT Type

Clinical Features

MALT-type MZBL frequently arise in extranodal sites commonly devoid of a regular lymphatic parenchyma. Therefore, MALT has to be introduced in organs such as the stomach, the lungs, the thyroid and salivary glands, the ocular adnexa, the skin or the mammary gland (the most frequent localizations) by chronic inflammatory processes such as chronic infections or autoimmune diseases prior to the development of these enigmatic tumours. The gastrointestinal tract is the most common site of involvement. Gastric MALT-type MZBL frequently (in 90% of cases) arise in the background of a chronic *Helicobacter pylori* (HP) gastritis. Upon eradication of the bacterium, about 80% of MALT-type MZBL regress and hence patients may be cured by this antibiotic therapy. However, clonal rearrangements for the IgH and IgL chain genes may be demonstrated also after complete regression of the lymphoma, the prognostic significance of which is not yet entirely understood. In rare cases, after eradication, a monoclonal plasma cell population may still be present in biopsies, representing a plasma cellular maturation of the tumour cells.

The majority of patients present with stage I or II disease, reflecting the particular feature of these tumours to be confined to their site of origin for long times.

Morphology

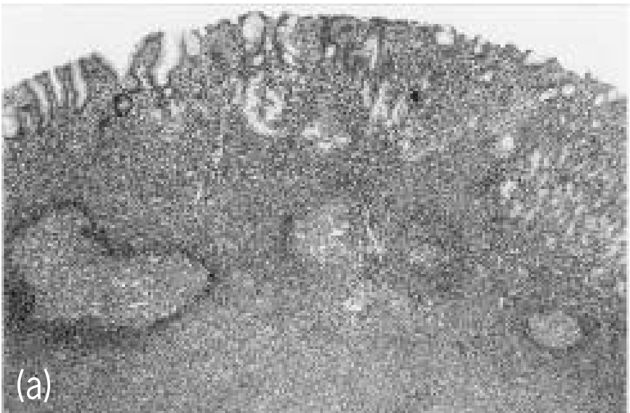
Extranodal MZBL, in early lesions, infiltrate the marginal zones of frequently preserved reactive follicular structures and, as a rule, present with an invasive and destructive growth potential forming so-called lymphoepithelial lesions (**Figure 4**). On the cytological level, marginal zone B cells are small- to medium-sized with a small to moderately broad, sometimes pale cytoplasm and slightly indented 'centrocytoid-like' nuclei. These tumours may be associated with a diffuse large B cell component and should then be designated as 'diffuse large B cell lymphomas with an extranodal MZBL of MALT-type component' (not as 'low- and high-grade MALT-type lymphoma' or 'transformed MALT-type lymphoma').

Immunophenotype

MALT-type MZBL are CD5−, CD10−, CD23−, CD43−/+ and IgD−. In contrast to mantle cell lymphomas (frequently presenting as primary gastrointestinal tumours, the so-called malignant lymphomatous polyposis), they are consistently cyclin D1 negative.

Genetic Features

The t(11;18)(q21;q21) chromosome translocation, juxtaposing the *API2* and *MLT1* genes, has been identified as the most common structural cytogenetic alteration in extranodal MZBL of MALT-type accounting for about 30% of cases (and even 50% of cases without any large-cell component). Interestingly, this translocation



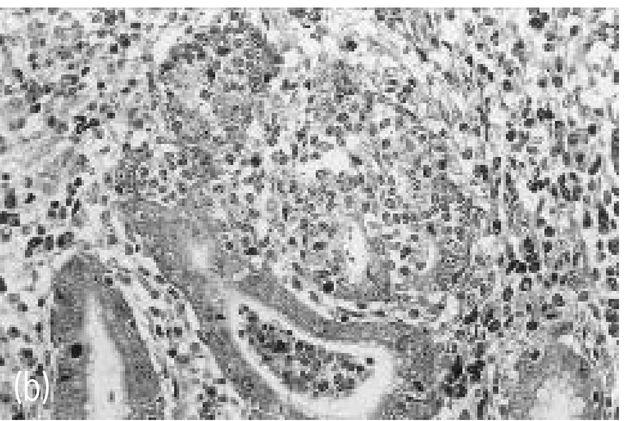


Figure 4 Extranodal marginal zone B cell lymphoma of MALT type. (a) Gastric lymphoma. The infiltrate colonizes the marginal zone areas of preserved follicles and spreads out into the mucosa and submocosa. (b) The tumour cells (centrocyte-like cells) invade and destroy epithelial structures, forming lymphoepithelial lesions.

has not been found in extranodal large B cell lymphomas with or without an extranodal MZBL MALT-type component.

Splenic MZBL ($\pm$Villous Lymphocytes)

Clinical Features

Splenic marginal zone lymphomas (SMZL), a distinctive type of primary splenic lymphoma, has to be differentiated from secondary splenic involvement occurring in B-CLL, B-PLL, mantle cell lymphoma, immunocytoma and follicular lymphoma. SMZL involves the spleen and frequently the bone marrow. Hilar splenic and abdominal lymph nodes may be infiltrated, and leukaemic dissemination often occurs. Peripheral lymphadenopathy is uncommon. SMZL is a rare disease and usually follows an indolent course.

Morphology

The tumour cells characteristically infiltrate the splenic marginal zone and, on the cytological level, resemble extranodal MALT-type MZBL cells. In most cases, the central parts of the splenic white pulp nodules are composed of small lymphoid cells with dark nuclei, and merge with surrounding, slightly larger, sometimes 'monocytoid-like' cells with a frequently pale and broader cytoplasm. Transformed blasts may be interspersed, and the splenic red pulp is involved to varying degrees. In splenic hilar lymph nodes, sinuses are generally preserved and distended, and the infiltrate surrounds germinal centres. About one third of cases may present with a leukaemic course and the appearance of 'villous' lymphocytes in the peripheral blood. Bone marrow infiltrates characteristically are found in an intertrabecular localization and sometimes sinusoidal infiltration may be encountered (**Figure 5**).

Immunophenotype

The tumor cells express pan B cell antigens and IgM, but are CD5−, CD10− and CD23−. In contrast to MALT-type MZBL, they are, in most cases, IgD-positive. Plasmacytic differentiation, as in other types of MZBL, may occur.

Genetic Features

On the cytogenetic level, splenic MZBL are consistently t(11;18)-negative, and some of the cases may show trisomy 3 and structural aberrations in 7q22–32 and 10q22–24. In fact, the apparent cytogenetic diversity of this neoplasm has elicited speculations on a different biological background of tumours designated as splenic MZBL.

Nodal MZBL

Clinical Features

Nodal marginal zone B cell lymphomas, by definition, are malignant lymphomas primarily manifesting in lymph nodes without extranodal or splenic involvement. It has been shown, however, that by careful clinical staging procedures, an occult extranodal manifestation may be present in a fraction of cases. Many patients present with advanced disease stages, but the disease is rather less aggressive.

Morphology

The small- to medium-sized tumour cells may resemble monocytoid B cells or centrocytoid B cells, and frequently show secretory differentiation with a plasmacytoid component. In most cases, large B cells are interspersed. In early stages, they colonize the perifollicular and interfollicular areas with remnants of germinal centres still being present (**Figure 6**). In later stages, however, these may be entirely destroyed and invaded by the tumour cells ('follicular colonization'). There may be cases in which the

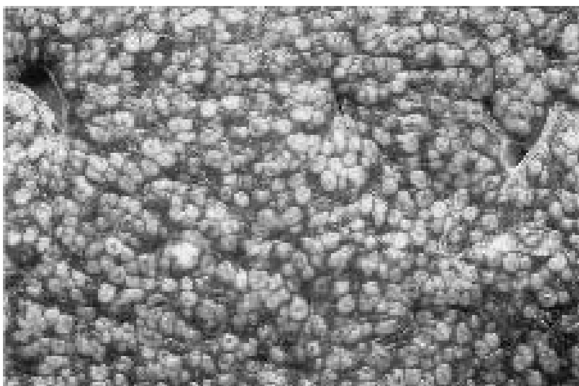

Figure 5 Splenic marginal zone B cell lymphoma. The cut surface of the spleen shows a prominence of tiny nodules representing infiltrated white pulp structures. Note that there is no merging of nodules in contrast to B-CLL splenic infiltrations.

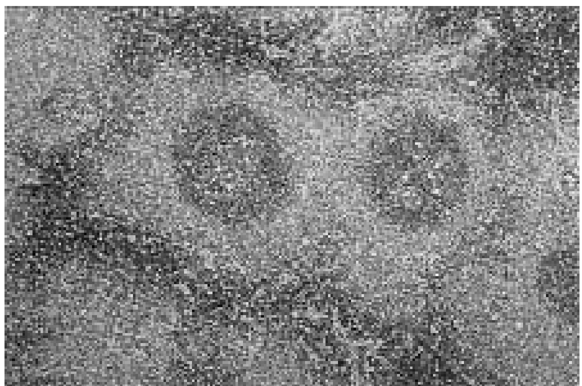

Figure 6 Nodal marginal zone B cell lymphoma. Preserved follicles are surrounded by neoplastic cells invading and broadening the perifollicular marginal zone.

tumour cells are entirely blastic in nature but with a preserved marginal zone growth pattern; we tend to classify these cases as ‘aggressive’ MZBL rather than diffuse large B cell lymphomas. Recently, two different types of nodal MZBL have been described, a ‘MALT’ type and a ‘splenic’ type. Apart from subtle morphological differences, splenic-type MZBL, as a rule, express IgD, whereas MALT-type MZBL are IgD-negative. It should be noted, however, that the designations of MALT and splenic types of nodal MZBL, at present, are only descriptive terms and it is not expected that these tumours represent secondary lymph node involvement by a primary extranodal or primary splenic lymphoma. While no splenic involvement has been found in the splenic-type nodal MZBL, around 50% of nodal MZBL designated as MALT type have been shown to be associated with an extranodal component, thus illustrating the present difficulties in discriminating true primary nodal MZBL from secondary lymph node involvement by a MALT-type lymphoma. On the other hand, characteristic clinical features have been described differentiating those tumours.

Immunophenotype

Most nodal MZBL are comparable to MALT-type lymphomas; however, some express IgD.

Genetic Features

Only single cases of presumably true nodal MZBL have been characterized on the cytogenetic level, and no unifying aberrations are known.

Lymphoplasmacytic Lymphoma (LPL)

Clinical Features

LPL is a disease of older adults, with a male predominance. Lymphoplasmacytic lymphomas are neoplasms only rarely manifesting as nodal tumours. They most commonly present with bone marrow and splenic infiltrations clinically corresponding to most cases of Waldenstrom macroglobulinaemia. Monoclonal serum paraproteins ($>3\ \mathrm{g\ dL^{-1}}$), autoimmune phenomena, cryoglobulinaemia, and hyperviscosity syndromes are frequent.

Morphology

This type of malignant lymphoma, by definition, lacks features of B-CLL, mantle cell, follicular, or marginal zone lymphomas. In the lymph node, there is a diffuse effacement of the normal architecture, sometimes however sparing preserved ‘naked’ germinal centres. The infiltrate consists of a mixture of small lymphocytes, plasmacytoid cells and mature plasma cells, and the demonstration of a monoclonal cytoplasmatic light chain is a *sine qua non* for the disease. Intranuclear immunoglobulin inclusions (Dutcher bodies) are frequently observed. In some cases, sinuses are preserved and even wide. In rare cases, a prominent epithelioid cell reaction may be seen.

Immunophenotype

These lymphomas are IgM (rarely IgG and IgA) cytoplasmic positive and IgD and CD5 negative. Some may express CD23. CD10 is always negative.

Genetic Features

A specific chromosome translocation, t(9;14)(p13;q32), has been demonstrated in 50% of cases, leading to the deregulation and over-expression of the *PAX 5* gene.

Diffuse Large B Cell Lymphomas (DLBL)

Clinical Features

Diffuse large B cell lymphomas constitute around 30–40% of adult non-Hodgkin lymphoma. Typically, patients present with a single, rapidly enlarging symptomatic mass at a single nodal or extranodal site. About one-third of DLBL are primary extranodal in origin, while the majority of cases arise in lymph nodes or other lymphatic organs, such as the tonsils or spleen.

Morphology

DLBL are principally composed of ‘large’ lymphoid cells, usually with nuclei at least twice the size of a small lymphocyte. The cytoplasm is moderately to deeply basophilic, and nuclei are large with a vesicular chromatin structure and prominent nucleoli. As can be seen from **Table 5**, diffuse large B cell lymphomas, in the WHO classification, are subdivided into distinct clinical subtypes and variants.

DLBL Variants

The **centroblastic** variant is characterized by a tumour cell population that may be either predominantly composed of cells with round to oval nuclei, a vesicular chromatin structure and membrane-bound nucleoli, or by a mixture of these centroblasts with immunoblasts. By convention, in the centroblastic variant, as much as 90% immunoblasts may be present (**Figure 7a**).

Table 5 Subtypes and variants in diffuse large B cell lymphomas

Variants:	Centroblastic
	Immunoblastic
	T cell- or histiocyte-rich
	Anaplastic large B cell
Subtypes:	Mediastinal (thymic) large B cell lymphoma
	Intravascular large B cell lymphoma
	Primary effusion lymphoma

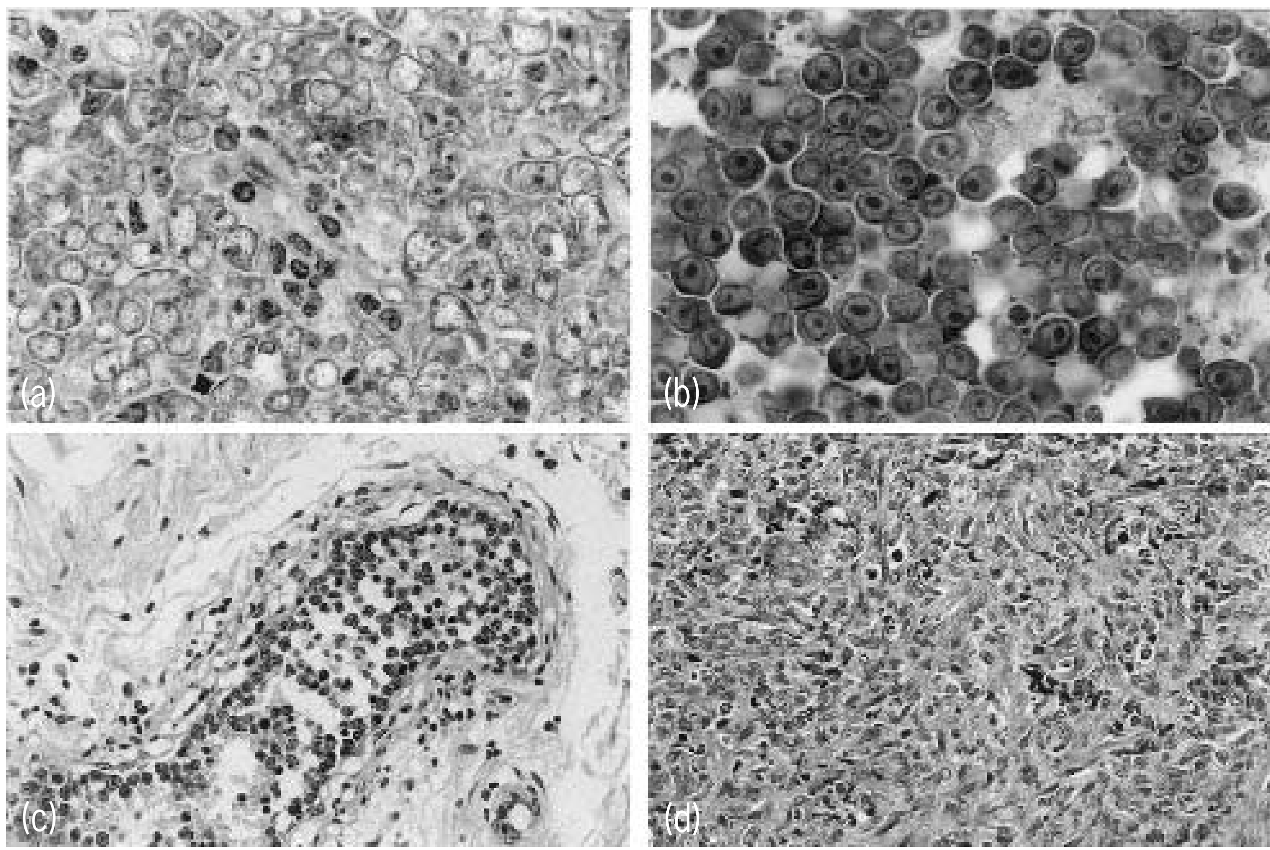

Figure 7 Diffuse large B cell lymphoma. (a) Centroblastic variant. Tumour cells are medium- to large-sized and possess a narrow rim of moderately basophilic cytoplasm. The nuclei are round to oval. Within the vesicular nuclear chromatin, 1–3 nucleoli are attached to the nuclear membrane. (b) Immunoblastic variant. Tumour cells are large with abundant cytoplasm, vesicular nuclei and single prominent central nucleoli. (c) DLBL, intravascular subtype. The blastic tumour cells are seen in the lumina of medium-sized vessels. (d) DLBL, mediastinal (thymic) large-cell subtype. Tumour cells of large size are embedded in a sclerosing stroma.

In the **immunoblastic** variant of DLBL, typical centroblasts comprise less than 10% of the total cellular infiltrate. The most cells are large with a central prominent nucleolus and a broad basophilic cytoplasm. Plasmablastic differentiation is common (**Figure 7b**).

The **anaplastic** variant comprises tumours with large, 'anaplastic,' oval or polygonal cells with pleomorphic, sometimes bizarre nuclei, sometimes reminiscent of Hodgkin or even Reed–Sternberg cells.

T cell- or **histiocyte-rich** large B cell lymphomas are characterized by a prominent reactive inflammatory infiltrate, comprising more than 90% of the total cell population.

Immunophenotype

Diffuse large B cell lymphomas, in all variants, consistently express B cell-associated antigens (CD20 and CD79a). Other B cell antigens are variably present. CD5 and CD23 immunoreactivity may be found in around 10% of cases, sometimes pointing to an underlying small lymphocytic lymphoma/B-CLL from which the diffuse large B cell lymphoma had evolved. CD10 expression is more commonly found in centroblastic variants (30%). CD30 is expressed in the anaplastic variant, but may also be demonstrated in centroblastic or immunoblastic types.

Genetic Features

Diffuse large B-cell lymphomas have their IgH and IgL chain genes clonally rearranged in a high percentage of cases and show a high load of somatic mutations. DLBL, therefore, in most cases, represent germinal or post-germinal neoplasias, having undergone germinal centre passage (and possibly antigen selection).

Chromosomal aberrations involving chromosomal band 3q27, the localization of the BCL-6 gene, seem to constitute the most frequent recurring genetic alterations in DLBL. In 20–30% of DLBL, the t(14;18) is found, and these tumours may have evolved from an (occult) follicular lymphoma. Little is known on the significance of the so-called secondary chromosomal aberrations in DLBL, although these are definitely non-random and may even be different in different variants. The most common secondary aberrations

involve deletions in the long arm of chromosome 6 and complete or partial trisomies for chromosomes 3, 5, 7, 11, 12, 18 and X. An exciting new finding in DLBL is the demonstration of different RNA expression profiles, delineating a 'germinal centre-like' and an 'activated B cell-like' subtype and, hence, possibly pointing to different transformation pathways. The recognition of these different pathways may even have profound prognostic importance.

DLBL subtypes

Primary mediastinal (thymic) B cell lymphoma is a tumour possibly derived from thymic B cells. The tumours commonly arise in the anterior mediastinum of younger, often female patients and frequently are characterized on the cytological level by large, clear cells. Prominent sclerosis is a characteristic structural feature.

Apart from the expression of B cell-associated antigens, these tumours are negative for immunoglobulins and may express CD30. The notion of a distinct biological entity has been further substantiated by the finding of characteristic chromosomal aberrations, namely a gain of material in the short arm of chromosome 9 and an amplification of the *REL* oncogene on chromosome 2p (**Figure 7d**).

Intravascular (angiotropic) B cell lymphoma is a rare disease characterized by the almost exclusive infiltration of small- to medium-sized blood vessels by large B blasts. Lymph nodes are rarely involved, and the diagnosis is commonly rendered in organ biopsies such as from the skin, the CNS or the renal parenchyma (**Figure 7c**).

Primary effusion lymphoma represents a rare body cavity-associated lymphoma and is constantly found in association with HIV and HHV8 (human herpes virus type 8) infection.

There are other characteristic clinico-pathological manifestations of diffuse large B cell lymphomas, at present regarded as provisional entities. Recognition as distinct entities is still pending and will require additional evidence for biological significance. Among those are ***AIDS-associated primary CNS lymphomas***, which are consistently associated with Epstein–Barr virus (EBV) infection, ***plasmablastic lymphomas***, frequently presenting in the oral cavity and, as a rule, evolving in the setting of HIV infection as well, and ***primary extranodal DLBL***, e.g. primary gastric or intestinal lymphomas, or primary cutaneous DLBL.

It should be pointed out, however, that neither reliable pathological or biological criteria for the subclassification of DLBL nor distinctive therapies recommended for clinical practice are available at present. For these reasons, the Clinical Advisory Committee of the WHO agreed that the subclassification of DLBL should be optional at present. However, it was agreed that the site of involvement should be clearly stated in the pathology report.

Burkitt Lymphoma (BL)

There is an endemic form (EBV-associated African Burkitt lymphoma), a so-called sporadic form occurring in Western countries, and tumours that occur in the setting of HIV infection. (See the chapters *Human DNA Tumour Viruses* and *RNA Viruses*.)

Clinical Features

Burkitt lymphoma is most common in children (one-third of paediatric lymphomas in Western countries). In African cases, the jaws and other facial bones are frequently involved. In non-endemic cases, BL tends to occur in extranodal sites, most commonly in the distal ileum, caecum and/or mesentery. In rare cases, the tumour presents as acute leukaemia. BL is a specific type of HIV-associated non-Hodgkin lymphoma.

Morphology

The tumour cells of Burkitt lymphoma are medium-sized and are characteristically arranged in cohesive sheets. They possess a deeply basophilic cytoplasm and round, monomorphic nuclei with several, usually prominent, nucleoli. Large macrophages with a broad cytoplasm and ingested apoptotic tumour cells ('tingible body macrophages') are regularly present, thus imparting a characteristic 'starry sky' appearance of the tumour. The proliferation index as measured by the Ki67 antibody is very high (>90–95% of cells) (**Figure 8**).

Immunophenotype

The tumour cells express B cell-associated antigens and are characteristically CD10+, BCL-6+ and BCL-2−.

Genetic Features

The cytogenetic hallmark of Burkitt lymphoma is the translocation t(8;14)(q24.1;q32) or one of the related translocations t(2;8) or t(8;22). On the molecular level, these translocations invariably involve the c-*myc* locus in chromosome band 8q24.1, but different breakpoints in the IgH or IgL chain genes. In endemic (African) cases, the breakpoint in chromosome 14 involves the IgH joining region in contrast to non-endemic (Western) cases in which the IgH switch region is targetted.

The WHO Steering Committee, after thorough discussion, decided to remove the tumours that in the REAL classification proposal were termed 'high-grade B cell lymphoma, Burkitt-like' (and regarded as a provisional entity) from the category of diffuse large B cell lymphomas and include those as variants under the general term of (atypical) Burkitt lymphoma. These variants commonly show, in contrast to classical Burkitt lymphoma, some unusual features either related to cell size (slightly larger), or to immunohistochemical features (cytoplasmic Ig

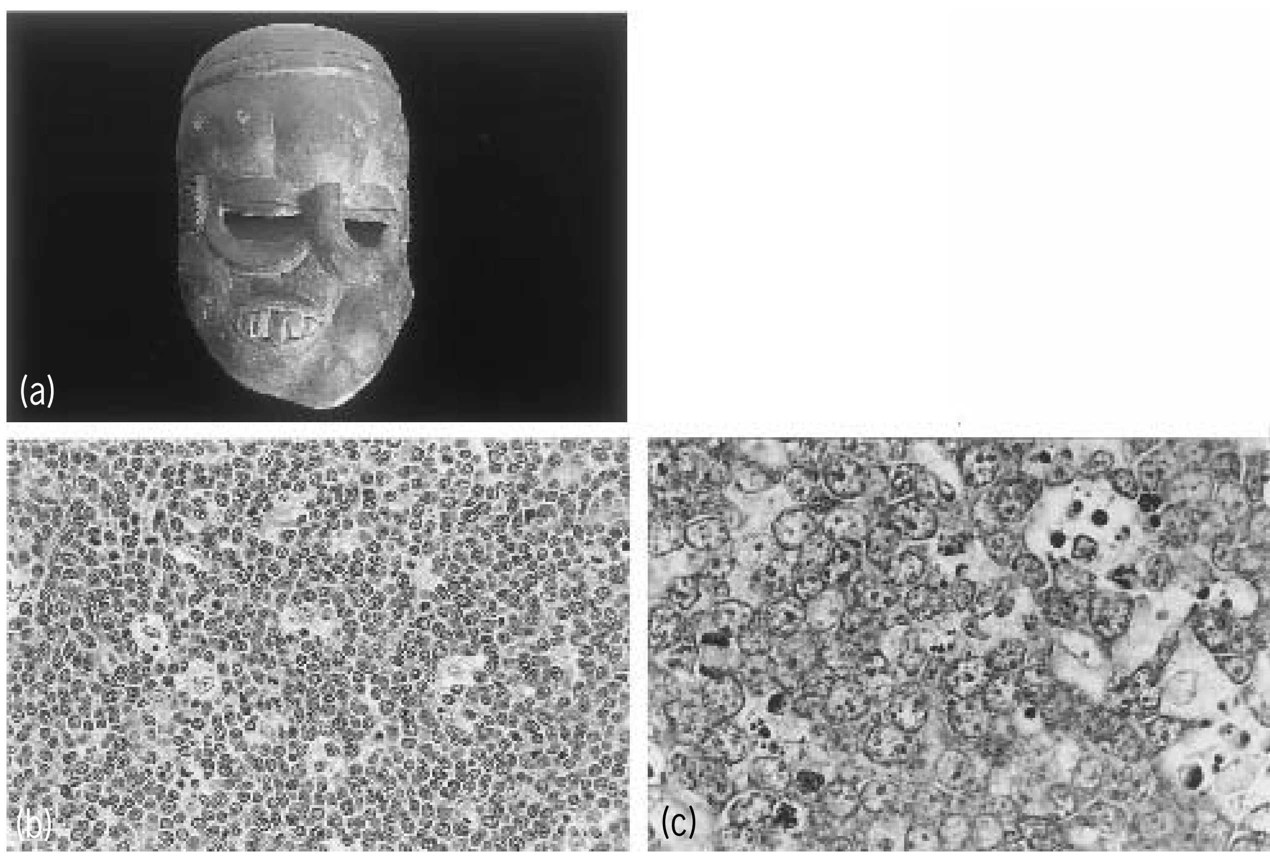

Figure 8 Burkitt lymphoma. (a) Gangoza mask from equatorial Africa (courtesy of Prof. Seeliger, Würzburg, Germany) illustrating the characteristic infiltration of the jaw bones and ensuing displacement of midfacial structures in endemic (African) cases. (b) Low-power view of a lymph node showing cohesive sheets of medium-sized blasts with interspersed macrophages imparting a starry sky pattern. (c) High-power view illustrating medium-sized blasts with round nuclei, coarsely reticulated chromatin and small nucleoli.

expression). Of note, extranodal 'Burkitt-like' lymphomas nevertheless frequently are t(8;14) positive and in the majority of cases are CD10+ and BCL2−. Therefore, these features, together with an exceedingly high proliferation index, should be considered when diagnosing 'Burkitt-like' lymphoma. The term for these tumours has now been changed to 'atypical Burkitt lymphoma'.

B Cell Lymphomas Rarely Infiltrating Lymph Nodes

Plasmacytoma rarely manifests in lymph nodes. In these cases, nodal infiltrates represent a secondary phenomenon in generalized multiple myeloma. Typically, the neoplastic plasma cells are diffusely infiltrating the lymphatic parenchyma without a lymphoid or lymphoplasmacytoid cell component. On immunohistochemistry, plasmacytomas are SIg−, CIg+ (G, A, rarely IgD or E or light chain only), CD20-negative and CD79a-positive in 50% of cases. VS38c and CD138 (syndecan) are expressed in the cytoplasm. Recently, the MUM-1 protein has been described as consistently expressed in the nucleus. Plasmacytomas represent postfollicular neoplasms with somatic hypermutations of IgH and IgL genes, but without ongoing mutations. Some specific cytogenetic aberrations have been reported, such as the t(4;14)(q16;q32) involving *FGFR3*, the t(6;14)(p25;q32) involving the *MUM-1/IRF 4* gene locus and t(11;14)(q13;q32) deregulating cyclin D1.

Hairy cell leukaemia is diagnosed only rarely in lymph nodes. Tumour cells predominantly infiltrate the spleen and bone marrow, resulting in splenomegaly and pancytopenia. In the peripheral blood, circulating tumour cells may be present with circumferential 'hairy' projections. Splenic involvement occurs in the red pulp. In lymph nodes, this neoplasm may primarily invade the subcapsular and intertrabecular sinuses. On the cytological level small- to medium-sized monomorphic lymphoid cells with a rather broad, pale cytoplasm and dense, bean-shaped nuclei are seen. The characteristic immunophenotype, CD5−, CD23−, CD11c+, CD25+, CD103+, DBA44+, along with its unique clinical features (prominent splenomegaly and infiltration of the bone marrow), helps in the diagnosis. No consistent cytogenetic alterations have been described so far.

LYMPHOMAS OF T CELL LINEAGE

Precursor T Cell Lymphoblastic Leukaemia/Lymphoma (Precursor T Cell Acute Lymphoblastic Leukaemia)

Clinical Features

Patients are adolescents or young adults, with male predominance. T-LBL accounts for roughly 40% of childhood lymphomas. T-LBL constitute 20% of precursor cell acute lymphatic leukaemias. Clinically, patients may present with large thymic tumours or peripheral lymphadenopathy. The disease is aggressive, but potentially curable.

Morphology

The morphology of the tumour cells is virtually identical with that of precursor B-LBL (**Figure 9**).

Immunophenotype

Most cases will express T cell-associated antigens CD3 (cytoplasmic) and CD7. CD4 and CD8 may be double-positive or double-negative. Sometimes, expression of NK cell antigens can be noted. Typically, TdT is positive.

Genetic Features

TCR genes are clonally rearranged. A number of recurring cytogenetic aberrations have been described, frequently involving 14q11 and 7p15 or 7q34-36 (the chromosomal bands in which the T cell receptor (TCR) genes are located); 25% of tumours have been reported to carry *SCL/TAL-1* rearrangements.

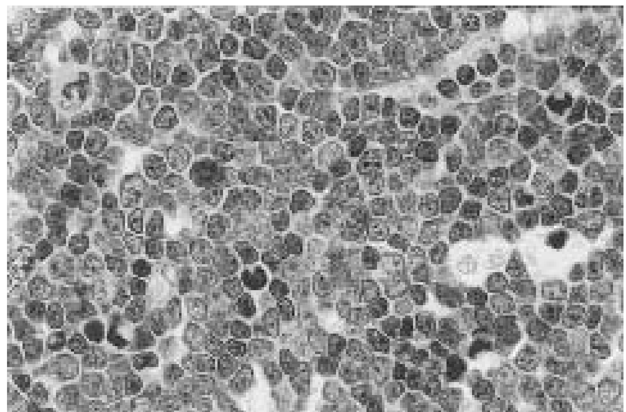

Figure 9 Precursor T cell lymphoblastic leukaemia/lymphoma. The tumour cells have round to irregular nuclei, a faint dust-like chromatin and scant cytoplasm. Note some interspersed large macrophages.

Peripheral T and T/NK Cell Neoplasias

Peripheral T and T/NK cell lymphomas are rare neoplasms in Western countries, but, they are more frequent in Oriental and Asian countries. Although the Clinical Advisory Committee of the WHO classification did not recommend a clinical grouping of the various entities of NHL, peripheral T and T/NK neoplasias may be subdivided according to their predominant clinical features into those that are primarily leukaemic or disseminated, primary nodal or primary extranodal in origin (Chan, 1999).

PREDOMINANTLY LEUKAEMIC (DISSEMINATED) PERIPHERAL T AND T/NK CELL NEOPLASMS

T Cell Prolymphocytic Leukaemia (T-PLL)

Clinical Features

T-PLL is a disease of older adults comprising only 1% of CLL. Patients present with marked leukocytosis ($100\times10^9/1$) and bone marrow, spleen, liver and lymph node infiltrates. Occasionally, cutaneous or mucosal involvement is seen. The disease is more aggressive than B-CLL.

Morphology

T-PLL diffusely infiltrates the paracortical lymph node areas, sometimes sparing pre-existing follicles. In contrast to B-CLL, no pseudo-follicular structures are present. Cytology is characterized by small- to medium-sized lymphocytes with scant cytoplasm and sometimes marked nuclear irregularity. One of the most powerful diagnostic hallmarks of T-PLL is the presence of numerous small high-endothelial venules. They often contain tumour cells, within both the lumens and vessel walls, so that the vessel walls appear to be transmigrated by the tumour (**Figure 10**). Splenomegaly is due to the infiltration of the splenic red pulp.

Immunophenotype

T-PLL cells display a mature T cell immunophenotype with positivity for CD2, CD3, CD5 and CD7. Most cases are CD4+.

Genetic Features

The *TCR* genes are clonally rearranged. In around 80% of cases, a characteristic chromosomal aberration, inv(14)(q11;q32), is present involving the *TCL-1* oncogene in 14q32. Frequently, there is also a partial trisomy for the long arm of chromosome 8. Deletion of the *ATM* gene has been observed in a considerable portion of cases.

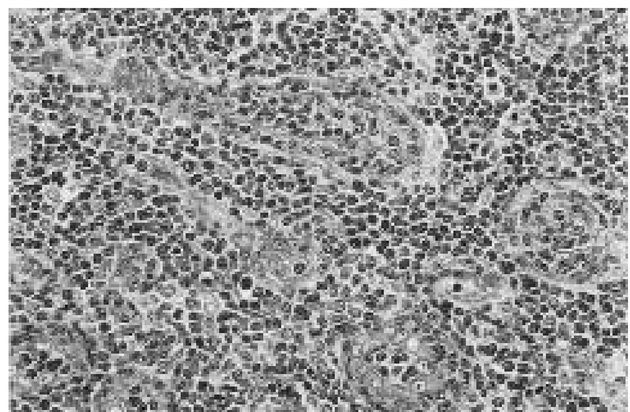

Figure 10 T cell prolymphocytic leukaemia. A characteristic hallmark of the disease is the transmigration of neoplastic cells through the walls of numerous high-endothelial postcapillary vessels.

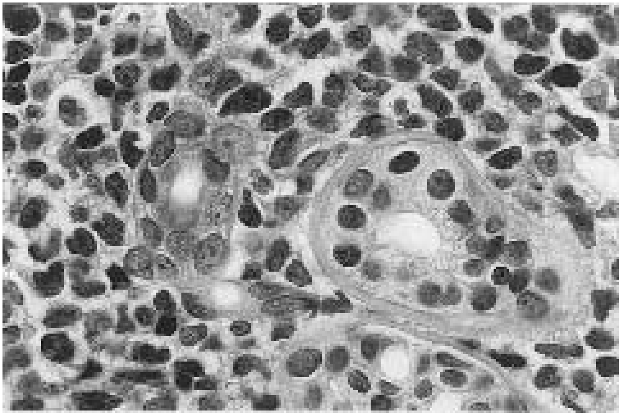

Figure 11 Aggressive NK cell leukaemia/lymphoma. Medium-sized blastic cells with irregular nuclear contours surround and invade adnexal structures in the skin. Note finely dispersed nuclear chromatin.

T Cell Large Granular Lymphocytic Leukaemia (T-LGL)

Clinical Features

T-LGL is a disease of adults frequently presenting with rheumatoid diseases and PB neutropenia and anaemia. Usually, there is mild leukocytosis ($20\times10^9/1$) and mild to moderate splenomegaly. Although the clinical course of T-LGL is usually indolent, more aggressive types may be found with an NK cell phenotype. T cell types are usually indolent, with morbidity related to cytopenias.

Morphology

T-LGL only rarely involves lymph nodes. Generally, there is infiltration of the bone marrow and leukaemic dissemination. Splenic red pulp and hepatic sinus infiltrations are common. In peripheral blood smears, T-LGL cells usually are small and characteristically show a wide rim of eccentric pale blue cytoplasm and the presence of azurophilic granules. The nuclei are round to oval, sometimes with nucleoli.

Immunophenotype

Most frequently, there is a T cell-associated phenotype with CD2+, CD3+, CD7+, CD16−/+, CD56−, CD57+ marker constellation. In rarer cases, an NK cell phenotype may be present with CD2+, CD3-, CD16+, CD56+, CD57+/−.

Genetic Features

In most of the cases with T cell phenotype, clonal rearrangements of the TCR genes may be found. NK cell cases usually are germline. There may be an association with Epstein–Barr virus in Asian cases.

Aggressive NK Cell Leukaemia/Lymphoma

Clinical Features

This is an exceedingly rare neoplasm in Western countries, while most of the cases have been described in Orientals. There apparently is some overlap with nasal NK/T cell lymphoma, however, there is infiltration of the bone marrow and peripheral blood lymphocytosis.

Morphology

The cytological picture has been described as composed of monotonous-appearing medium-sized lymphoblastoid cells with small cytoplasm, round to oval vesicular nuclei and inconspicuous nucleoli. Numerous mitotic figures are present (**Figure 11**).

Immunophenotype

Tumour cells are usually CD2+, CD3−, CD3ε+, CD56+, TIA-1+, granzyme B+.

Genetic Features

No clonal rearrangements of the TCR genes are present. As a rule, there is an association with Epstein–Barr virus infection.

Adult T Cell Leukaemia/Lymphoma (ATL/L)

Clinical Features

ATL/L is a very rare neoplasm in Western countries, and most cases have been reported in patients from south western Japan and the Caribbean. Patients are HTLV1

retrovirus positive. Several clinical variants have been described with differing clinical presentations such as an 'acute', 'lymphomatous', 'chronic' and 'smoldering' form. The acute form with high peripheral blood count, hypercalcaemia, lytic bone lesions and hepatosplenomegaly is most common.

Morphology

Histology may vary with respect to the cytological composition of the infiltrate. In most cases, a mixture of small and large cells, sometimes pleomorphic in shape, can be seen. Also, multinucleated giant cells may be present, reminiscent of Reed–Sternberg cells.

Immunophenotype

The tumour cells usually express T cell-associated antigens CD2, CD3 and CD5, but characteristically lack CD7, but are CD25+. A CD4+ phenotype is much more common than CD7+ types.

Genetic Features

The prerequisite for the diagnosis of ATL/L is the demonstration of integrated HTLV-1 genomes in virtually all cases. TCR genes are clonally rearranged. Some recurring structural and numerical chromosome aberrations have been reported, among them trisomies 3 and 5 and structural alterations involving chromosomal band 14q11.

Hepatosplenic γ/λ T Cell Lymphoma

Clinical Features

This primary splenic T cell lymphoma is a rare, albeit distinct, form of primary splenic lymphoma with cytotoxic features. The disease rarely affects peripheral lymph nodes, but may be suspected in leukaemic cases owing to its classical immunophenotye. The spleen shows moderate to distinct enlargement.

Morphology

In the spleen, there is a diffuse infiltration of the red pulp with sinus involvement by small- to medium-sized cells with sometimes more abundant pale cytoplasm and usually small round to ovoid nuclei. The white pulp is atrophic and sometime entirely absent. In the bone marrow, the infiltrate may manifest purely intrasinusoidal, a feature which in fact is a diagnostic hallmark of the disease in trephine specimens.

Immunophenotype

The tumour cells are CD3+ and also other T cell-associated antigens positive (CD2, CD5, CD7); however, they do not express either CD4 or CD8. No expression of TCRα/β receptor is present, but TCRγ/λ markers are expressed. Most characteristically, the tumour cells express both cytolytic/cytotoxic proteins, such as TIA-1, perforin and granzyme B, as well as NK cell-associated antigen CD56.

Genetic Features

The TCRα/β chain genes are germ-line, but the TCRγ and -λ chain genes are clonally rearranged. A characteristic chromosomal abnormality, i(7)(q10), has been recognized, sometimes associated with trisomy 8. Interestingly, rare TCRα/β variants of the disease have been described with identical chromosome aberrations.

Primary Nodal T/NK Cell Lymphomas: Angioimmunoblastic T Cell Lymphoma (AIL-T)

Clinical Features

AIL-T is a T cell lymphoma that can be suspected by clinicians because of its characteristic features. Typically, there is a generalized lymphadenopathy, fever, weight loss, localized or generalized erythema and polyclonal hypergammaglobulinaemia. Interestingly, occasional spontaneous remissions have been reported. Disease course is aggressive. Infectious complications are common, and progression to aggressive lymphomas of T cell or, rarely, B cell type may occur.

Morphology

In most cases, the nodal architecture is diffusely effaced, although rare cases have been described in which secondary follicles are still present, presumably representing early stages of the disease. The subcapsular sinuses may be preserved. The lymphoid infiltrate usually is composed of a mixture of small- and medium-sized lymphocytes, some immunoblasts and in some cases there may be an admixture of clear cells with pale or clear cytoplasm and pleomorphic nuclei. Epithelioid histiocytes, plasma cells and sometimes large numbers of eosinophils may be interspersed. Characteristically, a proliferation of small arborizing high endothelial venules with PAS-positive vessel walls is present throughout the lymph node, and also extending beyond the capsule (**Figure 12**). Sometimes, in routine H&E sections, expanded aggregates of follicular dendritic cells may be seen, in some cases forming characteristic onion-shaped 'burned-out'germinal centre nodules.

Immunophenotype

The tumour cells express T cell-associated antigens and usually are CD4+. Expanded and loosely structured

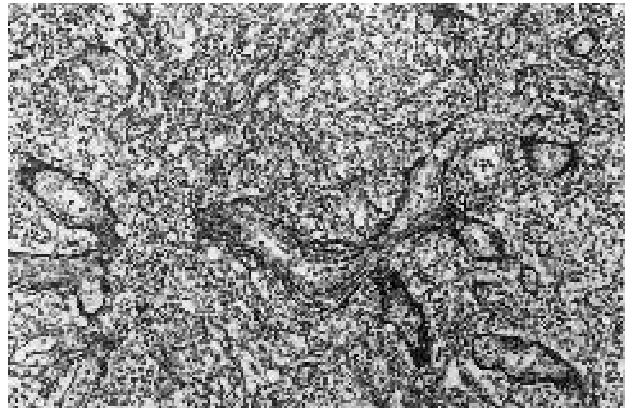

Figure 12 Angioimmunoblastic T cell lymphoma. The lymph node architecture is diffusely effaced. Note conspicuous proliferation of arborizing high-endothelial vessels.

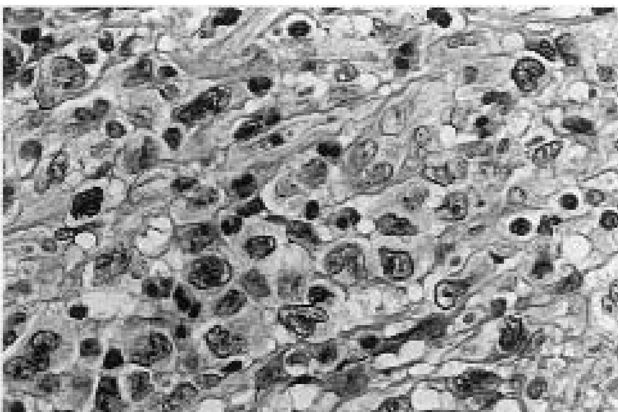

Figure 13 Peripheral T cell lymphoma (unspecified). There is a predominance of medium- to large-sized cells with moderate to broad cytoplasm and irregular nuclei varying in size and shape.

follicular dendritic cell clusters are recognized on staining with FDC markers such as CD21 or CD23. In rare cases, a prominent admixture of large atypical CD20+ B blasts may be present either haphazardly distributed in the infiltrate, or forming small to larger cell clusters. These cells, which often are reminiscent of Hodgkin and Reed–Sternberg cells, may either be CD30+, CD15+ or be CD20+, CD30+, and characteristically express LMP-1 due to Epstein–Barr virus infection.

Genetic Features

TCR genes are rearranged in most cases. Paradoxically, IgH rearrangements may be detected in 20–30% of cases. By *in situ* hybridization, EBV early repeat (EBER) transcripts have been noted, in varying numbers, in >95% of cases. Recurring chromosomal aberrations in AIL-T are trisomies 3 and 5 and, less frequently, an additional X chromosome.

Peripheral T Cell Lymphoma, Unspecified (PTCL-NOS)

This category comprises a large group of peripheral T cell neoplasms that cannot be subcategorized under one of the distinct, nodal or extranodal, entities. It comprises cases which in the Kiel classification have been described as T zone lymphoma, lymphoepithelioid (Lennert's) lymphoma, pleomorphic T cell lymphoma and T immunoblastic lymphoma. At present, it is not clear if this category contains several biological disease entities. The striking variability of the morphological picture, however, suggests that this could be in fact the case.

Clinical Features

PTCL-NOS is more frequent in advanced age groups. The disease is more common in Eastern countries, and in Western countries it comprise only 10–15% of all lymphomas. Aside from lymph nodes, the disease may frequently also involve the skin, liver, spleen and bone marrow. The disease is aggressive, but potentially curable.

Morphology

In most cases, the lymph node architecture is completely destroyed. In rare cases, however, an interfollicular infiltration pattern may be present with sparing of B cell follicles. Cytologically, peripheral T cell lymphomas typically are characterized by a mixture of small and large atypical cells. The appearance of the cytoplasm is variable, but in contrast to B cell lymphomas, the neoplastic cells, as a rule, have more irregular nuclei and vary considerably in size and shape. In some cases, large blasts reminiscent of Hodgkin and Reed–Sternberg cells are present (**Figure 13**). The background infiltrate may be equally variable in its cytological composition. There may be eosinophils or epithelioid histiocytes and plasma cells present. The number of high endothelial venules is not as striking as in AIL-T. In contrast to angioimmunoblastic T cell lymphoma, expanded meshworks of follicular dendritic cells usually are absent.

Immunophenotype

Peripheral T cell lymphomas are positive for T cell-associated antigens, but they may display selective loss of expression for all T cell markers, especially for CD7. Most cases are CD4+ and CD8−, but rare CD8+, CD4− peripheral T cell lymphomas may be encountered, often with an associated expression of cytotoxic molecules. Others may be CD4−, CD8−.

Genetic Features

The TCR genes are clonally rearranged in most cases. Ig genes are germ line. No unifying cytogenetic aberration

has been described in PCTL-NOS. Recurring chromosomal alterations involve chromosomes 7 and 14 (the bands in which the T cell receptor genes are localized). Recurring deletions have been described in the short arm of chromosome 1, the long arm of chromosome 6 and the short arm of chromosome 17. Gains are common in chromosomes 3, 7 and X. PTCL-NOS of the large cell type are frequently characterized by a tetraploid karyotype.

Anaplastic Large Cell Lymphoma (ALCL)

ALCLs were recognized in 1985 by their characteristic expression of the CD30 antigen. Although it soon became clear that other T cell or even B cell lymphomas may occasionally express CD30, the classical morphology of ALCL of T and null cell types justified its recognition as a distinct entity. CD30-positive B cell lymphomas with 'anaplastic' morphology have now been recognized as a variant of diffuse large B cell lymphoma.

Clinical Features

The majority of patients are children or adolescents, but a second peak in age distribution is seen in (older) adults. In the systemic form, lymph nodes and extranodal sites are involved, including the skin. The disease is moderately aggressive, but cure rates are high in the ALK+ variants.

Morphology

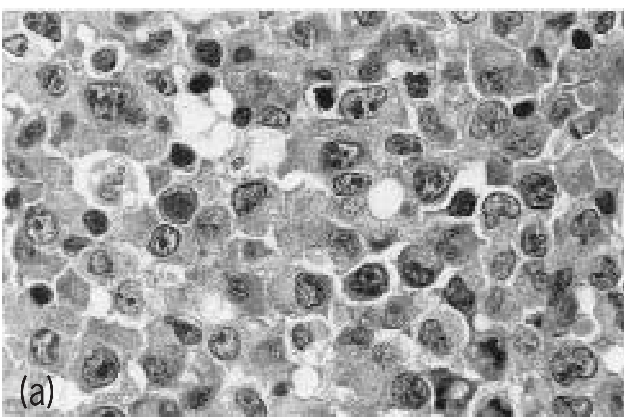
The majority of anaplastic large cell lymphomas is composed of large blastic cells with a broad eosinophilic cytoplasm on H&E sections (and grey–blue cytoplasm on Giemsa stain). The nuclei are large with a vesicular chromatin structure and a single prominent or multiple nucleoli. They may be round or, more often, horseshoe-shaped or pleomorphic. In contrast to peripheral T cell lymphomas, unspecified (which in some cases may also be CD30+), the cell size at least in the 'common' variant shows relatively little variation. The tumour cells are often arranged in cohesive sheets and infiltration of the lymph node sinuses, at first glance suggesting involvement of a solid tumour, is a key feature of the disease (**Figure 14**). In addition to this common type, a small-cell variant and a so-called lymphohistiocytic variant have been described.

In the small-cell variant, the infiltrate is mainly composed of small- to medium-sized cells with irregular nuclei and pale cytoplasm. However, typically, the characteristic large 'anaplastic' blasts are also present. In the lymphohistiocytic variant of the disease, the tumour cells comprise only a minority of the infiltrate. There are numerous histiocytes present, frequently with a broad and foamy cytoplasm, greatly obscuring the neoplastic cells. Other variants, e.g. sarcomatoid, granulocyte-rich and giant-cell types, may be encountered.

There may be an overlap with tumour cell-rich or syncytial variants of Hodgkin lymphoma (sometimes termed 'grey zone' or 'borderline' cases), in which a clear decision may be difficult. However, with the description of more and more antigens that are differentially expressed in Hodgkin lymphoma and ALCL, such as ALK-1, LMP-1, CD15 and others, in most cases a clear diagnosis can be rendered (**Table 6**).

Immunophenotype

The tumour cells, by definition, are CD30+, and in most cases also express the leukocyte common antigen. Irrespective of T or null cell origin, most of the tumours (roughly 75%) are positive for the epithelial membrane antigen (EMA) and CD25. Also, most cases of both T and null cell types express cytotoxic molecules (e.g. perforin, TIA-1 and granzyme B), pointing to the derivation of ALCL from cytotoxic cells. T cell-associated antigens may be variably present in T-ALCL. As a rule, CD20 and other B cell-associated antigens are negative.



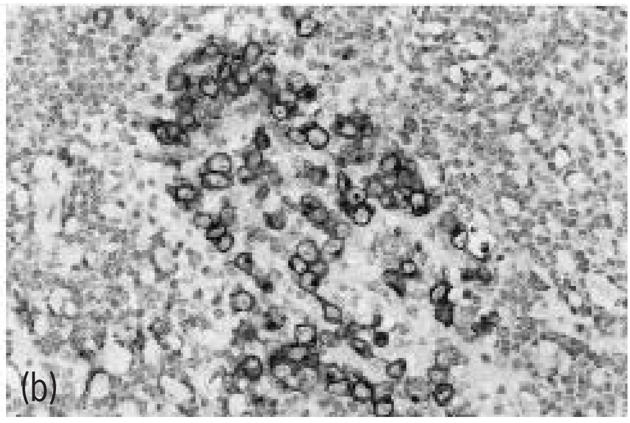


Figure 14 Anaplastic large cell lymphoma. (a) Diffuse proliferation of large cells with broad cytoplasm and round to oval nuclei and prominent nucleoli. (b) CD30 staining of the tumour cells highlighting the characteristic sinus infiltration pattern.

Table 6 Antigen expression patterns in classical Hodgkin lymphoma (cHL) and anaplastic large-cell lymphoma (ALCL)

	CD30	CD15	CD20	T cell markers	CD45	EMA	LMP	TIA1	ALK1
cHL	+	+/−	−/+	−	−	−/+	+/−	−/+	−
ALCL	+	−	−	+/−	+/−	+/−	−	+/−	+/−

Genetic Features

A reciprocal chromosome translocation, t(2;5)(p23;q35), has been detected in 40–60% of ALCL, generating a fusion protein that consists of the nucleophosmin (*NPM*) gene in 5q35 and the anaplastic lymphoma kinase (*ALK*) gene in 2p23. By virtue of the translocation, the ALK kinase is constitutively overexpressed and activated. After the generation of a monoclonal antibody directed against the kinase domain of the ALK protein, it became possible to detect the translocation even in paraffin sections. In cases with this classical translocation, the fusion protein is expressed both in the nucleus and the cytoplasm, while in rare variant translocations also involving ALK, but different fusion partners, the fusion protein is only seen in the cytoplasm. Although it was noted that ALK-positive ALCL comprise a wide morphological spectrum with common, lymphohistiocytic and small cell types being ALK-positive, it was shown that patients with ALK-positive ALCL are generally younger and predominantly of male gender. In comparison with ALK-negative ALCL, patients with tumours expressing the fusion protein show a distinctly favourable clinical course (with 10-year survival rates as high as 70–90%). Because of this important difference, ALK-positive anaplastic large-cell lymphomas are today regarded as a distinct disease entity.

PREDOMINANTLY EXTRANODAL T/NK CELL LYMPHOMAS

Primary Cutaneous Anaplastic Large Cell Lymphomas and Cutaneous CD30-positive Lymphoproliferative Disease (CD30 + LPD)

CD30-positive lymphoproliferative disorders in the skin represent a spectrum of diseases ranging from lymphomatoid papulosis to anaplastic large-cell lymphoma. Since a reliable distinction of these diseases on purely morphological grounds may be difficult, it was suggested to diagnose, in all of these cases, a primary cutaneous CD30-positive lymphoproliferative disease and to subcategorize lymphomatoid papulosis and primary cutaneous ALCL with respect to clinical features.

Morphology

In primary cutaneous CD30 + lymphoproliferative disease, the skin is infiltrated by sometimes cohesive sheets of large neoplastic cells with anaplastic morphology. In other cases, these cells are more loosely distributed, and there is a prominent reactive infiltrate of small lymphocytes and histiocytic cells rendering the differential diagnosis to lymphomatoid papulosis difficult. A single (large) tumour favours anaplastic large-cell lymphoma, while lymphomatoid papulosis tends to present with multiple, waxing and waning, small-sized lesions. By definition, primary cutaneous ALCL may only be diagnosed if the skin is the only site involved.

Immunophenotype

Primary cutaneous LPD express CD30, and frequently are positive for T cell-associated antigens. Cytotoxic markers (TIA1, perforin and/or granzyme B) are frequently found. In contrast to the systemic form, the epithelial membrane antigen is negative, and the cutaneous lymphocyte antigen HECA452 may be positive in most cases. Expression of the ALK kinase is an absolute rarity in this disorder. If ALK protein is expressed, one is more likely to be dealing with a cutaneous infiltration of primary systemic ALCL.

Genetic Features

TCR genes are clonally rearranged in most cases.

Nasal NK/T Cell Lymphoma and NK/T Cell Lymphoma of Nasal Type

Clinical Features

These tumours are rare in Western countries, but are more common in the East. They arise predominantly extranodal, in the nose, the nasopharynx and the paranasal sinuses. Because of their resemblance to nasal NK/T cell lymphoma, tumours with a similar morphology and immunophenotype in the skin, the soft tissue, the gastrointestinal tract or in other localizations, these tumours are diagnosed as ‘of nasal type’. The most frequent manifestation of the disease, however, is in the midfacial structures, hence the old term of ‘lethal midline granuloma’.

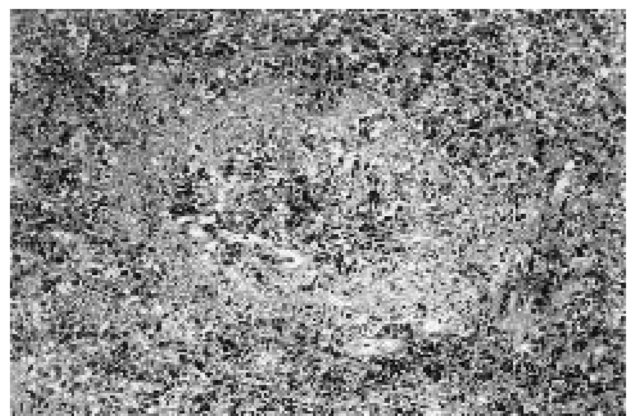

Figure 15 Nasal NK/T cell lymphoma. Tumour cells invade and destroy a larger blood vessel. Note necrosis of adjacent tissue compartments.

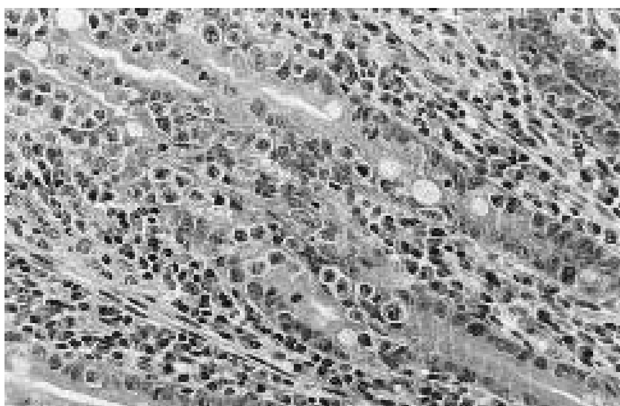

Figure 16 Enteropathy-type T cell lymphoma. The neoplastic cells invade preserved epithelial structures of the mucosa adjacent to a deeply ulcerated small intestinal tumour.

Morphology

Nasal and nasal type NK/T cell lymphomas are in many, but not all, cases characterized by a prominent angiocentric and angiodestructive growth pattern (**Figure 15**) leading to sometimes marked necrosis. The cytological spectrum may be variable with some tumours predominantly consisting of small cells, and some of medium- to large-sized cells. An admixed inflammatory infiltrate may be prominent. Frequently, the nuclei are irregular or pleomorphic, and the chromatin structure may be finely dispersed or granular. Because of their sometimes close similarity to T cell lymphomas, the immunophenotype plays a pivotal role in the diagnosis of the disorder.

Immunophenotype

Nasal NK/T cell lymphomas and NK/T cell lymphomas of nasal type invariably express the CD56 antigen and cytotoxic molecules. T cell-associated antigen CD2 is present in most cases, while CD3 is not found, but CD3ε(cytoplasmic) is expressed.

Genetic Features

Usually, no clonal rearrangements for TCR genes are found; however, in some cases they may be present pointing to a derivation of the tumour cells from T lymphocytes (hence the term NK/T cell lymphoma). In most cases, the tumour cells are infected with the Epstein–Barr virus, rendering EBER *in situ* hybridization an important diagnostic tool if the disease is suspected.

Enteropathy-Type T Cell Lymphoma

Clinical Features

Patients are adults, frequently with a history of gluten-sensitive enteropathy. In others, signs of enteropathy may only be observed in resection specimens, or be entirely absent. Disease course is aggressive. Most often, the disease manifests in the jejunal parts of the small intestine, and because of the difficult clinical diagnosis, may only be recognized if a small bowel segment is resected, frequently because of perforation. This disease was originally thought to represent a histiocytic disorder ('malignant histiocytosis of the intestine'), but has now been conclusively shown to be a T cell lymphoma.

Morphology

The tumours show a broad morphological spectrum ranging from small- and medium-sized to medium- and large-sized or anaplastic tumour cells. There may be diffuse infiltration throughout the bowel wall, and large ulcerations may be present. In the vicinity of these lesions (**Figure 16**), in preserved mucosal parts, there may be a characteristic infiltration of tumour cells into the crypt epithelium, sometimes reminiscent of lymphoepithelial lesions. The adjacent mucosa may or may not show villous atrophy, crypt hyperplasia and a high content of interepithelial T cells (which may be neoplastic as well).

Immunophenotype

T cell-associated antigens are usually expressed, as are cytotoxic molecules. A characteristic finding, which, however, is not present in all cases, is the expression of the mucosal homing receptor CD103 antigen. Some of the cases may be CD8+, and a rather monomorphic variant of small- to medium-sized tumour cells has been described with expression of CD56.

Genetic Features

The TCR genes are clonally rearranged in most cases.

(b) High magnification illustrating lymphocytic and histiocytic (L&H) cells in a background of small lymphocytes. (c) L26 staining showing positivity of the L&H cells and of the background lymphoid cells for CD20. (d) CD3 staining illustrating 'rosetting' of T cells around the tumour cells.

HODGKIN LYMPHOMA

Hodgkin disease is histologically diverse and may be classified into two main entities, namely nodular lymphocyte predominance Hodgkin lymphoma (NLPHL or paragranuloma) and classical Hodgkin lymphoma.

Principally, the diagnosis of Hodgkin disease or Hodgkin lymphoma requires a malignant proliferation of Hodgkin and Reed–Sternberg cells (in the case of classical Hodgkin disease) or of the so-called lymphocytic and histiocytic cells (of NLPHD) and their variants in an 'appropriate background' of reactive, non-neoplastic bystander cells. The tumour cells as such comprise only a minority of the cellular infiltrate. The appropriate inflammatory background in the infiltrate, that is required for the diagnosis, varies widely in its structure and cytological composition and may contain variable numbers of small lymphocytes, eosinophils, histiocytes, plasma cells, neutrophils and epithelioid cells.

Nodular Lymphocyte Predominance Hodgkin's Disease (NLPHD, Paragranuloma)

Clinical Features

NLPHD occurs in all age groups. Usually, peripheral lymph nodes are involved. Often, the disease is localized (Stage I) at diagnosis. Prognosis, usually, is excellent, but transformation to DLBL may occur.

Morphology

NLPHD or paragranuloma mainly infiltrates the lymph nodes in a vaguely nodular pattern. Within this nodular proliferation, small lymphocytes, histiocytes and the characteristic tumour cells, the so-called lymphocytic and histiocytic or 'popcorn' cells, are seen (**Figure 17a and b**). The latter are large cells with a small- to medium-sized cytoplasm and large, usually folded or lobated, nuclei with

a vesicular chromatin structure and a single to several medium-sized nucleoli. In some cases, they may resemble classical Hodgkin or Reed–Sternberg cells. Sometimes, the tumour cells are surrounded by (in comparison with normal lymphocytes) slightly larger cells (expressing the CD57 antigen).

Diffuse areas may be present. When these comprise more than 30% of the lymph node, the case should be classified as nodular paragranuloma with diffuse areas. Diffuse paragranulomas comprise cases in which less than 30% of the infiltrate show a nodular pattern. Rare, purely diffuse paragranulomas are virtually indistinguishable from T cell-rich B cell lymphoma. Adjacent to the tumour infiltrate, a reactive follicular hyperplasia, sometimes with progressive transformation of the germinal centres, may be present (Mason *et al*., 1994).

Immunophenotype

The neoplastic cells in NLPHD constantly express B cell-associated antigens CD20 and CD79a and, in most cases, are positive for the J-chain. In roughly 60% of cases, the epithelial membrane antigen (EMA) is expressed; however, in contrast to classical Hodgkin disease, the tumour cells are negative for CD30, CD15 or the latent membrane protein (LMP-1) of the Epstein–Barr virus. In rare tumours, a monotypic immunoglobulin light-chain expression may be noted. In contrast to classical Hodgkin lymphoma, the small lymphocytes in the background infiltrate are also CD20-positive, and frequently coexpress IgD, like the cells of the normal perifollicular mantle zone. There is, however, a so-called 'rosetting' of CD3-positive T cells and CD57-reactive NK cells directly around the tumour cells of NLPHD (**Figure 17d**).

Genetic Features

By virtue of single-cell PCR analysis, a clonal rearrangement for IgH chain genes was found in all cases investigated. The finding of a high load of somatic mutations in the rearranged Ig genes and the presence of ongoing mutations suggests that NLPHD is derived from germinal centre B cells (Marafioti *et al*., 1997).

Classical Hodgkin Lymphoma

Clinical Features

Hodgkin lymphoma of nodular sclerosis type is most common in adolescents and young adults. The mediastinum is frequently involved. HD, mixed cellularity is a disease of adults, and more widespread disease is common involving lymph nodes, spleen, liver or bone marrow. Lymphocyte-depleted HD is the least common variant, predominantly occurring in older patients and in HIV-infected individuals. In spite of advanced disease stages, HD of all types are curable.

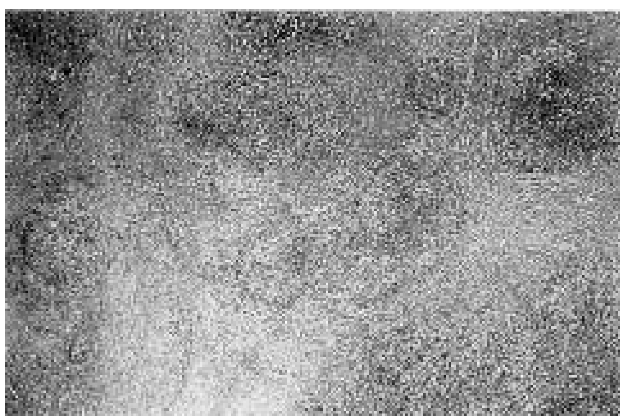

Figure 18 Classical Hodgkin lymphoma, nodular sclerosis type. Note cellular nodules surrounded by broad bands of densely packed collagen.

Morphology

Classical Hodgkin lymphoma is characterized by the presence of Hodgkin and Reed–Sternberg cells with a classical immunophenotype and an appropriate, albeit variable, background infiltrate. Several subtypes are now recognized, each presenting with a more or less unique infiltrate structure (Lukes and Butler, 1966).

Nodular sclerosing HL

Most Hodgkin lymphomas are of nodular sclerosis subtype, which is characterized by the formation of abundant collagen organized in broad bands surrounding cellular nodules (**Figure 18**). This collagen mantle shows birefringence on polarization and is PAS-positive. The thickened capsule normally is integrated into this fibrosing process, and even localized bands of fibrosis warrant the diagnosis of nodular sclerosis subtype, irrespective of the histological appearance of the remainder of the lymph node. The cellular nodules contain a sometimes wide morphological range of tumour cells, including Hodgkin, Reed–Sternberg and the so-called 'lacunar' cells. The lacuna-like appearance of these cells results from fixation artifacts. The reactive background is composed mainly of small lymphocytes and eosinophils. The so-called 'cellular phase' of nodular sclerosing Hodgkin lymphoma may be diagnosed if the capsule of the lymph node is thickened and tumour cells of lacunar type show a (frequently vague) nodular arrangement.

Classical Lymphocyte-rich Hodgkin Lymphoma, Nodular

Classical lymphocyte-rich Hodgkin lymphoma represents one end of a spectrum leading over mixed cellularity to lymphocytic depletion. In classical lymphocyte-rich Hodgkin lymphoma, the lymph-node structure is effaced and a varying degree of nodularity is present. The background infiltrate is mainly composed of lymphocytes,

while eosinophils and neutrophils are only rarely found. In the (more common) nodular form the lymphocytes are mainly B cells and, sometimes, in the centre of the nodules, regressively changed germinal centres may be found (**Figure 19**). In contrast, in the diffuse form the background infiltrate is mainly composed of T lymphocytes. The distinction from NLPHD is not always possible on histological grounds alone; however, immunohistochemistry will as a rule help in this distinction.

Mixed Cellularity

This subtype is histologically intermediate between classical lymphocyte-rich Hodgkin lymphoma and lymphocytic depletion (**Figures 20 and 21**). The diagnosis in fact is made whenever in a case of Hodgkin lymphoma the criteria for the other subtypes are not fulfilled. Partial or interfollicular involvement of the lymph node, by definition, is classified as mixed cellularity.

Figure 19 Classical Hodgkin lymphoma, lymphocyte-rich, nodular. The overview shows large tumour nodules with sometimes preserved germinal centres. Tumour cells are vaguely seen in the broadened follicular mantle zone.

Lymphocytic Depletion

Lymphocyte-depleted type Hodgkin lymphoma is rare (< 5% of all cases) and the diagnosis is often made in relapse or in patients with the acquired immunodeficiency syndrome. In lymphocytic depletion, there may be a diffuse fibrosis with the presence of disorderly orientated reticulin fibres that tend to surround individual cells. The overall cellularity is low, and diagnostic Reed–Sternberg cells may be rare. In the reticular variant, the key feature is the presence of numerous bizzare and anaplastic-appearing Hodgkin and Reed–Sternberg cells together with a depletion of small lymphocytes.

Immunohistochemistry

No significant differences in antigen expression are encountered between the subtypes of classical Hodgkin lymphoma. The tumour cells typically are positive for CD30, and in most of the cases also express CD15 and vimentin. In roughly 20% of the cases, CD20 may be positive, but usually is expressed only weakly and inconsistently in a part of the tumour cells. Other B cell-associated antigens (CD79a, J-chain) are absent. In 10–50% of cases (depending on the histological subtype), the latent membrane protein (LMP-1) of the Epstein–Barr virus is expressed. The positivity of the tumour cells for CD3 or cytotoxic proteins (TIA-1 or perforin) is a rarity. The cellular background is composed (with the exception of nodular lymphocyte-rich classical Hodgkin lymphoma) mainly of CD3-positive T cells and histiocytes. In contrast to paragranuloma, cytotoxic proteins are expressed in a significant number of the small background lymphocytes (**Table 7**).

Genetic Features

The cellular derivation of Hodgkin and Reed–Sternberg cells lymphoma remained enigmatic until, in 1994, by the use of single-cell PCR studies, both the clonal nature and

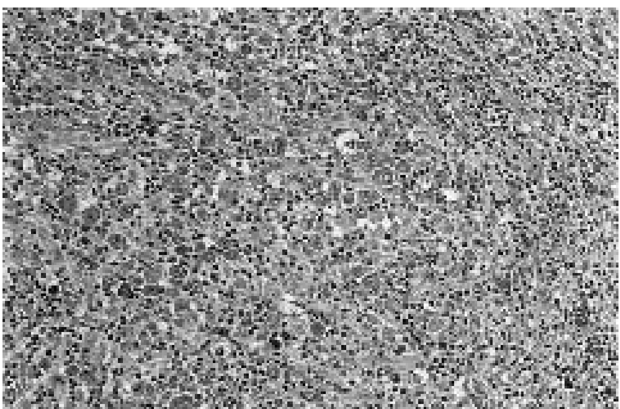

Figure 20 Classical Hodgkin lymphoma, mixed cellularity. Numerous Hodgkin and Reed–Sternberg cells are seen in a reactive background infiltrate.

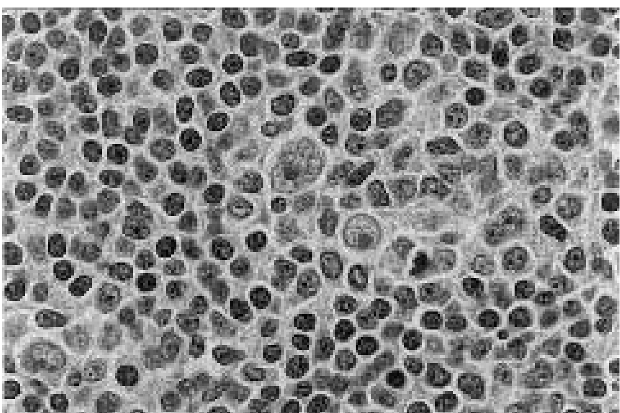

Figure 21 Classical Hodgkin lymphoma. One Hodgkin cell and one multinucleate Reed-Sternberg cell are seen embedded in a reactive background infiltrate.

Table 7 Antigen expression patterns in classical Hodgkin lymphoma (cHL), T cell-rich B cell lymphoma (TCRBCL) and nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL)

	Tumour cells						**Background**	
	CD30	**CD15**	**CD20**	**CD79a**	**J-chain**	**Vimentin**	**TIA/CD57 ratio**	**B cells**
cHL	+	+/–	Weak, uneven	–	–	+	↑	↓
TCRBCL	–	–	+	+/–	–/+	–	↑	↓↓
NLPHL	–/+	–	+	–/+	+/–	–	↓	↑

B lymphocyte origin of Reed–Sternberg cells was revealed in over 95% of cases (Küppers *et al.*, 1994). More recent results indicate that a very small proportion of cases may actually be derived from T cells. As in nodular lymphocyte predominant Hodgkin's disease, the immunoglobulin genes in classical Hodgkin lymphoma are highly mutated, giving evidence for a germinal centre origin of the tumour cells. Although Hodgkin and Reed–Sternberg cells are derived from B cells, they are not able to express immunoglobulins. It has been suggested that this perplexing phenomenon was due to so-called 'crippling' mutations in Ig genes. However, more recent results suggest that the Ig promotor region is not active, thereby preventing the transcription of the Ig genes. The expression of several antiapoptotic proteins may be the reason why the cells are able to escape from apoptosis.

The role of the Epstein–Barr virus in the pathogenesis of classical Hodgkin lymphoma still remains to be elucidated. The virus is found, with slightly varying frequencies in the subtypes recognized, in 40–60% of HL. It has been suggested that the latent membrane protein 1, that posseses transforming capacities *in vitro*, may be involved in tumorigenesis via its homologies to members of the tumour necrosis factor receptor molecules. By complexing in the cell membrane, LMP-1, therefore, is able to activate intracellular signal transduction factors ultimately leading to the activation of the nuclear factor (NF) κB. However, the presence of the EBV in the tumour cells of Hodgkin lymphoma does not necessarily imply that the virus is directly involved in the pathogensis of the neoplasm. A strong argument in favour of a pathogenetic role of EBV in HL is the monoclonal origin of the virus in the tumour cells. Large population studies showed that patients who developed Hodgkin lymphoma had abnormally high titres of some anti-EBV antibodies in prediagnostic sera, indicating that infection occurred prior to clonal expansion of the tumour and was not just due to a manifestation of immunosuppression secondary to the emergence of the neoplastic clone.

Lymphoproliferations in Immunologically Compromised Patients

Lymphoproliferative disorders in the immunosuppressed patient represent a spectrum of diseases different from sporadic lymphomas. The pathogenetic concepts involved result in problems of classification and diagnosis of these tumours and also of treatment options (Knowles, 1999).

Post-transplantation Lymphoproliferative Disorders (PTLDs)

In PTLDs, the allograft type and immunosuppressive regimen applied are most important. The incidence of PTLDs is approximately 1% and 2% for renal and hepatic transplants, respectively, whereas it varies from 2 to 10% for heart, combined heart–lung and bone-marrow transplants. These differences, however, appear to be more related to different degrees of immunosuppression than to the organ itself. With increasing organ mass and tissue type, entirely different factors become more important, such as the number of allogeneic passenger lymphocytes, frequency of allograft rejection and graft versus host disease. PTLD in conventional immunosuppression (antilymphocyte immunoglobulin and azathioprin) is about 1–5% in cardiac transplants. After the introduction of cyclosporin A, initially much higher frequencies of PTLD were observed (9–13%). More recently, as a result of dose reduction and serum level monitoring of the drug, lower frequencies in the range 1–2% are observed.

The majority of PTLDs occur shortly after transplantation, in most instances at a mean time of 6 months, within the first 2 years after transplantation. However, a small but steady number of PTLDs continue to occur throughout the following years. Whereas EBV-positive cases are seen early after transplantation, EBV-negative PTLDs and T cell lymphomas tend to occur in the later post-transplant period.

Clinical Features

There is considerable variability in clinical presentations of PTLDs. Very often the disease starts, especially in younger patients, with mononucleosis-like symptoms (tonsillar enlargement, cervical lymphadenopathy), rapidly transforming into general lymphadenopathy. About half of these patients in a survey of the University of Minnesota took a rapidly fatal course whereas in the other half the disease was self-limiting. Another type of presentation consists of a localized tumour mass occuring very often at extranodal sites, such as the gastrointestinal tract, the central nervous

system or unusual sites (liver, lung, oral cavity, skin or uterus). Involvement of the allograft itself is rare (10–15%) and in some cases was related to donor cell origin of the tumour. Donor cell origin is especially frequent in bone marrow transplantation and increased when T cell depletion of the graft had been performed in order to avoid graft-versus-host disease. Most other PTLDs are of host cell origin representing a reactivation or *de novo* infection by EBV.

PTLDs were considered in the early days as frankly malignant disease and treated (mostly unsuccessfully) by antitumoral combined cytostatic regimens. This view was challenged when spontaneous regression of tumours was reported upon reduction or discontinuation of immunosuppressive therapy. A favourable response is seen in 31% of PTLDs. Early onset lesions and polymorphous rather than monomorphous lymphoproliferations are more likely to respond. However, exact predictive diagnosis has to take into account morphological, molecular and karyotypic as well as virological data.

Pathological Classification of Post-transplant Lymphoproliferative Disorders

Early lesions of mononucleosis-like type or plasmacytic hyperplasias are terms used for PTLD occuring early after organ transplantation (mean time 3–4 months) and frequently involving adenoids, tonsils and superficial nodes, but also extranodal localizations, in children or young adults. The histological pattern is overlapping, showing plasmacytic hyperplasia without destruction of the underlying architecture of lymphoid or organ tissues. Plasma cells do not show light chain restriction. EBV can be demonstrated in most instances showing either a polyclonal, oligoclonal or monoclonal type of infection. These lesions tend to regress spontaneously or after reduction of immunosuppressive treatment, but rarely can progress to higher histological grades, accompanied by more aggressive clinical behaviour or even be fatal, as can infectious mononucleosis in other conditions.

Polymorphic PTLDs are invasive and destructive lesions leading to the effacement of the underlying normal architecture of lymphoid tissues or involved organs. In contrast to sporadic B cell lymphomas, these tumour masses consist of a mixture of cell types including the full range of B cell maturation from centroblasts to immunoblasts and plasma cells and a background inflammatory component of different T cell populations. There may be areas of necrosis, which may be prominent in some cases. The proliferative activity is high.

Immunophenotyping on paraffin sections reveals monotypic light-chain restriction and immunoglobulin secretion in some cases, but no immunoglobulin production in others. EBV may be detected in most cases, the antigen expression profile suggesting EBV latency type 2 or 3.

Polymorphic PTLDs may show partial or complete regression after discontinuation of immunosuppressive treatment or resolution with surgery, radiation therapy or chemotherapy less frequently. Other cases may progress in spite of therapy.

Most cases of **monomorphic PTLD** fulfil diagnostic criteria used for the designation of aggressive lymphomas on morphological grounds, and show a B cell phenotype. The designation of these lymphomas should follow the rules of the WHO classification, but include the term PTLD for clinical and prognostic reasons. Grossly, monomorphic PTLDs are aggressive and invasive tumours destroying the architecture of the lymph node or extranodal tissues. Most frequently these lymphomas are composed of large transformed immunoblasts or plasmablasts, with little or no differentiation toward plasma cells. The term also may be used in cases containing bizarre or multinucleated cells. Immunophenotyping reveals B cell-associated antigens in most cases. CD20 may be negative in plasmablastic lymphoma or anaplastic myeloma which, however, are rarely seen as PTLD. If immunoglobulin production is detected, light-chain restriction is present. The proliferative fraction is high. Most monomorphic PTLDs representing malignant non-Hodgkin lymphomas or multiple myelomas after organ transplantation tend to occur in a higher age group (after the age of 50 years) and do not regress after discontinuation of immunosuppressive treatment or progress despite cytostatic treatment.

EBV Infection

EBV infection is detected in 90% of PTLDs by EBER *in situ* hybridization techniques. Plasmacytic hyperplasias and early lesions of mononucleosis-like type usually show polyclonal EBV infection patterns involving increased numbers of EBV-positive small lymphocytes or activated blast cells. Polymorphic PTLD and monomorphic PTLD show monoclonal EBV integration and a positive result of EBER *in situ* hybridization in most if not all tumour cells. These cases usually also show LMP1 expression in at least some tumour cells, but in fewer cells than detected by EBER *in situ* hybridization. Half of the cases of polymorphic PTLD also express EBNA2, suggesting that these cases are latency type 3, while the others are of latency type 2. Latency type 1, lacking the expression of EBNA2 and LMP1, is seen in some of the malignant lymphomas or monomorphic PTLDs, respectively.

Clonality Studies

Using Southern blot hybridization techniques or PCR-based immunoglobulin heavy-chain CDRIII region amplification, early lesions of PTLDs usually show a polyclonal smear or, rarely, a weak clonal predominance. In polymorphic PTLD, clonality analyses usually demonstrates a monoclonal or oligoclonal result. The investigation of multiple tumour nodules within one organ (e.g.

Table 8 Molecular genetic features in PTLD

Category	IgH clonality	EBV/clonality	Oncogene/tumour-suppressor gene alterations	Clinical course
Plasma cell hyperplasia	Polyclonal	Absent Polyclonal Clonal	Absent	Non-aggressive
Polymorphic PTLD	Monoclonal	Clonal	Absent	?
Monomorphic PTLD	Monoclonal	Clonal	Yes	Aggressive

gastrointestinal tract) may show different clones in each lesion. Malignant (monomorphic) lymphoma occuring as PTLD harbour monoclonal tumour cell populations (Knowles *et al*., 1995).

Genetic Alterations

The status of proto-oncogenes and tumour suppressor genes has been intensively studied. Early lesions and polymorphic PTLD characteristically lack evidence of *BCL1*, *BCL2*, c-*MYC*, *RAS* and *p53* gene alterations, whereas monomorphic lymphomas after organ transplantation consistently contain structural alterations of one or more proto-oncogenes or tumour suppressor genes, most commonly involving *RAS*, c-*MYC* or *p53* genes. More recently, analysis of the *BCL-6* gene in these tumours revealed frequent mutations, the presence of which strongly predicted shorter survival and refractoriness to reduced immunosuppression and/or surgical excision (Cesarman *et al*., 1998). An overview on these findings is summarized in **Table 8**.

Rare types of post-transplantation lymphoproliferative disorders include EBV-negative B cell-related PTLDs, classical Hodgkin lymphoma and peripheral T cell lymphoma.

Iatrogenic Non-transplantation-induced Lymphoproliferative Disorders

Clinical Features

Iatrogenic non-transplantation-induced lymphoproliferative disorders have been recognized only very recently. The most characteristic clinical setting for the occurrence of these disorders is represented by methotrexate treatment in rheumatological diseases, especially rheumatoid arthritis. In contrast to solid organ transplant recipients, where the occurrence of PTLD is considered to be related to the kind and severity of medical immunosuppression, it is usually not known whether and to what extent a state of immunosuppression exists or is active in patients with rheumatoid arthritis receiving methotrexate therapy. Clearly, not all malignant lymphomas that occur in patients with rheumatological diseases are related to their immunomodulatory treatment.

Lymphoproliferative disorders related to immunosuppressive or immunomodulatory treatment appear to comprise only a minority of lymphomas in these patients. Most lymphomas that occur are likely coincidental with rheumatological disease and not the effect of immunosuppression. Most lymphomas in patients with rheumatoid arthritis, similar to other autoimmune diseases, represent malignant lymphomas that are EBV negative and in their histology are similar to lymphomas seen in patients without rheumatological disease. Most iatrogenic lymphoproliferative disorders are EBV positive.

Morphology

The morphological features of iatrogenic lymphoproliferative disorders reported are seen in three main categories:

Atypical polymorphous lymphoproliferative disorders occurring in lymph nodes or extranodal tissues tend to efface the organ architecture and contain a mixture of lymphoid cells at various stages of activation and maturation. These cases show clonal immunoglobulin gene rearrangement or light-chain restriction. Nevertheless, many of them regress after discontinuation of immunosuppressive treatment.

Diffuse aggressive non-Hodgkin lymphomas cytologically represent different types of diffuse large B-cell lymphomas either of large cell or of Burkitt-like type. Some of these proliferations reveal pleomorphic features and focally show Reed–Sternberg-like cells. EBV may be detected in almost all cases by EBER *in situ* hybridization in most, if not all, tumour cells.

Hodgkin lymphoma and lymphoproliferations resembling Hodgkin lymphoma show the most intriguing morphology in the group of iatrogenic lymphoproliferative disorders. The diagnosis of these tumors is difficult, since features of Hodgkin disease may be evident in one place and diffuse large B cell lymphoma in others. The immunophenotype of Hodgkin cells very often is positive for CD20 and CD30, which renders the distinction between classical Hodgkin lymphoma and lymphoproliferations resembling Hodgkin disease in this setting difficult. Hodgkin disease in iatrogenic lymphoproliferative disorders may show diagnostic features of mixed cellularity or nodular sclerosing variant of classical Hodgkin lymphoma including a typical phenotype of Hodgkin cells. The exact diagnosis requires morphological, immunophenotypic and detailed studies on EBV status, including the definition of the latency type.

'Sporadic' Atypical Lymphoproliferative Disorders

As has been pointed out, the pathological features of lymphoproliferative disorders after organ transplantation and/or immunomodulatory treatment differ from sporadic cases of malignant lymphoma. However, their morphology is by no means specific. Therefore, similar, if not identical, cases are also seen without a clinical report of the respective conditions. EBV is also found in 5–10% of aggressive non-Hodgkin lymphomas in the general population and polymorphic lymphoproliferations associated with EBV with or without Hodgkin disease-like features are definitely found outside manifest immunosuppression or immunomodulatory treatment.

Therefore, the question is still unresolved as to whether PTLD and iatrogenic lymphoproliferations represent the well-defined, quasi-experimental condition allowing one to recognize a specific morphology of immunodeficiency-related lymphomas and lymphoproliferative disorders which may also be seen in sporadic, less well-defined states of immunodeficiency or postchemotherapy immunosuppression in elderly patients predisposing to a so-far undefined type of 'sporadic' lymphoproliferative disorder.

INTRODUCTION

Bone tumours are relatively uncommon, but comprise an interesting group of neoplasms (**Table 1**). As a whole, these tumours occur in a younger age group than most other tumours, particularly frequent at the time of maximal bone growth in the teens. Recent advances in modern chemotherapeutic regimens have significantly improved the prognosis in selected types. The chapter will summarize the pertinent pathological features of the most common types of bone tumours. Excellent specialized tests are recommended for rare entities not covered in this chapter (Dahlin and Unni, 1986; Fechner and Mills, 1993; Unni, 1996; Dorfman and Czerniak, 1998).

Adamantinoma
Angiosarcoma
Multiple myeloma and plasmacytoma of bone
Malignant lymphoma
Langerhans cell histiocytosis

NORMAL DEVELOPMENT AND STRUCTURE

The bones are derived from the mesenchyme of the mesoderm. They can be classified into three main types: the flat bones, including the skull, scapula, clavicle, pelvis and sternum; the tubular bones, including most of the bones of the extremities and the ribs; and epiphysioid bones, including the carpal (wrist) and tarsal (ankle) bones and the patella. The tubular bones grow until adulthood by virtue of a cartilaginous growth plate located near the ends

of the bones. The region between the growth plate and the end of the bone is called the epiphysis, the region around the growth plate is called the metaphysis and the region between the metaphyses is known as the diaphysis. Different bone tumours often have distinct predilections for specific regions of the bone.

Mature bone is a combination of two main types of bone, including cortical bone, dense bone present at the exterior, and trabecular bone, a looser meshwork of bone enclosing the medullary cavity containing the bone marrow. The matrix of bone is composed of collagen, proteoglycans and calcium-containing hydroxyapatite. The cellular composition of bone includes osteoblasts, the specialized cells responsible for the synthesis of the bony matrix; osteocytes, osteoblasts that have been incorporated into the bony matrix and responsible for the maintenance and metabolic activity of bone; and osteoclasts, multinucleated cells of monocyte/macrophage lineage responsible for the resorption and remodelling of bone. Cartilage is present at the joint surfaces and the immature growth plate. It consists of S-100 protein-expressing, specialized cells called chondrocytes embedded in an avascular matrix rich in proteoglycans. The external lining of the bone is a fibrous membrane called the periosteum.

The tubular bones are usually formed by a process called endochondral ossification, in which a cartilaginous intermediary forms a scaffold for the deposition of bone. Growth of the bone occurs at the cartilaginous growth plate by calcification of the cartilaginous matrix accompanied by apoptosis of chondrocytes and osteoblastic differentiation, with conversion of the cartilage to immature bone. Flat bones are usually formed by a process called intramembranous ossification, in which fetal mesenchymal cells directly differentiate into osteoblasts without a pre-existing cartilage matrix. Immature bone that lacks a calcified matrix is known as osteoid. The first bone formed lacks normal organisation and is called woven bone. In time, woven bone is organized into concentric layers surrounding blood vessels (haversion canals) forming the osteons of mature lamellar bone.

EPIDEMIOLOGY AND AETIOLOGY

Bone tumours are relatively rare tumours, accounting for about 0.2% of all malignancies, or about 1 in 100 000 individuals (Dorfman and Czerniak, 1995). There has been no discernible trend toward a change in the frequency in recent years. In general, there is a bimodal age distribution, with one peak occurring in adolescence (at the time of greatest bone growth) and a second peak in patients older than 60 years. There is a slightly higher incidence of bone tumours in whites than blacks, and in males than females. However, each specific bone tumour has its own characteristic age, race and sex predilections. Since bone tumours are so rare, there are no effective programmes for screening and prevention.

Most bone tumours have no known aetiology. A small percentage of bone tumours are due to genetic predisposition. There are several well-known syndromes in which specific bone tumours are markedly increased in frequency. Multiple hereditary exostoses is a rare autosomal dominant disorder in which patients develop multiple osteochondromas associated with bone deformities of the affected sites. Some families with this syndrome have a genetic defect at a gene called *EXT-1* present on chromosome 8q24.1 (Ahn *et al*., 1995). Other families have a different genetic defect at a gene called *EXT-2* on chromosome 11p11–13, while still other families may have an abnormality on chromosome 19 (Strickens *et al*., 1996). About 20% of patients develop secondary malignancies, usually a chondrosarcoma arising in a previous osteochondroma. Ollier disease is a rare, nonhereditary congenital disorder characterized by multiple enchondromas. Malignant transformation, again usually with chondrosarcoma, occurs in about 20–25% of patients with Ollier disease (Goodman *et al*., 1984). Mafucci syndrome is similar to Ollier disease in the development of multiple enchondromas, but patients also have co-existing soft tissue angiomas (Bean, 1958). The incidence of complicating chondrosarcoma is even higher in these patients, at approximately 50%; in addition, a variety of other extraskeletal neoplasms have also been reported. Chondrosarcoma may also arise as a rare complication of solitary enchondromas and osteochondromas.

Patients with Li–Fraumeni syndrome carry a germline mutation in the *TP53* gene, leading to an increase in the frequency of numerous neoplasms, including osteosarcoma. In addition, families carrying mutations in the retinoblastoma (*RB*) gene also have a greatly increased risk of osteosarcoma. In addition, there may be a familial osteosarcoma syndrome, independent of the above two disorders. Finally, Rothmun–Thomson syndrome is an extremely rare syndrome characterized by skin, endocrine and neural abnormalities, in which there is an increased incidence of squamous cell carcinoma of the skin and osteosarcoma, which may be multicentric (Vennos *et al*., 1992).

Nongenetic aetiological factors include pre-existing Paget disease of bone, which predisposes to a variety of high-grade sarcomas; osteomyelitis with sinus tract formation, which predisposes to squamous cell carcinoma; bone infarcts, which predispose to bone sarcoma, usually malignant fibrous histiocytoma; and radiation injury, which predisposes to a variety of bone sarcomas. Finally, some investigators have suggested that Kaposi sarcoma-associated human herpesvirus (HHV)-8 may be present in bone marrow antigen presenting cells in cases of multiple myeloma (Berenson and Vescio, 1999). HHV-8 produces viral interleukin-8, which may act as a stimulator of plasma cells, the precursor cells of multiple myeloma.

However, the issue is highly controversial at present, as the findings are inconsistent within the numerous laboratories that have attempted to confirm the original findings.

PATHOLOGY OF BENIGN TUMOURS

Osteoid osteoma and osteoblastoma are the two main benign bone-forming tumours (Healy and Ghelman, 1986). Osteoid osteoma usually occurs in patients between the ages of 5 and 25 years, with a male predilection. It is usually less than 1 cm in size and typically occurs in the tubular bones in the extremities. Histologically, bone formation by benign osteoblasts is seen (**Figure 1; see colour plate section**). Osteoblastoma usually occurs in patients between the ages of 10 and 40 years, with a male predilection. It is usually larger than 1.5 cm in size and typically occurs in the vertebral column. The histological features are very similar to those seen in osteoid osteoma. Osteochondroma is more a hamartomatous (developmental) anomaly than a true neoplasm (Milgram, 1983). It is a common lesion that has a peak incidence between 10 and 30 years of age, with a male predilection. It typically occurs on the surface of the metaphyseal region of the large tubular bones of the extremities. Pathologically, there is an external benign cartilage cap, usually less than 1 cm in thickness, with an underlying support of benign trabecular bone (**Figure 2; see colour plate section**). The histological features resemble the normal sequence of endochondral ossification.

Enchondroma, chondroblastoma and chondromyxoid fibroma are the three most common benign tumours of cartilage. Enchondroma is common neoplasm that occurs in patients of a wide age range, with no clear sex predilection (Mirra *et al*., 1985). It usually occurs in the medullary cavity of tubular bones, particularly in the hands and feet. Clinically, it is usually unassociated with pain (in contrast to some other tumours of cartilage including chondrosarcoma), and histologically, it is composed of mature cartilage with a lobular architecture and containing chondrocytes with small nuclei that lack atypia (**Figure 3; see colour plate section**). Chondroblastoma is an uncommon neoplasm that typically occurs in patients between the age of 10 and 20 years, with a male predilection (Dahlin and Ivins, 1972). It usually occurs in the epiphysis of the large tubular bones of the extremities. It is often associated with pain clinically, and histologically consists of varying numbers of chondroblasts, chondrocytes and multinucleated giant cells in a matrix that varies from immature to mature cartilage, often with a distinctive 'chicken wire' pattern of calcification (**Figure 4; see colour plate section**). Chondromyxoid fibroma is a relatively rare neoplasm that typically occurs in patients between the age of 10 and 30 years, with a male predilection (Rahimi *et al*., 1972). It usually occurs in the metaphysis of the large tubular bones of the extremities. It is usually associated with pain, and histologically shows areas of immature myxoid mesenchymal tissue with variable areas showing primitive cartilage formation.

Fibrous dysplasia is a dysplastic disorder of bone characterized by the inability to form mature lamellar bone (Reed, 1963). It occurs in two major forms. The monostostic form occurs as a single focus in one bone, while the polyostostic form occurs as multiple foci in several bones, either unilateral in one area (monomelic) or widespread (polymelic). The Albright–McCune syndrome is the combination of polyostotic fibrous dysplaia, with endocrine abnormalies (typically precocious puberty in females). Mutations of signal-transducing G proteins may underly this syndrome (Shenker *et al*., 1994). Histologically, fibrous dysplasia displays abnormal immature woven bone with an intervening stroma of spindle cells. Osteofibrous dysplasia is a rare lesion that occurs in infants and children in the bones of the lower leg that histologically has a close resemblance to fibrous dysplasia.

Nonossifying fibroma (fibrous cortical defect) is a very common lesion that typically occurs in patients aged between 5 and 15 years, without a distinct sex predilection. It is often an incidental finding discovered during a radiological study, and usually occurs in the metaphyses of the long tubular bones. Histologically, a bland but cellular spindle cell proliferation is seen (**Figure 5; see colour plate section**). Left alone, most lesions regress spontaneously, evidence that nonossifying fibroma probably represents a developmental disorder due to incomplete ossification. Benign fibrous histiocytoma is a rare neoplasm that occurs in patients of all ages, with no sex predilection (Roessner *et al*., 1981). It most commonly involves the pelvis and the ribs. The histological features are identical with those seen in nonossifying fibroma, with the distinction made on its clinical and radiological features; however, benign fibrous histiocytoma probably represents a true neoplasm.

Haemangioma is a benign tumour of blood vessels (Wold *et al*., 1982). It most often occurs in adults, and is most commonly seen in the skull or the spine. Grossly, they are red–brown, well-demarcated, medullary lesions. Histologically, they are composed of capillary-sized (capillary haemangioma) or slightly larger (cavernous haemangioma) vessels lined by bland endothelial cells. Mixtures of the two patterns are most frequently seen. Lymphangioma is a rare benign tumour of lymphatics. Histologically, it consists of a dilated, thin-walled lymphatic filled with a proteinaceous fluid. Both haemangiomas and lymphangiomas may be multiple. Regional angiomatosis involves one or several bones in a single anatomical region, whereas disseminated (cystic) angiomatosis affects multiple sites within bones of the trunk. Multiple lymphangiomas are often asscoiated with soft tissue lymphangioma or systemic lymphangiomatosis. A rare sporadic syndrome known as Gorham disease is an

aggressive form of angiomatosis in which massive osteolysis occurs which eventually effaces the normal bone architecture. The disease may stabilize or, in some cases, lead to death.

GIANT CELL TUMOUR OF BONES

In contrast to the preceding tumours, giant cell tumour of bone is a locally aggressive neoplasm with a high propensity for local invasion, frequent recurrence and rare pulmonary metastases (Dahlin, 1985). It usually occurs in patients between 20 and 40 years of age, without a sex predilection, and it may have an increased incidence in Chinese patients. It typically affects the epiphyses of the large tubular bones (**Figure 6; see colour plate section**). Histologically, one sees sheets of plump, spindle cells in which numerous multinucleated giant cells are evenly interspersed (**Figure 7; see colour plate section**). The giant cells are distinctive and may have up to 100 nuclei, which are said to resemble the nuclei of the mononuclear spindle cells. The lineage of the mononuclear and giant cells is not yet entirely clear. The giant cells show some features of the monocyte/macrophage lineage, similar to benign osteoclasts, while the mononuclear cells have suggestive but not definite features of monocyte/macrophage lineage. Furthermore, it is not clear which cell population (or whether both) represents the neoplastic element. A high proportion of giant cell tumours are aneuploid, and the majority of cases show chromosome aberrations, particularly telomeric fusion. Patients with giant cell tumour are usually treated by thorough curettage and bone grafting. Rare cases of giant cell tumour may be complicated by secondary malignancy; many of these patients have received prior radiotherapy. Rarer cases represent *de novo* malignant giant cell tumour, characterized by overtly atypical histological features.

OSTEOSARCOMA

Osteosarcoma represents the most common sarcoma of bone, accounting for about one-quarter of all primary malignancies of bone and about one-third of all bone sarcomas (Dorfman and Czerniak, 1998). It is defined as a malignant mesenchymal neoplasm that shows differentiation towards bone formation. Osteosarcoma may be divided into the common intramedullary variant and the much rarer surface oestosarcomas. In conventional intramedullary osteosarcoma, there is a bimodal age distribution with a large peak in patients between the age of 10 and 20 years (corresponding to the peak of bone growth) and a second smaller peak in older patients; there is a male predilection. The locations of the neoplasms in the peak in adolescence are those areas with the greatest growth rate; therefore, the metaphyses of the large tubular bones are the most commonly affected sites. On radiological studies, osteosarcomas may be lytic or sclerotic, depending on the amount of bone formation in the lesion. The borders of the lesion are usually ill-defined, and a soft tissue component is often seen. Grossly, the cut section of an osteosarcoma is variegated, with areas of bony, chondroid and soft tissue, usually with foci of haemorrhage and necrosis (**Figure 8; see colour plate section**). Histologically, a wide variety of patterns can be seen, united by the presence of malignant cells forming bone, even if very focal (**Figure 9; see colour plate section**) (Dahlin and Unni, 1977). Thus, although an osteoblastic pattern with obvious bone formation is most common, chondroblastic, fibroblastic, malignant fibrous histiocytoma-like, osteoblastoma-like, giant cell-rich, small-cell, epithelioid and telangiectatic variants occur, which have little to no impact on prognosis, but may cause great difficulty in differential diagnosis. Mixtures of several patterns are often seen in an individual case. One histological variant that may have an impact on prognosis is well-differentiated intramedullary osteosarcoma. Microscopically, this variant has deceptive bland cytological features combined with a relatively mature pattern of bone. Although most of the histological variants of osteosarcoma are considered to be of high grade, well-differentiated intramedullary osteosarcoma is the one exception that is of low grade when it is the only histological component present.

DNA ploidy studies have usually demonstrated highly aneuploid populations in osteosarcoma (Mandahl *et al.*, 1993). Classical cytogenetic studies confirm this, often showing grossly aneuploid karyotypes, with numerous extra chromosomes, marker chromosomes or loss of chromosomes, particularly loss of chromosomes 3, 10 and 12 (Mertens *et al.*, 1993). Even cases with a normal complement of chromosomes usually have evidence of structural rearrangements, particularly in chromosome 1q. On a molecular level, a high proportion of cases of osteosarcomas has mutations in the *RB* gene, similar to those seen in patients with familial retinoblastoma (and possibly explaining the high frequency of osteosarcoma in these patients) (Miller *et al.*, 1996). In addition, many cases also show mutations in the *TP53* gene (possibly explaining the increased frequency of osteosarcoma in patients with the Li–Fraumeni syndrome). The double minute 2 (*MDM2*) gene is amplified in a high proportion of metastatic lesions, providing another mechanism of *TP53* gene inactivation in osteosarcoma (Ladanyi *et al.*, 1993).

Untreated, conventional osteosarcoma is always fatal, and if treated with surgery alone, patients with osteosarcoma have survival rates no higher than 10–20%. However, patients with resectable lesions and without evidence of metastases are now often treated with

aggressive preoperative chemotherapy followed by complete surgical excision (often limb-sparing) followed by postoperative chemotherapy (Link *et al.*, 1986). These patients now have 5-year survivals greater than 50%. The degree of tumour necrosis observed in the resection specimen is of critical importance as patients with 90% or more necrosis in their tumours have survival rates greater than 80%, whereas patients with less than 90% necrosis have survival rates less than 20%. Other prognostic factors include the site of the neoplasm (patients with tumours in the long bones do better than those with tumours in the trunk), tumour size, the degree of aneuploidy, the status of the *TP53* gene and the status of the multidrug resistance gene (*MDRI*) (upregulation is associated with chemoresistance and decreased survival) (Baldini *et al.*, 1995). Metastases are most commonly seen in the lung and liver. Patients with solitary or even several metastases may benefit from surgical resection and adjuvant chemotherapy.

There are three main types of surface osteosarcoma: parosteal osteosarcoma, periosteal osteosarcoma and high-grade surface osteosarcoma. High-grade surface osteosarcoma is a rare type of high-grade osteosarcoma that develops on the surface of a long bone without the usual medullary involvement. Other than the lack of medullary involvement, it has an epidemiology, pathology and natural history similar to those of conventional osteosarcoma. However, parosteal osteosarcoma and periosteal osteosarcoma are distinctive low-grade forms of osteosarcoma. Parosteal osteosarcoma is a rare variant characterized by location on the surface of long tubular bones on top of the periosteum and a distinctive microscopic appearance (Unni *et al.*, 1976a). The peak incidence is between 20 and 30 years, with a female predilection. These neoplasms are characteristically located on the posterior aspect of the distal portion of the femur, just above the knee joint, or just opposite the knee joint in the posterior aspect of the proximal portion of the tibia. Grossly and radiologically, there is an exophytic (mushroom-like) growth on the periosteum, without elevation of the periosteum. Microscopically, there is a bland spindle-cell proliferation admixed with well-formed bony trabeculae. These tumours when pure have an excellent prognosis following radical surgical excision alone; however, the presence of focal areas of high-grade osteosarcoma seen microscopically is associated with a much higher incidence of metastases, and patients with such neoplasms are often treated with postoperative chemotherapy. Periosteal osteosarcoma is a rare low- to intermediate-grade variant of osteosarcoma that develops on the surface of long tubular bones, but in contrast to parosteal osteosarcoma, it occurs beneath the periosteum (Unni *et al.*, 1976b). It is also rare, with a peak occurrence between 10 and 30 years, with a female predilection. These tumours characteristically occur in proximal tibia or the distal femur. Grossly and radiologically, the lesion is present on the surface of the cortex, with elevation of the periosteum above the tumour. This often induces periosteal reactive new bone formation as perpendicular striae within the tumour and parallel striae at the edges where it attaches to the cortex, the latter often forming a characteristic ‘Codman triangle’ that may be observed on radiographs. Histologically, one sees prominent cartilaginous differentiation, with only focal areas of bone formation, identifying the neoplasm as an osteosarcoma. The tumour nuclei are usually of intermediate to high grade. Patients with periosteal osteosarcoma are usually treated by radical surgical excision, with a survival of about 70%.

CHONDROSARCOMA

Chondrosarcoma of bone is the second most common sarcoma of bone, accounting for about one-fifth of all primary bone malignancies and about one-quarter of all bone sarcomas. It is defined as a malignant tumour forming cartilaginous matrix, without any evidence of bone formation directly synthesized by the neoplastic cells (Sanerkin, 1980).

Chondrosarcoma may be divided into the common conventional chondrosarcoma and the rarer dedifferentiated, clear-cell and mesenchymal variants. Conventional chondrosarcoma is a neoplasm of older adults, with an increasing incidence with increasing age; there is no sex predilection. It occurs most frequently in the pelvis, ribs and proximal extremities, and is very rare in the spine and craniofacial bones. Patients usually present with a dull aching pain (in contrast to most benign lesions of cartilage), often with local swelling due to a mass effect. Radiographically, it usually appears as a clearly demarcated radiolucent lesion with discrete calcified opacities originating in the medullary cavity. Rarely, the neoplasm may arise in a subperiosteal site on the bone surface, a variant termed juxtacortical chondrosarcoma. Grossly, chondrosarcoma usually consists of lobulated hyaline nodules, with areas of calcification, particularly at the periphery of the lobules (**Figure 10; see colour plate section**). An extraosseous component is often present, and high-grade lesions may show areas of haemorrhage and necrosis. Histologically, the hallmark of a chondrosarcoma is the presence of a hyaline cartilage matrix, usually in a lobulated architecture. There is often a variable degree of calcification in the cartilage matrix, and variable degrees of myxoid change (a loose, gelatinous matrix) may be present. Bone may be present in the lesion, but this bone arises from the cartilage via endochondral ossification, and not directly from the neoplastic cells; the presence of the latter would mandate a diagnosis of osteosarcoma.

The neoplastic cells in chondrosarcoma are chondrocytes of varying degree of atypia, graded I–III (Rosenthal *et al.*, 1984). Grade I chondrosarcomas have

cells whose nuclei differ only subtly or not at all from the chondrocytes in benign enchondromas, with the distinction between the two neoplasms best made based on the radiological appearance rather than the pathological findings (**Figure 11; see colour plate section**). Grade II chondrosarcoma features chondrocytes with a greater degree of cytological atypia. Grade III chondrosarcomas are rare, but feature chondrocytes with overtly malignant nuclear features. Both grade I and grade II chondrosarcomas may progress to higher grade chondrosarcomas when recurrence (or metastasis) occurs. Similar to normal chondrocytes, the neoplastic cells in chondrosarcoma express S-100 protein.

Essentially all grade I, and many grade II, chondrosarcomas are diploid, while many grade II and essentially all grade III chondrosarcomas have an aneuploid DNA population. Classical cytogenetic studies reveal complex karyotypes, particularly in high-grade neoplasms, with nonrandom abnormalities in chromosome 1p. High-grade chondrosarcomas have been reported to have mutations or abnormal overexpression of the *TP53* gene in many cases (Nawa *et al*., 1996).

The primary treatment for chondrosarcoma is complete surgical excision, with adjuvant chemotherapy and radiotherapy only effective in high-grade chondrosarcomas. Prognostic factors include histological grade, size, anatomical location, location (extremities better than axial skeleton), presence of aneuploidy, S-phase measurements and presence of TP53 mutation. In general, grade I chondrosarcoma has the potential to recur, but generally does not metastasize, while grade II chondrosarcoma has a higher potential to recur and metastasizes in 10–20% of cases. Overall, grade I and II chondrosarcomas have a 5-year survival greater than 80%, although the disease may recur years after treatment. Grade III chondrosarcoma is a high-grade tumour with a high propensity for recurrence and metastasis, and a 5-year survival of about 20%. Metastases most often occur in lungs and liver.

In about 10% of cases of chondrosarcoma, a phenomenon known as dedifferentiation may occur (McCarthy and Dorman, 1982). In a dedifferentiated chondrosarcoma, a grade I or grade II chondrosarcoma is associated with a distinct area of a high-grade sarcoma, with a clear demarcation between the two areas. Patients with dedifferented chondrosarcoma have similar epidemiological characteristics as those with conventional chondrosarcoma, but often give a clear history of an increase in pain, which may in about half of patients may represent a pathological fracture. The radiological and gross appearance usually shows an area characteristic of conventional chondrosarcoma with an adjacent lytic region corresponding to a fleshy mass. Microscopically, the high-grade sarcoma often has features of a malignant fibrous histiocytoma or osteosarcoma. DNA studies have shown that the low-grade component is usually diploid whereas the dedifferentiated component is aneuploid. Cytogenetic studies have shown abnormalities common to both components, with additional abnormalities in the high-grade component, consistent with a common origin. The dedifferentiated areas consistently show overexpression of the p53 protein, consistent with mutations in the *TP53* gene (Simms *et al*., 1995). In addition, loss of the *RB* gene and/or loss of Bcl-2 protein present in the low-grade component is seen in most cases. The prognosis of dedifferentiated chondrosarcoma is very poor, with few long-term survivors.

Clear-cell chondrosarcoma is a rare variant of chondrosarcoma with characteristic epidemiological and pathological features (Bjornsson *et al*., 1984). It has a peak of incidence between 20 and 30 years, with a strong male predilection. It occurs most often at the proximal ends of the long tubular bones, usually extending to the articular cartilage. Radiologically, a lytic defect is usually seen. Grossly, it is usually a well-circumscribed soft, grey mass, often with focal calcifications. Histologically, one observes distinctive variants of chondrocytes with abundant clear cytoplasm in a loose cartilaginous matrix, often with varying foci of calcification. Ultrastructural and histochemical studies demonstrate that the clear cytoplasm is due to the presence of abundant glycogen. Preliminary cytogenetic studies suggest that clear-cell chondrosarcoma may possess a hypodiploid karyotype distinct from other forms of chondrosarcoma. Clear-cell chondrosarcoma is a low-grade malignancy, but metastasis may occur.

Mesenchymal chondrosarcoma is a very rare variant of chondrosarcoma that has a peak of incidence between 20 and 30 years with no sex predilection (Nakashima *et al*., 1986). It usually affects the bones of the jaws, the vertebrae or the ribs. Radiologically, it most often is a lucent lesion with varying degrees of calcification, and grossly it is usually a well-circumscribed soft grey mass, with foci of calcification. Mesenchymal chondrosarcoma is defined by its characteristic histological appearance, with cellular areas of round to spindle cells and other areas showing cartilaginous differentiation of varying maturation, often with calcification (**Figure 12; see colour plate section**). The proportion of the two elements may vary widely from case to case. Only the cells in the cartiliginous component express S-100 protein. Mesenchymal chondrosarcoma is a high-grade neoplasm, with a propensity for recurrence and metastasis; the 5-year survival is under 50%.

EWING SARCOMA/PERIPHERAL NEUROECTODERMAL TUMOUR OF BONE (PNET)

Ewing sarcoma/PNET comprises about 15% of primary bone sarcomas. A similar neoplasm also occurs in soft

tissue sites. In bone, it essentially occurs in patients under the age of 30 years with a peak between 10 and 20 years (Kissane *et al*., 1983). There is a slight male predilection, and the neoplasm only rarely occurs in blacks. It occurs in all bones, but has a slight preference to involve the long tubular bones, pelvis and ribs; when it occurs in the ribs, it has been known as the Askin tumour. Radiologically, one sees an ill-defined, lytic lesion that involves the intramedullary spaces. When long bones are affected, the diaphysis is usually the site of origin. There is often an extensive soft tissue component. Grossly, the neoplasm is a grey–white tumour that fills the medullary cavity, permeates the cortex, grows subperiosteally and usually forms an extensive soft tissue mass (**Figure 13; see colour plate section**). Microscopically, Ewing sarcoma/PNET consists of a highly homogeneous population of small cells with a fine chromatin pattern, indiscernible nucleoli and a thin rim of cytoplasm; thus, it is the prototype of the 'small, round, blue cell tumour' (**Figure 14; see colour plate section**). The mitotic rate is generally high, and there is usually a high number of apoptotic cells. In a subset of cases, the cells focally form rosettes around stroma, a pattern termed the Homer–Wright rosette, which is suggestive evidence of neural differentiation. The ultrastructural correlate of the Homer–Wright rosette is the presence of cytoplasmic projections, with their organisation toward a central core. Other ultrastructural features that suggest neural differentiation in a subset of tumours is the presence of neurosecretory granules, neurofilaments or neurotubules. Ultrastructural and histochemical studies demonstrate that the cytoplasm contains abundant glycogen in most cases, whereas immunohistochemical studies demonstrate that the cell membrane has consistent (although not highly specific) strong staining for CD99, the *MIC2* gene product (Llombart-Bosch *et al*., 1996). The neoplasm shows a spectrum of expression of neuroendocrine markers, including the chromogranin family of proteins, CD57, protein gene product 9.5 (PGP9.5), neurofilaments, S-100 protein, neuron-specific enolase and synaptophysin. Some pathologists consider neoplasms that possess two or more markers of neuroendocrine differentiation, Homer–Wright rosettes, or ultrastructural evidence of neural differentiation to represent PNET, while neoplasms that possess none or one neuroendocrine marker and lack ultrastructural markers of neural differentiation to represent Ewing sarcoma, whereas other pathologists prefer to consider all cases to represent one neoplasm regardless of the degree of neural differentiation, using the term Ewing's sarcoma/PNET for all tumours.

A characteristic molecular feature of Ewing sarcoma/PNET is the presence a translocation involving the *EWS* gene on chromosome 11 in over 90% of cases (Lopez-Terrada, 1996). A t(11;22)(q24;q12) occurs in about 90% of cases, and involves the *FLI-1* gene on chromosome 11, while the t(7;22)(p22;q12) and t(21;22)(q22;q12) are both rare, and involve the *ETV-1* gene on chromosome 7 and the *ERG-1* gene on chromosome 21, respectively. FLI-1, ETV-1 and ERG-1 are all transcription factors with DNA binding domains. In all three translocations, there is creation of a new fusion protein that uses the promoter of EWS to upregulate the transcription factor. Interestingly, a translocation has not been found in about 10% of cases of Ewing sarcoma. Additionally, there is a distinct soft tissue tumour, the small-cell desmoplastic tumour, that utilizes *EWS* in a distinct t(11;12)(p13;q12) involving another gene on chromosome 11, *WT-1*, that also codes for a transcription factor.

Ewing sarcoma/PNET is a highly aggressive tumour and, if untreated, will rapidly lead to death. Current treatment protocols include a combination of surgery, pre- and postoperative multidrug chemotherapy and radiotherapy, leading to a dramatic increase in survival, with 5-year survival rates of about 70% for those with resectable disease. Surgical removal of one to a limited number of lung metastases may improve overall survival. Prognostic factors include stage (particularly, the presence of metastases at diagnosis), tumour size, site (trunk lesions worse than extremity lesions) and the degree of necrosis in the resection specimen following preoperative chemotherapy (less than 90% necrosis worse than 90–100% necrosis). The presence or absence of neural differentiation is a controversial prognostic factor; some studies show the presence of neural differentiation to be associated with more aggressive tumours, when strict criteria are used.

CHORDOMA

Chordoma is a relatively uncommon neoplasm, representing about 5% of primary bone tumours, and about 8% of bone sarcomas. It is thought to originate from the remnants of the primitive notochord that is present in embryonal development and which forms the forerunner of the vertebral column. It occurs in all age groups, with a peak from 50 to 60 years (Dahlin and MacCarty, 1952). There is perhaps a slight male predominance and it is very rare in blacks. It almost always involves the axial skeleton, particularly the base of the skull and the sacrococcygeal region. Patients with chordoma usually present with pain or symptoms related to compression of adjacent structures. Radiologically, chordoma usually appears as a lytic lesion with scattered calcifications. Grossly, the tumours are grey–tan gelatinous multilobulated masses. Microscopically, chordomas have a resemblance to the normal notochord, with cords and nests of vacuolated cells in a myxoid matrix (**Figure 15; see colour plate section**). Immunohistochemical studies reveal differentiation similar to the cells of the primitive notochord with expression of S-100 protein and the epithelial markers keratin and epithelial membrane antigen. Cytogenetic studies have revealed abnormalities, most frequently involving chromosome 21.

Complete surgical excision is the treatment of choice. However, as these tumours frequently arise in the base of the skull, complete excision is not always feasible; in these cases, radiotherapy is often used after tumour debulking. Chordoma is a moderately aggressive tumour, marked by both recurrences and metastases, most commonly in the lung.

Dedifferentiated chordoma is a tumour consisting of conventional chordoma and a distinct adjacent component of a high-grade sarcoma, similar to that seen in dedifferentiated chondrosarcoma (Meis *et al*., 1987). It may occur in primary or recurrent lesions of chordoma. Radiologically, the neoplasm appears as a destructive lytic lesion. Grossly, the dedifferentiated component is a fleshy mass adjacent to a gelatinous region typical of chordoma. Histologically and immunohistochemically, the sarcomatous component is undifferentiated. The prognosis of dedifferentiated chordoma is very poor, with widespread metastasis and few survivors.

Chondroid chordoma is a controversial entity that contains an admixture of chordoid and cartilaginous areas (Wojno *et al*., 1992). It occurs in bones commonly affected by pure chordomas. Immunohistochemical studies usually show chordoid differentiation (keratin, epithelial membrane, and S-100 protein positive) in both areas of the tumour. Patients with these tumours appear to have a longer survival time than those patients with conventional chordoma.

MALIGNANT FIBROUS HISTIOCYTOMA AND FIBROSARCOMA

Malignant fibrous histiocytoma is a rare sarcoma of bone, comprising approximately 3% of all primary bone tumours and 5% of bone sarcomas. It is similar to the more common entity seen in the soft tissues now thought to be of myofibroblastic differentiation rather than derived from the monocyte–macrophage lineage. It occurs in all age groups, with an increasing incidence with age; there is no sex predilection (Capanna *et al*., 1984). It may involve any bone, but there is a predilecton for the metaphyses of the long tubular bones. Radiologically, a lytic lesion is seen, usually with an associated soft tissue mass. The gross appearance is that of a sarcoma, with a fleshy grey mass, usually with haemorrhage and necrosis. Histologically, a spindle cell proliferation is seen, forming whorls and fascicles. Storiform–pleomorphic, giant cell and myxoid variants are recognized, but there is often intermixture of these components within a single case. Bone formation by the neoplastic cells is not present, as this would mandate the diagnosis of osteosarcoma. The individual cells vary from highly spindled to oval. Nuclear atypia is usually marked, but can show a spectrum from case to case and within a given case (**Figure 16; see colour plate section**). Immunohistochemical studies are commonly performed to rule out other entities, but there are no specific findings in malignant fibrous histiocytoma. Although expression of smooth muscle actin is often seen and used to support a myofibroblastic differentiation, many other sarcomas may also express this antigen. There have been no specific molecular abnormalities found in malignant fibrous histiocytoma; this is not surprising as the entity probably represents a 'waste-basket' of cases of bone sarcoma that do not show specific features of other sarcomas. It is usually treated by radical surgical excision followed by systemic chemotherapy and/or radiotherapy, although newer approaches are examining treatment protocols similar to those used for osteosarcoma. The prognosis is poor, particularly in those patients whose tumours have arisen as a transformation event in a lower grade sarcoma. Metastases most often occur in the lungs.

Some pathologists separate fibrosarcoma from malignant fibrous histiocytoma and regard it as a separate bone sarcoma, whereas other pathologists classify these cases within the category of malignant fibrous histiocytoma. The epidemiological, radiological and gross characteristics of fibrosarcoma are similar to those seen in malignant fibrous histiocytoma (Dahlin and Ivins, 1969). Histologically, those pathologists who distinguish fibrosarcoma from malignant fibrous histiocytoma look for a well-developed fascicular architecture, often with a 'herring-bone' pattern between the different fascicles. The fascicles are formed by spindled cells, without the oval cells typical of malignant fibrous histiocytoma. Collagen formation is variable. The immunohistochemical findings are similar to those seen in malignant fibrous histiocytoma, and the molecular findings are similarly nonspecific. The treatment is usually the same as that for malignant fibrous histiocytoma. The survival figures for patients with fibrosarcoma may be superior to those of patients with malignant fibrous histiocytoma, but this may be because a higher proportion of fibrosarcomas are of lower histological grade.

ADAMANTINOMA

Adamantinoma is a rare primary epithelial neoplasm of bone (Weiss and Dorfman, 1977). It is currently subdivided into classical and differentiated types. The classical type usually occurs in adults, without a sex predilection. It exclusively involves the tibia or, less often, the fibula, the long tubular bones of the lower leg. Patients present with pain in the involved site, often accompanied by a mass. Radiological studies show a mixed lytic and sclerotic mass that may either be intracortical or may show complete cortical disruption with involvement of the medullary cavity, soft tissue or both. Grossly, it appears as a fleshy mass. Histologically, adamantinoma features

epithelial cells arranged in various patterns, including basaloid, spindle, tubular, squamoid and osteofibrous dysplasia-like (**Figure 17; see colour plate section**). The tumour cells in all patterns are keratin-positive on immunohistochemical studies, and ultrastructurally show prominent desmosomes and evidence of keratinization, consistent with epithelial cells. Cytogenetic studies have revealed complex chromosomal abnormalities. Classical adamantinomas are indolent tumours with a high recurrence rate; metastasis, mostly to lungs, occurs in about one-quarter of patients.

Differentiated adamantinoma is extremely rare and, in contrast to classical adamantinoma, usually in patients under the age of 20 (Baker and Coley, 1953). It also exclusively involves the tibia and the fibula, and synchronous lesions may occur. The radiological appearance is identical with that of the classical subtype. Grossly, the tumour appears fibrous rather than fleshy. Histologically, the tumour looks very similar to osteofibrous dysplasia (see above), with the exception that single epithelial cells and small nests of epithelial cells are present within the fibrous stroma. These cells are best identified by immunohistochemical studies for keratin. Cases of differentiated adamantinoma have not yet been reported to metastasize.

ANGIOSARCOMA

Angiosarcoma is a malignancy of endothelial cells. It is a rare primary sarcoma of bone, representing less than 1% of cases. It is separated into classical and well-differentiated epithelioid subtypes. Both classical and well-differentiated occur in all age groups, with a peak of incidence in young adulthood; there is a male predilection (Volpe and Mazabraud, 1982; Wold *et al*., 1982). The long tubular bones of the lower extremity are most often involved, and multifocal lesions are frequent. Radiological studies show usually show a lytic lesion or multiple lesions. They are bright red on cut section. Histologically, classical angiosarcoma typically consists of irregular anastomosing channels lined by individual or heaped up masses of highly atypical endothelial cells. Solid sheets of these cells may also be present focally, extensively or comprising the entire lesion. In contrast, well-differentiated epithelioid angiosarcoma features plump (epithelioid) cells that form sheets, cords, and occasionally lines spaces. They are frequently vacuolated – the vacuoles representing abortive attempts at vessel formation. The nuclei usually show mild to moderate degrees of atypia. The proliferating cells of both subtypes of angiosarcoma express markers of vascular cells, including CD31, CD34 and factor VIII-related antigen. Expression of keratin and, occasionally, epithelial membrane antigen is seen in a subset of cases. Ultrastructural studies demonstrate Weibel–Palade bodies, cytoplasmic structures found in normal endothelial cells.

Classical angiosarcoma is a high-grade sarcoma, usually requiring radical surgery. The prognosis is poor, with a high propensity for metastasis, particularly to the lungs. In contrast, epithelioid angiosarcomas are indolent neoplasms, with local invasion and only occasional metastasis, (also to the lungs). They are usually treated by more conservative surgery with postoperative radiotherapy.

MULTIPLE MYELOMA

Multiple myeloma (plasma cell myeloma) represents a malignant neoplasm of plasma cells, the terminally differentiated cells of the B-lymphocyte lineage that secrete immunoglobulins (Bataille and Harousseau, 1997). Multiple myeloma is a relatively common tumour, occurring more frequently than all primary bone sarcomas combined. It occurs in adults, with an increasing frequency with age. There is a slight male predilection, and there is a higher incidence in blacks than whites. The spine, skull, pelvis and the ribs are most frequently involved. Patients typically present with bone pain and often have recurrent infections and symptoms of renal disease, either at presentation or during the course of the disease. Laboratory abnormalities include anaemia, hypercalcaemia, a monoclonal gammopathy in serum and/or urine and reduced levels of normal polyclonal immunoglobulins. The monoclonal gammopathy derives from the neoplastic plasma cells, and usually consists of IgG (about half of cases) or IgA (one-quarter of cases) in the serum and/or kappa or lambda light chains (called Bence Jones protein) in the urine. Radiological studies usually demonstrate multiple sharply delimited lytic lesions. Grossly, the lesions are usually soft and grey. Microscopically, a uniform proliferation of plasma cells is seen in biopsies from lesions, of varying levels of cytologic atypia (**Figure 18; see colour plate section**) (Bartl *et al*., 1987). Plasma cells are distinctive cells with a round, eccentrically placed nucleus with a clumped chromatin pattern and abundant cytoplasm with a paranuclear pale zone. In addition, an atypical plasmacytosis may also be seen in random biopsies or aspirates from random sites of bone such as the iliac crest that do not appear to be radiologically involved. Immunohistochemical studies usually demonstrate lack of the leucocyte common antigen CD45 and the B-lineage markers CD20 and CD19, because these markers are usually absent on terminal differentiated B-lineage cells. However, there is positivity for the B cell marker CD79a, which is expressed throughout the complete gamut of B cell maturation. In addition, there is usually expression of the plasma cell marker CD38 and the adhesion markers CD138 (syndecan-1), CD56 and CD58. Most importantly, there is almost always monotypic expression of immunoglobulin light and heavy chains, usually of the IgG or

IgA class. Some myeloma cells may express the immature B cell antigen CD10 (common acute lymphoblastic leukaemia antigen (CALLA)), myelomonocytic antigens or T cell antigens. In general, multiple myeloma has a relatively low proliferative index, indicating that the primary abnormality in this neoplasm may be lack of cell death due to loss of cell death mechanisms rather than active proliferation due to loss of growth control mechanisms.

Molecular studies demonstrate monoclonal rearrangements of the heavy and light chain immunoglobulin genes. Classical cytogenetic studies reveal consistent clonal structural abnormalities in about 40% of cases. The most common abnormalities involve chromosomes 11, 13 and 14, with a t(11;14) involving the *BCL1/CCND1* gene on chromosome 11 and the immunoglobulin heavy chain gene on chromosome 14 have been seen in about 25% of cases. High levels of c-Myc have been reported in a subset of patients. Mutations of the *TP53* gene have also been reported in some patients. Alterations of the *PAX-5* gene have also been reported, and may account for the loss of B-lineage markers in multiple myeloma.

Malignant myeloma is usually treated by chemotherapy, although radiotherapy and even surgery may play a role in the treatment of individual lesions that are particularly symptomatic. Prognostic factors include tumour burden (tumour mass), cytological features, expression of CD10, high proliferative index, specific cytogenetic abnormalities and the presence of complications such as renal dysfunction or amyloidosis.

There are several uncommon variants of multiple myeloma. Plasma cell leukaemia is a rare variant with a dominant leukaemic component (Dahlin and Unni, 1986). Solitary myeloma (plasmacytoma of bone) is defined as a neoplastic plasma cell proliferation present in one site of bone (Woodruff *et al*., 1979). Random bone marrow examinations lack plasmacytosis and a serum or urine gammopathy is usually absent. In the majority of cases, progression to multiple myelomas occurs within a few years. Smouldering myeloma lacks overt bone lesions but contains a moderate marrow plasmacytosis, while indolent myeloma has a lesser degree of marrow plasmacytosis but may have up to three bone lesions (Kyle and Griepp, 1980). Finally, monoclonal gammopathy of unknown significance is defined as the presence of a monoclonal gammopathy in the absence of bone lesions or significant marrow plasmacytosis (Kyle, 1978).

MALIGNANT LYMPHOMA PRESENTING IN BONE

Malignant lymphoma involves bones most commonly secondary to spread from other sites, but rarely may present as a primary lesion in bone (Baar *et al*., 1994). Primary bone lymphoma usually represents non-Hodgkin lymphoma. Most cases occur in adults with a slight male predilection. The large tubular bones, pelvis and the spine are most frequently involved, and multifocality may be seen (**Figure 19; see colour plate section**). About two-thirds of cases represent diffuse large B cell lymphoma, with peripheral T cell lymphoma, including cases of anaplastic large cell lymphoma being relatively rare. Hodgkin disease rarely presents in bone without extraskeletal involvement; it most commonly involves the lower spine or the pelvis (Gold and Mirra, 1979). The histological features of non-Hodgkin lymphomas and Hodgkin disease are identical with those seen in the more commonly involved sites.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (histiocytosis X) is a rare neoplastic proliferation of Langerhans cells (Lieberman *et al*., 1996). Most cases occur in childhood, with a predilection for males. The disease is rare in blacks. There are three overlapping syndromes, all of which may involve bone: unifocal disease (solitary eosinophilic granuloma), multifocal, unisystem disease (Hand–Schuller–Christian disease) and multifocal, multisystem disease (Letterer–Siwe disease). In unifocal disease, a single bone is affected, most commonly the skull, femur, pelvic bones or ribs). In multifocal, unisystem disease, there is involvement of several bones, usually the craniofacial bones. In multifocal, multisystem disease, multiple organ systems are involved, but the bones are commonly included, usually in a diffuse fashion. In general, the younger the patient at diagnosis, the more extensive is the pattern of involvement. Histologically, one sees a proliferation of Langerhans cells, in a milieu which typically includes eosinophils, histiocytes, neutrophils and lymphocytes. Langerhans cells have a characteristic grooved nucleus and abundant histiocyte-like cytoplasm (**Figure 20; see colour plate section**). Langerhans cells express CD1 and S-100 protein, and ultrastructurally show characteristic organelles called Birbeck granules. There is a wide spectrum of clinical behaviour, with the number of organs affected at presentation being the critical factor. Survival is greater than 95% in patients with unifocal disease, 80% in patients with multifocal unisystem disease and poor in patients with multisystem disease. The last type of patients are typically treated with multidrug chemotherapy.

DEVELOPMENT AND STRUCTURE OF SOFT TISSUES AND SOFT TISSUE NEOPLASMS

Soft tissue is a broad and poorly defined term that includes distinct tissue types, including connective or supporting tissues, vascular tissue and peripheral nerve tissue. Connective tissues develop from the embryonic mesoderm and are composed of mesenchymal cells. Connective tissues include cartilage, fat, ligaments, tendons, capsules, fasciae, aponeuroses, skeletal muscle, smooth muscle and bone. Bone is excluded from the definition of soft tissue because of its unique histological characteristics. Vascular tissue, which is composed of endothelial cells, is also a mesoderm-derived tissue, originating from primitive mesenchymal cells (angioblasts) during the third week of the embryonic development. Peripheral nerve tissue, in contrast to the other soft tissues, is an ectoderm-derived tissue predominantly originating from the neural crest.

New concepts on soft tissue oncogenesis are being advanced; to avoid misconceptions, we shall discuss some ideas briefly. First, soft tissue tumours currently are considered to be a group of distinct neoplasms showing predominantly mesenchymal differentiation. The word histogenesis will be abandoned, at least for the time being. The erroneous idea that soft tissue tumours are originated from well-developed adult tissue has little clinicopathological support in most cases. Two examples that challenge the concept of histogenesis are liposarcoma and rhabdomyosarcoma. These tumours frequently arise in areas devoid of adipose tissue and skeletal muscle, respectively. Mesenchymal cells are mesoderm-derived motile and nonpolarized embryonic connective tissue cells that can undergo differentiation into distinct cell types. Accordingly, the current hypothesis on soft tissue oncogenesis is that genetic alterations in mesodermal progenitor cells lead to many types of soft tissue tumours. The line of differentiation seems to depend mainly on two factors: the level of commitment of these mesodermal progenitors to development into a certain type of cell when the oncogenic events occur and on the differential pattern of gene expression during the clonal evolution of the tumour. However, it is important to note that even the concepts of mesoderm progenitors or cell of origin will not be blindly adopted or denied. Research has challenged traditional ideas of cell differentiation, dedifferentiation and transdifferentiation, finding a deeper phenotypic cellular plasticity than previously thought (Orkin, 2000). Furthermore, nothing precludes the possibility that oncogenic processes also occur in well-developed cells. Some tumours of smooth muscle and neural differentiation are examples of this point.

Second, soft tissue neoplasms are not necessarily restricted to the same patterns of development and differentiation as are normal tissues. In neoplasms, uncontrolled and cumulative genetic and epigenetic alterations result in cell phenotypes that are distinct from those of normal cells. Searching for counterparts in normal cell types is helpful mainly for classification purposes; this activity should not obligate us to current paradigms of differentiation.

Third, soft tissue neoplasms need not be exclusively restricted to mesenchymal differentiation. The same tumorigenic alterations described above may result in other

cell phenotypes, such as epithelial. There are numerous examples of soft tissue neoplasms with a biphasic appearance, or aberrant differentiation; an example is the biphasic synovial sarcoma. Epithelial–mesenchymal and mesenchymal–epithelial transitions are well-known developmental processes that also can occur during tumorigenesis.

Fourth, the traditional and academic distinction between benign and malignant soft tissue tumours is blurred because many soft tissue tumours behave in a benign fashion despite malignant-like clinicopathological features. The reverse is also true. Examples that do not exactly fit the traditional view include deep fibromatoses (desmoid tumours) and metastasizing benign leiomyomata. Therefore, a spectrum of tumours ranging from the very benign to the fully malignant does exist.

Fifth, soft tissue tumour oncogenesis does not follow the current model of carcinogenesis. At our present level of knowledge, concepts of dysplasia or preneoplastic lesions do not readily apply in most cases of soft tissue sarcoma. Malignant transformation of benign soft tissue tumours into malignant tumours seems very rare; the best example is the malignant transformation of neurofibroma in malignant peripheral nerve sheath tumour in patients with neurofibromatosis.

Sixth, soft tissue sarcomas should not be regarded as rare tumours refractory to any kind of treatment. They comprise various neoplasms with distinct epidemiological, clinicopathological and genetic features that respond differently to various therapeutic modalities. Many advances in cancer genetics and treatment have come from basic and clinical research on soft tissue neoplasms.

In this chapter we discuss the general classification, epidemiology, pathogenesis, clinical features, histological features (including current grading systems), relevant immunohistochemical and ultrastructural findings, cytogenetics, molecular genetics and treatment of soft tissue sarcomas. Emphasis on the pathogenesis and molecular aspects of soft tissue sarcomas will fill the gap present in most textbooks on the subject. New and relevant concepts are discussed as appropriate. Owing to space limitations, clinicopathological features of exceedingly rare sarcomas arising in visceral locations and benign soft tissue tumours, including pseudosarcomatous lesions, are not discussed. The reader is referred to comprehensive reviews on the subject for additional information. For mesothelial tumours, including solitary fibrous tumours, see chapter on *Pleura and Peritoneum.*

CLASSIFICATION

The current World Health Organisation classification of soft tissue tumours is based primarily on clinicopathological features (Weiss and Sobin, 1994). The tumours are classified according to their resemblance to normal tissues or their line of differentiation and clinical behaviour (**Table 1**). The tumours are generally classified as benign or malignant (malignant tumours also are known as sarcomas, from the Greek words *sarx*, flesh, and *oma*, tumour). Many specific entities and variants exist within each category. Despite the efforts of several experts in soft tissue pathology to create a useful and rational classification, the current one, like any other, is not perfect. The field of soft tissue pathology is one of the most dynamic areas in diagnostic and experimental pathology and, because of tremendous technical advances in immunohistochemistry, cytogenetics and molecular genetics, previously unrecognized tumours have been described and fully characterized, and many similarities between apparently disparate entities have been identified. Therefore, future classifications are expected to incorporate this new information.

Table 1 World Health Organisation's histological classification of soft tissue tumours

1. Fibrous tissue tumour
Benign
Fibroma
Keloid[a]
Nodular fasciitis[a]
Proliferative fasciitis[b]
Proliferative myositis[b]
Elastofibroma[b]
Fibrous hamartoma of infancy[c]
Myofibromatosis, solitary and multicentric[c]
Fibromatosis colli[c]
Calcifying aponeurotic fibroma[c]
Hyaline fibromatosis[c]
Fibromatosis
Superficial fibromatosis
Palmar and plantar fibromatosis[a]
Infantile digital fibromatosis (digital fibroma)[c]
Deep fibromatosis
Abdominal fibromatosis (desmoid tumour)[a]
Extra-abdominal fibromatosis (desmoid tumour)[a]
Intra-abdominal and mesenteric fibromatosis[a]
Infantile fibromatosis[c]
Malignant
Fibrosarcoma
Adult fibrosarcoma[b]
Congenital or infantile fibrosarcoma[c]
2. Fibrohistocytic tumours
Benign
Fibrous histiocytoma
Cutaneous histocytoma (deramtofibroma)[a]
Deep histiocytoma[a]
Juvenile xanthogranuloma[c]
Reticulohistiocytoma[b]
Xanthoma[b]
Intermediate
Atypical fibroxanthoma[b]
Dermatofibrosarcoma protuberans[a]
Pigmented dermatofibrosarcoma protuberans (Bednar tumour)[a]

Table 1 (*Continued*)

- Giant cell fibroblastoma[c]
- Plexiform fibrohistiocytic tumour[a]
- Angiomatoid fibrous histiocytoma[a]
- Malignant
  - Malignant fibrous histiocytoma
  - Storiform-pleomorphic[b]
  - Myxoid[b]
  - Giant cell[b]
  - Xanthomatous (inflammatory)[b]

3. Lipomatous tumours

- Benign
  - Lipoma[a]
  - Lipoblastoma (foetal lipoma)[c]
  - Lipomatosis[a]
  - Angiolipoma[a]
  - Spindle cell lipoma[b]
  - Pleomorphic lipoma[b]
  - Angiomyolipoma[a]
  - Myelolipoma[b]
  - Hibernoma[b]
  - Atypical lipoma[b]
- Malignant
  - Well-differentiated liposarcoma[b]
  - Lipoma-like
  - Sclerosing
  - Inflammatory[b]
  - Myxoid liposarcoma[a]
  - Round cell (poorly differentiated myxoid) liposarcoma[b]
  - Pleomorphic liposarcoma[b]
  - Dedifferentiated liposarcoma[b]

4. Smooth muscle tumours

- Benign
  - Leiomyoma[a]
  - Angiomyoma[a]
  - Epithelioid leiomyoma[a]
  - Leiomyomatosis peritoneales disseminata[b]
- Malignant
  - Leiomyosarcoma[b]
  - Epithelioid leiomyosarcoma[b]

5. Skeletal muscle tumours

- Benign
  - Rhabdomyoma
  - Adult[b]
  - Genital[a]
  - Fetal[c]
- Malignant
  - Rhabdomyosarcoma
  - Embryonal rhabdomyosarcoma[c]
  - Botryoid rhabdomyosarcoma[c]
  - Spindle cell rhabdomyosarcoma[c]
  - Alveolar rhabdomyosarcoma[c]
  - Pleomorphic rhabdomyosarcoma[b]
  - Rhabdomyosarcoma with ganglionic differentiation (ectomesenchymoma)[c]

6. Endothelial tumours of blood and lymph vessels

- Benign
  - Papillary endothelial hyperplasia[a]
  - Haemangioma

Table 1 (*Continued*)

  - Capillary haemangioma[a]
  - Cavernous haemangioma[a]
  - Venous haemangioma[a]
  - Epithelioid haemangioma (angiolymphoid hyperplasia, histiocytoid haemangioma)[a]
  - Pyogenic granuloma (granulation tissue type haemangioma)[a]
  - Acquired tufted haemangioma (angioblastoma)[a]
  - Lymphangioma[a]
  - Lymphangiomyoma[a]
  - Lymphangiomyomatosis[a]
  - Angiomatosis[a]
  - Lymphangiomatosis[c]
- Intermediate: haemangioendothelioma
  - Spindle cell haemangioendothelioma[a]
  - Endovascular papillary angioendothelioma (Dabska tumour)[c]
  - Epithelioid hemangioendothelioma[a]
- Malignant
  - Angiosarcoma[b]
  - Lymphangiosarcoma[b]
  - Kaposi's sarcoma[b]

7. Perivascular tumours

- Benign
  - Benign haemangiopericytoma[a]
  - Glomus tumour[a]
- Malignant
  - Malignant haemangiopericytoma[b]
  - Malignant glomus tumour[b]

8. Synovial tumours

- Benign
  - Tenosynovial giant cell tumour
  - Localized[a]
  - Diffuse (extra-articular pigmented villonodular synovitis)[a]
- Malignant
  - Malignant tenosynovial giant cell tumour[b]

9. Mesothelial tumours

- Benign
  - Solitary fibrous tumour of pleura and peritoneum (localized fibrous mesothelioma)[b]
  - Multicystic mesothelioma[a]
  - Adenomatoid tumour[b]
  - Well-differentiated papillary mesothelioma[a]
- Malignant
  - Malignant solitary fibrous tumour of pleura and peritoneum (malignant localized fibrous mesothelioma)
  - Diffuse mesothelioma[a]
  - Epithelial
  - Spindled (sarcomatoid)
  - Biphasic

10. Neural tumours

- Benign
  - Traumatic neuroma[a]
  - Morton neuroma[b]
  - Neuromuscular hamartoma[c]
  - Nerve sheath ganglion[a]
  - Schwannoma (neurilemoma)[a]
  - Plexiform schwannoma[a]

Table 1 (*Continued*)

Cellular schwannoma[a]
Degenerated (ancient) schwannoma[b]
Neurofibroma
Diffuse[a]
Pacinian[a]
Plexiform[a]
Epithelioid[a]
Granular cell tumour[a]
Melanocytic schwannoma[b]
Neurothekeoma (nerve sheath myxoma)[a]
Ectopic meningioma[a]
Ectopic ependymoma[a]
Ganglioneuroma[a]
Pigmented neuroectodermal tumour of infancy (retinal enlage tumour, melanotic progonoma)[c]
Malignant
Malignant peripheral nerve sheath tumour (MPNST) (malignant shwannoma, neurofibrosarcoma)
MPNST with rhabdomyosarcoma (malignant Triton tumour)[a]
MPNST with glandular differentiation[a]
Epithelioid MPNST[a]
Malignant granular cell tumour[a]
Clear cell sarcoma (malignant melanoma of soft parts)[a]
Malignant melanotic schwannoma[a]
Neuroblastoma[c]
Ganglioneuroblastoma[c]
Neuroepithelioma (peripheral neuroectodermal tumour, peripheral neuroblastoma)[a]

11. Paraganglionic tumours
Benign
Paraganglioma[a]
Malignant
Malignant paraganglioma[a]

12. Cartilage and bone tumours
Benign
Panniculitis ossificans[b]
Myositis ossificans[a]
Fibrodysplasia (myositis) ossificans progressiva[c]
Extraskeletal chondroma[a]
Extraskeletal osteochondroma[a]
Extraskeletal osteoma[a]
Malignant
Extraskeletal chondrosarcoma[a]
Well-differentiated chondrosarcoma
Myxoid chondrosarcoma
Mesenchymal chondrosarcoma
Dedifferentiated chondrosarcoma
Extraskeletal osteosarcoma[b]

13. Pluripotential mesenchymal tumours
Benign
Mesenchymoma[a]
Malignant
Malignant mesenchymoma[a]

14. Miscellaneous tumours
Benign
Congenital granular cell tumour[c]
Tumoural calcinosis[a]
Myxoma
Cutaneous[a]
Intramuscular[b]
Angiomyxoma[a]
Amyloid tumour[b]
Parachordoma[a]
Ossifying fibromyxoid tumour[a]
Juvenile angiofibroma[c]
Inflammatory myofibroblastic tumour (inflammatory fibrosarcoma)[a]
Malignant
Alveolar soft part sarcoma[a]
Epithelioid sarcoma[a]
Extraskeletal Ewing sarcoma[a]
Synovial sarcoma[a]
Monophasic fibrous type
Malignant (extrarenal) rhabdoid tumour[c]
Desmoplastic small cell tumour of children and young adults[a]

15. Unclassified tumours

[a]Although this tumour is known to present more often in children than in adults, it is not strictly considered a neoplasm of either age group.
[b]More than 90% of cases present in patients beyond the third decade of life.
[c]Most tumours of this type present before the age of 20 years.
[From Weiss, 1994, *Histological Typing of Soft Tissue Tumours*, 2nd edn (Springer, Berlin), by permission of the publisher.]

EPIDEMIOLOGY, AETIOLOGY AND PATHOGENESIS

Soft tissue tumours are common if one considers the occurrence of benign and malignant tumours, the latter being 100 times less common than the former. Sarcomas represent approximately 1% of all malignant tumours in adults and 15% of all malignant tumours in children. According to a recent report, almost 8000 new cases of soft tissue sarcoma occur and more than 4000 patients die annually of this condition in the USA (Landis *et al.*, 1999). Soft tissue sarcomas are slightly more common in males and can occur anywhere in the body. The most common nonvisceral anatomical sites are the extremities and retroperitoneum.

The aetiology of soft tissue sarcomas is still largely unknown. Environmental and genetic factors have been associated with their development. Ionizing radiation for the treatment of other neoplasms, such as lymphomas and breast and cervical carcinomas, was found to induce high-grade sarcomas, most commonly osteosarcoma and malignant fibrous histiocytoma. Megavoltage and orthovoltage radiation have been implicated. Postradiation sarcomas usually arise 2–3 years after radiation therapy, and a higher risk is observed with cumulative doses greater than 10 Gy. The criteria proposed for the diagnosis of a postradiation sarcoma, which have been constantly modified over the years, require tumour development in a previously

unaffected area within the radiotherapy field and a minimum latency period of 2–3 years. However, the risk of radiation therapy is very low; postradiation sarcoma develops in only 0.1% of patients with cancer who survive more than 5 years after diagnosis.

Many chemicals have been implicated in the aetiology of sarcomas, including thorotrast, poly(vinyl chloride), arsenic, alkylating agents, phenoxyacetic acids, chlorophenols and dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin, or TCDD). The causal role of the three last-mentioned agents in the development of soft tissue sarcomas is controversial. The associations between the development of hepatic angiosarcomas and thorotrast, poly(vinyl chloride) and arsenic are better established.

Viruses have been implicated in the aetiology of a few sarcomas. The best example is the association between Kaposi sarcoma and the human herpes virus 8 (also known as Kaposi sarcoma-associated herpes virus, KSHV). KSHV has been detected in more than 95% of Kaposi sarcomas in all clinical settings. KSHV encodes proteins that disrupt cell cycle and apoptosis control mechanisms. Interference with the normal function of the retinoblastoma and p53 tumour-suppressor proteins as well as derepression of the c-*MYC* oncogene are caused by KSHV-derived proteins (Antman and Chang, 2000). KSHV also has been implicated in the pathogenesis of primary effusion lymphoma and multicentric Castleman disease.

Epstein–Barr virus has also been implicated in the pathogenesis of some sarcomas. Sequences of Epstein–Barr virus have been found in smooth muscle tumours that arise in children with acquired immune deficiency syndrome (AIDS) (McClain *et al*., 1995) and in the rare follicular dendritic cell sarcoma. More recently, the expression of the adenovirus early region 1A gene (*E1A*) in normal human fibroblasts and keratinocytes was found to induce the classical Ewing sarcoma translocation t(11;22)(q24;q12) with the formation of the fusion transcript *EWS/FLI1*. However, these intriguing results are unconfirmed.

A history of trauma is common in patients with soft tissue and bone sarcomas. However, the causal role of trauma is questionable. It is currently believed that trauma near or over the tumour area does not cause but rather leads to the discovery of the tumour. The short time between trauma and the diagnosis of sarcoma supports this view.

Chronic lymphoedema has been correlated with the development of lymphangiosarcoma (currently considered angiosarcoma) in different clinical settings. Stewart–Treves syndrome, the classical example, is characterized by the development of angiosarcoma in a lymphoedematous arm after radical mastectomy. Breast irradiation can also cause chronic arm lymphoedema and secondary angiosarcoma outside the irradiation field. Stewart–Treves syndrome is rarely observed today because of major modifications in the surgical and postsurgical management of patients with breast cancer. Filarial-induced lymphoedema has also been implicated in the development of angiosarcoma.

Several genetic disorders have been associated with an increased risk for the development of soft tissue sarcomas (see Section B). Li–Fraumeni syndrome, neurofibromatosis type I (von Recklinghausen disease), Gardner syndrome, familial retinoblastoma and Beckwith–Wiedemann syndrome are well-known examples. Li–Fraumeni syndrome is a rare familial syndrome characterized by an inherited predisposition to epithelial and nonepithelial tumours, including soft tissue sarcomas, osteosarcomas, breast and lung adenocarcinomas, medulloblastomas, adrenal cortical tumours, leukaemias and others. In 75% of cases, Li–Fraumeni syndrome results from germline mutations of the *TP53* gene on chromosome 17q13. However, germline mutations of the *CHK2* gene (*CH*eckpoint *K*inase *2*) have been described in a subset of patients with Li–Fraumeni syndrome (Bell *et al*., 1999). Neurofibromatosis type I is characterized by germline mutations of the *NF1* (*N*euro*F*ibromin) gene on chromosome 17q11.1. The NF1 protein normally inhibits the protein product of the *RAS* proto-oncogene (*RA*t *S*arcoma virus). Inactivation of *NF1* predisposes to neurofibromas, malignant peripheral nerve sheath tumours and glial tumours. Gardner syndrome is characterized by mutations of the *APC* gene (*A*denomatous *P*olyposis *C*oli) located on 5q21. Multiple intestinal adenomatous polyps develop in patients with Gardner syndrome; these patients have an increased risk for colon cancer and mesenteric fibromatosis (desmoid tumours). Patients with familial retinoblastoma carry a germline mutation in one of the *RB1* gene (*R*etino*B*lastoma *1*) alleles on chromosome 13q24. Loss of the wild-type allele on the homologous chromosome predisposes to retinoblastoma, osteosarcoma, pinealoma and soft tissue sarcomas. Beckwith–Wiedemann syndrome is a sporadic or autosomal-dominant disorder characterized by generalized overgrowth, hemihypertrophy and a tendency for neonatal hypoglycaemia, among other conditions, and an increased risk for Wilms tumour, adrenocortical carcinoma, hepatoblastoma and embryonal rhabdomyosarcoma. The syndrome seems frequently to be caused by loss of imprinting of the *IGFII* (*I*nsulin *G*rowth *F*actor-*II*) and *H19* genes on chromosome 11p15.5. Other disorders associated with an increased incidence of soft tissue sarcomas include tuberous sclerosis, Gorlin syndrome, Werner syndrome and Carney triad. (For additional information, see chapter on *Inherited Predispositions to Cancer*.)

GENETICS AND MOLECULAR BIOLOGY

Genetic alterations in soft tissue sarcomas can be tumour specific or nonspecific. Tumour-specific alterations include genetic alterations highly characteristic of certain soft tissue sarcomas and most commonly represented by chromosomal translocations (**Table 2**). Tumour-nonspecific alterations include genetic abnormalities seen

Table 2 Characteristic chromosomal and genetic abnormalities in sarcomas

Tumour type	Chromosomal abnormality	Fusion transcript or genetic abnormality	Prevalence (%)
Alveolar soft part sarcoma	t(X;17)(p11.2;q25)	*TFE3/ASPL*	>99
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14)	*PAX3/FKHR*	75
	t(1;13)(p36;q14)	*PAX1/FKHR*	10
Angiomatoid fibrous histiocytoma	t(12;16)(q13;p11)	*TLS/ATF1*	?[a]
Clear cell sarcoma (malignant melanoma of soft parts)	t(12;22)(q13;q12)	*EWS/ATF1*	>85
Congenital fibrosarcoma/mesoblastic nephroma	t(12;15)(p13;q25)	*ETV6/NTRK3*	>99
Dermatofibrosarcoma protuberans /giant cell fibroblastoma	t(17;22)(q22;q13)	*COL1A1/PDGFB*	>99

in various tumours and often associated with the clonal evolution of the tumour.

Since the discovery of the translocation t(11;22)(q24;q12) in Ewing sarcoma/peripheral primitive neuroectodermal tumour (PNET) in 1983 (Aurias *et al*., 1983; Turc-Carel *et al*., 1983), an explosion of new knowledge has contributed to our understanding of the molecular biology of soft tissue tumours. Many soft tissue sarcomas are characterized by specific, recurrent, balanced chromosomal translocations that result in the fusion of two constitutional genes into a new chimaeric aberrant gene. These chimaeric genes usually function as altered DNA transcription factors and seem to participate in the pathogenesis of these tumours. The fusion between the *EWS* gene (*EW*ing *S*arcoma) on chromosome 22q12 with the *FLI1* gene (*F*riend *L*eukaemia virus *I*ntegration *1*) on chromosome 11q24 is the best-known example (de Alava and Gerald, 2000). *EWS* encodes for a ubiquitously expressed protein involved in mRNA transcription. The structure of *EWS* protein includes an N-terminal domain homologous to the eukaryotic RNA polymerase II and a C-terminal domain that contains an RNA-binding sequence. *FLI1* encodes for a protein member of a large family of DNA-binding transcription factors that contain a highly conserved amino acid sequence, the ETS domain (*E*rythroblastosis virus-*T*ransforming *S*equence), in the C-terminal end. During the translocation process, the 5′ end of the *EWS*, which contains the *EWS* promoter region, fuses with the 3′ end of the *FLI1*, which contains the ETS domain, resulting in a potent DNA transcription factor (Sandberg and Bridge, 2000) (**Figure 1**).

Similar translocation mechanisms occur in other sarcomas and often involve similar genes (**Table 2**). For example, *EWS* fuses with several ETS family members in other translocations observed in Ewing sarcoma/PNET and related tumours: *ERG* (*E*TS-*R*elated *G*ene), *ETV-1* (*E*TS *T*ranslocation *V*ariant-*1*), *E1AF* (*E1A* *F*actor), *FEV* (*F*ifth *E*wing *V*ariant) and *ZSG* (*Z*inc finger *S*arcoma *G*ene). In addition, *EWS* is fused with other gene partners in clear cell sarcoma (melanoma of soft parts), desmoplastic small round cell tumour, myxoid liposarcoma and extraskeletal myxoid chondrosarcoma (**Table 2**). Other genes involved in sarcoma and leukaemia chromosomal translocations show striking similarities to *EWS*. *FUS/TLS*, *RPB56/hTAFII68*, and *EWS* genes, which contribute their 5′ end to many chimaeric

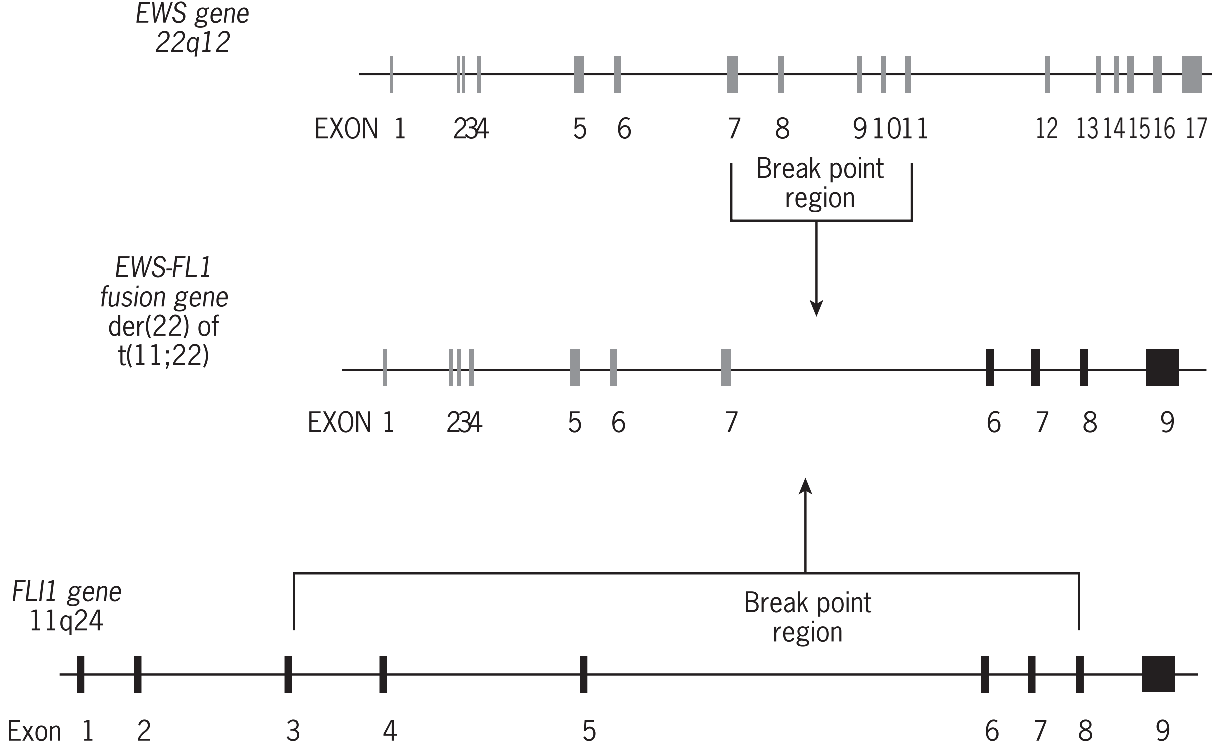

Figure 1 Schematic diagram representing the fusion of the *EWS* gene on chromosome 22q12 with the *FLI1* gene on chromosome 11q24. Fusions of exon 7 of *EWS* with exon 6 (type I) and exon 7 (type II) of *FLI1* occur in 70–75 and 15–25% of cases, respectively. *EWS/FLI* type I gene has been correlated with a low proliferative rate and prolonged survival in Ewing sarcoma. (Adapted from de Alava and Gerald, 2000.)

genes, have similar structures and seem to be originated from the same ancestor gene (**Figure 2**). *FUS/TLS* or *EWS* fuses with the *CHOP* gene in myxoid liposarcoma, and *EWS* or *RPB56/hTAFII68* fuses with the *CHN* gene in extraskeletal myxoid chondrosarcoma. *FUS/TLS* also fuses with the *ERG* gene in acute myeloid leukaemia. Other chromosomal translocations generate chimaeric proteins that function as growth factors (see Dermatofibrosarcoma Protuberans and Giant Cell Fibroblastoma, below) and tyrosine kinase proteins (see Congenital Fibrosarcoma, below).

The underlying mechanism responsible for the genesis of these translocations is still unknown. However, some clues have been found. DNA sequences near the breakpoints of the *FUS/TLS* and *CHOP* genes in myxoid liposarcoma and in the *PAX3* and *FKHR* in alveolar rhabdomyosarcoma are homologous to translin– and topoisomerase II–DNA binding sequences, suggesting the involvement of these proteins or their DNA binding sequences for the genesis of the translocations. In addition, a LINE-1 DNA sequence was found to be present in the translocation t(11;22)(p13:q24) breakpoint in desmoplastic small round cell tumour. It has been proposed that a series of constraint factors collaborate at the level of chromosomal rearrangements, gene expression and gene product function to determine the acquisition and maintenance of a specific translocation (Barr, 1998).

Inactivation of the tumour-suppressor gene *TP53* is commonly observed in soft tissue sarcomas. Loss of heterozygosity of 17p and missense mutations of the *TP53* are the most common mechanisms, occurring in 30–50% of cases. Overexpression of the p53 protein occurs after DNA damage and results in G1/S cell cycle arrest, induction of DNA repair systems, and apoptosis activation (see the chapters *Regulation of the Cell Cycle* and *Genetic Instability and DNA Repair*). Missense mutations of *TP53* result in an abnormal p53 protein that has a prolonged half-life and accumulates above the levels for immunohistochemical detection. Immunoreactivity for mutant p53 protein was found in approximately 27% of cases in a series of 211 soft tissue sarcomas and correlated with decreased survival (Cordon-Cardo, 1994). In the same series, mutant p53 protein expression did not always correlate with *TP53* mutation. Other studies have found a correlation between mutant p53 protein and high-grade histology or poor survival.

The tumour-suppressor gene *RB1* is commonly inactivated in soft tissue sarcomas. Normally, the hypophosphorylated Rb1 protein forms a complex with the transcription factor E2F, arresting the cell cycle in the G1/S checkpoint. Complexes of cyclins and cyclin-dependent kinases phosphorylate Rb1, releasing E2F and promoting cell cycle progression (see the chapter *Regulation of the Cell Cycle*). Loss of Rb1 protein

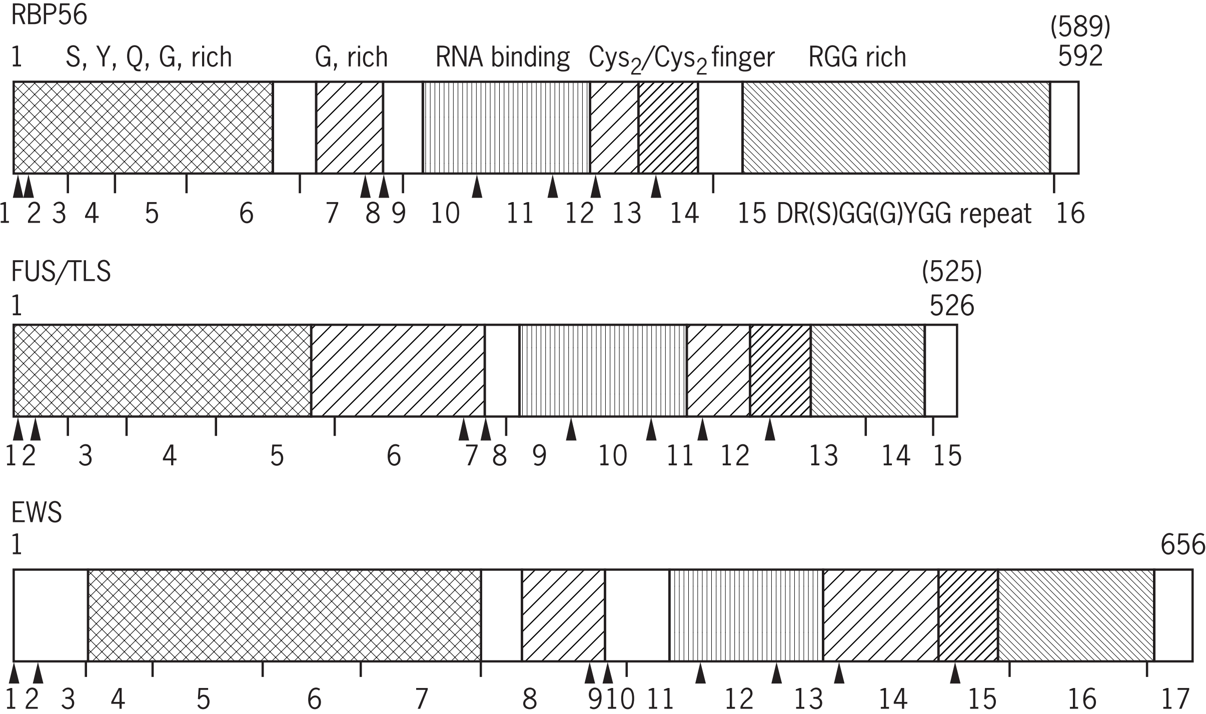

Figure 2 Structural similarities of RBP56, FUS/TLS and EWS proteins suggest that the respective genes originated from the same ancestral gene. *RBP56(hTAFII68)* is rearranged in extraskeletal myxoid chondrosarcoma. *TLS* is rearranged in myxoid liposarcoma and some acute leukaemias. A single case of angiomatoid malignant fibrous histiocytoma also showed a *TLS* rearrangement. *EWS* is rearranged in Ewing sarcoma, clear cell sarcoma, myxoid liposarcoma, extraskeletal myxoid chondrosarcoma and desmoplastic small round cell tumour. (From Morohoshi *et al*., 1998, Genomic structure of the human RBP56/hTAFII68 and FUS/TLS genes. *Gene*, **221**, 191–198, copyright 1998, with permission from Elsevier Science.)

expression has been correlated with a worse prognosis in some (Cance *et al*., 1990) but not all series of soft tissue sarcomas (see Prognostic Factors, below).

MDM2 (*M*urine *D*ouble *M*inute *2*) gene amplification and protein overexpression are commonly observed in soft tissue sarcomas (Oliner *et al*., 1992). *MDM2* is mapped on 12q13 and has its transcription regulated by the p53 protein in a negative feedback loop. Mdm2 protein seems to form a trimeric complex with both p53 and Rb1. Mdm2 protein inhibits apoptosis and stimulates cell cycle progression by inactivating the p53 protein. *MDM2* gene amplification is not always correlated with Mdm2 protein overexpression detected by immunohistochemical analysis. Overexpression of Mdm2 protein was correlated with a worse prognosis in large series of patients with soft tissue sarcomas.

Additional genetic alterations have been observed in soft tissue sarcomas. On the same region of *MDM2* (12q13-15), other genes, including *HMGI-C*, *SAS*, *GLI* and *CDK4*, were found to be amplified. The *HMGI-C* gene (*H*igh *M*obility *G*roup Protein *I-C*) encodes for a DNA transcription factor. *HMGI-C* has been found to be rearranged or amplified in lipomas and atypical lipomatous tumours (well-differentiated liposarcomas). The *SAS* gene (*S*arcoma *A*mplified *S*equence), a member of the transmembrane 4 superfamily of proteins, is involved in cell growth regulation and was found to be amplified in malignant fibrous histiocytomas and liposarcomas. The *GLI* gene (*GLI*oma) encodes a transcription factor and is amplified in gliomas and high-grade childhood sarcomas. *CDK4* (*C*yclin *D*ependent *K*inase *4*) encodes a cell cycle protein kinase, and its amplification may favour cell proliferation. Deletions or rearrangements, but not point mutations, of the genes *INK4A* (*IN*hibitor of Cyclin Dependent *K*inase *4A*, which encodes for the cell cycle inhibitors p16 and p19ARF) and *INK4B* (which encodes for the cell cycle inhibitor p15) on the chromosome 9p21 were found in high-grade sarcomas and correlated with poor survival after adjustment for size and grade. Mutations of K-*RAS* (*K*irsten) and H-*RAS* (*H*arvey) oncogenes were found in a few series of soft tissue sarcomas and were more common in malignant fibrous histiocytoma. Interestingly, these mutations are common in Korean patients and rare in American patients.

HER2/neu (*H*uman *E*pidermal growth factor *R*eceptor *2*) gene amplification or protein overexpression as well as microsatellite instability seem uncommon in soft tissue sarcomas, but the data are limited. (See Synovial Sarcoma later in this chapter for additional information on HER2/neu).

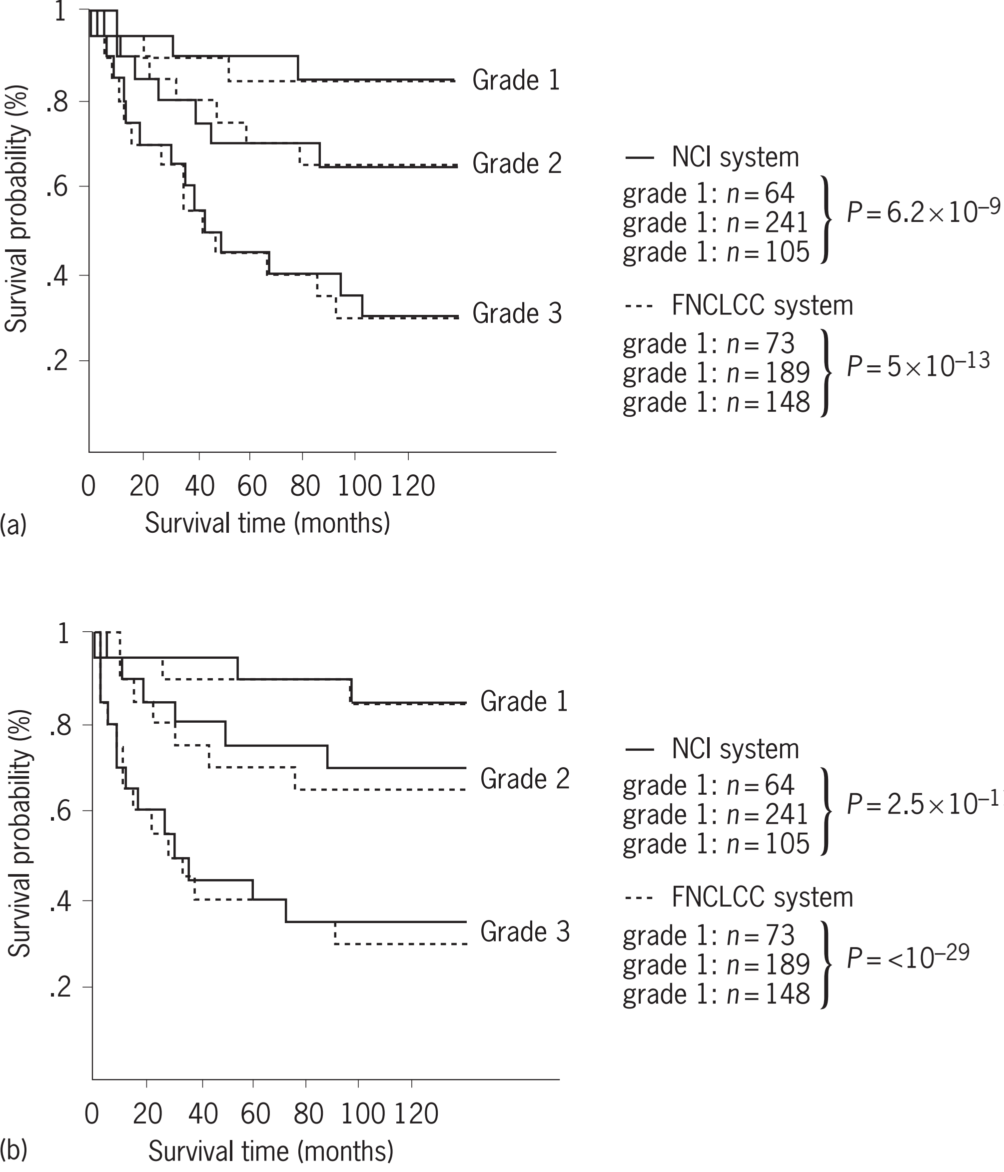

Figure 3 Survival curves according to histologic grade using the National Cancer Institute (NCI) and French Federation of Cancer Centres (FNCLCC) systems. (a) Overall survival; (b) metastasis-free survival. (From Guillou *et al.*, 1997, by permission of the American Society of Clinical Oncology.)

GRADING AND STAGING SYSTEMS

Many systems have been proposed for the grading and staging of soft tissue sarcomas. Their main goal is to identify patient groups with comparable clinicopathologic features for treatment optimization, prognostication and data comparison among cancer centres.

Histological grading has been considered the most powerful independent prognostic factor for soft tissue sarcomas and is based on the assessment of morphological features. Degree of tumour differentiation (resemblance to normal tissue counterparts), mitotic activity, necrosis and cellularity are histological variables commonly evaluated during the grading process. Currently, the French Federation of Cancer Centres (Trojani *et al.*, 1984) and the National Cancer Institute (Costa *et al.*, 1984) grading systems are the most commonly used and provide similar results (**Figure 3**) (Guillou *et al.*, 1997). The French Federation of Cancer Centres uses a 3-grade system that combines tumour differentiation, mitotic count, and necrosis to create a score (**Table 3**). The NCI also uses a three-grade system based on histological subtype and the amount of necrosis. The prognostic information obtained with each system has been validated in many reports but problems remain. Subjectivity on the assessment of some histologic variables, uneven representation of specific

Table 3 French Federation of Cancer Centres system for sarcoma grading

A. Tumour differentiation score[a]	B. Tumour necrosis score[b]
1 Well-differentiated liposarcoma	0 No necrosis
Well-differentiated fibrosarcoma	1 ≤50% tumour surface examined
Well-differentiated MPNST	2 >50% tumour surface necrosis
Well-differentiated leiomyosarcoma	
Well-differentiated chondrosarcoma	
2 Myxoid liposarcoma	C. Mitotic activity score
Conventional fibrosarcoma	1 0–9 mitoses/10 HPF
Conventional MPNST	2 10–19 mitoses/10 HPF
Well-differentiated malignant haemangiopericytoma	3 ≥;20 mitoses/10 HPF
Myxoid MFH	
Typical storiform/pleomorphic MFH	
Conventional leiomyosarcoma	
Myxoid chondrosarcoma	
Conventional angiosarcoma	
3 Round cell liposarcoma	Final grade
Pleomorphic liposarcoma	Score A + score B + score C
Dedifferentiated liposarcoma	
Poorly differentiated fibrosarcoma	
Poorly differentiated MPNST	Score
Epithelioid malignant schwannoma	2–3 Grade 1 sarcoma
Malignant Triton tumour	4–5 Grade 2 sarcoma
Conventional malignant haemangiopericytoma	6–8 Grade 3 sarcoma
Giant cell and inflammatory MFH	
Poorly differentiated/pleomorphic/epithelioid leiomyosarcoma	
Synovial sarcoma (any subtype)	
Rhabdomyosarcoma (any subtype)	
Mesenchymal chondrosarcoma	
Poorly differentiated/epithelioid angiosarcoma	
Extraskeletal osteosarcoma	
Extraskeletal Ewing sarcoma/PNET	
Alveolar soft part sarcoma	
Malignant rhabdoid tumour	
Clear cell sarcoma	
Undifferentiated sarcoma	

[a]Tumours showing close similarity to normal adult tissue are scored 1, sarcomas of certain histological sybtype are scored 2 and sarcomas of uncertain histological subtype are scored 3.
[b]Estimated by microscopic review only.
HPF, high-power field (1 HPF = 0.174 mm^2); MFH, malignant fibrous histiocytoma; MPNST, malignant peripheral nerve sheath tumour; PNET, peripheral neurectodermal tumour.

sarcomas and lack of standardization of cutoff points among the reported series are factors that preclude universal acceptance of a particular grading system. Because soft tissue sarcomas are rare, prospective multicentre studies are needed to determine useful histological variables for each type of sarcoma.

The two most common staging systems are the American Joint Committee on Cancer/Union Internationale Contre le Cancer (AJCC/UICC) staging system (Fleming *et al.*, 1997) (**Table 4**) and the Enneking system (Enneking *et al.*, 1980). These systems are chiefly designed for the staging of adult soft tissue sarcomas. The AJCC/UICC system is a four-stage system based on tumour size, presence or absence of lymph node involvement and distant metastases and histological grade. Approximate 5-year overall survival rates for patients with soft tissue sarcomas in stages I, II and III are 95, 80, and 45%, respectively (**Figure 4**) (Pisters and Brennan, 2000). Important limitations of the AJCC/UICC system are the inclusion of lymph node status and the noninclusion of the anatomic site or the adequacy of the surgical margins. The first is a limitation in that lymph node metastases occur infrequently (2.6–5.9%) in sarcomas, in contrast to epithelial tumours. However, epithelioid sarcoma, angiosarcoma and rhabdomyosarcoma often do metastasize to lymph nodes. Most sarcomas metastasize hematogenously, and distant metastases are often present when lymph node involvement is discovered. Anatomical site is omitted in the AJCC/UICC system. Retroperitoneal, visceral and head and neck sarcomas are less likely to be completely resected without affecting vital structures; these

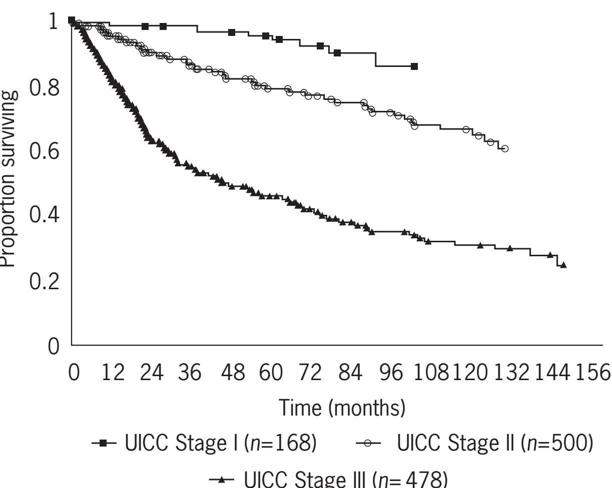

Figure 4 Overall survival for 1146 patients with primary soft tissue sarcoma according to the Union Internationale Contre le Cancer (UICC) staging system. Patients were treated at Memorial Sloan-Kettering Cancer Center, New York. (From Pisters and Brennan, 2000, by permission of Churchill Livingstone.)

sarcomas tend to be associated with a worse prognosis (see Treatment, below).

The Enneking system is surgical staging based on anatomical compartments and histological grade (Enneking *et al.*, 1980). The primary tumour is considered intracompartmental or extracompartmental according to its confinement within well-defined anatomic boundaries. Each of the system's three stages carries its own prognosis.

DIAGNOSIS

The diagnosis of soft tissue sarcoma requires a multidisciplinary approach. Physical examination, imaging studies, histological evaluation and ancillary techniques such as immunohistochemical analysis, electron microscopy, and cytogenetics molecular studies are important steps toward a correct diagnosis.

Clinical History and Physical Examination

Clinical findings alone are not specific for the diagnosis of a soft tissue tumour, but some clues point toward the possibility of a sarcoma. Information on age, sex, tumour location, the presence of genetic syndromes and the duration and quality of symptoms narrow the differential diagnosis substantially. In general, a soft tissue sarcoma presents as a painless mass of a few months' duration. Short duration of symptoms suggests a reactive process, such as that observed in nodular fasciitis (a pseudosarcomatous lesion commonly seen in the upper extremities of young patients). In contrast, long duration of symptoms suggests a benign tumour. Pain, paresthesias and paresis are observed when there is direct involvement or compression of major neurovascular structures and can occur with benign and malignant tumours. Organ-specific dysfunction also may occur due to the same causes. For example, large retroperitoneal liposarcomas can lead to renal dysfunction due to ureter compression. Paraneoplastic syndromes are seen rarely; examples include fever, weight loss, anaemia and paraproteinaemia occasionally seen in angiomatoid fibrous histiocytoma (see Angiomatoid Fibrous Histiocytoma, below); increased hepatic transaminases in the absence of liver metastases in patients with malignant peripheral nerve sheath tumour (Stauffer syndrome); osteomalacia in patients with phosphaturic mesenchymal tumour; and hypoglycemia in patients with solitary fibrous tumour. Patients who present with metastatic disease have symptoms and signs according to the location of the metastases.

Imaging Studies

After the initial clinical assessment, imaging studies often are needed for better delineation of soft tissue masses and their relation to surrounding normal structures. Simple radiographs have a limited role in the evaluation of soft tissue masses. However, simple radiographs can detect a soft tissue calcification or ossification, involvement of adjacent bone, or a possible bone origin of a soft tissue tumour (Kransdorf and Murphey, 1997). Computed tomography (CT) has been largely replaced by magnetic resonance imaging (MRI) in the evaluation of soft tissue tumours. Nonetheless, CT remains the best imaging technique for detecting pulmonary metastases, providing essential information for staging and

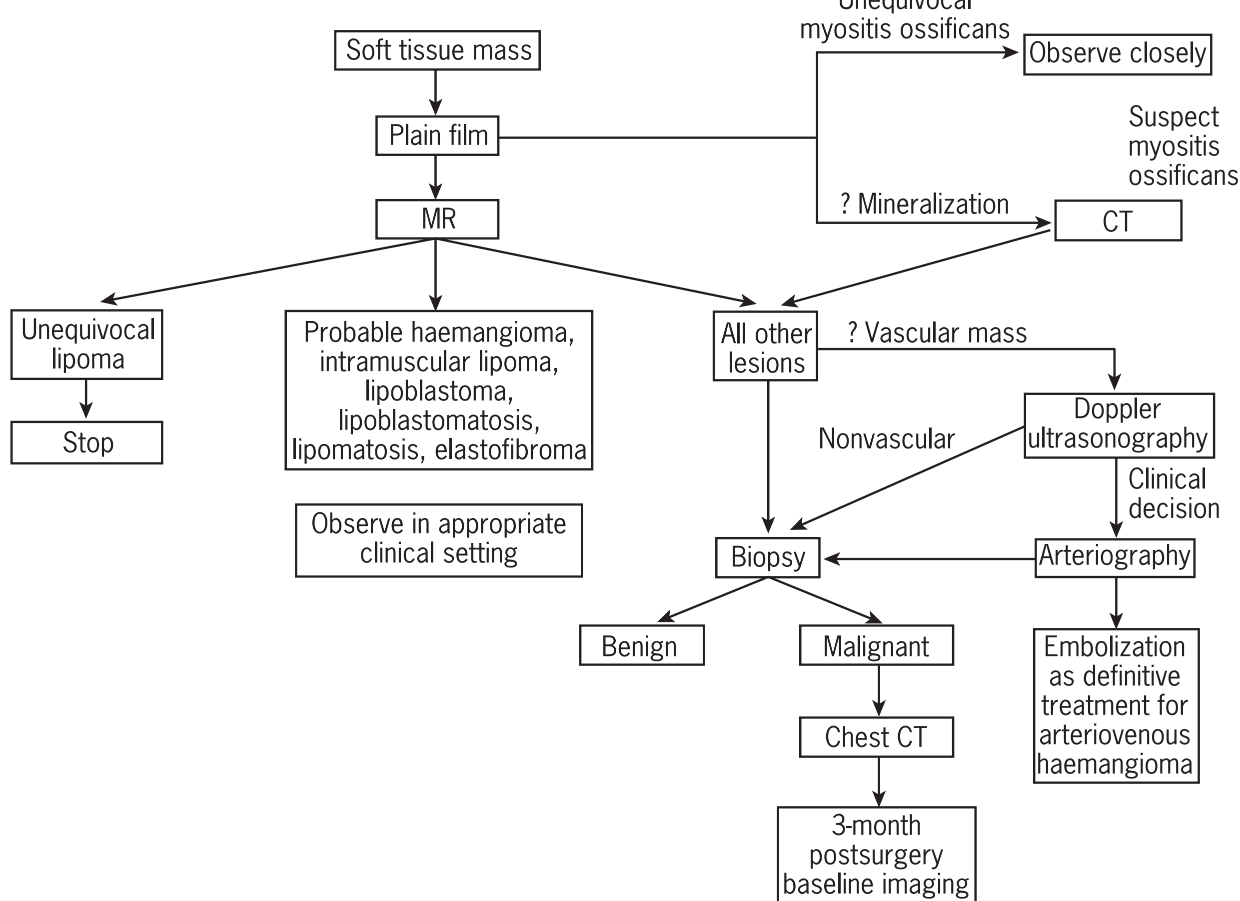

Figure 5 Algorithm for imaging evaluation of soft tissue masses proposed by Kransdorf and Murphey. CT, computed tomography; MR, magnetic resonance. (From Kransdorf and Murphey, 1997, by permission of WB Saunders.)

management. CT is superior in detecting calcification or ossification in soft tissue masses, such as zonal ossification in myositis ossificans, and has higher sensitivity than simple radiographs in detecting subtle bone involvement. Ultrasonography is useful for distinguishing between a solid and a cystic lesion and between soft tissue oedema and a soft tissue mass; it is also useful for guiding percutaneous biopsy. MRI is considered the gold standard because it provides precise information regarding tumour size, depth, local extension and relationship to normal structures such as vessels, bone and nerves. However, MRI is not usually diagnostic. Soft tissue lesions for which MRI can allow diagnosis include haemangioma, myositis ossificans, elastofibroma, fibromatosis, lipoma and liposarcoma, ganglion, haematoma, neurofibroma and malignant peripheral nerve sheath tumour (MPNST). Scintigraphy usually is not needed except to differentiate bone metastases from soft tissue tumours. Other imaging techniques are seldom used at present. An algorithm for imaging evaluation of soft tissue masses is shown in **Figure 5** (Kransdorf and Murphey, 1997). (Additional information can be found in the section on Diagnostic Imaging and Image-Guided Intervention.)

Biopsy and Basic Histological Assessment

Biopsy is usually the final step in the evaluation of soft tissue masses (see section on *Diagnostic Imaging*). It is generally advisable to perform a biopsy on any enlarging soft tissue mass (larger than 4–5 cm) with a median duration of 4–8 weeks in an adult patient (Pisters and Brennan, 2000). The biopsy can be closed or open. Closed procedures include core-needle biopsy and fine-needle aspiration (FNA). Open procedures include incisional and excisional biopsies. In incisional biopsies only part of the tumour is resected; in excisional biopsies the entire lesion is removed. Closed procedures, particularly core-needle biopsies, are the preferred method in most centres. FNA also is routinely used in many institutions and usually provides satisfactory results. In addition, ancillary techniques can be performed on FNA-obtained material. However, the most important role of FNA is documentation of tumour recurrence or metastasis. The major disadvantages of core biopsies and FNA are that tumour sampling is inadequate for precise histological analysis and, when

preoperative treatment with radiotherapy or chemotherapy is contemplated, a limited amount of tumour material is available for future studies. In these latter cases, the tumour is often largely necrotic after preoperative treatment and has few or no viable cells. Open procedures, such as excisional biopsies, are sometimes indicated for small superficial lesions, usually smaller than 4–5 cm. Imaging techniques such as CT and ultrasonography are important for guiding biopsy procedures.

Assessment of tumour type and histological grade is performed on paraffin-embedded, formalin-fixed material stained with haematoxylin and eosin. However, frozen material stained with haematoxylin and eosin or toluidine blue is commonly used in some institutions for a fast preliminary diagnosis.

Immunohistochemical Analysis

Immunohistochemical analysis has been extensively used in the study of soft tissue tumours and is primarily based on enzymatic methods, which work well on formalin-fixed material. The avidin–biotin–enzyme complex is one of the most commonly used methods. More than 30 markers are routinely used to evaluate soft tissue tumours, mainly for diagnostic purposes. Vimentin is a 57-kDa cytoplasmic intermediate filament present in almost all soft tissue tumours but also in some carcinomas and melanomas. In the analysis of soft tissue tumours, vimentin primarily is used as an internal control marker; its presence indicates preservation of tissue antigenicity. It is important to emphasize that vimentin is not useful to distinguish between sarcomas and other tumour types.

Cytokeratins are much more useful than vimentin for differentiating soft tissue sarcomas from carcinomas. However, cytokeratin expression is found in up to 5% of soft tissue sarcomas and is considered diagnostic for certain sarcomas. Well-known examples of sarcomas that express cytokeratins are synovial sarcoma, epithelioid sarcoma, desmoplastic small round cell tumour, MPNST, angiosarcoma, leiomyosarcoma, epithelioid haemangioendothelioma and rhabdoid tumour.

Epithelial membrane antigen (EMA) is a complex of proteins isolated from the human milk fat globule membrane. EMA is commonly expressed in synovial sarcoma, epithelioid sarcoma, MPNST, and other soft tissue tumours.

Muscle markers include desmin, muscle-specific actin (MSA HHF35), alpha smooth muscle actin (SMA 1A4), MyoD1 (also known as Myogenic Factor 3), myoglobulin, myogenin, calponin and caldesmon. Desmin is a 52-kDa intermediate filament expressed in leiomyosarcoma, rhabdomyosarcoma and other tumours of muscle differentiation. MSA comprises alpha (skeletal, smooth and cardiac) and gamma smooth muscle actin. MSA is expressed in more than 90% of leiomyosarcomas and 95% of rhabdomyosarcomas. SMA also is expressed in smooth muscle neoplasms such as leiomyosarcoma but is seldom expressed in rhabdomyosarcoma (1–2%). SMA expression frequently indicates the presence of myofibroblastic or myoid differentiation in nonmuscle tumours. MyoD1 is a 45-kDa protein member of a group of myogenic regulatory nuclear proteins that also includes myogenin, myf5 and mrf4-herculin/myf-6. MyoD1 is expressed in an early stage of skeletal muscle differentiation and is found primarily in rhabdomyosarcoma. Myoglobulin is a highly specific but not sensitive marker for rhabdomyoblastic differentiation, considering that it is primarily expressed in more differentiated rhabdomyosarcomas.

CD31, Factor VIII-related antigen (Factor VIIIRa) and CD34 are commonly used markers for endothelial differentiation. CD31 (glycoprotein gpIIa) is a membrane protein from the immunoglobulin supergene family. CD31 shows the highest sensitivity and specificity for endothelial differentiation, being detected in more than 80% of angiosarcomas. Factor VIIIRa is less sensitive than CD31 but is a useful marker for endothelial differentiation. CD34 (also known as haematopoietic progenitor cell antigen) is a 110-kDa transmembrane protein primarily expressed by human haematopoietic stem cells and endothelial cells. CD34 is sensitive but not specific for endothelial differentiation. CD34 expression is also of diagnostic importance in nonendothelial tumours such as DFSP, giant cell fibroblastoma, solitary fibrous tumour, and gastrointestinal stromal tumour.

S-100 protein, which is principally expressed by melanocytic tumours, also is expressed by soft tissue tumours, such as clear cell sarcoma (malignant melanoma of soft parts; 90% of tumours) and MPNST (50–70% of tumours). Nonetheless, S-100 expression has also been identified in other soft tissue sarcomas. CD68 is a 110-kDa lysosomal glycoprotein found mainly in monocytes and macrophages. In the past, CD68 and Factor XIIIa were considered markers of histiocytic differentiation. However, studies have shown the lack of specificity of both markers for this aim, limiting their diagnostic applicability. In addition, expression of CD68 and factor XIIIa by tumour-infiltrating histiocytes can lead to false-positive results.

p30/32 MIC2 (*M*onoclonal *I*mperial *C*ancer Research Fund *2*) or CD99 is a 32-kDa cell membrane glycoprotein encoded by the *MIC2* pseudoautosomal gene located on chromosome Xpter-p22.32. MIC2 is expressed by more than 95% of Ewing sarcoma/PNET. However, MIC2 also is expressed by other neoplasms, such as lymphomas, rhabdomyosarcomas, synovial sarcoma and mesenchymal chondrosarcoma.

Recently, immunohistochemical techniques have been developed to detect abnormal chimaeric proteins or amino acid sequences associated with specific sarcomas. It is expected that they will be used commonly in the future. Prognostic markers detected by immunohistochemical analysis include Ki-67, p53, Mdm2, Rb1 and p-glycoprotein (see Prognostic Factors, below).

Ultrastructural Analysis

With the advent of immunohistochemical and molecular techniques, the role of ultrastructural analysis in the diagnosis of soft tissue tumours is more limited but still important. Generally, ultrastructural analysis is required when histological, immunohistochemical and cytogenetic and molecular studies are inconclusive. Ultrastructural studies are useful in the identification of poorly differentiated rhabdomyosarcoma, the differentiation of sarcomatoid carcinoma or spindle cell melanoma from spindle cell sarcomas such as MPNST and monophasic synovial sarcoma and the identification of atypical forms of alveolar soft part sarcoma. Electron microscopy remains an important research tool, however, providing ultrastructural support for new morphological and immunohistochemical findings in many of the previously and most of the recently recognized tumours. For example, neuroendocrine differentiation in extraskeletal myxoid chondrosarcoma was confirmed through detection of neurosecretory granules by electron microscopy.

Cytogenetics, Molecular Cytogenetics and Molecular Genetics

Cytogenetic and molecular techniques are important adjuvant tools in the diagnosis of soft tissue sarcomas. Traditional cytogenetic evaluation has provided fundamental information regarding chromosomal abnormalities in soft tissue sarcomas. However, this technique depends on the availability of fresh viable tumour material and is time- and labour-intensive. Therefore, it is of limited clinical use in many centres.

Fluorescence *in situ* hybridization (FISH) was a considerable technical advance for chromosomal analysis. FISH relies on the use of fluorochrome-labelled complementary DNA (cDNA) probes that hybridize to specific DNA sequences. FISH can be performed not only in fresh tumour material but also in frozen and paraffin-embedded tissue. Both metaphase chromosomal spreads and interphase cells can be studied. In addition, FISH provides direct cell visualization, allowing correlation between histological and cytogenetic features. *In situ* hybridization can also be performed using enzymatic methods, such as the colorimetric *in situ* histochemistry (CISH).

Another important technique in the diagnosis of soft tissue sarcomas is the reverse transcriptase–polymerase chain reaction (RT-PCR), a variant of PCR. RT-PCR is used for detecting abnormal chimaeric mRNA transcripts on frozen and paraffin-embedded material. RT-PCR is preferred to standard PCR because chimeric mRNAs have more structural consistency than native chimeric genes owing to splicing of intronic sequences. More recently, RT-PCR has been tested to detect minimal disease in the peripheral blood in patients with Ewing sarcoma/PNET, rhabdomyosarcoma and myxoid liposarcoma. Southern blot is occasionally used but requires large amounts of frozen material (Ladanyi and Bridge, 2000). Because these methods have advantages and disadvantages, they should be viewed as complementary diagnostic tools. **Table 2** lists some chromosomal and genetic abnormalities that can be investigated with the above techniques.

CLINICOPATHOLOGICAL FEATURES

In this section, we discuss clinicopathological, immunohistochemical, ultrastructural and genetic features of specific sarcomas following the same schema (with some modifications) as used by the World Health Organisation for classification of soft tissue tumours. Rare sarcomas are not discussed; the reader is referred to comprehensive references on the subject.

Tumours of Fibroblastic and Myofibroblastic Differentiation

Fibromatoses

Fibromatoses are locally aggressive lesions without metastatic potential. They are broadly divided into superficial and deep (desmoid type). The main types of superficial fibromatosis are palmar fibromatosis (Dupuytren disease), plantar fibromatosis (Ledderhose disease) and penile fibromatosis (Peyronie disease). Fibromatoses usually occur in adults and can be bilateral. They are characterized by slow nodular fibroblastic and myofibroblastic proliferations that arise in fascias and aponeuroses. Immunohistochemical analysis shows the expression of vimentin and actin. A weak association of Dupuytren disease with alcoholism and epilepsy has been suggested. Cytogenetic studies often show trisomies 7, 8 and 14.

Deep fibromatosis or desmoid tumours are divided anatomically into three main types: extra-abdominal, abdominal and intra-abdominal. They frequently occur in young adults, and there is a female predominance. These tumours can be sporadic or familial. Intra-abdominal (mesenteric) fibromatosis occurs in 5–15% of patients with Gardner syndrome. Abdominal desmoid tumours are more common in females and tend to occur during or after pregnancy. Desmoid tumours commonly present as large tumours, usually exceeding 5 cm. They are characterized by a fascicular fibroblastic and myofibroblastic proliferation with infiltrative borders. Desmoid tumours are considered clonal lesions. Trisomies 8 and 20 and deletion of 5q (region of the *APC* gene) are common cytogenetic abnormalities. Overexpression of β-catenin has been implicated in the pathogenesis of desmoid tumours and seems related to mutations in the *APC* gene. In addition, β-catenin gene mutations have been found in sporadic desmoid tumours.

Clinically, desmoid tumours are characterized by high rates of recurrence (40%; 90% in some old series). Surgical excision followed or not by radiotherapy has been

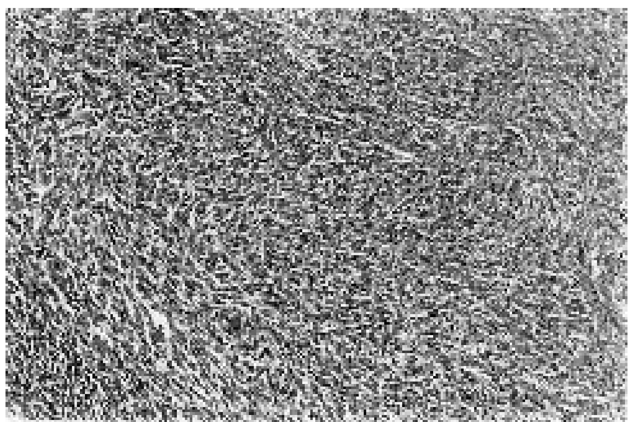

Figure 6 Fascicular spindle cell proliferation in a herringbone pattern is characteristic of but not specific for fibrosarcoma.

considered the therapy of choice. In a series including almost 200 patients, the overall 5- and 10-year relapse rates were 30 and 33%, respectively. Wide local excision with negative surgical margins provided the best results (Ballo *et al*., 1999). However, the need for negative surgical margins to prevent recurrence is not universally accepted. Because desmoid tumours express oestrogen receptors, the use of tamoxifen and anti-inflammatory drugs has been suggested, but the efficacy of these treatments is questionable. Chemotherapy has been attempted in patients with progressive disease.

Fibrosarcoma

Fibrosarcoma was a commonly diagnosed soft tissue sarcoma before the 1980s. However, major advances in immunohistochemistry, electron microscopy, cytogenetics and molecular genetics resulted in the reclassification of most cases as monophasic synovial sarcoma or MPNST. Currently, fibrosarcoma represents less than 5% of soft tissue sarcomas and is considered a diagnosis of exclusion. Fibrosarcoma usually occurs between the fourth and sixth decades of life, and there is a slight male predominance. The lower extremities and the trunk are the most common locations. Histological analysis shows fascicular spindle cell proliferation in a herringbone pattern, which is characteristic but not specific (**Figure 6**). Collagen deposition is usually small, and the cellularity is higher than that observed in deep fibromatoses. However, a low-grade fibrosarcoma can be misdiagnosed as a desmoid tumour. Fibrosarcoma shows immunoreactivity for vimentin only. Cytokeratin, EMA, actins, desmin and S-100 protein must be absent to rule out other differential diagnoses. No specific cytogenetic or molecular findings have been described for the adult type of fibrosarcoma. A study of more than 100 patients from the late 1980s found a 5-year overall survival rate of 40% (Scott *et al*., 1989).

Congenital Fibrosarcoma

Congenital or infantile fibrosarcoma (CF) occurs mainly during the first 2 years of life, has a male predominance and usually arises in the distal extremities. Histologically, it is characterized by a proliferation of oval to round cells with prominent mitotic activity arranged in shorter fascicles than the adult fibrosarcoma. A vascular pattern resembling that of haemangiopericytoma and a rich lymphocytic infiltrate are other frequently observed histological findings. The immunohistochemical profile of CF is similar to that of adult fibrosarcoma. The nonrandom chromosomal translocation t(12;15)(p13;q25) fusing the *ETV6* (*TEL*) gene (*ETS V*ariant *6*) on chromosome 12p13 and the *NTRK3*(*TRKC*) gene (*N*eurotrophin *T*y*R*osine *K*inase type-*3* receptor) on chromosome 15q25 has been found in CF and the cellular variant of congenital mesoblastic nephroma, supporting the view that they have a common pathogenesis. Trisomy 11 is also common in both tumours. Interestingly, the same chimeric gene *ETV6/NTRK3* is found in some cases of acute myelogenous leukaemia. Clinically, CF is characterized by its excellent prognosis (5-year survival rate >80%) and low metastatic potential (10%).

Fibrosarcoma Variants and Related Tumours

Some variants of fibrosarcoma or related lesions with distinct clinicopathologic features have been recognized. They include the low-grade fibromyxoid sarcoma, which should not be confused with myxofibrosarcoma (see Malignant Fibrous Histiocytoma below), the closely related hyalinizing spindle cell tumour with giant rosettes, sclerosing epithelioid fibrosarcoma, acral myxoinflammatory fibroblastic sarcoma and low-grade myofibroblastic sarcoma (myofibrosarcoma).

Inflammatory Myofibroblastic Tumour

Inflammatory myofibroblastic tumour (IMT) is also known as inflammatory pseudotumour, plasma cell granuloma, inflammatory myofibrohistiocytic proliferation, intra-abdominal myxoid hamartoma and inflammatory fibrosarcoma. IMT is a clonal disorder characterized by fascicles of deceptively bland myofibroblastic cells admixed with a prominent inflammatory infiltrate rich in plasma cells, lymphocytes and eosinophils. IMT occurs predominantly during childhood and is commonly associated with systemic symptoms. The abdominal cavity, retroperitoneum and lungs are commonly affected sites. IMT shows immunoreactivity for actin, which supports its myofibroblastic nature. Cytogenetically, recurrent rearrangements of the *ALK* gene (*A*naplastic *L*ymphoma *K*inase) on chromosome 2p23 with the tropomyosin genes *TPM3* and *TPM4* have been found in some cases of IMT (Lawrence *et al*., 2000). Interestingly, the chimaeric *TPM3/ALK* gene also has been described in anaplastic

large cell lymphoma. Expression of Alk protein can also be detected by immunohistochemical analysis. Clinically, IMT is characterized by local recurrence in up to 25% of cases and very low metastatic potential.

Tumours of Fibrohistiocytic Differentiation

The idea of fibrohistiocytic differentiation was introduced in the 1980s and was based on erroneous conclusions drawn from morphological, immunohistochemical and cell culture studies of poorly differentiated sarcomas. Currently, it is largely believed that most of these tumours show some degree of fibroblastic or myofibroblastic differentiation. In this chapter, the term fibrohistiocytic is used in accordance with the current literature and for purposes of classification only.

Atypical Fibroxanthoma

Atypical fibroxanthoma (AF) is a superficial fibrohistiocytic tumour with a bimodal age incidence. In older individuals, AF occurs in areas of solar exposure, such as the head and neck. In young patients, it commonly affects the trunk and extremities. However, it has been suggested that the pleomorphic variant of benign fibrous histiocytoma accounts for most cases of AF in young patients. Clinically, AF presents as small cutaneous nodules that sometimes ulcerate. Histologically, it is characterized by a storiform or fascicular proliferation of spindle and epithelioid cells exhibiting striking pleomorphism and high mitotic activity. Cellular lipidization is common. AF shows immunoreactivity for vimentin and other nonspecific markers. Actin has been detected in some cases, suggesting myofibroblastic differentiation. In a study using digital image analysis, the pleomorphic cells were shown to be aneuploid. In contrast, the spindle cells had a diploid DNA content. The prognosis is excellent, with very low recurrence rates (5%) and an exceedingly small metastatic potential. Local surgical excision using micrographic surgery (Mohs technique) seems to be the treatment of choice.

Dermatofibrosarcoma Protuberans and Giant Cell Fibroblastoma

Dermatofibrosarcoma protuberans (DFSP) and giant cell fibroblastoma (GCF) seem to represent two ends of the same spectrum of tumours. DFSP is a superficial sarcoma that occurs mainly during the third and fourth decades of life. The trunk and upper extremities are the most common locations. Histologically, DFSP is characterized by a storiform proliferation (resembling a rush mat) of spindle cells with minimal mitotic activity and infiltrative margins. The pigmented variant of DFSP, also known as Bednar tumour, is characterized by the presence of abundant melanin-pigmented dendritic spindle cells.

In contrast, GCF frequently occurs in male patients during the first decade of life. The thorax and lower extremities are the most common sites. Histologically, GCF is characterized by pseudovascular (angiectoid) spaces and solid areas where giant cell fibroblasts similar to florete cells are found in variable amounts. Mitotic activity is minimal. Immunohistochemistry shows that DFSP and GCF express vimentin and CD34. Neural, muscular and endothelial markers are usually absent. Ultrastructural analysis shows the presence of modified fibroblasts known as veil cells in both GCF and DFSP. Traditionally, cytogenetic studies have shown ring chromosome 17 in more than 75% of cases of DFSP. It has been further shown that these ring chromosomes harbour a nonrandom translocation t(17;22)(q22;q13) involving the *PDGFβ* gene (*P*latelet-*D*erived *G*rowth *F*actor β-chain) on chromosome 22q13 and the *COL1A1* gene (*COL*lagen type *I* *A*lpha *1*) on chromosome 17q22 in DFSP and GCF (Simon *et al.*, 1997). PDGFβ stimulates cell proliferation and transformation and COL1A1 is an important connective tissue matrix constituent. The chimaeric protein was shown to transform NIH3T3 fibroblast cell lines via an uncontrolled autocrine mechanism, reflecting its oncogenic ability. Clinically, DFSP is characterized by high recurrence rates (up to 75%) and low metastatic potential (1%). The presence of fibrosarcoma or malignant fibrous histiocytoma areas has been associated with higher metastatic rates (15%). This last impression, however, was questioned in one report. GCF also presents a high recurrence rate (up to 50%) but metastases have not been reported so far.

Plexiform Fibrohistiocytic Tumour

Plexiform fibrohistiocytic tumour (PFT) is a rare neoplasm that occurs predominantly in the dermis and subcutaneous tissue of the upper extremities during the first two decades of life. There is a strong female predilection. Histologically, PFT is composed of nodules of histiocyte-like and osteoclast-like giant cells (plexiform areas) separated by fascicles of spindle cells. Haemorrhage and haemosiderin deposition are common in the plexiform areas. Immunohistochemical studies have shown the presence of CD68 in the histiocyte-like and osteoclast-like giant cells and actin in the spindle cells. PFT shows a diploid DNA content. Cytogenetic studies are rare. PFT recurs locally in up to one-third of cases and metastasizes in one-fifth. Because of the tendency of PFT to recur locally, wide local surgical excision seems to be the treatment of choice.

Angiomatoid Fibrous Histiocytoma

Angiomatoid fibrous histiocytoma (AFH), previously known as angiomatoid malignant fibrous histiocytoma, is a rare subcutaneous tumour that arises predominantly in the extremities. AFH commonly occurs in the first three decades of life and does not show sex predilection. AFH may be associated with systemic symptoms, including fever, weight loss, anaemia and paraproteinaemia. These

seem to be caused by cytokines released by the tumour or by the associated inflammatory cells. Histologically, AFH is characterized by a nodular proliferation of oval to spindle cells associated with pseudovascular spaces. A rich lymphoplasmacytic infiltrate often surrounds the lesion. Immunohistochemical studies have shown the presence of vimentin, CD68, actin and desmin, which suggests that AFH has a line of differentiation similar to that of myoid fibroblastic reticulum cells found in the connective tissue of lymph nodes. Ploidy studies have shown a diploid DNA content in most cases. The chromosomal translocation t(12;16)(q13:p11) involving the *ATF-1* gene (*A*ctivating *T*ranscription *F*actor-*1*; see Clear Cell Sarcoma, below) on chromosome 12q13 and the *FUS* gene (*FUS*ion; see Myxoid and Round Cell Liposarcomas, below) on chromosome 16p11 was found in a case of AFH. Despite the need for confirmatory studies, this finding opened new avenues for the understanding of the pathogenesis of this tumour. AFH is characterized by low rates of local recurrence (10–20%) and limited metastatic potential (<2%). Surgical excision is considered the treatment of choice.

Malignant Fibrous Hystiocytoma

Malignant fibrous histiocytoma (MFH) comprises a heterogeneous group of undifferentiated neoplasms characterized by high pleomorphism and cellular atypia. In the past, a fibrohistiocytic origin was attributed to these neoplasms on the basis of morphological and functional similarities to fibroblasts and histiocytes found in studies of cell cultures. This misinterpretation was supported by the detection of nonspecific histiocytic markers on MFH. With advances in the immunohistochemical techniques and careful tissue sampling, many cases diagnosed as MFH have been reclassified as other high-grade tumours, such as pleomorphic liposarcoma, dedifferentiated liposarcoma, pleomorphic rhabdomyosarcoma, pleomorphic leiomyosarcoma, undifferentiated carcinoma and anaplastic large cell lymphoma. However, there is still a group of tumours that lack specific features and thus remain unclassifiable. Therefore, MFH is currently regarded as a group of tumours with fibroblastic characteristics but undetermined or aberrant lines of differentiation as compared with normal cell types. MFH is considered a diagnosis of exclusion.

MFH was once the most common soft tissue sarcoma. MFH most commonly occurs between the fifth and eighth decades of life and usually arises in the lower extremities (particularly thigh), upper extremities and retroperitoneum (Weiss and Enzinger, 1978). Males are affected slightly more frequently than are females. Histologically, MFH is divided into four variants: storiform/pleomorphic, myxoid, giant cell and inflammatory. Storiform/pleomorphic MFH is characterized by a proliferation (in a pattern resembling a rush mat) of spindle to oval cells and bizarre multinucleated cells showing prominent mitotic activity (**Figure 7**) (Weiss and Enzinger, 1978). Myxoid MFH, also known as myxofibrosarcoma, has a multinodular and mucinous appearance and tends to be more superficial than the storiform/pleomorphic variant. Myxoid MFH is unusual in the retroperitoneum. Extensive myxoid areas characterize this histological variant; these areas are rich in hyaluronic acid, have high vascularization and contain lipoblast-like cells (pseudolipoblasts). It is currently believed that the giant cell variant of MFH probably encompasses a group of distinct neoplasms rich in osteoclast-like giant cells; this variant includes giant cell-rich extraskeletal osteosarcoma, giant cell-rich pleomorphic leiomyosarcoma, giant cell-rich undifferentiated tumours and the soft tissue counterpart of the giant cell tumour of bone. Inflammatory MFH, the least common variant (<5%), most commonly is found in the retroperitoneum and often is associated with peripheral leucocytosis and systemic symptoms. Histologically, it is characterized by the presence of an inflammatory infiltrate rich in neutrophils, xanthomatous histiocytes, lymphocytes and eosinophils among bizarre Reed–Sternberg-like cells. MFH has no specific immunohistochemical profile; cytogenetic studies have shown very complex karyotypes.

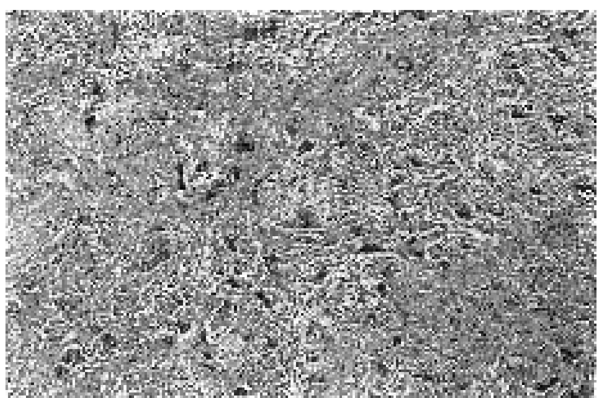

Figure 7 Malignant fibrous histiocytoma showing bizarre giant cells in a vague storiform pattern.

The prognosis of MFH is dictated primarily by its grade and stage. However, other clinicopathological features have been correlated with tumour aggressiveness. A retroperitoneal location and the inflammatory variant have been associated with a poor prognosis. In contrast, myxoid MFH tends to run a less aggressive clinical course. In a series of 216 patients with localized MFH, 5-year disease specific-free, metastasis-free and local recurrence-free survival rates were 70, 63 and 63%, respectively. The presence of high-grade histological features was considered the most important prognostic factor for metastasis-free and disease specific-free survival (Le Doussal *et al.*, 1996).

Sarcomas of Adipose Tissue Differentiation

Sarcomas of adipose tissue differentiation, or liposarcomas, are currently considered the most common soft

tissue sarcoma. This group comprises four major variants with distinct clinicopathological and genetic features: well-differentiated, myxoid/round cell, pleomorphic and dedifferentiated.

Well-differentiated Liposarcoma

Well-differentiated liposarcoma arises most commonly in the extremities and retroperitoneum. Histologically, well-differentiated liposarcoma is divided into three major subvariants: lipoma-like (adipocytic), sclerosing and inflammatory. A spindle cell variant also has been recognized. The lipoma-like variant is the most common and is predominantly composed of uniloculated adipocytes and scattered atypical multivacuolated lipoblasts. The sclerosing variant, which occurs most frequently in the retroperitoneum, has extensive fibrillary fibrotic areas where scattered multivacuolated lipoblasts are found. The inflammatory (or lymphocyte-rich) variant is characterized by the presence of lymphoplasmacytic nodular aggregates and may be misdiagnosed as inflammatory myofibroblastic tumour or Castleman disease. This variant often arises in the retroperitoneum. Well-differentiated liposarcomas arising in superficial locations also are known as atypical lipomas because they have an excellent prognosis and no metastatic potential. However, controversies regarding this nomenclature remain. Cytogenetic studies frequently show rings or giant rods derived from chromosome 12 in all subtypes of well-differentiated liposarcomas. These structures contain amplified 12q13-15 sequences, which include the *MDM2*, *SAS*, *HMGI-C* and *CDK4* genes. The clinical course of well-differentiated liposarcomas is usually excellent, with overall 5-year survival rates >90%. However, a worse prognosis has been found in retroperitoneal and dedifferentiated tumours. Local recurrence seems to be prevented by wide local excision and is more common in the retroperitoneum.

Myxoid and Round Cell Liposarcomas

Myxoid liposarcoma is the most common subtype of liposarcoma, representing 35–45% of all liposarcomas. It occurs mainly during the fifth decade of life, has a male predilection, and most commonly arises in the lower extremities, particularly the thigh (Kilpatrick *et al*., 1996). Histologically, myxoid liposarcoma is composed of spindle and stellated cells immersed in a myxoid matrix rich in hyaluronic acid. A chicken-wire pattern of vascularization is characteristic (**Figure 8**). Lipoblasts occasionally are found, and cystic degeneration of the matrix (resembling lymphangioma) is common.

Round cell liposarcoma is the cellular and poorly differentiated form of myxoid liposarcoma. Histologically, it is composed of round and larger cells with high mitotic and apoptotic activity. Cytogenetic and molecular studies have shown that myxoid and round cell liposarcomas share the same chromosomal translocations. The translocation

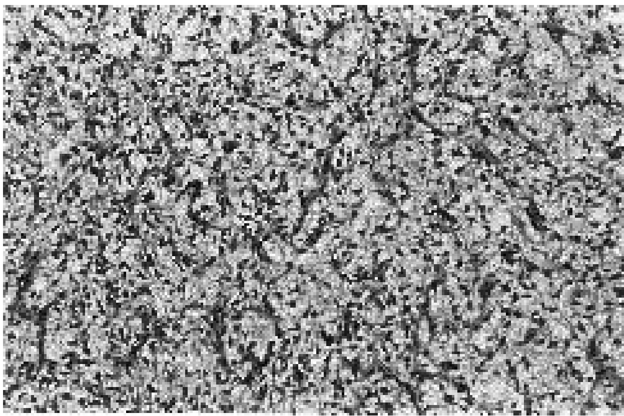

Figure 8 A chicken-wire pattern of vascularization is characteristic and almost diagnostic of myxoid liposarcoma.

t(12;16)(q13;p11) occurs in 95% of cases and involves the *TLS* gene (*T*ranslocated in *L*iposarcoma) or *FUS* gene (*FUS*ion) on chromosome 16p11 and the *CHOP* gene (*C*CAAT/enhancer binding protein *HO*mologous *P*rotein) or *DDIT3* (*D*NA-*D*amage-*I*nducible *T*ranscript *3*) on chromosome 12q13 (**Figure 9**) (Crozat *et al*., 1993; Rabbitts *et al*., 1993). *TLS* encodes for RNA-binding protein similar to the EWS protein (**Figure 2**). *CHOP* encodes for DNA-damage-inducible negative transcription regulator, which also is involved in adipocyte differentiation. In the second chromosomal translocation t(12;22)(q13;q12), which occurs in <5% of cases, the *EWS* gene on chromosome 22q12 fuses with *CHOP* (**Figure 9**). Both chimaeric proteins TLS/CHOP and EWS/CHOP can transform NIH3T3 fibroblasts, reflecting their oncogenic properties.

Myxoid liposarcoma has been associated with a relatively good prognosis, with a 5-year overall survival rate of 75%. Round cell differentiation has been considered the single most important adverse prognostic factor in myxoid liposarcoma (Kilpatrick *et al*., 1996). More recently, expression of the cell cycle inhibitor p27^{kip1} was associated with a prolonged metastasis-free and overall survival in myxoid/round cell liposarcoma (Oliveira *et al*., 2000).

Dedifferentiated Liposarcoma

Dedifferentiated liposarcoma is traditionally defined as a well-differentiated liposarcoma showing an abrupt transition to areas of high-grade pleomorphic histological features, similar to storiform/pleomorphic MFH or fibrosarcoma. However, low-grade dedifferentiated areas also have been recognized. Dedifferentiated liposarcoma is predominantly found in the retroperitoneum and appears to occur as a *de novo* phenomenon in >90% of cases. Divergent differentiation to osteosarcoma, chondrosarcoma, rhabdomyosarcoma, leiomyosarcoma and neural-like areas have been described.

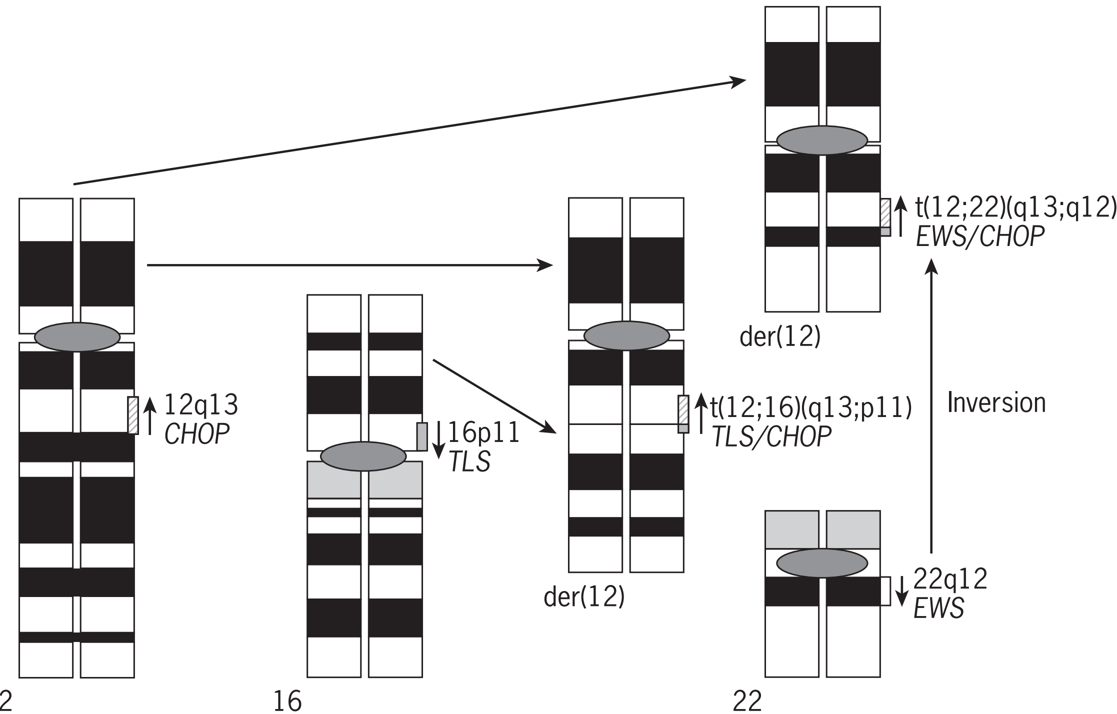

Figure 9 Schematic diagram showing two chromosomal translocations in myxoid liposarcoma: t(12;16)(q13;p11) and t(12;22)(q13;q12). The most common translocation (95% of cases) involves the fusion of the *CHOP* gene on chromosome 12q13 with the *TLS* gene on chromosome 16p11. Observe that the 5′ end of *TLS* gene on chromosome 16 fuses with the downstream sequences of the *CHOP* gene on the derivative chromosome 12. In the least common translocation (5% of cases), the 5′ end of *EWS* gene fuses with downstream sequences of *CHOP*. Observe that the *EWS* gene is read from centromere to telomere (c→t) on chromosome 22 and that the *CHOP* gene is read from telomere to centromere (t→c) on chromosome 16. This suggests that an inversion involving the *EWS* gene must occur before its fusion with the *CHOP* gene, which may explain the lower frequency of this second chromosomal translocation in myxoid liposarcoma. The derivative chromosomes 16 and 22 are not shown (arrowhead, 3′ end; arrow tail, 5′ end).

Immunoreactivity for S-100 protein, frequently found in liposarcomas, is not observed in the dedifferentiated areas. Mdm2 protein overexpression is common, and *TP53* gene mutations are rare. The amount and histological grade of the dedifferentiated component have not been correlated with outcome. In a large series of patients with dedifferentiated liposarcomas, the local recurrence, metastatic and disease-related mortality rates were 41, 17 and 28%, respectively. Overall 5-year survival rates of 50–70% have been estimated.

Pleomorphic Liposarcoma

Pleomorphic liposarcoma comprises <5% of the cases of liposarcoma and most frequently occurs in the extremities. Pleomorphic liposarcoma is a high-grade sarcoma showing MFH-like histological features, including the finding of scattered multiloculated lipoblasts. The incidence of pleomorphic liposarcoma is expected to increase because of ongoing reclassification of cases of MFH. The prognosis of pleomorphic liposarcoma parallels that of other high-grade sarcomas.

Sarcomas of Smooth Muscle Differentiation

Leiomyosarcoma is the single example of this group and probably represents 3–5% of soft tissue sarcomas. Leiomyosarcomas arising in soft tissues are clinically divided into four main types: cutaneous, subcutaneous and intramuscular, vascular and intra-abdominal. All types are morphologically and immunohistochemically indistinguishable. They are characterized by a fascicular proliferation of eosinophilic spindle cells with cigar-shaped nuclei and perinuclear vacuolization. The tumour fascicles tend to cross each other obliquely, a feature not readily appreciated in pleomorphic variants. Immunohistochemical studies show smooth muscle actin (SMA) in >90% of cases and desmin in 50–70% of cases. Approximately 40% of leiomyosarcomas express cytokeratin and epithelial membrane antigen. Cytogenetic studies frequently show complex karyotypes, and no consistent recurrent chromosomal abnormality has been identified. It has been suggested that 1p36 and 8p21p-ter chromosomal losses

may be associated with a more aggressive clinical course, but studies are needed to confirm these initial impressions.

Cutaneous Leiomyosarcoma

Cutaneous leiomyosarcoma occurs most frequently in the lower extremities of young adults. Clinically, they are painful tumours with almost no metastatic potential. Local recurrences occur in up to one-third of cases and seem strongly related to the adequacy of the surgical excision.

Subcutaneous and Intramuscular Leiomyosarcomas

Subcutaneous and intramuscular leiomyosarcomas occur more frequently in the thigh but the retroperitoneum also is a common site. In contrast to the cutaneous form, subcutaneous and soft tissue leiomyosarcomas frequently metastasize to the lungs. A 5-year overall survival rate of 64% was found in a large series of cases (Gustafson *et al*., 1992).

Vascular Leiomyosarcoma

Vascular leiomyosarcoma represents <5% of all cases of leiomyosarcoma. It arises most commonly in the inferior vena cava and in veins of the lower extremities (Enzinger and Weiss, 1995). There is no sex predilection except for those arising in the inferior vena cava, where a striking female predilection is observed. The pulmonary artery is the single most commonly affected arterial site. In a review of 144 cases of inferior vena cava leiomyosarcoma, radical tumour excision was associated with a better overall survival, despite high recurrence rates (50%) (Mingoli *et al*., 1991).

Intra-abdominal Leiomyosarcoma

Intra-abdominal leiomyosarcoma most commonly occurs in the retroperitoneum, omentum and mesentery and seems more common in females. These tumours can reach large sizes and often follow an aggressive clinical course. In a series of 44 cases, the overall 5-year survival rate was 21% (Hashimoto *et al*., 1985). However, with the advent of immunohistochemical analysis, some intra-abdominal leiomyosarcomas have been reclassified as extragastrointestinal stromal tumours (see the chapters *Upper Gastrointestinal Tract (Oesophagus, Stomach)* and *Lower Gastrointestinal Tract (Small Intestine, Appendix, Colon, Rectum, Anus*).

Sarcomas of Skeletal Muscle Differentiation

Rhabdomyosarcoma and its subtypes comprise this group of sarcomas. However, rhabdomyoblastic differentiation may be observed in other soft tissue sarcomas, such as malignant peripheral nerve sheath tumour with rhabdomyoblastic differentiation (Triton tumour), dedifferentiated liposarcoma and others.

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common peadiatric soft tissue sarcoma (Qualman *et al*., 1998). Classically, it is divided into the embryonal, botryoid, alveolar and pleomorphic types. However, modifications of this traditional classification are taking place and no schema is universally accepted. Currently, three histological variants are recognized: embryonal (50–60), alveolar (25–30) and pleomorphic (5%).

Embryonal rhabdomyosarcoma occurs most commonly in the first decade of life and is most commonly found in the head and neck area and in the genitourinary tract. It is characterized by a proliferation of small basophilic spindle cells associated with a variable number of rhabdomyoblasts (strap or tadpole cells) in a myxoid stroma. Variants of embryonal rhabdomyosarcoma include the spindle cell and botryoid. Spindle cell rhabdomyosarcoma occurs primarily in the paratesticular area and is associated with an excellent prognosis (5-year overall survival >85%). Botryoid rhabdomyosarcoma has a grape-like macroscopic appearance and most commonly occurs in the genitourinary tract. The characteristic histological finding is the condensation of the rhabdomyoblasts underneath the epithelial lining (cambium layer).

Alveolar rhabdomyosarcoma occurs more commonly in adolescents and frequently arises in the extremities, particularly in the distal segments of the upper extremities, and the trunk. It is characterized by nests of round basophilic cells separated by fibrous septa, simulating the pulmonary parenchyma. Osteoclast-like giant cells frequently are seen in the fibrous septa, and rhabdomyoblasts are scarce.

Pleomorphic rhabdomyosarcoma arises more commonly in the extremities of adults after the fourth decade of life and is associated with an aggressive clinical course. Histologically, it is similar to storiform/pleomorphic MFH and occasionally has large eosinophilic rhabdomyoblasts.

Two other rhabdomyosarcoma variants have been recognized: anaplastic and undifferentiated sarcoma. These terms are in the International Classification of Rhabdomyosarcoma (ICR). Anaplastic rhabdomyosarcoma is considered the pleomorphic variant of rhabdomyosarcoma that occurs in children. Undifferentiated sarcoma, which does not show any rhabdomyoblastic differentiation, is included in the ICR because it has a similar response to the chemotherapy used for other rhabdomyosarcomas (Qualman *et al*., 1998).

Immunohistochemical studies are important in the differential diagnosis of other tumours, such as Ewing sarcoma/PNET and desmoplastic small round cell tumour. Rhabdomyosarcoma cells express MSA (94%), desmin (80–95% of tumours), MyoD1 (90–95%) and myogenin (75–99%). Myoglobin is expressed in more differentiated rhabdomyoblasts and consequently is less sensitive (60–78%). SMA is present in a minority of cases (<5%).

Ultrastructural studies show the presence of thick myosin filaments associated with ribosomes and Z bands; this finding indicates muscle differentiation. Ultrastructural studies are particularly useful for the diagnosis of poorly differentiated rhabdomyosarcomas, such as pleomorphic and anaplastic rhabdomyosarcoma.

Cytogenetic and molecular studies have shown that alveolar rhabdomyosarcoma is associated with two chromosomal translocations. The translocation t(2;13)(q35;q14) occurs in 75% of cases and involves the fusion of the transcription factors *PAX3* gene (*PA*ired bo*X 3*) on chromosome 2q35 and *FKHR* gene (*F*or*KH*ead *R*elated) on chromosome 13q14 (Galili *et al*., 1993). In the translocation t(1;13)(p36;q14), which occurs in approximately 10% of cases, *FKHR* is fused with another partner, *PAX7*. *PAX3* and *PAX7* are specifically expressed during the development of the dorsal neural tube and somites. *PAX3* is also important for the migration of myoblasts to the limbs. Gene expression analyses using cDNA microarrays in alveolar rhabdomyosarcoma have shown that the *PAX3/FKHR* fusion transcript induces the expression of several genes involved in myogenic differentiation, including *MyoD1* and myogenin. In addition, PAX3 protein and the chimaeric protein FKHR/PAX3 stimulate the expression of the antiapoptotic protein BCL-X_L and the *MET* proto-oncogene. PAX7/FKHR fusion transcript in alveolar rhabdomyosarcoma was associated with a younger age at presentation, extremity location, prolonged event-free survival and a trend for a prolonged overall survival in a small series of cases (Kelly *et al*., 1997).

Embryonal rhabdomyosarcoma frequently shows loss of heterozygosity on 11p15, and this may contribute to the commonly observed overexpression of insulin-like growth factor-II (IGFII). The mechanism underlying this effect seems to result from loss of imprinting or loss of heterozygosity of the normally silent *IGFII* maternal-derived gene allele (see Epidemiology, Aetiology and Pathogenesis, above). Furthermore, loss of heterozygosity of the 11p15 locus can lead to loss of the tumour-suppressor gene *GOK*.

Three staging systems for rhabdomyosarcoma have been proposed: the Clinical Group System (CGS), the TNM system from the Union Internationale Contre le Cancer (UICC) and the TNM system from the American Joint Committee on Cancer (AJCC). The CGS is a surgico-pathological system based on the surgical resectability of the tumour. The TNM system proposed by the UICC is based on the invasiveness of the tumour according to the presence or absence of tumour confinement to a specific organ or muscular group. The TNM system proposed by the AJCC relies primarily on tumour size (Fleming *et al*., 1997). In the Intergroup Rhabdomyosarcoma Study-V, the information provided by these three systems has been combined to establish prognostic groups (**Table 5**).

Table 5 Prognostic groups for rhabdomyosarcoma

Stage	Group[a]	Site[b]	Size[c]	Age (years)	Histology[d]	Lymph nodes[e]	Distant metastasis[e]	Disease-free survival
1	I	Favourable	a or b	<21	Embryonal	N0	M0	
1	II	Favourable	a or b	<21	Embryonal	N0	M0	
1	III	Orbit only	a or b	<21	Embryonal	N0	M0	Excellent (>85%)
2	I	Unfavourable	a	<21	Embryonal	N0 or NX	M0	
1	II	Favourable	a or b	<21	Embryonal	N1	M0	
1	III	Orbit only	a or b	<21	Embryonal	N1	M0	
1	III	Favourable (no orbit)	a or b	<21	Embryonal	Any	M0	
2	II	Unfavourable	a	<21	Embryonal	N0 or NX	M0	Very good (70–85%)
3	I or II	Unfavourable	a	<21	Embryonal	N1	M0	
3	I or II	Unfavourable	b	<21	Embryonal	Any	M0	
2	III	Unfavourable	a	<21	Embryonal	N0 or NX	M0	
3	III	Unfavourable	a	<21	Embryonal	N1	M0	
3	III	Unfavourable	a	<21	Embryonal	Any	M0	Good (50–70%)
1 or 2 or 3	I or II or III	Any	a or b	<21	Alveolar	Any	M0	
4	Any	Any	a or b	<10	Embryonal	N0 or N1	M1	
4	IV	Any	a or b	>10	Embryonal	N0 or N1	M1	Poor (<30%)
4	IV	Any	a or b	<21	Alveolar	N0 or N1	M1	

[a]Group I, localized tumour, completely excised; group II, total gross tumour excision with evidence of regional spread; group III, incomplete excision with gross residual tumour; group IV, distant metastasis present at onset.
[b]Favourable sites are orbit and eyelid, nonparameningeal head and neck and nonbladder and nonprostate genitourinary tract; unfavourable sites are bladder, prostate, extremity, parameningeal and others.
[c]a, tumour size $\leq$5 cm; b, tumour size >5 cm.
[d]Embryonal, including also botryoid and spindle cell variants; alveolar, including also solid alveolar, anaplastic, and undifferentiated variants.
[e]N0, regional lymph nodes not clinically involved; N1, regional lymph nodes clinically involved; NX, lymph node status unknown; M0, no distant metastases; M1, distant metastases present.
Adapted from Wexler *et al*., 2000, Soft tissue sarcomas of childhood. In: Bust, R. C., Jr, *et al*. (eds), *Cancer Medicine*, 5th edn. 2198–2203. (B. C. Decker, Hamilton, ON), by permission of the publisher.

Treatment of rhabdomyosarcoma commonly entails chemotherapy, radiotherapy and surgical excision. Chemotherapy is indicated for unresectable tumours, to allow subsequent surgical excision, for elimination of microscopic disease after primary surgical excision and for metastatic disease. Radiation therapy is used to provide local tumour control after surgical excision or for metastatic disease. Vincristine, D-actinomycin, and cyclophosphamide are commonly used drugs (Arndt and Crist, 1999).

Clinical features and the histological subtypes of rhabdomyosarcoma seem the most important factors in predicting the overall prognosis (**Table 5**). The International Classification of Rhabdomyosarcoma divides rhabdomyosarcomas into those associated with a superior prognosis (botryoid and spindle cell variants of embryonal rhabdomyosarcoma), intermediate prognosis (embryonal rhabdomyosarcoma) and poor prognosis (alveolar and anaplastic or undifferentiated) (Newton *et al*., 1995; Qualman *et al*., 1998). In a large series of cases from the Intergroup Rhabdomyosarcoma Study, 5-year overall survival rates of 95, 88, 64 and 53% for botryoid, spindle cell, embryonal and alveolar subtypes, respectively, were found. By multivariate analysis, the histological categories retained their prognostic significance after adjustment for other prognostic factors in rhabdomyosarcoma, such as tumour sizes primary site, and clinical group (Newton *et al*., 1995).

Sarcomas of Endothelial and Pericytic Differentiation

The three most important sarcomas showing endothelial differentiation are epithelioid haemangioendothelioma, Kaposi sarcoma and angiosarcoma. These sarcomas and haemangiopericytoma are discussed below.

Epithelioid Haemangioendothelioma

Epithelioid haemangioendothelioma is a rare vascular tumour that occurs most commonly in the superficial and deep soft tissues, liver and bone. The tumour affects mainly adults in the fourth to sixth decades of life. Approximately 60% of cases arise in a vessel, usually a vein of medium size or larger. Histologically, it is characterized by cords and nests of round to spindle eosinophilic cells arranged in a myxohyaline stroma. The cells commonly exhibit an intracytoplasmic vacuolization (signet ring-like cells) in which erythrocytes occasionally are found. Mitotic activity is usually very low. Immunohistochemical studies show the expression of vascular markers, such as factor VIIIRa, CD31 and CD34. Expression of cytokeratin and actin is frequently found. Ultrastructural studies support its endothelial differentiation. Cytogenetic and molecular studies are almost nonexistent, but the balanced chromosomal translocation t(1;3)(p36.3;q25) was recently found in two cases. Epithelioid haemangioendothelioma is less aggressive than angiosarcoma, but it metastasizes in 20% of cases and has a mortality rate of 17% when it occurs in soft tissues. Higher mortality rates are seen in hepatic and pulmonary tumours.

Kaposi Sarcoma

Kaposi sarcoma is a unique tumour showing features of lymphatic endothelial differentiation. Whether Kaposi sarcoma is a reactive process or a true neoplasm remains to be settled because monoclonality has been shown by some but not all investigators (Gill *et al*., 1998). A multicentric clonal evolution has been proposed to explain the pathogenesis of Kaposi sarcoma. In this elegant model, Kaposi sarcoma arises from independent cells and acquires clonal characteristics during tumour progession (Gill *et al*., 1998).

Kaposi sarcoma traditionally has been divided into four clinical variants: classical, endemic, post-transplant-associated or immunosuppression-associated and epidemic or acquired immunodeficiency syndrome (AIDS)-associated (Antman and Chang, 2000). The classical form is prevalent in Eastern Europe and the Mediterranean and typically presents as indolent purple–blue cutaneous nodules on the lower extremities of elderly men. An increased risk of haematological disorders, particularly Hodgkin lymphoma, has been attributed to this variant. The endemic form occurs in human immunodeficiency virus (HIV)-negative individuals and commonly manifests as indolent nodular lesions associated with localized or generalized lymphadenopathy. A more aggressive form is commonly found in children (Antman and Chang, 2000). The transplant-associated or immunosuppression-associated Kaposi sarcoma is an aggressive form that occurs months or years after transplantation or the beginning of immunosuppression. It often is characterized by lymphatic or visceral manifestations (Antman and Chang, 2000). The epidemic or AIDS-associated Kaposi sarcoma is a very aggressive form that involves the skin, mucosas, viscera and lymph nodes. It is more commonly seen in homosexual AIDS patients.

Independent of clinical presentation, all Kaposi sarcoma are histologically similar. The relationship between Kaposi sarcoma and Kaposi sarcoma-associated herpes virus is discussed above (see Epidemiology, Aetiology and Pathogenesis, above). Histologically, Kaposi sarcoma is characterized by a spindle cell nodular proliferation separated by slit-like thin-walled vascular channels. Extravasated erythrocytes, haemosiderin deposition and hyaline intracytoplasmic and extracytoplasmic PAS-positive globules are commonly seen. Immunohistochemical analysis shows CD31 and CD34 in most cases and variable expression for factor VIIIRa, consistent with Kaposi sarcoma endothelial differentiation. Treatment includes surgical excision (simple excisions), radiation therapy and single or multiple agent chemotherapy, including interferon-α (Antman and Chang, 2000).

Angiosarcoma

Known in the past as malignant haemangioendothelioma or lymphangiosarcoma, angiosarcoma is a highly malignant neoplasm of endothelial differentiation. The term angiosarcoma encompasses blood and lymphatic vascular tumours because no current technique reliably differentiates the two. However, new markers specific for the lymphatic endothelium, such as M2A oncofoetal antigen may shed some light on this issue. Aetiological factors associated with the development of angiosarcoma are discussed above (see Epidemiology, Aetiology and Pathogenesis).

Clinically, angiosarcomas are divided into four groups: cutaneous, soft tissue, postirradiation and visceral. Cutaneous angiosarcoma not associated with lymphoedema shows a predilection for elderly men and most frequently occurs in the head and neck region, particularly in the scalp. It is characterized by a haemorrhagic appearance and multinodularity. The prognosis is reserved, with 5-year overall survival rates <35%. Cutaneous angiosarcoma associated with chronic lymphoedema is discussed above (see Epidemiology, Aetiology and Pathogenesis).

Soft tissue angiosarcoma occurs predominantly in the abdominal cavity, including the retroperitoneum, and lower extremities of older men. As in the cutaneous form, the prognosis is very poor, with more than 50% of patients dying before 1 year after the diagnosis. In a large series of cases, older age, the presence of retroperitoneal tumours and high expression of the proliferative marker Ki-67 were associated with a more aggressive clinical course (Meis-Kindblom and Kindblom, 1998).

Postirradiation angiosarcoma is a highly aggressive tumour that tends to have a shorter latent period than other irradiation-induced sarcomas. Postirradiation angiosarcoma should not be confused with the cutaneous angiosarcoma associated with chronic lymphoedema. Visceral angiosarcoma often occurs in the liver, breast and spleen and is discussed in the respective chapters.

Histologically, all clinical types of angiosarcoma are characterized by an infiltrative proliferation of anastomosing irregular vascular spaces lined by atypical and pleomorphic endothelial cells. Immunohistochemical studies show the expression of Factor VIIIRa, CD31 and CD34 in most cases and the expression of cytokeratin in 35%. However, immunoreactivity for some endothelial markers tends to be lost in more undifferentiated areas. Cytogenetic and molecular studies are limited, and no specific abnormality has been found. *TP53* and K-*RAS2* gene mutations are common. A proliferative autocrine loop mediated by vascular endothelial growth factor (VEGF) and its receptor FLT has been proposed for the pathogenesis of angiosarcoma.

Haemangiopericytoma

Haemangiopericytoma has been considered a controversial entity since it was first described more than 50 years ago. Its putative pericytic nature was suggested by its morphological similarities to normal pericytes. However, this analogy has not been confirmed by immunohistochemical analysis since most haemangiopericytomas do not express actin, which is normally expressed by pericytes. Most cases diagnosed as haemangiopericytoma have been reclassified as entities such as monophasic synovial sarcoma, mesenchymal chondrosarcoma and solitary fibrous tumour. Currently, the most prevalent opinion is that haemangiopericytoma is a morphological pattern shared by distinct entities, and only a few unclassifiable cases should be termed haemangiopericytoma. Moreover, the old subdivision of haemangiopericytoma into adult and infantile forms no longer holds because the latter has been reclassified as myofibroma. Cases that still deserve the label haemangiopericytoma are some soft tissue tumours that arise in the retroperitoneum and pelvis, meningeal haemangiopericytoma (previously known as angioblastic meningioma), and sinonasal haemangiopericytoma.

Histologically, haemangiopericytomas are composed of a vague nodular proliferation of basophilic oval cells arranged around dilated thin-walled vessels with a characteristic staghorn appearance. Nuclear atypia, high mitotic activity, high cellularity and necrosis and haemorrhage tend to be associated with a more aggressive clinical course. Immunohistochemical analyses show the expression of vimentin and CD34. Actin is expressed more consistently by sinonasal haemangiopericytomas. Clinically, some haemangiopericytomas are associated with hypoglycaemia, which seems to be caused by IGF and IGF receptor expression by the tumour. Meningeal haemangiopericytomas often are associated with an aggressive clinical course characterized by local recurrences and metastases. Sinonasal haemangiopericytomas tend to recur locally but do not mestastasize.

Sarcomas of Peripheral Neuroectodermic Differentiation

Extraskeletal Ewing Sarcoma and Peripheral Primitive Neuroectodermal Tumour (PNET)

Extraskeletal and skeletal Ewing sarcoma and peripheral primitive neuroectodermal tumour (PNET) (also known as neuroepithelioma) represent opposite ends of a continuum of primitive tumours showing various degrees of neuroectodermic differentiation. Ewing sarcoma is the more undifferentiated tumour and PNET the more differentiated tumour. In extraskeletal sites, they tend to occur in the paravertebral areas, thoracopulmonary region (Askin tumour) and lower extremities of adolescents and young adults. There is no sex predilection but African Americans are rarely affected.

Histologically, sheets or lobules of small round cells separated by strands of fibrous tissue are characteristic

but not specific. Homer Wright rosettes frequently are found in PNET. Brisk mitotic activity and areas of confluent necrosis (filigree pattern) are found in both Ewing sarcoma and PNET. Immunohistochemical studies show the expression of the MIC2 protein in both tumours. Expression of neuron-specific enolase, synaptophysin, Leu-7 (CD57), neurofilament, S-100 protein and the protein gene product 9.5 (PGP 9.5) as well as the presence of Homer Wright rosettes have been suggested as diagnostic criteria for PNET because they indicate neuroectodermal differentiation. (See also the chapter *Bones*.)

Cytogenetic studies done mostly in skeletal tumours have shown the balanced translocations t(11;22)(q24;q12) and t(21;22)(q22;q12) in 95% and 5% of cases, respectively (Sandberg and Bridge, 2000). In these translocations, the *EWS* gene on chromosome 22q12 fuses with *FLI1* gene on chromosome 11q24 or *ERG* gene on chromosome 21q22, respectively. Other translocations have been identified involving the *EWS* gene in a minority of cases (**Table 2**). *EWS/FLI1* has been shown to transform mouse NIH3T3 fibroblasts in transfection experiments, which reflects its oncogenic properties. Among several types of *EWS/FLI1* transcripts, the fusion of the *EWS* exon 7 with the *FLI1* exon 6 is the most common (type I) (**Figure 1**) and has been associated with a more aggressive disease independent of stage, tumour location and age (de Alava *et al*., 1998). However, the clinical significance of individual transcripts other than those of type I remains unknown. Other common cytogenetic abnormalities are trisomies 8 and 12, der(16)t(1;16)(q12;q11.2) and deletion 1p36. The first two appear to represent independent events during tumour evolution. The inactivation by distinct mechanisms of the tumour suppressor gene $p16^{INK4}$ has been correlated with a worse prognosis in Ewing sarcoma.

Many other prognostic factors have been suggested for Ewing sarcoma/PNET but detection of distant metastases at presentation, which occurs in approximately 25% of patients, is the most adverse (Terrier *et al*., 1996). The value of neuroectodermal differentiation as a prognostic factor in Ewing sarcoma/PNET remains controversial. Treatment of localized skeletal Ewing sarcoma/PNET consists of a combination of surgical excision, radiotherapy and chemotherapy. The most commonly used agents are vincristine, doxorubicin, cyclophosphamide, D-actinomycin, etoposide and ifosfamide. The 5-year overall survival rate can reach 70% for patients with localized disease and 20–30% for those who presented with distant metastasis (Arndt and Crist, 1999). Treatment and survival data on extraskeletal Ewing sarcoma/PNET are limited, and the clinical course seems more aggressive. The overall 5-year survival rate appears to be <40%. Potential new treatments for Ewing sarcoma/PNET have been reported. The use of monoclonal anti-CD99 and nanocapsules with antisense *EWS/FLI1* were shown to inhibit Ewing sarcoma cells in both *in vitro* and *in vivo* experiments.

Malignant Peripheral Nerve Sheath Tumour

Malignant peripheral nerve sheath tumour (MPNST), formerly known as malignant schwannoma and neurofibrosarcoma, is divided into three clinical groups: neurofibromatosis type I-associated (40–50%), sporadic (40–50%) and postirradiation (5–10%). The lifetime risk for the development of MPNST in patients with neurofibromatosis type I (NF1) is estimated to be 2%. The anatomical distribution is wide, and there is a male predominance. The incidence of NF1-associated MPNST peaks during the fourth decade of life. The sporadic form occurs more often in the lower extremities, shows no sex predilection and peaks during the fifth decade of life. The postirradiation form is the least common and occurs up to 30 decades after the radiation therapy.

Histologically, MPNST is characterized by a fascicular spindle cell proliferation in which there is an abrupt transition from more cellular areas to more myxoid areas. Whorling of tumour cells around vascular spaces is another characteristic feature. In 10% of cases, rhabdomyoblastic differentiation is observed (Triton tumour), which portends a more aggressive clinical course. MPNST shows epithelioid phenotype in 5% of cases. This variant tends to be superficially located and is associated with a more favourable outcome. A pigmented variant also has been described. The traditional criteria for the diagnosis of MPNST relied on the presence of a spindle cell tumour with ultrastructural evidence of Schwann cell differentiation arising in association with a nerve or a benign peripheral nerve tumour (i.e. neurofibroma) in a patient with neurofibromatosis. However, better recognition of MPNST's morphological features and the advent of immunohistochemical analysis has changed this view. MPNST expresses S-100 protein in approximately 50% of cases.

Cytogenetic studies have shown complex karyotypes in most cases, but structural abnormalities involving chromosomes 17 and 22 are occasionally found. Accumulation of mutant p53 protein was found to be higher in MPNSTs than in neurofibroma, suggesting a role for *TP53* mutations in neurofibroma transformation to MPNST. In addition, the proliferative marker Ki-67 tends to be higher and the cell cycle inhibitor $p27^{kip1}$ lower in MPNST than in neurofibroma.

The overall 5-year survival rates for patients with MPNST are approximately 50% for those with the sporadic form, 25% for those with NF1 and 10% for those with postirradiation MPNST. In two large series of cases, tumour size larger than 5 cm, history of NF1 and incomplete surgical excision were associated with a worse prognosis.

Clear Cell Sarcoma (Malignant Melanoma of Soft Parts)

Clear cell sarcoma of tendons and aponeuroses, also known as malignant melanoma of soft parts, is a rare soft

tissue sarcoma that tends to occur in adolescents and young adults. The foot and ankle, followed by the knee, are the most commonly affected sites, despite a wider anatomical distribution. Histologically, clear cell carcinoma is characterized by nests of polygonal or spindle cells separated by delicate fibrous septa. The cells have a clear or eosinophilic cytoplasm and prominent nucleolus. Mitoses are uncommon. Giant cells and melanin pigmentation are seen with some frequency. Ultrastructural studies show the presence of premelanosomes in approximately 50% of cases. Immunohistochemical analyses show expression of S-100 protein, HMB-45 and Melan A.

Cytogenetically, clear cell carcinoma is characterized by the chromosomal translocation t(12;22)(q13;q12), which results in the fusion of the DNA-binding domain of the *ATF-1* gene (*A*ctivating *T*ranscription *F*actor-*1*) located on chromosome 12q13 with the $5'$-end of the *EWS* gene. The chimaeric protein EWS/ATF-1 binds to ATF-DNA binding sites and leads to altered induction of cAMP-inducible promoters. Studies have shown that antibodies against the EWS/ATF-1 protein trigger tumour apoptosis. In addition, the somatostatin gene promoter may be a potential target for drug therapy.

Clear cell sarcoma is characterized by the development of metastasis in 50% of patients, most commonly to lungs and lymph nodes. The overall 5-year survival rate is 65% according to the results in one series. Factors associated with a more aggressive clinical course include larger tumour size, presence of necrosis and nondiploid DNA content. Local radiation therapy was associated with prolonged survival by univariate analysis in a series of 30 cases.

Sarcomas of Osseous or Cartilagenous Differentiation

Extraskeletal Osteosarcoma

Extraskeletal osteosarcoma (ESO) represents <1% of soft tissue sarcomas and occurs mainly after the sixth decade of life. Males are more commonly affected than females. The lower extremities, particularly the thigh, are more frequently involved. Histologically, ESO is similar to malignant fibrous histiocytoma, with a high degree of pleomorphism and brisk mitotic activity. Osteoid formation, present in ESO, differentiates it from malignant fibrous histiocytoma. Extensive areas of necrosis are also common. Immunohistochemical studies are largely nonspecific. However, the expression of osteocalcin and osteonectin, common bone proteins, by tumour cells and osteoid matrix can be used to differentiate ESO from other pleomorphic soft tissue sarcomas. Cytogenetic and molecular data are almost nonexistent, in contrast to data on bone osteosarcoma. Clinically, ESO follows an aggressive clinical course characterized by multiple local recurrences and metastases in >60% of patients. The 5-year overall survival rate is approximately 20–35%. Tumour size smaller than 5 cm, chondroblastic differentiation and a Ki-67 index <24% seem to be associated with a better survival.

Mesenchymal Chondrosarcoma

Mesenchymal chondrosarcoma occurs most often in bone (65%) and soft tissues (35%) of adolescents and young adults. In soft tissues, the most common anatomical sites are the head and neck region and the lower extremities. Histologically, it has a biphasic appearance in which islands of well-developed cartilage are intermixed with areas composed of primitive small ovoid cells. Haemangiopericytoma-like areas are also common. Immunohistochemical studies show expression of S-100 protein in the cartilage areas and MIC2 in the small round cells. Cytogenetic and molecular studies are rare. Investigation of the differential expression of collagen subtypes has suggested that mesenchymal chondrosarcoma has a line of differentiation consistent with premesenchymal chondroprogenitor cells. Mesenchymal chondrosarcoma is characterized by an aggressive clinical course with frequent lung metastasis. The overall 5-year survival rate is approximately 50%.

Extraskeletal Myxoid Chondrosarcoma

Extraskeletal myxoid chondrosarcoma (EMC) occurs predominantly in the lower extremities of individuals in the fifth to eighth decades of life. Histologically, EMC is a multilobular neoplasm composed of cords of small eosinophilic cells immersed in a myxoid matrix. Intracisternal bundles of parallel microtubules and scattered neurosecretory granules are characteristic but not specific ultrastructural findings. Immunohistochemical analysis shows the expression of vimentin and synaptophysin in most cases, indicating neuroendocrine differentiation, and S-100 protein in a minority of cases. Cytogenetic and molecular studies have shown the presence of the chromosomal translocations t(9;22)(q22;q12) and t(9;17) (q22;q11) in 75 and 25% of cases, respectively. In these translocations the *CHN* gene, a member of the steroid/thyroid receptor gene superfamily located on chromosome 9q22 is fused with either *EWS* on chromosome 22q12 or $RPB56/hTAF_{II}68$ on chromosome 17q11, respectively. Clinically, EMC is characterized by an indolent clinical course in most but not all patients. Metastases, most commonly to the lungs, occur in up to 50% of patients. The 5 and 10-year overall survival rates are 90% and 70–80%, respectively.

Sarcomas of Uncertain Line of Differentiation

This group of sarcomas is mainly represented by synovial sarcoma, epithelioid sarcoma, alveolar soft part sarcoma, desmoplastic small round cell tumour and extrarenal rhabdoid tumour.

Synovial Sarcoma

Synovial sarcoma was placed in the category of sarcomas of uncertain line of differentiation because its putative synovial differentiation has not been confirmed. It represents approximately 10% of all soft tissue sarcomas, but this figure is expected to increase owing to better recognition of monophasic and poorly differentiated variants using immunohistochemical, cytogenetic and molecular techniques. Synovial sarcoma has a slight predilection for males and occurs at any age, particularly affecting adolescents and young adults. It can arise in any site but is more common in the lower extremities. Despite its common periarticular location, intra-articular synovial sarcoma is exceedingly rare.

Histologically, synovial sarcoma is classified into biphasic, monophasic and poorly differentiated variants. The biphasic variant is composed of epithelial and spindle cell components. The epithelial component has a glandular appearance; the spindle cell component comprises fascicles of spindle cells frequently arranged in a herringbone pattern similar to that in fibrosarcoma (**Figure 7**). Monophasic synovial sarcoma can be purely epithelial, which is very rare, or purely spindled. Areas with a haemangiopericytoma-like vascular pattern as well as mast cell infiltration are common. Calcification and metaplastic ossification are also frequent, being detected in plain films in up to 30% of cases. The undifferentiated form of synovial sarcoma has a round cell shape that may simulate Ewing sarcoma/PNET.

Immunohistochemical analysis shows expression for vimentin, epithelial membrane antigen (EMA) and cytokeratin. EMA and cytokeratin are commonly expressed by the epithelial component and only focally expressed by the spindle cell component. In addition, it has been shown that synovial sarcoma commonly expresses cytokeratins 7, 13 and 19 but not cytokeratins 8 and 18. S-100, MIC2, and the antiapoptotic protein Bcl-2 also are expressed in many cases. More recently, *Her-2/neu* gene amplification and protein overexpression were found in cases of synovial sarcoma.

With the use of modern cytogenetic techniques, the characteristic translocation t(X;18)(p11.2;q11.2) is found in most cases (>99%), including cases of poorly differentiated tumours (**Table 2**). This translocation results in the fusion of the *SYT* gene (*SY*novial sarcoma *T*ranslocation) on chromosome 18q11.2 with members of the *SSX* family of genes (*S*ynovial *S*arcoma *X* chromosome breakpoint) on chromosome Xp11.2 (*SSX-1*, *SSX-2*, and, more rarely, *SSX-4*; the other members, *SSX-3*, *SSX-5*, and *SSX-6* have not been detected in synovial sarcoma translocations) (Clark *et al*., 1994). Whereas *SYT* encodes for a ubiquitously expressed nuclear protein that seems to function as a transcriptional coactivator, *SSX* encodes for transcription repressor proteins. The mechanism of action of the chimaeric protein remains unknown, but it has been suggested that it works through recruitment of the PcG complex of proteins involved in transcriptional repression.

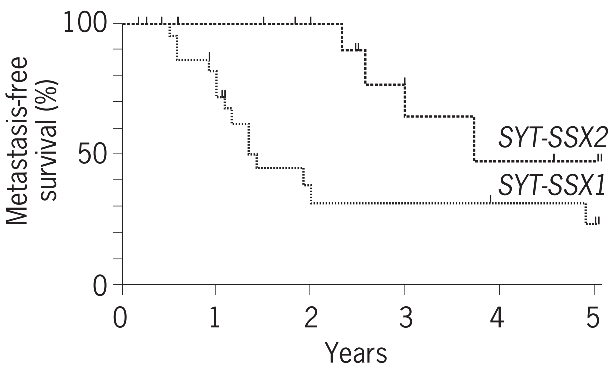

Figure 10 In synovial sarcoma, patients with the *SYT/SSX-1* fusion transcript had shorter metastasis-free survival than patients with the *SYT/SSX-2* fusion transcript (hazard ratio = 3; 95% confidence interval = 1.1–8; $P = 0.03$; Cox regression model). (From Kawai *et al.*, 1998, SYT-SSX gene fusion as a determinant of morphology and prognosis in synovial sarcoma. *New England Journal of Medicine*, **338**, 153–160, by permission of the Massachusetts Medical Society.)

It has also been shown that the *SYT/SSX-1* fusion transcript, which is detected in 65% of cases, is associated with biphasic histological findings, a high proliferation rate, and shorter metastasis-free survival (**Figure 10**). The specificity of the t(X;18) for synovial sarcomas has been questioned because it also has been found in some cases of MPNST, suggesting that MPNST and synovial sarcoma may be part of the same spectrum of tumours. However, these intriguing results need further confirmation.

Many adverse prognostic factors have been proposed for synovial sarcoma, including older age, larger tumour size, poorly differentiated histological features, nuclear grade, necrosis, mitotic activity, low mast cell infiltration, Ki-67 expression, *TP53* mutations, bone or neurovascular invasion, *SYT/SSX-1* chimaeric gene and hepatocyte growth factor. However, the clinical utility of most of these prognostic factors remains to be settled. Synovial sarcoma metastasizes in 50% of cases, most commonly to lungs and lymph nodes, and 5-year overall survival rates between 24 and 64% have been reported. Treatment involves surgical excision, radiotherapy and chemotherapy. Chemotherapy often includes ifosfamide because synovial sarcoma seems to be particularly sensitive to this drug.

Epithelioid Sarcoma

Epithelioid sarcoma is a rare soft tissue sarcoma that occurs predominantly in adolescents and young adults. It presents most commonly as dermal or subcutaneous nodules in the distal portions of the upper extremities, particularly the hands and wrists. However, its anatomical distribution is wider. Epithelioid sarcoma occurring

around the pelvic region also has been termed proximal type and seems to follow a more aggressive clinical course. Histologically, epithelioid sarcoma has a multinodular architecture with a granuloma-like appearance. The nodules are composed of epithelioid or spindle cells often surrounded by an inflammatory infiltrate rich in lymphocytes. Necrotic areas are common, often assuming a map-like pattern. Immunohistochemical studies show the expression of vimentin, EMA and cytokeratin in most cases and CD34 in approximately half.

Cytogenetic studies show frequent rearrangements or deletions involving chromosome 22, particularly the band 22q11. Interestingly, this chromosomal band often is deleted or rearranged in rhabdoid tumour (see Extrarenal Malignant Rhabdoid Tumour, below), an entity that shares some degree of morphological overlap with epithelioid sarcoma. Epithelioid sarcoma has a high local recurrence rate, up to 80% in some series, owing to its extensively infiltrative margins along tendons and fascia, often well beyond the apparent clinical limits of the tumour. Metastases are very common, mostly to regional lymph nodes, lungs and scalp. The estimated 5-year survival rate is approximately 50–70%. Some prognostic factors associated with a worse outcome include tumour size larger than 5 cm, necrosis, vascular invasion, lymph node metastasis and proximal location.

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma (ASPS), also known as Christopherson tumour, represents <1% of soft tissue sarcomas and commonly occurs in lower extremities in patients between the second and third decades of life. In children, the head and neck are preferentially involved. Female patients are slightly more affected. Histologically, ASPS is characterized by a pseudoalveolar architecture composed of richly vascularized fibrous septa lined by polygonal cells with low mitotic activity and minimal pleomorphism. PAS-positive intracytoplasmic rod-like inclusions are common and are seen to have a characteristic crystalline rhomboid shape on ultrastructural analysis. The line of differentiation of ASPS is still subject to debate, and a putative skeletal muscle differentiation has been suggested. However, the expression of muscle markers, such as desmin and MyoD1, is inconsistently detected.

Cytogenetic and molecular studies have shown that the nonreciprocal translocation t(X;17)(p11.2;q25) is characteristic of ASPS (100% of cases) and results in the fusion of the transcription factor *TFE3* gene (*T*ranscription *F*actor binding to IGHM *E*nhancer *3*) on chromosome Xp11.2 with the *ASPL* gene (*A*lveolar *S*oft *P*art sarcoma *L*ocus) on chromosome 17q25. Interestingly, the *TFE3* gene commonly is rearranged in some cases of renal papillary carcinoma. ASPS is associated with a poor long-term prognosis, with 5- and 10-year overall survival rates of 46–67% and 38%, respectively. Metastases to lungs, brain and bone are common. Younger age and tumours smaller than 10 cm in diameter tend to be associated with a better prognosis.

Desmoplastic Small Round Cell Tumour

Desmoplastic small round cell tumour (DSRCT) is a highly malignant sarcoma that most commonly occurs in the peritoneal cavity of adolescents and young adults of the male sex. DSRCT usually forms large intra-abdominal whitish masses that are histologically characterized by nests or strands of small round cells surrounded by a dense desmoplastic stroma. Mitoses, apoptotic bodies, necrosis and lymphatic invasion are common. Immunohistochemical studies show the expression of several proteins, including cytokeratin, EMA, neuron-specific enolase and desmin, supporting its divergent differentiation. Desmin expression is usually paranuclear and of globular appearance. MIC2 expression is not uncommon and may cause problems in the differential diagnosis with Ewing sarcoma/PNET.

Cytogenetic analyses show the chromosomal translocation t(11;22)(p13;q12) in almost all cases of DSRCT. This results in the fusion of the tumour-suppressor gene *WT1* on chromosome 11p13 to the *EWS* gene on chromosome 22q12. The causal mechanism of this translocation is unknown but insertion of LINE-1 DNA sequences at the genomic breakpoint of DSRCT has been identified. The chimaeric product has oncogenic attributes and seems to activate the *IGF1* gene promoter with higher affinity that the WT1 protein alone. DSRCT follows a highly aggressive clinical course, often characterized by multiple local recurrences. Distant metastases are uncommon. Despite intensive chemotherapy regimens, radical surgical procedures and radiotherapy, most patients die less than 3 years after diagnosis.

Extrarenal Malignant Rhabdoid Tumour

Malignant rhabdoid tumour (MRT) used to be a highly controversial entity because the so-called rhabdoid phenotype can be found in several other tumours. However, recent findings have shed some light on this issue. Currently, it seems that renal MRT and extrarenal MRT are characterized by deletions or mutations of the chromatin remodelling gene *hSNF5/INI1* located on chromosome 22q11.2. In addition, germ-line mutations of the *hSNF5/INI1* gene also have been described, predisposing the carriers to renal MRT, extrarenal MRT and other tumours in the so-called rhabdoid predisposition syndrome. In soft tissues, MRT tends to occur in young patients and in a wide anatomical distribution. Histologically, MRT is characterized by sheets of polygonal cells with hyaline globular cytoplasmic inclusions and vesicular nuclei. By immunohistochemical analysis, the cells consistently express vimentin, cytokeratin and EMA. Ultrastructural analysis demonstrates that the cytoplasmic inclusions are composed

of whorls of intermediate filaments. Clinically, soft tissue MRTs follow a very aggressive clinical course with higher rates of metastasis. Death usually occurs less than 2 years after diagnosis.

PROGNOSTIC FACTORS

Several prognostic factors have been proposed for soft tissue sarcomas, but only a few are universally accepted and routinely used. The large void between the identification and the clinical application of prognostic factors for soft tissue sarcoma exists for many reasons. First, the prognostic factors proposed so far have been incompletely validated. Theoretically, the validation of proposed prognostic factors is carried out in three major steps: exploratory studies, retrospective clinical studies and prospective clinical trials. The first step is the study of a plausible prognostic factor in relationship to outcomes and the predictive data available. This step is fundamental to hypothesis formulation. The second step confirms the initial observations through large studies in which multivariate analysis establishes the independence of the investigated prognostic factor in relation to known predictors. Definition and validation of cutoff points in two or more distinct data sets are tasks involved in the second step. The third step consists of well-designed multi-institutional prospective studies with a large number of patients using pre-established cutoff points (Hall and Going, 1999). Unfortunately, almost all studies of prognostic factors in soft tissue sarcomas have not gone beyond the second step.

Other important problems include (1) the uneven representation of specific sarcomas in heterogeneous series, (2) the number and type of variables included in multivariate analysis and how they are selected and modelled, including pre-establishment of cutoffs, (3) the statistical power of the study for detecting differences between groups of patients, (4) standardization of specific outcomes (local recurrence, metastasis, disease-free and overall survival) and (5) appropriateness of the statistical methods. In addition, the identification of a prognostic factor does not necessarily mean that it has clinical utility. A meaningful prognostic factor should also influence clinical decisions.

Despite numerous problems associated with histological grading systems, histological grade has been considered the most powerful prognostic factor in heterogeneous series of patients with soft tissue sarcoma (**Figure 3**) and frequently incorporates other factors such as mitotic count, necrosis and degree of differentiation (see Grading and Staging Systems, above). In a retrospective series involving more than 1000 cases of soft tissue sarcomas, the presence of high-grade histological features was the most powerful independent prognostic factor for metastasis-free survival ($P = 0.0001$; relative risk (RR) = 4.3; confidence interval (CI) = 2.6–6.9) and disease-specific overall survival ($P = 0.0001$; RR = 4.0; CI = 2.5–6.6), but not for local recurrence-free survival (Pisters *et al.*, 1996). Tumour size has been considered an adverse prognostic factor in many but not all series including more than 100 patients. Standardization of cutoffs for tumour size and other problems already described partially explain these divergent results.

Several other prognostic factors have been evaluated. DNA ploidy, S-phase fraction, AgNORs (silver staining for nucleolar organizer regions; segments of DNA containing ribosomal genes whose expression reflects the proliferation activity of the tumour), Ki-67, Mdm2, p53, *RB1* gene product, c-Myc, PDGFβ (platelet-derived growth factor β) and Bcl-2 have been correlated with histological grade and decreased metastasis-free or overall survival in many but not all studies. Overexpression of the transmembrane p-glycoprotein, product of the multiple resistance gene 1 (*MDR-1*), has been correlated with decreased sensitivity to chemotherapy and survival. Specific chimaeric mRNA transcripts have been shown to have a prognostic role in synovial sarcoma and Ewing sarcoma (**Figure 9**) (see Extraskeletal Ewing Sarcoma and Peripheral Primitive Neuroectodermal Tumour, above, and Synovial Sarcoma, above).

TREATMENT

The treatment of soft tissue sarcomas commonly combines combination of surgical excision, radiation therapy and chemotherapy. The therapeutic approach is chosen after adequate imaging and pathological studies and determination of whether the patient has localized, locally recurrent or metastatic disease. With this information, a specific therapeutic plan is best chosen based on individual characteristics of the patient and results obtained in clinical trials.

Overview of Sarcoma Treatment

Surgical excision is used primarily for the treatment of localized or locally recurrent sarcoma and is the only potentially curative treatment at present. However, surgical excision also can be used for the treatment of metastatic sarcoma, particularly pulmonary metastasis (metastasectomies). Radiation therapy is used primarily as an adjuvant treatment for the control of localized or locally recurrent sarcoma. Chemotherapy is used for localized and metastatic sarcomas.

Treatment of Clinical Groups

Localized Sarcoma

Local disease is defined when a soft tissue sarcoma is confined to a certain anatomical site or compartment without clinicoradiological evidence of systemic disease

(metastasis). In this situation, surgical excision is considered the mainstay therapy because it is the only potentially curative modality at present.

Surgical excision can be divided into five basic types: intralesional, marginal, wide, radical and amputation. In an intralesional excision (also known as curettage, debulking or incisional biopsy), the tumour is incompletely resected and gross disease is left behind. This surgical procedure is performed when broader excisions cannot be carried out without affecting vital structures. In marginal excisions, the tumour is excised through its pseudocapsule or perilesional reactive fibroinflammatory zone. Because there is a substantial risk for microscopic positive margins after this procedure, marginal excision is commonly indicated for benign soft tissue tumours or after successful preoperative radiotherapy or chemotherapy for sarcomas. Local recurrence rates of 60% or more have been reported with this type of resection alone.

Wide excision, which is currently the most common type of surgical excision performed, includes a rim of normal tissue surrounding the tumour. Wide excision is used for low-grade and high-grade sarcomas with or without adjuvant treatment. Local recurrent rates of up to 30% have been reported when wide excision is performed alone. Because of this, there is a general arbitrary recommendation that a surgical margin of at least 2 cm around the tumour be achieved. Radical excision involves the removal of the entire anatomical compartment, i.e. all tissues within the natural anatomical boundaries. Radical excision often is indicated for recurrent sarcomas or when imaging studies were inconclusive for defining the tumour's anatomical limits. Amputation, often used in the past, is performed uncommonly now because a limb-sparing operation followed by postoperative radiotherapy provide similar results. Amputation is indicated mainly (1) when it is impossible to obtain adequate margins without compromising vital structures in primary or locally recurrent disease, (2) when the dose and volume of adjuvant radiotherapy are likely to cause important local complications and (3) in certain situations when the use of a prosthesis will provide better postoperative results than a radical limb-sparing operation (O'Sullivan *et al.*, 1999).

Currently, radiotherapy commonly is used in combination with surgical excision for the management of localized soft tissue sarcoma. Radiotherapy can be delivered in the form of external-beam radiation or brachytherapy (from the Greek *brachys*, short). In the latter, the source of radiation is placed close to or in the tumour bed. Several retrospective and few prospective clinical trials have shown that the combination of radiotherapy and surgical excision provides better results than surgical excision alone in the management of localized soft tissue sarcoma. However, there is no clear evidence that local control of the disease automatically confers prolonged survival. Preoperative radiation therapy has the advantage of using smaller radiation fields and doses but has been associated with a higher risk of wound complications. Postoperative radiation therapy decreases the latter risk. Advantages of brachytherapy include cost-effectiveness and a short interval between the surgical procedure and the beginning of radiation therapy. However, brachytherapy seems to provide results that are inferior to those of external-beam radiation for low-grade tumours.

Several other types of adjuvant radiotherapy have been used for local disease control, including a combination of brachytherapy and external beam radiation, intraoperative radiotherapy, hyperfractionation, the use of radiosensitizers, and others. However, none has been shown to be superior to external-beam radiation.

The role of adjuvant chemotherapy for localized soft tissue sarcoma remains controversial despite convincing evidence of its clear though modest benefit (Benjamin, 1999). Despite the lack of statistical significance, most randomized trials have shown a clear trend for prolonged disease-free survival and overall survival in patients who received adjuvant chemotherapy with multiple regimens. Moreover, meta-analysis of some reported series has confirmed these impressions (**Figure 11**) (Sarcoma Meta-analysis Collaboration, 1997). Reasons accounting for some of the persistent controversies include large variation in the criteria for patient enrollment (tumour location, histological subtype and grade, size and depth), follow-up periods and chemotherapy regimens used.

Neoadjuvant or preoperative chemotherapy has been advocated for treating localized soft tissue sarcomas based on three theoretical assumptions: (1) elimination of occult micrometastases present at diagnosis, before the development of chemoresistant tumour clones, (2) reduction of tumour volumes, to allow less radical surgical procedures and (3) clinical and pathological assessment of tumour chemoresistance by an *in vivo* test (Pisters and Brennan, 2000). Nonrandomized studies have shown complete and partial response rates between 3 and 64% with the use of neoadjuvant chemotherapy. However, these results did not translate into a better outcome (metastasis-free or overall survival) for responders as compared with nonresponders or patients treated with adjuvant chemotherapy. In spite of these findings, patients with large high-grade tumours should be considered for neoadjuvant chemotherapy because of a high risk of development of metastasis.

Locally Recurrent Sarcoma

Soft tissue sarcomas recur in up to 90% of cases according to the adequacy of the surgical margins. Because head and neck and retroperitoneal sarcomas are difficult to resect without affecting vital structures, local recurrence rates are much higher than those observed in extremity sarcomas. The treatment of locally recurrent soft tissue sarcoma should be highly individualized, but surgical re-excision of the recurrent tumour should be attempted when feasible because good long-term results have been obtained with this approach. Amputation is indicated especially when dealing with

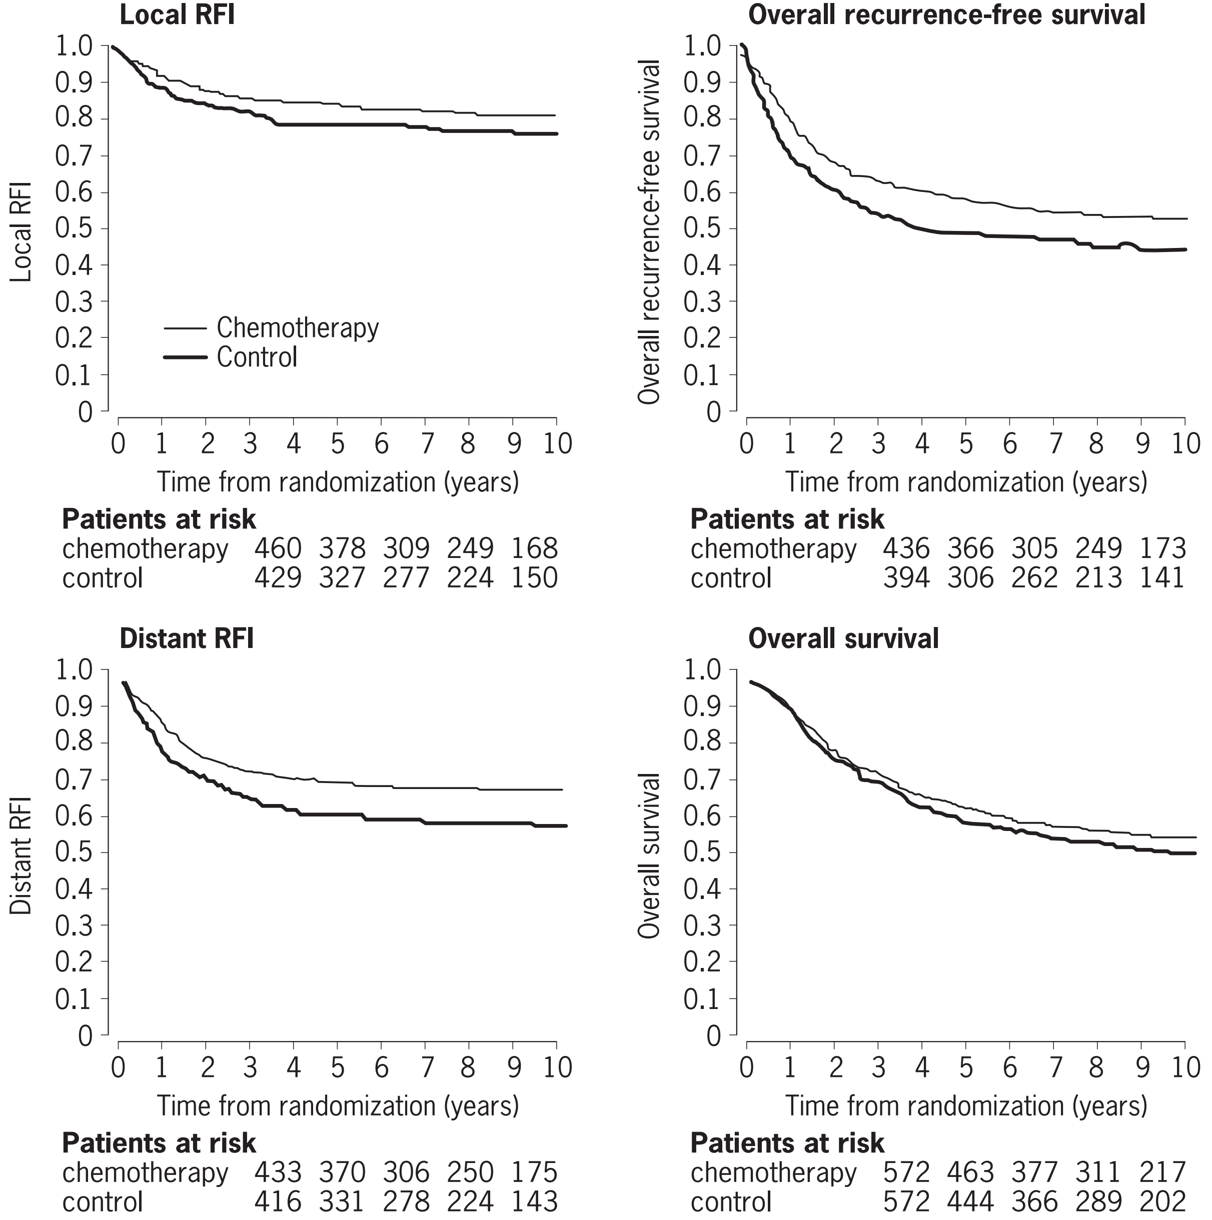

Figure 11 Kaplan–Meier curves obtained with a quantitative meta-analysis of data on 1568 patients from 14 clinical trials comparing doxorubicin-based adjuvant chemotherapy with control in localized soft tissue sarcoma. Prolonged local recurrence-free (hazard ratio (HR) = 0.73; 95% confidence interval (CI) = 0.56–0.94; $P = 0.016$), metastasis-free (HR = 0.70; 95% CI = 0.57–0.85; $P = 0.0003$), disease-free (HR = 0.75; 95% CI = 0.64-0.87; $P = 0.0001$) and overall survival (HR = 0.89; 95% CI = 0.76-1.03; $P = 0.12$) were observed. However, no statistical significance was reached for overall survival. RFI, recurrence-free interval. (From Sarcoma Meta-analysis Collaboration, 1999, Adjuvant chemotherapy for localized resectable soft-tissue sarcoma of adults: meta-analysis of individual data. *Lancet*, **350**, 1647–1654, by permission of The Lancet, Ltd.)

multiple local recurrences or tumour involvement of important neurovascular structures. The use of adjuvant radiation often is indicated if the tumour was not previously irradiated. Using this approach, local control was obtained in up to 80% of patients in some series. Additional radiation therapy in previously irradiated recurrent tumours should be evaluated on an individual basis, but local control can be attained in most patients. The role of chemotherapy for locally recurrent disease remains to be established.

Metastatic Sarcoma

Metastatic soft tissue sarcomas are primarily managed with chemotherapy or surgical excision (metastasectomy).

Chemotherapy is the main therapeutic modality and is indicated for nonresectable metastases. The most effective single agents are doxorubicin and ifosfamide. They induce objective response in more than 20% of patients and exhibit a dose–response relationship (O'Byrne and Steward, 1999). Doxorubicin-based combination regimens such as CYVADIC (cyclophosphamide, vincristine, doxorubicin (Adriamycin) and dacarbazine) and MAID (mesna, doxorubicin, ifosfamide and dacarbazine) have led to response rates in up to 70% of patients, but no improvement in overall survival has been demonstrated. Furthermore, no difference in terms of response rate, remission duration or overall survival was seen in a large prospective randomized phase III trial comparing CYVADIC, doxorubicin–ifosfamide, and doxorubicin alone for treatment of advanced soft tissue sarcoma. The concomitant use of recombinant human granulocyte macrophage colony-stimulating factor (hrGM-CSF) has been used by some investigators to allow more intensive chemotherapy regimens. Other treatments include hyperthermic isolated limb perfusion (HILP) using an antiangiogenic factor, such as recombinant tumour necrosis factor alpha (rTNFα), in combination with cytotoxic drugs and whole-body hyperthermia.

Surgical excision of metastatic disease has been investigated in several studies; the benefits are marginal. In a series of 135 patients who were treated at a single institution for metastatic sarcoma to the lungs, complete excision, incomplete excision and no excision of the metastatic sarcoma were associated with median survivals of 19, 10 and 8 months, respectively. However, the 3-year overall survival rate was only 23% for those in whom complete metastasectomy was achieved (Gadd *et al.*, 1993). A series evaluating 230 patients with pulmonary and nonpulmonary metastasis found that unresectability of distant metastases correlated with a shorter survival by multivariate analysis ($P = 0.0001$; HR = 2.3; CI = 1.2–3.7; **Figure 12**) (Billingsley *et al.*, 1999). Other investigations found similar numbers, with median survivals after development of pulmonary metastases ranging from 18 to 27 months. Comparison of surgical excision alone with the combination of surgical excision and chemotherapy has provided discordant results among studies. A prognostic system for use with patients who have pulmonary metastases has been proposed. It is based on the presence of metastases, number of metastases, metastasis-free period less than 18 months and size of the metastases larger than 2 cm (Choong *et al.*, 1995). It seems that complete metastasectomy is the single most important factor for prolonged postmetastasis survival and that careful patient selection is critical for achieving good results. Four criteria for pulmonary metastasectomy have been suggested: ability to control the primary tumour, absence of extra-thoracic metastases, clinical condition satisfactory for surgical excision and absence of a better treatment option (McCormack, 1990).

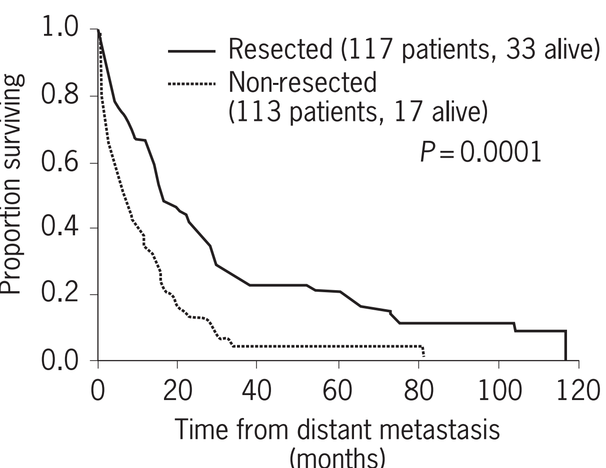

Figure 12 Overall survival curves comparing the effect of complete resection of metastatic soft tissue sarcoma with incomplete or no resection. Shorter overall survival was seen in patients with nonresected metastases (hazard ratio = 2.3; 95% confidence interval = 1.2–3.7; $P = 0.0001$). (From Billingsley *et al.*, 1999, by permission of the American Cancer Society.)

Future Treatments

Alternative treatments for soft tissue sarcomas have been investigated with promising results. These treatments include use of the peroxisome proliferator-activated receptor-gamma ligand troglitazone to induce terminal adipocytic differentiation in liposarcomas, antisense *FLI/EWS* and anti-MIC2 (CD99) for Ewing sarcoma/PNET, tyrosine kinase inhibitors (STI-576) for c-*KIT* proto-oncogene product expressing tumours, angiogenesis inhibitors and others. Additional information on current clinical trials for the treatment of sarcomas can be found at http://clinicaltrials.gov.

- Overview of Present Clinical Management

INTRODUCTION

Primary cancers of the pleura and peritoneum are uncommon in the general population. Nonetheless, such cancers – particularly those which arise from mesothelial cells and are therefore known as malignant mesothelioma – have commanded substantial attention in recent years. There are several reasons why mesotheliomas are subject to active discussion in the scientific and lay press. First, they often arise from exposure to asbestos fibres, and are thereby a public and occupational health concern. Second, they are a particularly deadly form of cancer. Third, diagnosis of mesothelioma is often difficult.

Malignant mesotheliomas are locally aggressive neoplasms in which the neoplastic proliferation originates from pleural, peritoneal or, rarely, pericardial mesothelial cells (Craighead and Mossman, 1982; Craighead, 1987; Antman, 1993). Mesotheliomas are linked epidemiologically to asbestos exposure and from that standpoint alone have been a major public health concern. Although mesotheliomas are often associated with extensive occupational asbestos exposure, a substantial 'bystander' risk has been documented, and as many as 50% of American patients have no history of known asbestos exposure (Craighead and Mossman, 1982). Advances in clinical recognition of mesothelioma have allowed the evaluation of additional risk factors. One known risk factor is inhalation of the airborne mineral dust erionite (Selcuk *et al.*, 1992), which is responsible for endemic mesothelioma in central Turkey. Another potential risk factor – albeit less convincingly implicated than asbestos – is exposure to SV40 virus. Accordingly, accurate diagnosis of mesothelioma is a global concern, and this concern will certainly persist after the present wave of asbestos-associated cases peaks and subsides.

Many other types of cancer can involve the pleura or peritoneum, but discussion of these entities, individually, is beyond the scope of this chapter. Such cancers are occasionally primary and can be multifocal and/or associated with familial cancer syndromes, as in the case of papillary serous carcinoma of the peritoneum (Schorge *et al.*, 1998). However, nonmesothelial pleural and peritoneal tumours are more often metastatic from another tissue site. Pleural or peritoneal metastases are generally manifested by shortness of breath or abdominal swelling/discomfort due to fluid accumulation, and they are sometimes the only evident metastases in carcinomas arising from organs such as lung, large bowel, ovary or breast. Patients can come to medical attention because of symptomatic pleural or peritoneal metastases at a time when the primary carcinoma is not yet evident. These scenarios emphasize the importance of distinguishing histologically and immunohistochemically between epithelial-type mesothelioma and carcinoma.

NORMAL DEVELOPMENT AND STRUCTURE

Mesothelial cells derive from the mesoderm, and they form a single cell layer lining the pleural, peritoneal and pericardial spaces. They allow relatively frictionless

movement of opposed surfaces, a function which is important for the organs they encompass. For example, they ease the motion of pleura and pericardial surfaces which is important during respiration and cardiac contraction/relaxation, respectively. Mesothelial cells also play vital roles in regulating transport of fluids and molecules across the pleural, peritoneal and pericardial spaces. The pleura and peritoneum proper include not only mesothelial cells but also fibrovascular connective tissue which provides support for the mesothelial cells. Cancers can arise from any of the cell types in the pleura and peritoneum, but this chapter will focus on those – malignant mesotheliomas – which originate from the mesothelial cells.

AETIOLOGY

Malignant mesothelioma was diagnosed infrequently prior to 1960, at which time Wagner *et al*. (1960) described a dramatically increased incidence in asbestos miners. Thereafter, mesothelioma was highly publicized owing, in part, to public health concerns. Subsequent epidemiological studies confirmed the striking association between asbestos exposure and mesothelioma. Mesothelioma was found to be common in groups as diverse as native Americans (occupational exposure during production of silver jewellery); carpenters, plumbers, and electricians (occupational exposure to asbestos insulation materials); and villagers of central Turkey (inhalation of the endogenous mineral erionite, a structural mimic of asbestos) (Craighead and Mossman, 1982; Craighead, 1987; Selcuk *et al*., 1992; Antman, 1993). The latency period between asbestos exposure and presentation with mesothelioma is typically 30–45 years. Mesothelioma incidence will probably increase over the next several decades because asbestos use rose in most countries after the Second World War and was not regulated until 1970. A registry of mesothelioma deaths has been maintained in England, Wales and Scotland since 1968, and annual deaths from mesothelioma in these populations rose from 154 in 1968 to 1009 in 1991 (Peto *et al*., 1995). Based on known occupational asbestos exposure in these countries, it is estimated that mesothelioma incidence will peak in year 2020 and will account for 1% of all deaths in the most highly exposed cohorts (men born during the 1940s) (Peto *et al*., 1995).

Asbestos belongs to a family of magnesium and calcium silicates that withstand extremely high temperatures. The thermoresistant properties of asbestos have been appreciated for many millenia, and were evident to the ancient Greeks, who used asbestos in wraps for cremation. In recent times, asbestos has found widespread use as insulation material in the walls of buildings and as heat-resistant material in engine parts and brake linings, among other applications. Asbestos fibres can be grouped into those which are wavy (serpentines) and straight (amphiboles), the latter being more often implicated in oncogenesis (Walker *et al*., 1992). As discussed below, it is likely that the oncogenic potential of asbestos is multifactorial.

Several *in vitro* studies provide fascinating clues to the pathogenesis of tumorigenic chromosomal rearrangements in mesothelioma. Addition of asbestos fibres to non-neoplastic mesothelial cell cultures results in pronounced chromosome damage that is mediated by physical interactions between asbestos fibres and chromosomes (Lechner *et al*., 1985; Ault *et al*., 1995). Asbestos fibres 'snare' whole chromosomes, or break off pieces of chromosomes, during mitosis, and these chromosomes and chromosome fragments are separated from the normal mitotic spindle apparatus (Ault *et al*., 1995). The end result is aberrant chromosome segregation with loss of a chromosome, or chromosome region, from one daughter cell. Therefore, these studies establish a scenario in which asbestos fibres are directly responsible for random chromosomal damage. Amongst the asbestos-exposed mesothelial cells are presumably those occasional cells in which the chromosomal damage results in loss of key tumour-supressor loci. These cells might represent the starting point for neoplastic mesothelial proliferation. *In vitro* models suggest that asbestos fibres also have a direct role in promoting mesothelial cell proliferation via nonmutational mechanisms (Pache *et al*., 1998; Timblin *et al*., 1998). Consequently, asbestos may inflict initial genotoxic damage, then promote proliferation of the damaged mesothelial cells, enabling them to acquire additional oncogenic mutations.

Considerable controversy attended recent reports that SV40 virus is found in many human mesotheliomas. The SV40 promoter is commonly used to drive expression of various genes which are introduced into mammalian cells as plasmid constructs for *in vitro* analyses. However, SV40 itself is generally nontransforming when expressed in human non-neoplastic cells. Nonetheless, there is substantial, although disputed, evidence that SV40 participates in the genesis of human mesotheliomas. Evaluation of human mesothelioma was prompted by the discovery, by Carbone *et al*., (1994) that Syrian hamsters developed mesothelioma following injection of wild-type SV40 virus into the pleural space. The same group noted that SV40-like sequences were demonstrable by polymerase chain reaction (PCR) in primary human mesotheliomas (Carbone *et al*. (1994). Other groups did not confirm this finding, or noted that the ability to identify SV40-like sequences depended on the specific SV40 oligonucleotide primers used for the PCR (Strickler *et al*., 1996). In addition, SV40 protein was not identified in human mesothelioma cell lines (Modi *et al*., 2000), and immunohistochemical studies of primary mesothelioma tumours revealed a weak, non-nuclear, expression pattern of putative SV40, which was

interpreted as inconsistent with a transforming role. These contrary findings raised the question of whether the apparent SV40 genomic sequences might represent trivial PCR contaminants, 'bystander' SV40 in non-neoplastic cells, or a closely related virus distinct from SV40. A follow-up, multi-instutional study again supported the presence of true SV40 DNA within primary human mesotheliomas, and recent studies show that SV40 synergizes with asbestos in transforming mesothelial cells *in vitro* (Bocchetta *et al*., 2000). Nonetheless, it is unclear whether the neoplastic cells in primary human mesotheliomas express SV40 protein. It is important that these questions be resolved inasmuch as the possibility of an SV40 role is a substantial public health concern. Millions of individuals, in the United States and in other countries, were potentially exposed to SV40 in poliovirus vaccines administered between 1955 and 1963.

SCREENING AND PREVENTION

Malignant mesothelioma is an asbestos-associated neoplasm that has been diagnosed with increasing frequency over the past two decades. Contemporary regulations on asbestos constitute one key measure in preventing mesotheliomas, but these measures are not expected to eradicate the disease. Many mesotheliomas develop in persons with no evident exposure to asbestos, and whose lung tissue does not contain elevated levels of asbestos fibres. Furthermore, several non-asbestos risk factors have been identified, including radiation therapy to the chest or abdomen, inhalation of certain environmental dusts and, potentially, exposure to the SV40 virus.

One strategy for mesothelioma prevention would involve screening at-risk individuals so that mesotheliomas could be detected at their earliest, *in situ*, stages and be cured surgically. Indeed, it would seem that the unique epidemiology of mesothelioma, particularly its relationship to asbestos exposure, should permit the development of effective screening measures. However, that has not been the case, and timely diagnosis remains a challenge. Only a small subset of individuals, presumably less than 5%, develop mesothelioma even after occupational exposures to large amounts of asbestos (Ribak *et al*., 1998). In addition, individuals exposed to asbestos develop benign pleural and peritoneal masses, known as 'plaques,' more often than they do malignant mesothelioma (Kannerstein *et al*., 1977). The challenges for screening are compounded because the latency period between asbestos exposure and clinical manifestations of disease is long, commonly more than 30 years, and conventional radiological screening methods, such as plain radiographs and CAT scans, do not distinguish early mesothelioma from benign asbestos-mediated pleural and peritoneal thickening or effusions. Further, patients often present with nonspecific symptoms, leading to delays in diagnosis, and mesothelioma progresses rapidly once clinically apparent. Given these challenges, it is perhaps more realistic to expect that improved survival in mesothelioma patients will result from better therapies rather than earlier detection. Most mesotheliomas are probably beyond the reach of surgical cure long before they first manifest clinically and radiologically. This is because mesothelioma cell shedding, and resultant pleural or peritoneal dissemination, occur early in the course of the disease.

CLINICAL PRESENTATION AND PATHOLOGY

Although the accuracy of mesothelioma diagnosis has improved dramatically over the past 20 years, many potential pitfalls remain. Most patients with malignant mesothelioma present with discomfort and/or respiratory distress due to mesothelioma bulk tumour, pleural effusion or ascites (Craighead, 1987; Antman, 1993). However, some patients present only with nonspecific symptoms, such as weight loss, fevers and fatigue. The most common radiographic sign is that of pleural effusion with or without pleural plaques, and cytological examination of effusion or ascites fluid is often the initial diagnostic procedure. Cytological diagnosis is challenging as the morphological similarities between malignant mesothelioma and reactive mesothelial hyperplasia may preclude differentiating between the two in fluid cytology. When overt cytological features of malignancy are present, distinction from adenocarcinoma (primary to the lung or from a distant site) may be impossible without employing immunocytochemical studies. Cytological diagnosis of malignancy was achieved in 22–66% of mesothelioma patients in several large series, whereas the remaining cases could not be distinguished from reactive mesothelial hyperplasia (Scherman and Mark, 1990; Boutin *et al*., 1993). Reactive mesothelial hyperplasia is a relatively nonspecific finding which can occur in response to almost any type of pleural or peritoneal insult. For example, pronounced mesothelial hyperplasia can be seen in association with pleural or peritoneal effusions secondary to infection, cirrhosis or rheumatoid arthritis. Although pleural or peritoneal thickening are demonstrated by computed tomography (CT) or magnetic resonance (MR) scanning in some patients with mesothelioma, these findings are also not conclusive for malignancy. Asbestos is well known to induce pleural or peritoneal plaques and/or diffuse thickening even in the absence of actual mesothelioma (Kannerstein *et al*., 1977).

Only 50% of mesotheliomas are associated with asbestos exposure. Based on this statistic, it is obvious that the recent surge in diagnosed mesothelioma cannot be due entirely to changing trends in asbestos use. A minor factor

is the growing number of cases occurring as second neoplasms after radiation therapy. A more significant variable, however, is the increasing sophistication of mesothelioma diagnosis. There is little question that many or most epithelial-type mesotheliomas were misdiagnosed as adenocarcinoma prior to 1970, whereas many or most spindle-cell mesotheliomas were misdiagnosed as sarcoma. Increased awareness of histological and immunohistochemical subtleties has allowed more accurate (and more frequent) diagnosis of mesothelioma over the past two decades. Accurate diagnosis of mesothelioma is of more than academic interest, because survival for patients with early-stage mesothelioma has improved with a combined approach of pleural or peritoneal stripping, multiagent chemotherapy and radiation to sites of bulky disease (Sugarbaker *et al*., 1999).

Histopathology

The gross appearance of mesothelioma often features numerous small nodules and plaques and/or generalized thickening of the pleura or peritoneum (**Figure 1; see colour plate section**) (Corson, 1997). As discussed above, there is invariably some degree of associated effusion. Invasion of the lungs proper (pulmonary parenchyma) is unusual in the early stages of pleural mesothelioma, whereas involvement of local lymph nodes is seen occasionally (Sugarbaker *et al*., 1993, 1999). Nonetheless, pulmonary function is often compromised by the combined restrictive effects of malignant pleural effusion and pleural encasement by the tumour (**Figure 1**). The histological appearance of malignant mesothelioma is variable. There are three major morphological presentations, which may be categorized into epithelial, biphasic and sarcomatoid types.

Most mesotheliomas are composed of round epithelial-like cells (**Figure 2; see colour plate section**), and such cases can be misdiagnosed as adenocarcinoma. Other mesotheliomas are composed of spindled cells (**Figure 3; see colour plate section**), and these tumours can be mistaken for various sarcomas, including monophasic synovial sarcoma, malignant peripheral nerve sheath tumour, solitary fibrous tumour and fibrosarcoma. Spindle-cell mesotheliomas can also be mistaken for epithelial cancers, which occasionally have a spindle-cell morphology. Furthermore, mesothelioma spindle cells can be innocent-looking in some cases, despite their invariably lethal behaviour, and can be mistaken for a non-neoplastic – or desmoplastic – spindle-cell proliferation. Immunohistochemistry and electron microscopy have been helpful in resolving these diagnostic considerations. A number of monoclonal antibodies facilitate differentiation of epithelial-type mesothelioma from adenocarcinoma, and other antibodies enable distinction of spindle-cell mesothelioma from sarcoma (Cagle *et al*., 1989; Brown *et al*., 1993; Weiss and Battifora, 1993; Ordonez, 1999). Cytogenetic and molecular analyses are also helpful in some cases. For example, synovial sarcoma, malignant peripheral nerve sheath tumour and solitary fibrous tumour can generally be distinguished based on their respective expression of *SYT–SSX* fusion oncogenes, S100 protein and CD34 and their lack of expression for the calretinin mesothelioma marker. On the other hand, neither immunohistochemistry nor electron microscopy has been helpful in distinguishing malignant mesothelioma from reactive mesothelial hyperplasia (Crotty *et al*., 1992).

Immunohistochemistry

Although all aspects of the clinicopathological evaluation must be considered in arriving at a diagnosis of mesothelioma, most would agree that immunohistochemistry is the key adjunct to routine histology. Indeed, the immunohistochemical evaluation of mesothelioma receives considerable attention in the pathology literature, and a full account of this dynamic field is beyond the realm of this chapter. Only representative highlights will be mentioned, such as the recent discovery that calretinin, a calcium-binding protein, is expressed in virtually all mesothelial cells (**Figures 2** and **4**). Calretinin is expressed in both normal and malignant mesothelial cells, and therefore does not serve to distinguish mesothelioma from reactive mesothelial hyperplasia. However, calretinin is seldom expressed in mesothelioma histological mimics (Doglioni *et al*., 1996), including adenocarcinomas metastatic to pleura or peritoneum, or spindle-cell sarcomas and sarcomatoid carcinomas (Doglioni *et al*., 1996; Attanoos *et al*., 2000). There are many other antibodies which discriminate mesothelioma from histological mimics, and which are suitable for paraffin section immunohistochemistry. None of these reagents provides perfect specificity or sensitivity, and they are therefore applied as panels in which complementary antibodies provide a more convincing final answer. Examples of antibody targets useful in distinguishing mesothelioma from adenocarcinoma include (1) Ber-EP4, which is expressed diffusely and strongly in most bronchogenic adenocarcinomas but absent or only focal in most mesotheliomas, (2) CEA, which is expressed in most adenocarcinomas but rarely in mesothelioma (**Figure 4; see colour plate section**), and (3) Leu-M1, which is also expressed generally in adenocarcinoma but not in mesothelioma. Similarly, TAG-72 (recognized by the antibody B72.3) and thyroid transcription factor-1 (TTF-1) are observed in a large percentage of pulmonary adenocarcinomas, but not in mesotheliomas.

It is important to emphasize that specificity and sensitivity of immunohistochemical detection is influenced by the epitope against which the antibody was raised and the method – particularly monoclonal versus polyclonal – of antibody preparation. Not surprisingly, there

are conflicting reports as to whether the above-mentioned antibodies are suitable for evaluation of mesothelioma. These discrepant results undoubtedly reflect both the use of different antibody preparations as well as the different techniques for immunohistochemical staining. CEA provides an illustrative example. It is well known that monoclonal antibodies to CEA vary in their sensitivity for detecting CEA in bronchogenic adenocarcinomas. Conversely, polyclonal antisera to CEA can recognize a nonspecific cross-reactive antigen which decreases their specificity. Preabsorption with mouse spleen powder is reported to decrease this nonspecific immunoreactivity but, nevertheless, a small percentage of malignant mesotheliomas are immunoreactive to antibodies directed against CEA. Further, immunohistochemical staining for CEA is less useful in evaluation of peritoneal mesothelioma, because a substantial number of ovarian carcinomas do not stain for this glycoprotein.

Keratin expression (**Figure 3**) is a near-universal finding in mesothelioma whereas it is uncommon and/or focal in some of the spindle-cell sarcomas which mimic sarcomatoid mesothelioma. Keratin staining is less useful in distinguishing epithelial-type mesothelioma from adenocarcinoma, although some observers report that the keratin staining pattern is diffuse and perinuclear in most epithelial-type mesotheliomas whereas it stains in a peripheral pattern, accentuating the cell membrane, in many adenocarcinomas (Corson, 1997).

Ultrastructure

Electron microscopy evaluation is less critical than immunohistochemistry in the diagnostic work-up of malignant mesothelioma. Nonetheless, there are characteristic ultrastructural differences – particularly between epithelial-type mesothelioma and adenocarcinoma – which can be useful in arriving at a diagnosis. Notably, epithelial-type mesotheliomas, and the epithelial-type components in mixed histology mesotheliomas, may often be distinguished from adenocarcinomas based on the size and number of microvilli which project from their cell surfaces (**Figure 5**). Epithelial-type mesotheliomas generally have numerous microvilli which are long, thin and branching, whereas adenocarcinomas typically have microvilli which are short and sparse (Corson, 1997).

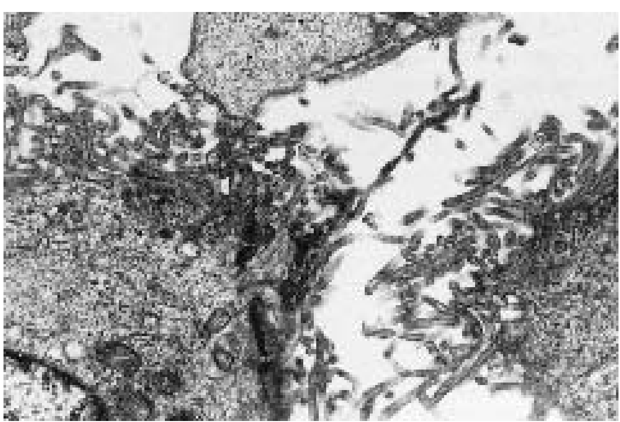

Figure 5 An ultrastructural hallmark of mesothelial cell differentiation is the finding of long branching microvilli at the cell surface (commonly referred to as bushy microvilli). In contrast, pulmonary and many extrapulmonary adenocarcinomas display short microvilli. In addition, perinuclear condensation of keratin intermediate filaments (tonofilaments) may be seen in mesothelial cells. Although ultrastructural examination remains useful in the diagnosis of mesothelioma, it is generally more cumbersome than immunohistochemical evaluation.

CYTOGENETIC AND MOLECULAR GENETIC FINDINGS

There is experimental evidence that asbestos fibres are directly responsible for chromosomal damage in mesothelial cells. Also, there is evidence that the SV40 virus serves as an oncogenic cofactor in promoting the development of some mesotheliomas. Mesotheliomas differ from many other solid tumours, however, in that the early, preinvasive, stages of the disease are rarely observed (Henderson *et al*., 1998). In addition, it can be very difficult to distinguish *in situ* mesothelioma from non-neoplastic mesothelial hyperplasia. Therefore, the *in situ* stage of mesothelioma has not been readily available for comparison with invasive mesothelioma, and the molecular mechanisms responsible for mesothelioma initiation remain to be defined. On the other hand, various studies have shed light on cytogenetic, molecular and cell biology mechanisms in invasive mesotheliomas. Several of these mechanisms are discussed below.

Cytogenetic Alterations

Cytogenetic studies have revealed a characteristic profile of chromosomal deletions in most mesotheliomas. These cytogenetic findings implicate loss of several tumour-suppressor genes as a critical event in mesothelioma pathogenesis. Although mesothelioma karyotypes are often described as 'complex,' they are in fact less complex than those in many carcinomas. In particular, epithelial-type mesothelioma karyotypes often have fewer than five chromosomal abnormalities per cell (**Figure 6**), whereas bronchogenic adenocarcinomas typically have more than 20 chromosomal abnormalities per cell. Sarcomatoid mesotheliomas, on the other hand, have more complex karyotypes than do the epithelial-type cases. A rather detailed account of mesothelioma chromosomal aberrations has emerged over the past 10 years (Taguchi *et al*., 1993), and it is clear that the nonrandom chromosomal

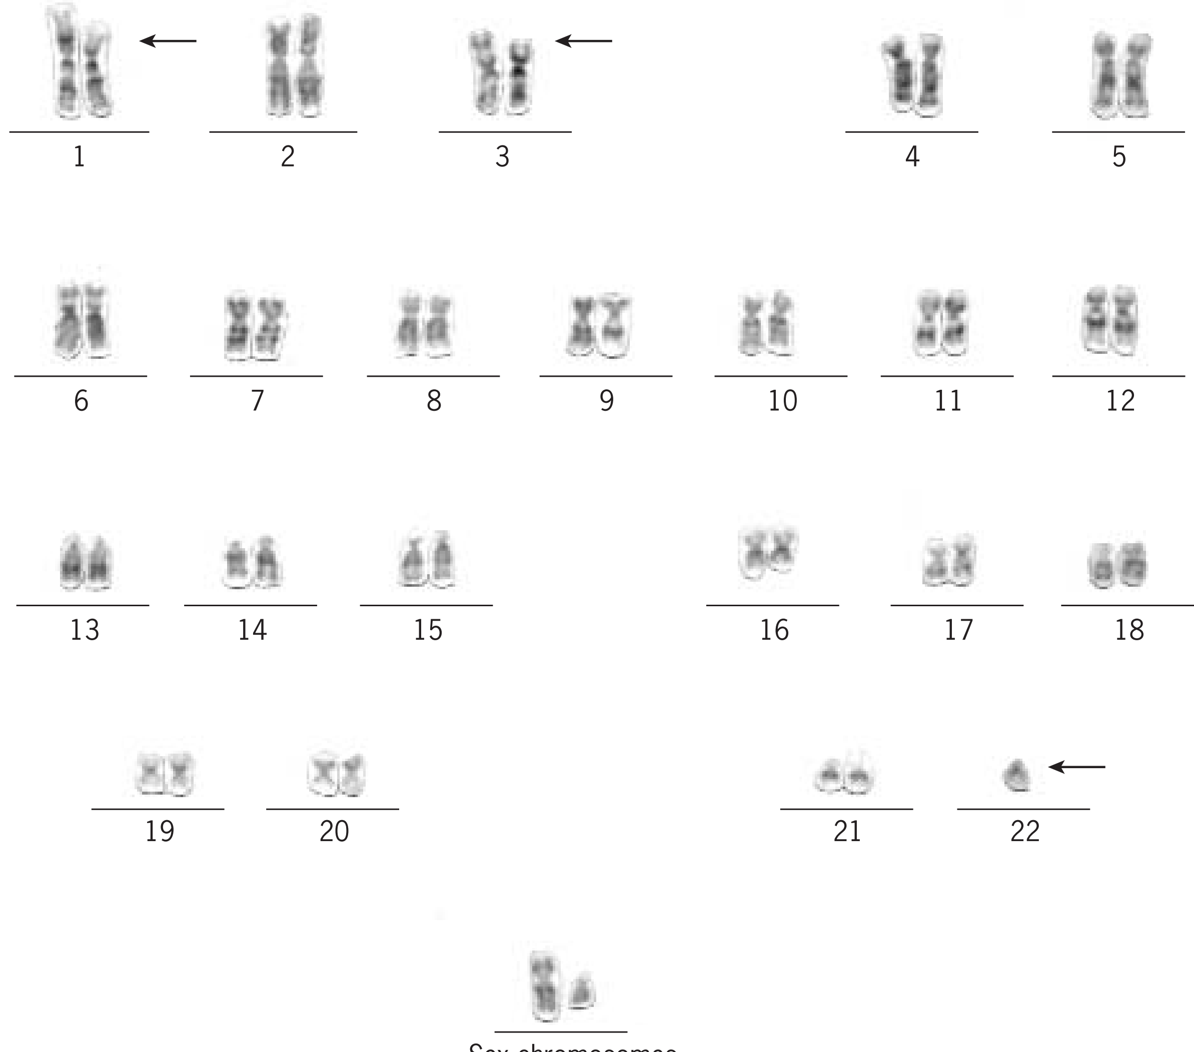

Figure 6 Noncomplex karyotype in an epithelial-type mesothelioma, showing characteristic losses of 1p, 3p and chromosome 22 (arrows).

deletions are found in mesotheliomas irrespective of histology (epithelial-type versus spindle-cell) or primary site (pleural versus peritoneal). The deletional hotspots are within the long arms of chromosomes 6 and 22 and within the short arms of chromosomes 1, 3 and 9 (**Figure 6**). Notably, the pathogenesis of some mesothelioma chromosome deletions may be directly attributable to asbestos-mediated chromosome damage (Lechner *et al.*, 1985; Ault *et al.*, 1995).

Molecular Alterations

Cytogenetic studies implicate loss of several tumour genes in the pathogenesis of virtually all mesotheliomas. However, the molecular targets for most of these chromosomal deletions are not yet known. Exceptions are the *CDKN2A* and *CDKN2B* genes, which are targetted by chromosome 9p deletions, and the *NF2* gene, which is targetted by chromosome 22q deletions (Cheng *et al.*, 1994). The *CDKN2A* and *CDKN2B* genes encode proteins which inhibit the CDK4 cell cycle checkpoint kinase and which thereby serve to block cell cycling. *CDKN2A* is targetted by chromosomal deletions in many human tumours, and *CDKN2A* genomic loss or functional inactivation, resulting in dysregulated cell cycling, is one of the more common tumour-suppressor mechanisms in human cancers. It is particularly interesting that *CDKN2A* mutations are often either/or in relationship to mutations of several 'downstream' effectors, including the CDK4 kinase and the retinoblastoma protein (Rb) (He *et al.*, 1995). CDKN2A inhibits the function of CDK4–cyclin D1 complexes, which, in turn, inactivate the Rb protein via phosphorylation. Hypophosphorylated Rb blocks cell entry into the S phase of the cell cycle, whereas phosphorylated Rb fails to block entry to S phase and thereby promotes cell proliferation. Hence CDKN2A, CDK and Rb

are control points along a single biological pathway, and disruption of any one of these points can disable normal constraints on cell cycling. These either/or relationships also appear to hold in mesothelioma, where CDKN2A inactivation is nearly universal, but Rb or CDK4 mutations are very uncommon (Cheng *et al*., 1994; Shimizu *et al*., 1994).

The NF2 protein is inactivated in virtually all mesotheliomas with chromosome 22 deletions (Sekido *et al*., 1995), and these represent approximately 75% of all mesotheliomas. NF2 was identified originally through analyses of its tumour-suppressor role in the genetic cancer syndrome, neurofibromatosis type 2, and through study of the various tumours, particularly benign schwannomas, which are characteristic of that syndrome. The normal functions of NF2 are poorly understood but it belongs to a family of proteins, each of which contains a so-called 'ezrin–radixin–moesin' domain, which communicate signals between cell surface receptors and the cytoskeleton. Recent studies show that NF2 interacts with substrates of the Met receptor tyrosine kinase and with scaffolding proteins interacting with the platelet-derived growth factor receptor tyrosine kinase. These findings suggest that NF2 modulates signal transduction pathways downstream of Met, PDGFR and other cell surface receptors. Such findings are relevant clinically because inhibition of receptor tyrosine kinases, whether by immunological or small molecule methods, has proved very effective in treatment of some cancers.

p53 is a seminal tumour-suppressor protein, whose inactivation contributes to the development of many human cancers. Initial reports suggested that p53 mutation was commonplace in mesotheliomas. This impression was not confirmed in other studies, and it is unlikely that p53 mutation plays a major role in mesothelioma pathogenesis (Mor *et al*., 1997). Nonetheless, it is possible that the p53 pathway is inhibited by other oncogenic mutations, and just such a role has been proposed for SV40 oncoproteins in some mesotheliomas.

Diagnostic Relevance

Further characterization of mesothelioma chromosomal and molecular aberrations may lead to improvements in diagnosis of mesothelioma (Granados *et al*., 1994). For example, virtually all mesotheliomas contain clonal chromosomal deletions whereas such alterations are not found in reactive mesothelial hyperplasia. Cytogenetic and molecular assays can be useful diagnostically because neoplastic and reactive mesothelial proliferations cannot be distinguished consistently using histological adjuncts such as immunohistochemistry and electron microscopy. There is also evidence that molecular assays are useful in distinguishing mesothelioma from adenocarcinoma (Sekido *et al*., 1995). Certain of the cytogenetic methods can now be performed routinely in cytological preparations (**Figure 7; see colour plate section**), and therefore should be useful in enabling a diagnosis of mesothelioma in pleural or peritoneal fluid specimens.

PROGNOSTIC FACTORS

Overall survival for patients with malignant mesothelioma is unquestionably poor. Nevertheless, intensive combined modality therapeutic strategies, as summarized below, have enabled a subgroup of patients to achieve 5-year survival. This accomplishment is striking, given that very few mesothelioma patients survive even 1 year when less intensive treatment methods are used. In the face of these therapeutic advances, it becomes more pressing to identify reliable prognostic factors. In particular, it is important to identify the subgroup of patients who will benefit from major surgical procedures, such as extrapleural pleuropneumonectomy.

Various potential prognostic variables have been evaluated in different mesothelioma series. Such studies have considered the prognostic implications of presenting symptoms (e.g. dyspnea, chest pain, cough), performance status, age, sex, histology, stage of disease and asbestos exposure. Tumour histology has been a major prognostic factor in all studies. Survival for patients who are untreated, or who receive single-modality therapy, is typically in the range of 4, 7 and 12 months depending on whether histology is sarcomatoid, mixed or epithelial-type, respectively (Fusco *et al*., 1993). The prognostic role of histology is also evident in patients receiving intensive treatment approaches, including the trimodality approach of extrapleural pleuropneumonectomy, chemotherapy and radiation therapy. In one such study, patients with epithelial-type mesothelioma had median survivals of 52 and 21% at 2 and 5 years, respectively, whereas only 16% of those with sarcomatoid mesothelioma survived for 2 years and none survived for 5 years (Sugarbaker *et al*., 1999). Primary site has also influenced prognosis in virtually all studies. Patients with peritoneal mesothelioma – with the exception of cases that are very well differentiated – have a median survival which is less than half of that in patients with pleural mesothelioma (Sridhar *et al*., 1992).

Although most mesotheliomas are disseminated locally at time of diagnosis, disease stage is nonetheless important prognostically (De Pangher Manzini *et al*., 1993). Not surprisingly, mediastinal lymph node involvement is an adverse prognostic factor in patients undergoing cytoreductive surgical approaches, such as extrapleural pleuropneumonectomy (Sugarbaker *et al*., 1993). Other prognosticators are undoubtedly influenced by the treatment approach. These include age less than 65 years, female gender, absence of pain, longer duration of symptoms, excellent performance status and absence of malignant cells in the associated effusion, all of which have been favourable prognostic factors in some studies but not in others (Fusco *et al*., 1993; Sugarbaker *et al*., 1993).

OVERVIEW OF PRESENT CLINICAL MANAGEMENT

Mesothelioma is relatively resistant to conventional chemotherapy and radiation therapy approaches. There are numerous reports, generally in small numbers of patients, which show impressive response rates – often in the range 25–50% for partial response – after single- or multiagent chemotherapy. Invariably, however, such findings have been refuted in follow-up studies, where the partial response rates prove to be well under 20%. Nonetheless, there are several chemotherapeutic agents, including doxorubicin and cisplatin, which unquestionably induce occasional partial responses, albeit typically lasting for no more than a few months (Taub and Antman, 1997). Multiagent chemotherapy protocols, e.g. cisplatin + doxorubicin, may achieve partial response rates in 20–30% of patients (Chahinian *et al*., 1993). Radiation therapy as a single modality is relatively ineffective, with very few partial responders, although some patients receive temporary benefit in the form of symptomatic improvement (Gordon *et al*., 1982). Likewise, mesothelioma is rarely eradicated by surgery alone, although meaningful palliation can be achieved (Butchart *et al*., 1981). Even the more radical surgical approaches invariably leave tumour cells behind, and are therefore cytoreductive rather than curative.

Although single modality therapies – whether with chemotherapy, radiation therapy or surgery – have been relatively ineffective, the combination of these methods has been highly successful in certain subgroups of patients. In particular, cytoreduction by extrapleural pleuropneumonectomy, when followed by multiagent chemotherapy and radiation therapy, leads to 5-year survival in many patients with epithelial-type mesothelioma (Boutin *et al*., 1993). Unfortunately, only one-third of pleural mesothelioma patients are candidates for this radical surgical approach, which involves *en bloc* removal of the lung, pleura, pericardium and diaphragm from the involved side of the chest (Boutin *et al*., 1993). In addition, combined modality methods have been less successful in patients with sarcomatoid mesothelioma, very few of whom survive for 2 years. Another constraint is that postoperative mortality is high, typically in excess of 10%, in centres which do not specialize in the radical surgical methods needed for effective cytoreduction (Rusch, 1999). Survival after the combined approach of extrapleural pleuropneumonectomy, chemotherapy and radiation therapy has been particularly prolonged in patients with epithelial-type histology whose resection margins and mediastinal lymph nodes were free of apparent tumour. This subgroup, represented by 31 of 176 extrapleural pleuropneumonectomy patients in one study, had 2- and 5-year survivals of 68 and 46%, respectively, whereas those for the overall group were 38 and 15%, respectively (Boutin *et al*., 1993). Similar trimodality approaches have also proved effective in pilot studies of peritoneal mesothelioma, where cytoreduction is accomplished by surgical debulking and then followed with chemotherapy and local irradiation to destroy residual tumour. Such studies often use intraperitoneal chemotherapy, which can be delivered readily using a Port-A-Cath set up. In one such study, with an intraperitoneal chemotherapy component of doxorubicin and cisplatin, three of five patients were disease-free at intervals of 46, 60 and 61 months after diagnosis (Lederman *et al*., 1988).

Despite the impressive advances provided by combined modality treatment, including a small but growing number of 10-year survivors, most mesothelioma patients do not survive past 2 years. This in part reflects the reality that many patients are fairly sick and/or inoperable at the time of diagnosis. Delays in diagnosis are common, particularly in those patients presenting with nonspecific symptoms, and many patients lose weight rapidly and develop significant respiratory compromise before therapy can be initiated. Therefore, improved survival for the overall group of mesothelioma patients probably depend on prompt diagnosis and development of more effective pharmacological interventions. Several novel therapies provide basis for optimism, although it is as yet unclear whether they will serve as effective solutions in their own right or as stepping stones in the quest for curative therapies. Examples include the intrapleural administration of immunomodulatory agents, such as interleukin-2 and γ-interferon, which have induced partial responses in up to 50% of patients with early-stage mesothelioma (Astoul *et al*., 1998). Beyond these tangible advances, it is certain that the growing understanding of mesothelioma biology, including oncogenes, tumour-suppressor genes and key growth factor signalling pathways, will translate in the near future to novel and biologically rational therapies.

- Ultrastructure/and Immunohistochemistry
- Molecular Genetic Findings
- Prognostic Factors
- Overview of Present Clinical Management

NORMAL DEVELOPMENT AND STRUCTURE

The heart forms as a tube which loops between 24 and 26 days postovulation. Ventricular and atrial septation occur by 39 and 43 days postovulation, respectively; at the latter time, the heart structure is generally complete. There is little information relating cardiac development and neoplasia of the heart, as cardiac embryology is studied primarily in the context of congenital cardiac malformations (Burke and Virmani, 1996). Cardiac masses that develop *in utero* include rare lesions such as rhabdomyomas (frequently seen in conjunction with extracardiac hamartomas as part of the tuberous sclerosis syndrome), cardiac fibromas, benign rests of endodermal tissues (primarily benign AV nodal tumours) and potentially malignant tumours derived from developmentally misplaced germ cells (cardiac teratomas and related lesions). Rhabdomyomas and fibromas are generally considered to be hamartomas, that is, they are benign growths, usually developmental, that are composed of cells native to the organ of origin. An AV nodal tumour is not strictly a tumour, in that it represents a cluster of misplaced cells that migrated incorrectly within the foetus. These three lesions (rhabdomyoma, fibroma and AV nodal tumour) are not, then, strictly tumours, and result in potentially lethal symptoms only because of their delicate location, often near the conduction system of the heart, and not in their capability to grow and metastasize, which is absent. Germ cell tumours of the heart and pericardial space occur as a neoplastic growth of germ cell rests that remained in the mediastinum due to arrested migration from the yolk sac to the gonads. Mediastinal germ cell tumours in themselves are fairly rare; nevertheless, they outnumber intrapericardial germ cell tumours by a large margin.

The cell of origin of the commoner heart tumours in adults, namely myxomas and sarcomas, is controversial, as is any potential relationship between these two entities. Cardiac myxoma arises almost exclusively in the endocardium of the atrial septum. This rare neoplasm is made of undifferentiated mesenchymal cells (derived from connective tissue) that elaborate a matrix rich in proteoglycans and inflammatory cells which release various growth factors and thrombogenic substances. The embryological origin of cells that become cardiac myxoma is unknown, but because of the location and myxoid appearance, it has been suggested that myxomas are derived from cells that make up the endocardial cushion. Cardiac sarcomas are a heterogeneous groups of tumours with presumably various cells of origin. The most common group appear to arise from the endocardial lining of the atria, often elaborate myxoid ground substance similar to cardiac myxomas, and generally demonstrate myofibroblastic differentiation. There is no evidence that they derive from the same cell as myxomas, however, in that they do not arise in benign myxomas, tend to originate in sites in the atrium away from the septum and are histologically similar to sarcomas that arise in the intima of great arteries (a site in which myxomas do not arise). The second most common group of cardiac sarcomas are angiosarcomas, which are histologically identical with angiosarcomas that arise in extracardiac sites, and arise from endothelial cells usually in the right atrium or pericardium. Despite the fact that the heart is comprised mostly of muscle, only a small fraction of cardiac sarcomas show characteristics of striated muscle (i.e. rhabdomyosarcomatous differentiation). Because

working heart muscle cells are terminally differentiated and show little propensity to divide, it is perhaps not a surprise that neoplasms of the heart are more likely to derive from less committed stromal cells that line the endocardium.

TUMOUR PATHOLOGY (CLINICAL, GROSS AND HISTOLOGICAL FEATURES)

For the purposes of this review, only primary cardiac neoplasms will be addressed (**Table 1**). Neoplasms arising in the heart include cardiac myxoma (about 75%) and cardiac sarcomas (less than 25%); other neoplasms, such as paragangliomas and teratomas, are extremely rare and will not be discussed in detail. Cardiac sarcomas are heterogeneous, but will be grouped into endocardial-based sarcomas, or myofibroblastic intimal sarcomas, which usually arise in the left atrium; angiosarcomas, which generally arise in the right atrium and pericardium; and miscellaneous sarcomas.

Two additional malignancies that arise in or near the heart need brief mention here. Malignant mesotheliomas of the pericardium, or the serosal lining of the heart, are rare neoplasms that share many clinical and pathological features with the much more common mesothelioma of the pleura. Pericardial mesotheliomas are often extensions of pleural mesotheliomas, and share the same pathological and epidemiological features as pleural mesotheliomas. The second rare malignancy of the heart that needs mention is the malignant lymphoma. Lymphomas generally arise from haematopoietic tissues that reside in lymph nodes, the spleen or the bone marrow, but may occasionally arise in parts of the body that do not normally possess large numbers of lymphoid cells. These locations include the soft tissue and internal organs, including brain, liver, and heart. The incidence of extranodal lymphomas has recently increased, because of the large numbers of people with immune deficiency syndromes, either due to infection with human immunodeficiency virus or because of iatrogenic immunosuppression in patients with allografts. Malignant lymphomas and malignant mesotheliomas will be discussed briefly in this chapter, but the reader is directed to other portions of this volume that address these neoplasms in greater detail. (See the chapters *Lymph Nodes* and *Pleura and Peritoneum*.)

Myxoma

Cardiac myxoma is a benign endocardial-based neoplasm that usually arises in the left atrium (70%) at the region of the oval fossa (**Figure 1**). About 20% of myxomas arise in the right atrium, also usually in the region of the atrial septum or, less commonly, in ventricular sites. Myxomas that originate on the valve surfaces are exceptionally rare, and many reported cases actually represent a different lesion, usually a papillary fibroelastoma, not a true neoplasm.

The mean age at presentation is 50 years in cases of sporadic myxoma (Burke and Virmani, 1996). Cardiac myxoma arises from the endocardial surface by a stalk, which may be either broad-based or pedunculated. There are two gross appearances which characterize the surface of cardiac myxoma. Approximately 70% of tumours have an intact, smooth, endothelialized surface, with no surface thrombus; these lesions appear to be quiescent, with little possibility for further growth. Such tumours cause symptoms generally by chronic obstruction of the mitral valve, often resulting in pulmonary hypertension and symptoms of congestive heart failure (**Figure 2**). Occasional tumours cause symptoms as a result of hormone-like substance (cytokines) that stimulate the immune system, causing fever, weight loss and other constitutional symptoms. Because cardiac imaging is becoming more sophisticated and commonplace, an increasing percentage of cardiac myxomas are being detected as incidental findings in asymptomatic patients. Although a routine chest X-ray is unlikely to detect a cardiac myxoma in the majority of cases, about 5% of left-sided myxomas and up to 50% of right-sided tumours, will be detected on the basis of tumour calcification. More non-specific findings, such as cardiomegaly or evidence of mitral valve obstruction, are common in left-sided myxomas.

The majority of cardiac myxomas have a smooth surface (**Figure 3; see colour plate section**). A small

Table 1 Classification of primary cardiac neoplasms[a]

Tumour type	Site in heart	Biological behaviour	Associations
Myxoma	Left atrium, right atrium	Benign	Myxoma syndrome (2%)
Sarcoma		Highly malignant	None
Myofibroblastic	Atria (left > right)		
Angiosarcoma	Right atrium, pericardium		
Other	Various		
Lymphoma	Atria, epicardium, ventricles	Malignant	Immunosuppression (50%)
Mesothelioma	Pericardium	Highly malignant	Asbestos (20–30%)

[a]Lesions that are variably considered hamartomas, such as rhabdomyoma, fibroma, haemangioma and papillary fibroelastoma, are not included. Likewise, primary neoplasms that are extremely rare, such as paraganglioma, are also not included.

	Left atrial	Right atrial	Multiple or ventricular
Number	106 (71%)	28 (19%)	16 (10%)
Mean age (years)	53 ± 17	54 ± 18	35 ± 16
Age range (years)	7–83	13–77	16–68
Syndrome	1 (1%)	1 (4%)	5 (31%)
M:F	52:54	16:12	6:10

Figure 1 Sites of occurrence, cardiac myxoma (150 tumours seen by the authors). Multiple and ventricular cardiac myxomas demonstrate a clinically distinct clinical profile. They arise in younger patients and are more likely to be associated with extracardiac lesions (myxoma syndrome).

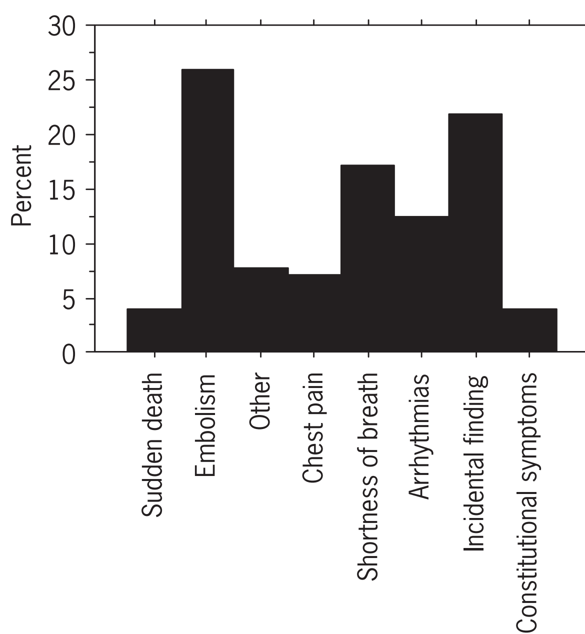

Figure 2 Cardiac myxoma, clinical symptoms at presentation. The most common single presentation relates to embolization. However, these tumours account for only 25% of cases. Sudden death may occur from cardiac myxoma by embolization to coronary vessels.

but significant proportion of cardiac myxomas (about 30%) have a rough, papillated surface partly covered by thrombus (**Figure 4; see colour plate section**). These tumours often cause symptoms because of embolization; that is, a portion of tumour or attached clot will break off and lodge somewhere in the patient's circulation. In most cases, the embolic site will be in the systemic circulation, as most cardiac myxomas are left-sided. Typical embolic sites are the brain, kidneys and arteries of the extremities. Emboli to the brain may be asymptomatic, or cause minor or even major strokes; if the retinal artery is involved, temporary blindness (amaurosis fugax) may ensue. Dislodged tumour is not synonymous with metastasis, as the myxoma does not seed organs and lymph nodes, forming new growths (metastatic deposits). However, embolic myxoma may occasionally cause weakness and aneurysm of the involved artery, especially in the cerebral circulation (Furuya *et al*., 1995). These aneurysms may be detected by angiography, but their relationship to a patient's symptoms is often unclear and, after removal of the primary tumour, they tend to regress. If a cardiac myxoma dislodges into the arteries of the arm or legs, ischaemic symptoms may result, including muscle cramping and pain, and rarely even gangrene.

Other symptoms that can be precipitated by cardiac myxoma include palpitations, syncope and chest pain. Right-sided tumours may cause pulmonary embolism if they possess an irregular surface. Approximately 2% of cardiac myxomas occur in families, and are associated with noncardiac diseases, including skin lesions and tumours and endocrine abnormalities (Singh and Lansing, 1996). In these patients, tumours tend to cause symptoms at an early age (childhood to young adulthood), by embolization.

The microscopic features of cardiac myxoma are heterogeneous, often within a single tumour, explaining the diversity of imaging findings, especially with contrast media. The name 'myxoma' derives from the abundant myxoid ground substance which is produced by the tumour cells (**Figure 5; see colour plate section**). Unlike most neoplasms, the tumour cells themselves are often a minority of the total cells of the tumour, which include reactive vessels, inflammatory cells and reactive stromal cells. Unlike sarcomas, myxomas never infiltrate the cardiac muscle, and respect the borders of the endocardium. The tumour cells are primitive, undifferentiated cells that form syncytia shaped as cords and rings, and have a variety of cytological features. In general, the nuclei are round to ovoid without prominent nucleoli, although in some tumours, large nucleoli may be present. The cytoplasm is abundant and eosinophilic. In many areas, especially away from the attachment to the myocardium, the tumour cells are intimately related to endothelial cells and capillaries, and appear to give rise to vascular structures. In 2% of cardiac myxomas, the tumour cells exhibit glandular differentiation, similar to the lining of the gastrointestinal tract. The interstitium of the tumour often contains dendritic cells, macrophages, lymphocytes, haemorrhage and breakdown blood products in the form of haemosiderin. In about 10% of myxomas, large deposits of haemosiderin may precipitate in elastic tissue of the interstitium, forming calcified structures that may be seen on radiographs (gamna-gandy bodies). In general, however, the majority of the haemosiderin is found engulfed within foamy macrophages. Ossification is also not infrequently present in cardiac myxoma, often those arising on the right side; approximately 10% of myxomas demonstrate radiographically detectable calcification (Basso *et al*., 1997).

Myofibroblastic (Intimal) Sarcoma

Myofibroblastic sarcomas are among the most common cardiac sarcomas, followed by angiosarcomas and undifferentiated sarcomas (**Figure 6**). Malignant neoplasms that occur in the atrial cavities are generally highly malignant myofibroblastic sarcomas grossly and clinically closely mimic the benign myxoma (Burke *et al*., 1992; Burke and Virmani, 1996). The initial symptoms may be similar to those of myxoma, including shortness of breath, chest pain, signs and symptoms of mitral valve or tricuspid valve obstruction and symptoms resulting from tumour embolism. Cardiac sarcomas tend to embolize less frequently than myxoma, however. Like myxoma, atrial sarcomas are often pedunculated, but are more likely to arise in the wall of the atria, and not the atrial septum, and often invade the wall of the atrium, epicardium or mitral valve. Those sarcomas that demonstrate infiltrative characteristics are easily distinguished from myxomas, which always respect the endocardial boundaries of the heart. Imaging studies may not be able to differentiated myxoma from sarcoma, although certain features suggest a malignancy, i.e. attachment site in the wall of the atrium and infiltration of the atrial wall. Contrast techniques that take advantage of the heterogeneous vascularity of cardiac myxomas and imaging studies that detect the large amount of haemorrhage within myxomas may also prove to be helpful adjuncts in the differential diagnosis of atrial myxoma and sarcoma. A small proportion (less than 20%) of intimal sarcomas of the heart arise in the cardiac ventricles, where they occur as endocardial-based tumours that obstruct blood flow.

The histological features of intimal sarcoma are heterogeneous, and include sarcoma subtypes that would by roughly synonymous with fibrosarcoma, malignant fibrous histiocytoma, osteosarcoma and chondrosarcoma. The

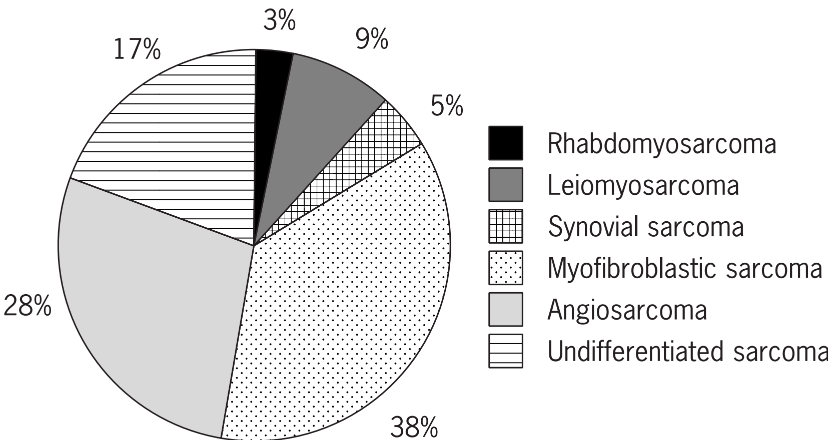

Figure 6 Histological types of cardiac sarcoma. In the authors' files, the majority of cardiac sarcomas include myofibroblastic, leiomyosarcomatous and undifferentiated tumours. Leiomyosarcomas are similar to myofibroblastic sarcomas, but are more purely smooth muscle cell in origin.

degree of osteo- or chondrosarcomatous differentiation is usually small, and it is rare to have a diffusely calcified sarcoma arising in the atrium. It must be kept in mind that ossifying tumours of the left atrium are usually malignant; small foci of ossification are not rare, however, in right atrial myxomas. The histological appearance of cardiac sarcomas is similar to that of sarcomas that arise in soft tissue and, overall, the full histological spectrum of soft tissue sarcomas may be encountered in the heart. However, those that arise within the atrium are primarily intracavitary. Because of their predominantly endoluminal growth, and because they are histologically very similar to sarcomas that arise within the great arteries (pulmonary artery and aorta), it is convenient for descriptive and taxonomic purposes to assume that they derive from the endocardium. Like the intima of arteries, the endocardium is composed of a layer of endothelial cells overlying an elastic layer, with a variable number of smooth muscle cells (or myofibroblastic cells) that occur sandwiched within. It is presumably these myofibroblastic cells, which are prone to proliferate, that undergo malignant transformation and result in the formation of sarcomas of the atria.

Angiosarcoma

Myofibroblastic sarcomas and angiosarcomas are the most common subtypes of cardiac sarcomas. The mean age at presentation for these sarcomas is 40 years (**Figure 7**). Angiosarcomas of the heart are one of the more common

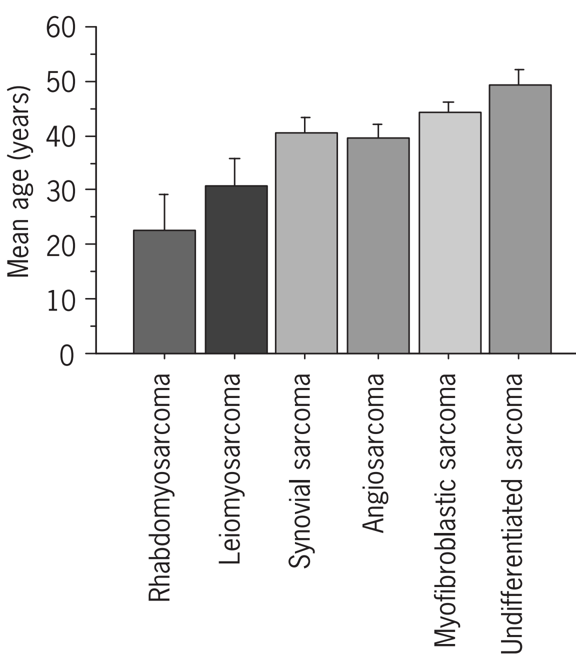

Figure 7 Mean age at presentation (years), by type of cardiac sarcoma. Rhabdomyosarcomas are tumours of adolescents and young adults. The overall mean age at presentation of cardiac sarcoma is 40 years.

cardiac sarcomas and, for unknown reasons, usually arise in the right atrium (Putnam *et al*., 1991; Burke *et al*., 1992; Tazelaar *et al*., 1992). There may be a slight bias for males over females (**Figure 8**). Unlike myofibroblastic sarcomas, they do not form pedunculated intracavitary masses, but invade early into the atrial wall and pericardium (**Figure 9; see colour plate section**). A few cardiac angiosarcomas are entirely confined to the pericardial space. The presenting symptoms of cardiac angiosarcomas, therefore, are typically related to pericardial disease, especially recurrent pericardial effusions or haemopericardium. A minority of cardiac angiosarcomas present with symptoms of obstruction of cardiac blood flow. Because cardiac angiosarcomas typically are right-sided, pulmonary metastases occur very early in the course of disease. In some patients, it is the presence of these lung lesions which cause the initial symptoms. The histological appearance of cardiac angiosarcoma is similar to that of soft tissue sarcomas. Rare examples of low-grade angiosarcomas (epithelioid haemangioendothelioma) have been described in the heart. However, epithelioid angiosarcomas, which are as lethal as histologically typical angiosarcomas, have not yet been reported to occur within the pericardium.

Miscellaneous Sarcomas

One would think initially that sarcomas with muscular differentiation (i.e. tumours composed of cells demonstrating features of striated muscle, or rhabdomyosarcomas) would predominate in the myocardium, as the bulk of the heart is composed of working muscle cells. However, cardiac muscle is terminally differentiated, with limited propensity for cellular division. Therefore, it makes sense that rhabdomyosarcomas are rare tumours, and make up less than 10% of all heart malignancies. As one would expect, the majority of these tumours occur in the walls of the heart, and they do not usually project into the lumen like intimal sarcomas, and rarely infiltrate the pericardium like angiosarcomas. Rhabdomyosarcomas of the heart are almost always of the embryonal type, and tend to occur in children and adolescents (Burke *et al*., 1992). Histologically, they are similar to embryonal rhabdomyosarcomas of soft tissue, although the so-called ‘alveolar’ subtype of rhabdomyosarcoma is infrequently seen in the myocardium.

Another variety of sarcoma that makes up about 5% of heart sarcomas is the synovial sarcoma, which, in the soft tissue, generally arises at or near joint spaces (Burke *et al*., 1992; Karn *et al*., 1994; Iyengar *et al*., 1995). The cell of origin of synovial sarcomas is unknown. These tumours typically demonstrate a biphasic histological growth pattern of spindle and glandular cells. In the heart, synovial sarcomas have a predilection for the pericardial space, but may occur in any cardiac site.

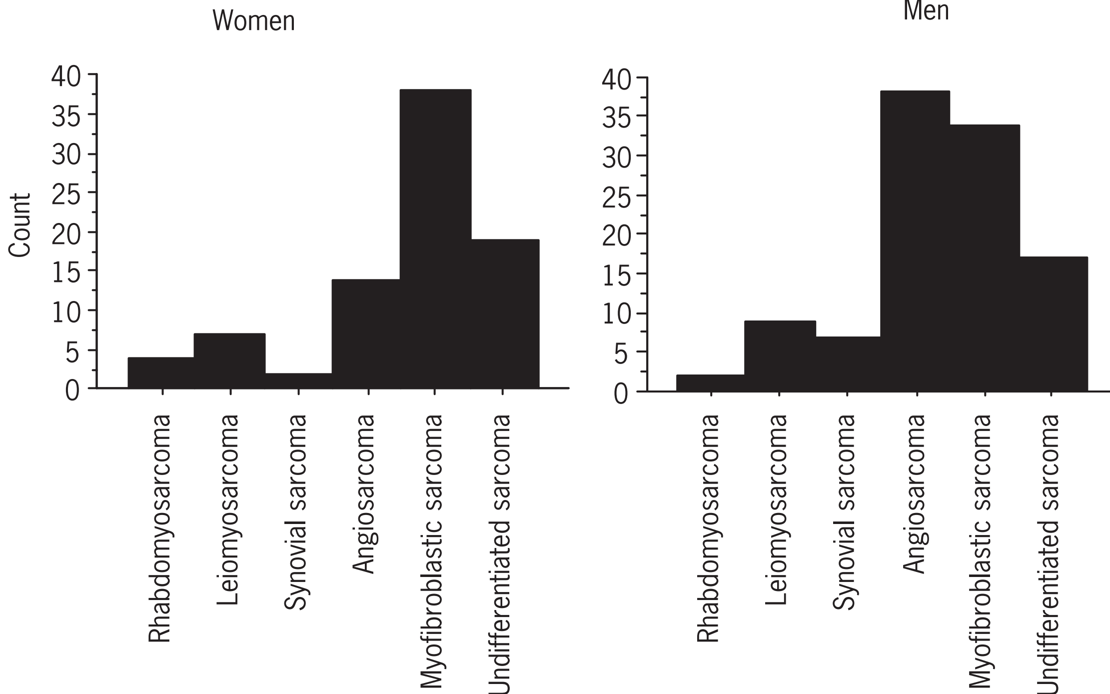

Figure 8 Gender distribution, cardiac sarcomas. There is no particular gender bias in cardiac sarcomas. In our experience, however, myofibroblastic sarcomas are slightly more common in women and angiosarcomas in men.

Sarcomas that are extremely rare in the cardiac location include liposarcomas, malignant localized fibrous tumours, malignant peripheral nerve sheath tumours and Ewing sarcoma (primitive neuroectodermal tumour). A fairly large proportion (up to 25%) of cardiac sarcomas defy classification, and represent a variety of undifferentiated spindle cell or small cell sarcomas.

Malignant Mesothelioma

Mesotheliomas are malignancies of the serosal lining tissues and, as such, may occur in the pleura, pericardium, peritoneum and inguinal sac. For reasons probably related to causation, they are most common in the pleura, which is at higher risk of exposure to inhaled asbestos than the other serosal sites. Pericardial mesotheliomas cause symptoms of chronic pericarditis, including pericardial pain, jugular venous distension, shortness of breath and eventually heart failure. The typical patient with pericardial mesothelioma may experience several episodes of pericarditis and pericardial effusion before a definitive diagnosis is made. The diagnosis may be confirmed only by biopsy sampling of pericardial tissue, and may be suggested by cytological analysis of pericardial fluid. Pericardial mesotheliomas, like angiosarcomas, often result in chronic effusion, but are much more likely to encase the heart in an unresectable constricting mass (**Figure 10; see colour plate section**). In early stages of disease, the primary differential diagnosis is chronic constrictive pericarditis, which is usually idiopathic, but may be related to autoimmune and other disorders (Burke and Virmani, 1996).

Pathologically, malignant mesotheliomas of the pericardium are identical with those of other sites. There is a bimodal appearance to these tumours microscopically, as there is for synovial sarcoma. However, the antigenic profile of mesothelioma is somewhat different from that of synovial sarcoma, and the latter tumour produces mucins not found in mesothelioma.

Malignant Lymphoma

Lymphomas arising in the heart are extremely uncommon; conversely, secondary involvement of the myocardium in patients with well advanced lymphomas arising in lymph nodes is not uncommon. Primary cardiac lymphomas are virtually all of B cell lineage, and may represent one of many histological subtypes, including low-, intermediate- and high-grade tumours (Burke and Virmani, 1996). For reasons that are not clearly understood, T cell lymphomas and Hodgkin disease are exceedingly rare as primary lesions within the heart or pericardium. The symptoms that cause lymphomas of the heart are varied, and depend on the site of origin within the myocardium. Typically, cardiac lymphomas arise within the walls of the organ, often in the atria with prominent epicardial involvement. There may be depressed cardiac function, obstruction to blood flow or pericardial effusions that produce the initial symptoms in patients with cardiac lymphoma.

Miscellaneous Neoplasms

Besides myxomas and sarcomas, primary neoplasms of the myocardium are vanishingly rare (Burke and Virmani, 1996). These include paragangliomas (phaeochromocytomas), neurofibromas and granular cell tumours. Cardiac paragangliomas generally occur in the atrial and atrial septum, where there are paraganglial tissues as a result of autonomic innervation of the heart. Cardiac paragangliomas may cause symptoms of hypertension. Rarely, cardiac paragangliomas may be malignant, and demonstrate the capability of developing distant metastases. However, in most patients, excision of the lesion is curative. The pathological and biological features of cardiac paraganglioma are similar to those that arise in paraganglial tissues elsewhere in the body, such as the adrenal gland and carotid bodies.

EPIDEMIOLOGY

Primary cardiac tumours are rare, so there are few accurate data to suggest their true prevalence. In general, it has been estimated that the incidence of cardiac neoplasms is approximately 0.01%, or one in 10 000 persons (Lam *et al*., 1993; Burke and Virmani, 1996). Of these, the majority of adult tumours are myxomas and sarcomas, at a ratio of between 2 : 1 and 8 : 1. The incidence of surgically excised cardiac tumours is estimated at more than three per million population per year (Reyen *et al*., 1998). There is no strong sex or racial predilection among primary heart tumours, although in some studies, more women than men suffer from cardiac myxomas, sometimes by a factor of 3 : 1 (Endo *et al*., 1997). In our experience, women are more likely to develop myofibroblastic sarcomas and men angiosarcomas (**Figure 8**). Epidemiological studies demonstrate that there are a variety of environmental factors and hereditary conditions that predispose to extracardiac soft tissue sarcomas. In the case of mesothelioma, it has become clear that there is a strong association with pericardial mesothelioma and asbestos exposure, as had been demonstrated for pleural and abdominal mesotheliomas. Pericardial mesotheliomas are rare, account for 1% of all mesotheliomas, and it has been estimated that there were 140 cases reported in the world literature in 1994 (Kaul *et al*., 1994), and fewer than 30 in the English literature (Thomason *et al*., 1994).

AETIOLOGY

Cardiac myxoma

There is little known about the aetiology of primary cardiac tumours. The aetiology of the various types of primary cardiac tumours is presumably the same as that for histologically similar neoplasms that arise in extracardiac sites. In the case of cardiac myxoma, which is unique to the heart, the only clues to aetiology come from those cases that are familial and may have a genetic basis. In 1980, Atherton *et al*. described a patient with skin pigmentation, neurofibromas and cardiac myxomas (Atherton *et al*., 1980). Later, the associations were refined to include lentigines, mucocutaneous myxomas and blue naevi, when it was recognized that the myxoid skin lesions were better classified as myxomas than myxoid neurofibromas. The list of associated conditions continues to grow, and includes Sertoli cell tumours of the testis, myxoid fibroadenoma of the breast, pituitary hyperactivity including growth hormone-producing adenoma, pigmented nodular adrenocortical disease and psammomatous melanotic schwannoma (Carney, 1995; Stratakis *et al*., 1996). The genetic mode of transmission of myxoma syndrome has not been determined, but autosomal dominant transmission is favoured in most families. It has been shown by several investigators that familial cardiac myxomas are more often multiple, recurrent and right-sided than sporadic myxomas.

Cardiac Sarcoma

The aetiology of cardiac sarcoma is unknown, and is probably similar to that of soft tissue sarcomas. Angiosarcoma may be induced by ionizing radiation, especially those of the liver in patients having received injections of radiation contrast material. There is a case report of a primary cardiac (pericardial) angiosarcoma in a patient with prior radiation therapy for mediastinal seminoma (Killion *et al*., 1996). In the majority of patients with cardiac angiosarcoma, however, there is no such prior history. Chromosomal and genetic defects have been described in soft tissue sarcomas but an extensive study of such defects in cardiac sarcomas has not been undertaken. It has been estimated that 7–33% of soft tissue sarcomas may have a genetic component (Hartley *et al*., 1993). A variety of exposures have been associated with extracardiac sarcomas, including arsenical pesticides and medications, phenoxy herbicides, dioxin, vinyl chloride, immunosuppressive drugs, alkylating agents, androgen-anabolic steroids, human immunodeficiency virus and human herpes virus type 8 (Zahm and Fraumeni, 1997).

Pericardial Mesothelioma

The most common site of malignant mesothelioma is the pleura. A majority of patients with pleural mesothelioma have a history of asbestos exposure. There is increasing evidence that at least a large minority of patients with pericardial mesotheliomas also have a history of asbestos exposure, and pericardial mesothelioma may be

experimentally induced by topical asbestos application (Burke and Virmani, 1996). The mechanism by which asbestos causes mesothelioma is uncertain, but it is known that certain forms of the inhaled element are more likely to result in malignancies than others. About 1% of asbestos-related mesotheliomas are pericardial and the rest are pleural and other sites. There are undoubtedly other stimuli for the development of mesothelioma, as some animals develop malignant mesothelioma of pericardium without any apparent asbestos exposure (Maltoni *et al.*, 1991; Chandra and Mansfield, 1999; Closa *et al.*, 1999). Simian virus induces pericardial mesotheliomas in hamsters, but a viral aetiology for human mesothelioma has not been demonstrated (Cicala *et al.*, 1993).

Cardiac Lymphoma

Approximately 50% of primary lymphomas of the heart arise in patients with acquired immunodeficiency, either iatrogenic (in cases of allograft recipients) or viral (in cases of AIDS) (Burke and Virmani, 1996). However, the heart is not a common site for the development of lymphomas in patients with AIDS or allografts (Tirelli *et al.*, 1994). The aetiology of immunosuppression-related lymphomas is believed related to infection by Epstein–Barr virus, which has the ability to transform B cells *in vitro*. In immunocompetent patients, Epstein–Barr virus is also associated with nasopharyngeal carcinomas and Burkitt lymphoma. Another virus which may have an aetiological role in immunosuppression-related lymphomas is another herpes virus, HHV-8, also known has Kaposi sarcoma-associated herpes virus. HHV-8-related lymphomas are often confined to serosal spaces without an identifiable contiguous tumour mass. The usual location for these lesions, however, is the peritoneum or pleura, with only rare examples occurring in the pericardium (Nador *et al.*, 1996).

The remaining 50% of primary cardiac lymphomas are not related to immunosuppression or herpes viruses (Bogaert *et al.*, 1995; Versluis *et al.*, 1995; Ito *et al.*, 1996). These tumours are fairly rare and aetiological agents have not been identified. Presumably, the pathoaetiology of cardiac lymphoma is similar to that of nodal lymphomas.

SCREENING AND PREVENTION

Because of the rarity of primary cardiac neoplasms, there is little if any role for screening or attempts at prevention. The only possible exception to this rule would be in easily identifying individuals at greatly increased risk for the development of a primary cardiac myxoma. In cases of myxoma syndrome, family relatives should be aggressively evaluated for the presence of cardiac myxoma, as these can present with embolization and even sudden death. We are aware of a case of a young boy with cutaneous features of the myxoma syndrome, whose father had a cardiac myxoma removed at a young age. The boy was not evaluated medically, and died suddenly due to coronary embolism from cardiac myxoma at a young age.

ULTRASTRUCTURE/AND IMMUNOHISTOCHEMISTRY

Cardiac Myxoma

The electron microscopic features of cardiac myxoma are of limited value in diagnosis, owing to the heterogeneous nature of cardiac myxoma and limited sampling afforded by ultrastructural techniques. Studies of myxoma have demonstrated myxoma cells to be primitive mesenchymal cells with intermediate filaments and cytoplasmic organelles. The cells are present either as single stellate cells, or groups, and have primitive tight intracellular junctions lacking desmosomes. Myxoma cells are best described ultrastructurally as embryonic cells that occasionally show features of myofibroblasts. The ground substance contains fine electron-dense granules which have been described as identical with the proteoglycan granules seen in the ground substance of cartilage (Feldman *et al.*, 1977; Goldman *et al.*, 1987).

The immunohistochemical features of cardiac myxoma indicate a pluripotent myxoma cell capable of divergent differentiation (Burke and Virmani, 1993, 1996; Berrutti and Silverman, 1996; Deshpande *et al.*, 1996). The most consistent antigenic type of cellular antigen expressed in myxomas is that of endothelial differentiation (Silverman and Berrutti, 1996). Other antigens found on myxoma cells have included smooth muscle cell antigens, neural antigens and epithelial antigens. The use of immunohistochemical techniques in the diagnosis of cardiac myxoma is limited. Recently, immunohistochemical data suggest that the myxoma is a weakly proliferative lesion without modulation of oncogene/tumour suppressor gene products (Suvarna and Royds, 1996).

Cardiac Sarcoma

Immunohistochemical studies are useful for distinguishing cardiac sarcomas from other processes, but are not particularly useful in subtyping the lesions (Burke *et al.*, 1992; Tazelaar *et al.*, 1992). An exception to this rule includes the diagnosis of rare types of sarcoma, such as malignant localized fibrous tumour (CD 34 positivity) and synovial sarcoma. Immunohistochemistry is currently of little use in providing prognostic data for cardiac sarcomas, which are uniformly lethal. In general, the immunohistochemical findings of cardiac sarcomas are similar to those of soft tissue sarcomas, and the reader is directed to relevant chapters in this volume. (See the chapter *Soft Tissues*.)

Cardiac Lymphoma and Pericardial Mesothelioma

The immunohistochemical and ultrastructural features of these neoplasms vary by cardiac or noncardiac origin. The reader is referred to other sections of this volume for immunohistochemical and ultrastructural characterization of lymphomas and mesotheliomas. (See the chapters *Lymph Nodes* and *Pleura and Peritoneum*.)

MOLECULAR GENETIC FINDINGS

Myxoma

Tissue cultures of cardiac myxoma cells have demonstrated chromosomal abnormalities both in familial and non-familial cases. A locus on chromosome 2p16 has been identified that may be involved in the regulation of genomic stability of dividing myxoma cells, in particular the structure of telomeres in replicating chromosomes (Stratakis *et al*., 1996). Other studies have shown clonal and non-clonal abnormalities including dicentric chromosomes and telomeric associations, clonal telomeric associations between chromosomes 13 and 15 and nonclonal telomeric associations between chromosomes 12 and 17 (Richkind *et al*., 1994; Dijkhuizen *et al*., 1995).

Cardiac Sarcoma

Molecular genetic and chromosomal abnormalities are helpful in the classification of soft tissue sarcomas (Pollock, 1994; Mohamed *et al*., 1997; Singer, 1999). In the heart, molecular diagnosis has been helpful in the classification of cardiac synovial sarcomas (Karn *et al*., 1994; Iyengar *et al*., 1995), specifically the X;18 translocation. The molecular aetiology of extracardiac soft tissue sarcoma involves growth factors and their receptors, nuclear and cytoplasmic oncogenes and tumour-suppressor genes (Pollock, 1994).

Cardiac Lymphoma

Most cardiac lymphomas are of B cell origin (Bogaert *et al*., 1995; Chao *et al*., 1995; Versluis *et al*., 1995; Ito *et al*., 1996; Chim *et al*., 1997). Those that arise in immunocompromised patients are often associated with Epstein–Barr virus. The molecular genetics of nodal lymphomas have been extensively studied, and are covered in other areas of this volume.

Pericardial Mesothelioma

The karyotypes of malignant mesotheliomas are complex, and often preclude the identification of primary chromosome abnormalities. Recently, peritoneal mesothelioma with a balanced t(3;3)(p14;q29) translocation has been described. Molecular genetic abnormalities of pericardial mesotheliomas have not been described.

PROGNOSTIC FACTORS

Cardiac Myxoma

The prognosis for cardiac myxoma is excellent. With adequate surgical excision, the recurrence rate is vanishingly small. Patients with recurrent myxoma should be considered possible myxoma syndrome victims, especially if they are younger than 40 years of age. Alternatively, an incorrect diagnosis should be considered, as many recurrent cardiac sarcomas are initially misdiagnosed as myxomas. In the majority of a series of cardiac myxoma, surgical treatment is curative in virtually all cases (Lazzara *et al*., 1991; Actis Dato *et al*., 1993; Bastos *et al*., 1995; Gawdzinski and Sypula, 1996; Bjessmo and Ivert, 1997). Reports of malignant myxoma should be regarded with suspicion. Rare well-documented examples of myxomas with embolization (‘metastasis’) to the cerebral vessels and skin have been reported (Reed *et al*., 1989; Scarpelli *et al*., 1997).

Cardiac Sarcoma

In stark contrast to cardiac myxoma, the prognosis of cardiac sarcoma is dismal, and generally measured in months. Although surgery is indicated for accurate diagnosis and palliation, and incurs a low mortality risk, the outcome is death within 2–3 years (Murphy *et al*., 1990; Putnam *et al*., 1991; Endo *et al*., 1997; Centofanti *et al*., 1999). The most important histopathological prognostic indicators are increased mitotic rate and the presence of necrosis (Burke *et al*., 1992). In addition, patients with right-sided tumours and those presenting with metastatic disease have an especially poor prognosis. Even in patients with completely resectable tumours, most recur at a median time of 10 months. The median time to progression, in one series, was shorter in patients presenting a cardiac angiosarcoma than other histological types (3 vs 14 months, $P < 0.01$), with an overall 2-year survival rate of 26% (Llombart-Cussac *et al*., 1998).

Pericardial Mesothelioma

The prognosis of pericardial mesothelioma is poor: 50% of patients are dead at 6 months, and an exceptional patient may live as long as 48 months. The mean survival of patients with pericardial mesothelioma is shorter than that of patients with pleural and peritoneal mesotheliomas (Hillerdal, 1983).

Cardiac Lymphoma

The prognosis of primary cardiac lymphoma is difficult to ascertain, because of the extreme rarity of the lesion,

and concomitant diseases in patients who are immunosuppressed. As with nodal lymphomas, the prognosis, and also the treatment, would vary by the grading of the lymphoma. As low-, intermediate- and high-grade lymphomas have all been described to arise in the heart, the prognosis would probably vary with the histological subtype.

OVERVIEW OF PRESENT CLINICAL MANAGEMENT

The clinical management of cardiac myxoma is that of surgical excision, which is curative (Mishra *et al*., 1991; Actis Dado *et al*., 1993; Castells *et al*., 1993; Bjessmo and Ivert, 1997). Occasionally, a patch repair of the atrial septum is required and, rarely, valve reconstruction or repair.

The initial treatment of cardiac sarcoma is surgical excision. In many cases, the preoperative diagnosis is cardiac myxoma. However, complete excision is often difficult, unlike myxoma, and surgical margins for adequacy of excision should be ascertained by intraoperative consultation with the pathologist. The long-term management of cardiac sarcomas is difficult, as the use of radiation and chemotherapy is of limited benefit (Noirclerc *et al*., 1997; Movsas *et al*., 1998). However, many centres offer these modalities of treatment, which are similar to those administered for soft tissue sarcomas. The only chance at a cure in a patient with heart sarcoma is orthotopic heart transplantation (Noirclerc *et al*., 1997); long-term survival has also been attained with fractionated radiation therapy (Movsas *et al*., 1998). Adjuvant chemotherapy has been advised in high-grade cardiac sarcomas (Ceresoli *et al*., 1999), although it has not been demonstrated to be effective (Llombart-Cussac *et al*., 1998).

NORMAL DEVELOPMENT AND STRUCTURE

The nervous system and skeletal muscular system are both electrically active and they have an intimate functional relationship. However, tumours that arise in these two systems are very different. Whereas primary tumours of neuroepithelial differentiation arising from the central nervous system (CNS) and peripheral nervous system (PNS) are common, primary tumours of skeletal muscular differentiation that arise from skeletal muscle are extremely rare. In contrast, most primary tumours in skeletal muscles have mesenchymal differentiation of other lineages and they presumably arise from nonmuscular tissue adjacent to or within the muscle. Interestingly, primary tumours with muscular differentiation (e.g. rhabdomyosarcoma) usually arise in soft tissue rather than skeletal muscle. Therefore, it is most appropriate to consider these tumours with other soft tissue tumours. The reader should refer to the chapter on soft tissue tumours in this section and the Further Reading section for further details.

Tumours of the nervous system display morphological, immunohistochemical and molecular features that recapitulate their normal developing and mature counterparts. Knowledge on normal development and anatomy of the nervous system is fundamental for the study of these tumours.

The mature nervous system is composed of neurons and their supporting cells. In the CNS, neurons and axons are supported by glial cells, namely astrocytes, oligodendrocytes, ependymal cells and microglia. Choroid plexus is neuroepithelial tissue specialized in the production of cerebral spinal fluid. Other supporting cells of the nervous system include the arachnoid cells and a variety of mesenchymal cells. Neurons and axons in the PNS are supported by Schwann cells that are of neuroepithelial (neurocrest) origin and other mesenchymal cells. Tumours of the nervous system can have features reminiscent of any or a combination of these components but they do not necessarily arise from these components.

Formation of the CNS and PNS is a highly organized process that involves induction, cell division, differentiation, migration and cell death. During early development, the ectoderm undergoes neural induction by the underlying chordamesoderm and becomes the neuroectoderm. The neuroectoderm becomes a thickened layer of cells and forms the neural plate that in turn folds into a tube that will eventually develop into the brain and spinal cord. Part of the neural plate will give rise to the neural crest cells that give rise to Schwann cells, adrenal medulla and cell types such as melanocytes, odontoblasts and many mesenchymal and musculoskeletal components of the head.

At the dawn of development, the neural tube is composed of a thick, pseudostratified, columnar neuroepithelium that is composed of primitive neuroepithelial cells. Then, these

cells segregate into a highly cellular ventricular zone and the paucicellular marginal zone. The ventricular zone will give rise to all neurons and glial cells with the exception of microglial cells that belong to the mononuclear phagocytic cell lineage. Through the guidance of radial glia, developing neurons and glial cells migrate out from the ventricular zone and segregate into several foetal layers between the ventricular zone and marginal zone. Such foetal laminations will evolve into the six-layer adult cortex during maturation.

The maturation process involves interaction between many temporally and developmentally regulated genes. Young neurons will lose their ability to divide as they develop into mature neurons and over 50% of the young neurons will undergo apoptosis during maturation. Glial cells will develop into several specialized forms including astrocytes, oligodendrogliocytes, ependymal cells and epithelium of choroid plexus. In contrast to neurons, glial cells maintain their ability to divide in the mature nervous system.

In-depth discussion on development is beyond the scope of this chapter and the reader is referred to the Further Reading section.

TUMOUR PATHOLOGY

The central goal of tumour classification is to correlate pathological and biological properties with prognostic data. Classification of tumours of the nervous system, similar to tumours of other organ systems, is essentially based on a comparison of similarities between the neoplastic tissue and normal mature or developing counterparts. In the past 100 years or so, such comparison has been limited primarily to morphological features. In the recent past, comparison of the molecular phenotypes, mainly achieved by utilization of immunohistochemical techniques, *in situ* hybridization and cytogenetics have been used. The World Health Organisation (WHO) Classification of Tumours of the Nervous System (Kleihues and Cavenee, 2000) was formulated on the basis of such information (**Table 1**). In general, tumours are named according to the cell type that they most resemble. For example, an astrocytoma is a tumour that has features resembling astrocytes. Recent advances in molecular biology and cell biology and recognition of molecular signatures specific to particular types of tumour will presumably play a more important role in future classification systems.

Tumours of the Central Nervous System

The pathology of CNS tumours is a vast topic and it is not the intention of the authors to cover every aspect in this

Table 1 2000 WHO Classification of Tumours of the Nervous System

Tumours of neuroepithelial tissue
Astrocytic tumours
Diffuse astrocytoma
Fibrillary astrocytoma
Protoplasmic astrocytoma
Gemistocytic astrocytoma
Anaplastic astrocytoma
Glioblastoma
Giant cell glioblastoma
Gliosarcoma
Pilocytic astrocytoma
Pleomorphic xanthoastrocytoma
Subependymal giant cell astrocytoma
Oligodendroglial tumours
Oligodendroglioma
Anaplastic oligodendroglioma
Mixed gliomas
Oligoastrocytoma
Anaplastic oligoastrocytoma
Ependymal tumours
Ependymoma
Cellular
Papillary
Clear cell
Tanycytic
Anaplastic ependymoma
Myxopapillary ependymoma
Subependymoma
Choroid plexus tumours
Choroid plexus papilloma
Choroid plexus carcinoma
Glial tumours of uncertain origin
Astroblastoma
Gliomatosis cerebri
Chordoid glioma of the 3rd ventricle
Neuronal and mixed neuronal–glial tumours
Gangliocytoma
Dysplastic gangliocytoma of cerebellum (Lhermitte–Duclos)
Desmoplastic infantile astrocytoma/ganglioglioma
Dysembryoplastic neuroepithelial tumour
Ganglioma
Anaplastic ganglioglioma
Central neurocytoma
Cerebellar liponeurocytoma
Paraganglioma of the filum terminale
Neuroblastic tumours
Olfactory neuroblastoma (aesthesioneuroblastoma)
Olfactory neuroepithelioma
Neuroblastomas of the adrenal gland and sympathetic nervous system
Pineal parenchymal tumours
Pineocytoma
Pineoblastoma
Pineal parenchymal tumour of intermediate differentiation
Embryonal tumours
Medulloepithelioma

Table 1 (*Continued*)

Ependymoblastoma
Medulloblastoma
Desmoplastic medulloblastoma
Large cell medulloblastoma
Medullomyoblastoma
Melanotic medulloblastoma
Supratentorial primitive neuroectodermal tumour (PNET)
Neuroblastoma
Ganglioneuroblastoma
Atypical teratoid/rhabdoid tumour
Tumours of peripheral nerves
Schwannoma (neurilemmoma, neurinoma)
Cellular
Plexiform
Melanotic
Neurofibroma
Plexiform
Perineurioma
Intraneural perineurioma
Soft tissue perineurioma
Malignant peripheral nerve sheath tumour (MPSNST)
Epithelioid
MPSNST with divergent mesenchymal and/or epithelial differentiation
Melanotic
Melanotic psammomatous
Tumours of the meninges
Tumours of meningothelial cells
Meningioma
Meningothelial
Fibrous (fibroblastic)
Transitional (mixed)
Psammomatous
Angiomatous
Microcystic
Secretory
Lymphoplasmacyte-rich
Metaplastic
Clear cell
Chordoid
Atypical
Papillary
Rhabdoid
Anaplastic meningioma
Mesenchyma, nonmeningothelial tumours
Lipoma
Angiolipoma
Hibernoma
Liposarcoma (intracranial)
Solitary fibrous tumour
Fibrosarcoma
Malignant fibrous histiocytoma
Leiomyoma
Leiomyosarcoma
Rhabdomyoma
Rhabdomyosarcoma
Chondroma
Chondrosarcoma
Osteoma
Osteochondroma
Osteosarcoma
Haemanagioma
Epithelioid haemangioendothelioma
Haemangiopericytoma
Angiosarcoma
Kaposi sarcoma
Primary melanocytic lesions
Diffuse melanocytosis
Melanocytoma
Malignant melanoma
Meningeal melanomatosis
Tumours of uncertain histiogenesis
Haemangioblastoma
Lymphomas and haematopoietic neoplasms
Malignant lymphomas
Plasmacytoma
Granulocytic sarcoma
Germ cell tumors
Germinoma
Embryonal carcinoma
Yolk sac tumour
Choriocarcinoma
Teratoma
Mature
Immature
Teratoma with malignant transformation
Mixed germ cell tumours
Tumours of the sellar region
Craniopharyngioma
Adamantinomatous
Papillary
Granular cell tumour
Metastatic tumours

chapter. The reader should consult the Further Reading section for further details.

Tumours of the CNS can be separated into several major categories (**Table 2**). First and foremost, they can be separated into primary and secondary tumours. Primary tumours are those that arise within the central nervous system and can be categorized into several major groups.

The first category consists of tumours that have features of primitive neuroepithelium. In the WHO Classification (Kleihues and Cavenee, 2000), this category includes the embryonal tumours and pineoblastomas. Some tumours such as olfactory esthesioneuroblastoma also belong to this category, although they do not occur within the cranial cavity. Essentially, these tumours resemble the primitive neuroectoderm or primitive neuroepithelium.

Table 2 Major biological categories of tumours of the nervous system

Central nervous system (CNS)
Category 1: Primary tumour with features of primitive neuroepithelial cell
Category 2: Primary tumour with features of mature neuroepithelial cell
Category 3: Primary tumour with features of meninges and mesenchyme
Category 4: Primary tumour with features of tissue normally found outside the central nervous system
Category 5: Secondary (metastatic) tumour
Peripheral nervous system (PNS)
Category 1: Primary tumours with features of neuroblasts/mature neurons
Category 2: Primary tumours with features of mature supporting elements of the peripheral nervous system
Category 3: Primary tumours of paraganglia
Category 4: Secondary tumour

The second category consists of tumours which display features of mature neuroepithelial cells such as glial cells and neurons. These tumours are further separated into three major subcategories. The first subcategory has features of glial cells, the supporting elements of the CNS. These are among the most common primary tumours of the CNS and they are formed by cells that resemble astrocytes and/or oligodendrocytes and/or ependymal cells. They are, therefore termed astrocytoma, oligodendroglioma and ependymoma, respectively. Not infrequently, they may have features of more than one type of glial cell in which case they are termed mixed gliomas. The second subcategory contains a variable neuronal component. Tumours composed exclusively of neoplastic neurons are uncommon. Very often, the neoplastic neurons or ganglion cells are mixed with neoplastic glial cells, most often neoplastic astrocytes. This category constitutes the neuronal and mixed neuronal–glial tumours of the WHO Classification. The third subcategory consists of choroid plexus tumours. Although the choroid plexus is regarded as modified ependyma, it has features of epithelial cells rather than glial cells. Choroid plexus tumours also behave like epithelial tumours rather than glial tumours. For this reason, choroid plexus tumours are regarded as a separate category.

The third category consists of tumours that have features resembling meninges and other supporting mesenchymal components of the CNS. Meningiomas have features of arachnoid cells that cover leptomeninges. Tumours composed of other mesenchymal elements are named after the mature tissue they most resemble. Melanocytic tumours of the CNS arise most commonly from the leptomeninges.

The fourth category consists of primary tumours that resemble mature and developing tissue that may or may not be normally present in the cranial cavity, including germ cell tumours, primary haematopoietic tumours such as lymphoma and craniopharyngioma.

Secondary (metastatic) tumours are extremely common, primarily in adults. In fact, they are the most common tumour of the CNS. This should not be surprising since the brain consumes about 20% of the cardiac output but comprises only about 2% of the body mass. Secondary tumours of the CNS include metastatic carcinomas, malignant melanomas and sarcomas as well as secondary involvement of the CNS by haematopoietic tumours such as lymphomas and leukaemias.

Tumours of the Peripheral Nervous System

Tumours of the PNS can also be separated into several major categories (**Table 2**). Similar to CNS tumours, there are PNS tumours that recapitulate features of primitive neuroepithelial cells or neuroblasts and some of them contain mature neuronal elements. These tumours are classified under neuroblastic tumours in the WHO Classification.

The second major category consists of tumours that have features of the mature supporting elements of the PNS such as Schwann cells. These tumours are named after their normal counterparts and are termed schwannoma, neurofibroma and perineuroma. Some have aggressive biological properties and cannot be clearly identified phenotypically clearly as schwannoma or neurofibroma. Because of their malignant behaviour and mixed histological features, they are collectively termed malignant peripheral nerve sheath tumours (MPNSTs) and stand by themselves in a distinct subcategory.

The third major category has features of paraganglia. Paraganglia are widely dispersed collections of specialized neural crest cells that arise in association with the segmental or collateral autonomic ganglia throughout the body. Histologically, they have features of neuroendocrine cells.

Owing to the small size of the PNS, metastatic tumours limited strictly to the PNS are extremely rare, although they may occur theoretically. Direct invasion of peripheral nerve by malignant tumour is common and peripheral nerves are preferentially invaded by some primary tumours such as prostate carcinoma and adenoid cystic carcinoma of the salivary gland.

EPIDEMIOLOGY

The overall incidence of primary brain tumours is around 11.8 per 100 000 persons per year. Congenital brain tumours are rare. With the exception of meningioma that affects women twice as often as men, they are more prevalent in man. In the United States, the incidence of

Table 3 Incidence of CNS tumours

Tumour	Incidence/age
Primitive neuroectodermal tumours of posterior fossa (medulloblastoma)	*Incidence:* About 0.5 per 100 000 persons per year *Age:* Peak incidence during the 1st decade of life, a small number of them are seen in adults
Diffuse astrocytoma	*Incidence:* About 0.2 per 100 000 persons per year *Age:* Mean age of onset is 34 years. Peak incidence between 20 and 45 years of age. About 15% of them are seen in children under 10 years old
Anaplastic astrocytoma	*Incidence:* About 0.5 per 100 000 persons per year *Age:* Peak incidence in the 4th to 5th decade. Uncommon in children
Glioblastoma	*Incidence:* Most common malignant astrocytic tumour and the incidence is about 2.0–3.2 per 100 000 persons per year *Age:* Peak incidence in the 5th to 7th decades. They also comprise about 8.8% of all brain tumours in children
Pilocytic astrocytoma	*Incidence:* Most common glioma in children and 85% of them occur in the cerebellum. The incidence is about 0.3 per 100 000 persons per year *Age:* Peak incidence in the first two decades
Pleomorphic xanthoastrocytoma	*Incidence:* Exact incidence is not known. They account for less than 1% of all astrocytic tumours *Age:* Usually seen in young adults with peak incidence in the 2nd decade
Oligodendroglioma	*Incidence:* Usually seen in adults, although children are also affected. Peak incidence in the 5th to 6th decade. The incidence is about 0.3 per 100 000 persons per year *Age:* The peak incidence is in the 4th to 6th decades
Ependymoma	*Incidence:* They account for about 3–9% of all neuroepithelial tumours and are frequently seen in the spinal cord. The incidence is about 0.2–0.3 per 100 000 persons per year *Age:* The first peak of incidence is in the 1st decade and second peak of incidence is in the 4th decade
Choroid plexus tumour	*Incidence:* They account for about 0.4–0.6% of all brain tumours, about 2–4% of all brain tumours in children *Age:* Peak incidence in the 1st decade
Ganglioglioma and gangliocytoma	*Incidence:* They represent about 0.4% of all CNS tumours and 1.3% of all brain tumours *Age:* They can be seen in all ages but are most common in children and young adults
Meningioma	*Incidence:* The annual incidence is about 2.8–6.0 per 100 000 persons per year. They account for 13–26% of primary intracranial tumours *Age:* Most common in middle-aged and elderly patients, peak incidence in the 6th decade
Malignant lymphoma	*Incidence:* Relatively uncommon in the general population, marked increase in incidence in immunocompromised patients *Age:* For immunocompetent patients, the peak incidence is in the 7th decade. Occur in young patients who are immunocompromised
Germ cell tumours	*Incidence:* The incidence is less than 0.1 per 100 000 population per year. They account for about 0.3–2% of all primary intracranial tumours. The incidence is lower in the West and higher in Asia *Age:* Most common in the first two decades
Craniopharyngioma	*Incidence:* 0.05–0.25 per 100 000 persons per year *Age:* Most common in children and a second peak in the 6th decade
Schwannoma	*Incidence:* They are most commonly seen in peripheral nerves. About 8% of all intracranial tumours and 29% of all spinal tumours are schwannomas *Age:* Peak incidence in the 4th to 6th decades
Neuroblastic tumours of adrenal gland and sympathetic system	*Incidence:* 0.7–1.0 per 100 000 persons per year *Age:* 85% occur before the age of 5 years

brain tumours, with the exception of meningioma and craniopharyngioma, has been consistently higher in whites than in blacks. The overall incidence of brain tumours has a bimodal pattern. The first peak occurs in infants and children and the second peak occurs at the sixth to seventh decade. Each individual tumour, however, has its own pattern of age distribution (**Table 3**). Patients affected by hereditary cancer syndromes may develop neoplasms at an earlier age than sporadic cases. There is also a general tendency for high-grade glial tumours to occur in older

patients. There is an apparent increase in the incidence of brain tumours both in the United States and in other countries. However, the increase in the early 1980s may partly reflect improved detection techniques, mainly the use of magnetic resonance image (MRI) and computed tomography (CT) scans. There also appears to be an increase in incidence of childhood brain tumours, most apparent in children under 5 years of age. Increase in the rate of primary CNS lymphomas is dramatic and correlates with the large population of patients with compromised immune system secondary to immune suppression, most often after solid organ transplantation, and human immunodeficiency virus (HIV). Some countries and geographic areas have higher incidences than others. The incidence of a particular tumour may be unusually high in some country. For example, germ cell tumour and craniopharyngioma are far more common in Japan than elsewhere. The overall survival of primary brain tumours varies significantly among the different histological types.

AETIOLOGY

Numerous epidemiological studies have been conducted in the search for risk factors and aetiological agents for brain tumours. Mutations of specific genes have been strongly associated with the development of brain tumours. Some of them are associated with hereditary cancer syndromes that involve the nervous system, others are found with increased frequency in some types of tumours. These genes will be discussed later.

It has been reported repeatedly that virus or virus-like particles have been observed in human cerebral tumours or tumour cell lines. Between 1955 and 1962, poliomyelitis vaccines were contaminated with Simian virus 40 (SV40), a member of the polyoma virus family. SV40 has been used to generate experimental choroid plexus tumour and primitive neuroectodermal tumours in transgenic mice. In addition, a partial genome of SV40 has been identified in a few ependymomas, meningiomas and primitive neuroectodermal tumours (also known as medulloblastomas). Despite these findings, there is no epidemiological evidence that the contaminated poliomyelitis vaccine is associated with any increase in incidence of primary brain tumours. JC and BK viruses, also members of the polyoma virus family, have been suspected for being tumorigenic in human brain tumours. To this date, however, there is no solid proof. The association of HIV infection and primary CNS lymphoma primarily rests on the destruction of immune tumour surveillance by HIV.

A wide variety of other physical and chemical agents have also been studied but ionizing radiation is the only proven risk factor for glial tumours and meningiomas. Children who receive therapeutic doses of X-rays (1.5 Gy) for treatment of tinea capitis have an overall increased relative risk of 8.4 for brain tumours. A correlation at higher dosages (1.0–6.9 Gy) is even stronger (Ron *et al.*, 1988). Correlation between risk of brain tumours and low-dose X-rays has not been well established, although association between dental X-rays and possible increase in meningiomas has been reported. The tumorigenic effects of electromagnetic fields on brain tumours have been shown in industrial settings but the relationship with weaker electromagnetic fields has not been well established and the results of different studies have been inconsistent.

Numerous other aetiological agents and risk factors, including *N*-nitroso compounds, diet, tobacco, alcohol and occupational factors, have also been studied. No conclusive evidence of their association with brain tumours has been identified.

SCREENING AND PREVENTION

Many organs, such as the vagina, uterine cervix, peripheral blood, skin, oral cavity and gastrointestinal tract, are easily accessible. Cancer screening involves simple procedures and is highly effective. The situation is different for the CNS. Except for germ cell tumours that may secret markers detectable in the serum, there is no reliable marker in the blood for most primary brain tumours. The anatomical complexity and bony encasement of the central nervous system make biopsy-based screening impossible. The only reliable method for detecting an asymptomatic or presymptomatic brain or spinal cord tumour is a high-resolution imaging technique such as MRI. This method, however, is too expensive, time consuming and complicated to provide a practical screening test for the general population.

Early Recognition of Brain Tumours

Early recognition of brain tumours relies on astute clinical evaluation since there are no specific symptoms or signs of brain tumours. However, headache, new-onset seizures, hemiparesis and mental-status abnormalities are among the most common symptoms. Diagnosis is largely dependent on imaging techniques such as MRI or CT scan. These tools have revolutionized the diagnosis of CNS tumours and other intracranial and intraspinal conditions.

CNS tumours, like any intracranial and intraspinal space-occupying lesions, generate two major problems. The first is increased intracranial pressure because of oedema and mass effect caused by the tumour or obstruction of the flow of cerebrospinal fluid, a typical situation when the tumour is located in or around the ventricles. Increased intracranial pressure produces headache, vomiting and papilloedema; occasionally, it may cause paralysis of the sixth cranial nerve (abducens nerve) due to excessive stretching. Recognition of papilloedema,

often an asymptomatic clinical sign, is important for presymptomatic recognition of brain tumours. Brain herniation is a life-threatening condition often associated with a severe increase in intracranial pressure.

Local effects of CNS tumours produce symptoms depending upon locations. For example, cortical lesions are prone to cause seizures. Tumours adjacent to the optic nerve often produce visual symptoms due to compression of the optic nerves and chiasma. Tumour masses compressing the cervical cord often cause hemiplegia or quadriplegia. The interested reader should refer to the Further Reading section for further details on clinical aspects of brain tumours.

High-risk Patients

Two major groups of patients have increased risk of developing brain tumours. The first includes those who have underlying nonhereditary conditions that predispose them to develop brain tumours, specifically patients with a primary carcinoma or melanoma in some other part of the body. Immune compromised patients also have an increased risk of developing primary CNS lymphoma.

Patients with hereditary syndromes that predispose them to develop tumours of the CNS comprise the second group. Typically, a variety of tumours from several organs occur in a syndromic manner. Recent advances in genetics and molecular biology have identified the genetic abnormalities in many of these syndromes (**Table 4**), and their molecular mechanisms will be discussed later. Well-structured periodic screening programmes have been invaluable in detecting and treating tumours in early stages. With these screening and treatment programmes, the expectancy and quality of life have been improved in these patients.

GROSS/HISTOPATHOLOGY/PREINVASIVE LESIONS/ULTRASTRUCTURE/ IMMUNOHISTOCHEMISTRY

Tumours of the CNS

Pathological features of brain tumours are diverse and fascinating. Pathological examination for diagnostic purposes must include a thorough macroscopic and microscopic evaluation that often includes utilization of immunohistochemical techniques. Occasionally, ultrastructural examination may be necessary. Molecular biology and/or cytogenetic studies may also provide crucial information for diagnostic and prognostic purposes in some cases. Although a full discussion of immunohistochemistry in CNS tumour is beyond the scope of this chapter, the reader should be familiar with a few commonly used diagnostic molecular markers such as Ki-67, synaptophysin, neurofilament proteins (NFPs), glial fibrillary acidic proteins (GFAPs), vimentin, S-antigen and epithelial membrane antigen (EMA) (**Table 5**).

Primary Tumours of Primitive Neuroepithelial Tissue

This is a family of CNS tumours, two of which recapitulate the phenotypic features of the developing nervous system, i.e. medulloepithelioma, primitive neuroectodermal tumours (PNETs) and related tumours. The third tumour in this group, atypical teratoid/rhabdoid tumour, displays unique features and a remarkably consistent cytogenetic abnormality.

Medulloepithelioma

Medulloepithelioma is a tumour that recapitulates the neural tube stage of the developing CNS. These tumours are rare and predominantly seen in infancy and early childhood. Over half arise in the lateral ventricles, occasionally in the posterior fossa and other locations. Macroscopically, they are well-defined, often massive tumours with extensive haemorrhage and necrosis, and are typically associated with extensive cerebrospinal dissemination. The microscopic appearance is highly distinctive and composed of tubular or papillary structures that are morphologically and immunohistochemically similar to the primitive epithelium (**Figure 1**) of the neural tube. Cytologically, they have hyperchromatic nuclei and a high nuclear-to-cytoplasmic ratio. Sheets of patternless undifferentiated tumour cells are invariably present. Ultrastructural examination of these areas also discloses extensive primitive lateral cell junctions and basal lamina, both features of the neural tube. The tumour cells may also differentiate along neuronal, astrocytric, ependymal, oligodendroglial and, on rare occasions, mesenchymal lineage.

Primitive Neuroectodermal Tumours (PNETs) and Related Tumours

This is a family of tumours that phenotypically resembles the primitive neuroectoderm of developing CNS. PNET of the posterior fossa, also known as medulloblastoma, is the prototype and such tumours can also occur in any CNS locations. PNET is the most common malignant childhood brain tumour but sometimes they are seen in adults, particularly young adults. With adequate treatment, the 5-year survival rate is about 60–80% (Packer *et al.*, 1999). PNETs arising in the posterior fossa typically present in midline and involve the vermis. They project into the fourth ventricle and often extend into the leptomeninges (**Figure 2**). The strategic location in the posterior fossa often leads to hydrocephalus (i.e. pathological expansion of the ventricles). Macroscopically they often appear as soft to firm masses with well-demarcated margins. The cut surface has a pale pink to tan colour and there may be a variable amount of haemorrhage. PNETs are typically composed of

Table 4 Hereditary tumour syndromes

Syndrome	Pathology	Genetics	Reference
Tuberous sclerosis	*Nervous system:* Cortical hamartomas (tuber), subependymal hamartoma and subependymal giant cell tumour *Extraneural:* Adenoma sebaceum and other manifestations of skin, retinal astrocytoma, renal angiolipoma, cardiac rhabdomyoma and other systemic manifestations	*Inheritance:* Autosomal dominant *Prevalence:* Between 1 in 5 000 and 1 00 000 Gene: *TSC1* gene (tuberin) on chromosome 9q34 and *TSC2* gene on chromosome 16p13.3.	Kandt *et al*. (1992); van Slegtenhorst *et al*. (1997)
Neurofibromatosis type 1	*Nervous system:* Neurofibromas and malignant peripheral nerve sheath tumour of the peripheral nerve, gliomas of the brain *Extraneural:* Multiple café-au-lait spots, rhabdomyosarcoma, phaeochromocytoma, carcinoid tumour, juvenile chronic myeloid leukaemia, bone lesions and other manifestations	*Inheritance:* Autosomal dominant *Prevalence:* 1 in 3000–4000 of the general population *Gene: NF1* gene (neurofibromin) on chromosome 17q2	Seizinger *et al*. (1987); Pollack and Mulvihill (1997); Von Deimling, *et al*. (2000)
Neurofibromatosis type 2	*Nervous system:* Bilateral vestibular schwannomas, peripheral schwannomas, meningiomas and meningioangiomatosis, ependymomas, astrocytomas, glial hamartoma, and cerebral calcifications *Extraneural:* Posterior lens opacity	*Inheritance:* Autosomal dominant *Prevalence:* 1 in 50 000 of the general population *Gene: NF2* gene (merlin) on chromosome 22q12	Trofatter *et al*. (1993); Pollack and Mulvihill (1997)
Von Hippel–Lindau disease	*Nervous system:* Haemangioblastoma of the retina and CNS *Extraneural:* Renal cysts and renal cell carcinoma, pancreatic cysts, islet cell tumours, phaeochromocytoma, and other manifestations	*Inheritance:* Autosomal dominant *Prevalence:* 1 in 36 000 to 1 in 45 500 of the general population *Gene: VHL* gene is located on chromosome 3p25.3	Latif *et al*. (1993); Maddock *et al*. (1996)
Naevoid basal cell carcinoma syndrome (Gorlin syndrome)	*Nervous system:* PNET in the posterior fossa *Extraneural:* Multiple basal cell carcinoma and keratocyst of the jaw. Abnormal ribs and other skeletal abnormalities, epidermal cyst, ovarian cysts and other features	*Inheritance:* Autosomal dominant *Incidence:* 1 in 57 000 of the general population *Gene:* Human homologue of the *Drosophilia* segment polarity gene patched (*PTCH*) on chromosome 9q22.3	Hahn *et al*. (1996); Vorechovsky *et al*. (1999)

Cowden disease	*Nervous system:* Dysplastic gangliocytoma of the cerebellum (Lhermitte–Duclos disease). Other pathologic changes include megalencephaly and heterotopic grey matter. Meningiomas and medulloblastomas have also been described *Extraneural:* Verrucous skin changes, papules and fibromas of oral mucosa, multiple facial trichilemmomas, hamartomas polyps of the colon, thyroid tumour and breast cancer	*Inheritance:* Autosomal dominant *Gene: PTEN/MMAC1* gene on chromosome 10q23.	Sutphen *et al.* (1999); Robinson and Cohen (2000)
Turcot syndrome (type 1)	*Nervous system:* Usually glioblastoma *Extraneural:* Café-au-lait spots. Small number of large colorectal polyps and high incidence of colorectal carcinoma. Some patients are associated with hereditary non-polyposis colorectal carcinoma syndrome (HNPCC)	*Inheritance:* Autosomal dominant *Gene:* Several genes involved in mismatch repair including *hMLH1* at chromosome 3p21, *hMLH2* at 2p16, *hMSH3* at 5q11-q13, *hMSH6/GTBP* at 2p16, *hPMS1* at 2q32 and *hPMS2* at 7p22	Paraf *et al.* (1997); Cavenee *et al.* (2000)
Turcot syndrome (type 2)	*Nervous system:* Usually PNET in the posterior fossa *Extraneural:* Associated with familial adenomatous polyposis syndrome (FAP). Patient has innumerable adenomatous colorectal polyposis and high incidence of colorectal carcinoma	*Inheritance:* Autosomal dominant *Gene: APC* gene on chromosome 5q21 that is associated with familial adenomatous polyposis syndrome (FAP)	Hamilton *et al.* (1995); Paraf *et al.* (1997); Cavenee *et al.* (2000)
Retinoblastoma (RB) gene deletion syndrome	*Nervous system:* Retinoblastoma in the retina with or without PNET in the pineal gland (pineoblastoma) *Extraneural:* Increased incidence of second malignancy, multiple congenital abnormalities and mental retardation	*Inheritance:* Autosomal dominant *Gene: RB1* gene on chromosome 13q14.2	Sopta *et al.* (1992); Pratt *et al.* (1994)
Li–Fraumeni syndrome	*Nervous system:* Astrocytic tumour, oligodendroglioma, PNET within and outside the posterior fossa, and choroid plexus tumour *Extraneural:* Tumour in various organs including the breast, lung, stomach, colon, pancreas, skin and others	*Inheritance:* Autosomal dominant *Gene: p53* on chromosome 17p13	Malkin *et al.* (1990); Tachibana *et al.* (2000)

Table 5 Diagnostic immunohistochemical markers for brain tumours

Protein	Properties	Application
Ki-67	Non-histone proteins that are present in all phases of the cell cycle, except G0 and the early G0–G1 transitional phase	Immunohistochemical recognition of Ki-67 is used to estimate the proportion of proliferating cells in brain tumours
Glial fibrillary acidic protein (GFAP)	This is a class III intermediate filament of 55 kDa. GFAP is expressed in mature astrocytes. It may co-express with other intermediate filaments in developing CNS	Expression of GFAP in a brain tumour is highly suggestive but not an absolute indicator of astrocytic differentiation
Synaptophysin	Synaptophysin is an acidic, *N*-glycosylated integral membrane glycoprotein of 38–42 kDa that is expressed in the CNS	Detection of neuroendocrine differentiation in CNS tumours
Chromogranin A	This is a 70–80-kDa protein that is found in neurosecretory granules. It is expressed in neuroendocrine cells outside the CNS	Detection of neuroendocrine differentiation in PNS tumours
Neurofilament proteins (NEPs)	Neurofilament proteins are class IV intermediate filaments that exist in three different isoforms (low, medium and high molecular mass) and different phosphorylation state	Expression of neurofilament proteins is highly suggestive but not an absolute indicator of astrocytic differentiation
Vimentin	This is class III intermediate filament of 56 kDa. It is widely expressed in the developing nervous system. It is not expressed in most mature neurons. It is co-expressed with GFAP in mature and developing astrocytes	Vimentin is strongly and extensively expressed by atypical teratoid/rhabdoid tumours. It is also variably expressed by many neuroepithelial tumours
S-antigen and rhodopsin	S-antigen and rhodopsin are proteins expressed by photoreceptor cells in the retina	Detection of photoreceptor differentiation in PNETs, retinoblastomas and pineal tumours
S-100	S-100 is an acidic protein that is widely expressed in the CNS, PNS and a variety of cells outside the nervous system	It is used in the diagnosis of tumours of the PNS and soft tissue
Cytokeratins	Cytokeratins are proteins of class I and II intermediate filaments. They are predominantly expressed by epithelial cells	Used in diagnosis of tumours with epithelial differentiation such as metastatic carcinomas and craniopharyngioma
Epithelial membrane antigen (EMA)	This is a group of high molecular mass molecules with a high carbohydrate content. They are widely expressed by many epithelial cells	Used in diagnosis of metastatic carcinomas. Some CNS tumours such as meningiomas, ependymomas and atypical teratoid/rhabdoid tumours also express EMA

solid sheets of small cells with an extremely high nuclear-to-cytoplasmic ratio and small hyperchromatic nuclei. The tumour cells inconstantly form Homer Wright rosettes (neuroblastic rosettes), but may arrange themselves in other patterns (**Figure 3**). Individual cell and small areas of necrosis are common but extensive necrosis is uncommon. The most common genetic aberration in PNETs arising from the posterior fossa is isochromosome 17 but other chromosomal abnormalities may also be found. Spinal leptomeningeal dissemination is common.

Desmoplastic medulloblastoma is a variant of PNET that tends to occur in cerebellar hemispheres rather than midline. They are also found in older patients. Histologically these tumours contain nodular, reticulin-free islands ('pale-islands') of tumour cells surrounded by densely packed PNET cells with dense intercellular reticulin deposition. The pale islands are usually less cellular and more differentiated than the surrounding cells. Medulloblastoma with extensive nodularity and advanced neuronal differentiation is a variant that is associated with favourable prognosis and contains intranodular cells that resemble mature neurons. Large cell medulloblastoma is a variant in which the tumour cells have large, round and pleomorphic nuclei, prominent nucleoli and more obvious cytoplasm. They usually carry a grave prognosis.

PNETs typically contain numerous mitoses and apoptotic bodies. Depending on the studies, the proliferation rate based on Ki-67 labelling may range from 5 to 80% (**Figure 4**). Such a high proliferation rate has been confirmed by other labelling method such as iododeoxyuridine that discloses a range of 3.9–38.2% (Onda *et al*., 1996).

Immunohistochemically, PNETs frequently express synaptophysin, a marker indicative of neuroendocrine differentiation. Many PNETs also express nestin, a marker for primitive neuroepithelial cells. Although PNET cells appear histologically similar, they may express different developmentally regulated antigens that recapitulate different developmental stages of the CNS. While some PNETs may

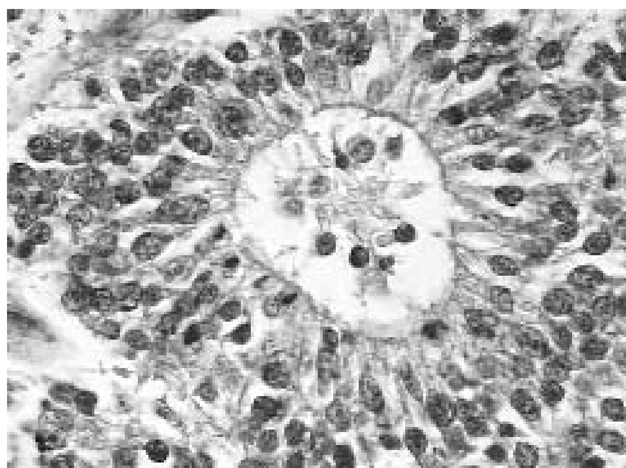

Figure 1 Medulloepitheliomas are characterized by small blue cells that arrange in glandular or tubular structures reminiscent of the primitive neuroepithelium. (Case courtesy of Dr Lucy B. Rorke, Children's Hospital of Philadelphia.)

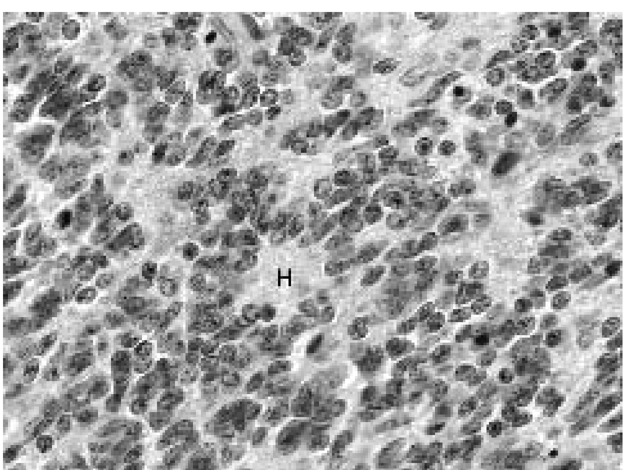

Figure 3 Homer Wright rosettes are formed by small islands of neoplastic neuropil surrounded by tumour cells. Same case as in **Figure 4**.

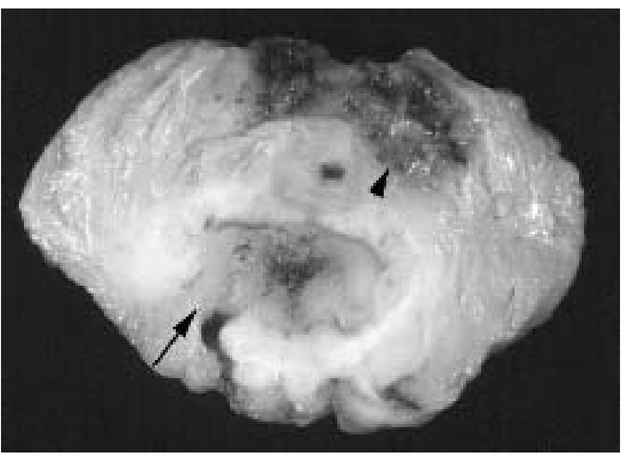

Figure 2 The fourth ventricle (arrow) is filled and expanded by this primitive neuroectodermal tumour. The haemorrhagic region (arrowhead) is in the leptomeningeal extension of the lesion.

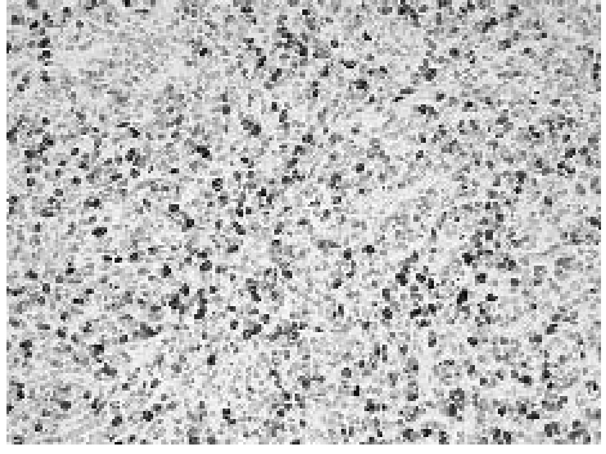

Figure 4 Proliferating cells express Ki67 strongly and comprise about 25% of the population in this primitive neuroectodermal tumour. Immunostaining for Ki-67, ABC peroxidase method.

express NFP indicative of neuronal differentiation, others may express GFAP indicative of glial differentiation and many PNETs express both. A small proportion of PNETs also express cytokeratins, intermediate filament proteins that are expressed in the very early stage of neural development. Ependymal differentiation can also be seen, in which case some investigators prefer to call them ependymoblastomas. Photoreceptor-specific proteins such as retinal S-antigen and rhodopsin are also expressed by a subpopulation of PNETs. Rarely, they express desmin or actually contain skeletal muscle cells in which case they are termed medullomyoblastoma. Melanotic medulloblastoma is the variant that contains melanin pigment. It is obvious that PNETs have the potential to differentiate along different lineages.

Ultrastructually, tumour cells may contain few, if any, specific ultrastructural features. Neurosecretary granules and synapses, an indication of differentiation towards neuronal lineage, may be seen in some tumours. Intermediate filaments are also common.

Less commonly, PNETs occur in supratentorial locations. In the WHO Classification, neuroblastoma and ganglioneuroblastoma are grouped under the heading of supratentorial PNET. These tumours are seen in early childhood. They occur most frequently in the frontal and frontoparietal regions but rare examples are seen in the spinal cord. Macroscopically, they are well-defined tumours. Histologically and immunohistochemically, they are very similar to if not identical to PNETs arising

in the posterior fossa (medulloblastoma). Although infratentorial and supratentorial PNETs are given different names in the WHO Classification (i.e. medulloblastoma vs neuroblastoma), they are best regarded as part of the spectrum of PNETs.

Atypical Teratoid/Rhabdoid Tumour (ATRT)

This is a highly malignant embryonal CNS tumour that contains rhabdoid cells (**Figure 5**). They are predominantly seen in infants under 2 years of age and the mean post-operative survival is less than 1 year. ATRTs are equally frequent in both infratentorial and supratentorial locations. Dissemination throughout the CNS is seen in about one-third of the cases at initial presentation. Macroscopically, they are well-demarcated tumours. Rhabdoid cells are round to oval cells with medium to large nuclei and distinct nucleoli. About two-thirds of ATRTs also have a PNET component. In addition, they may contain epithelial (carcinomatous) and mesenchymal (sarcomatous) components. The tumour cells typically express vimentin, smooth muscle actin and epithelial membrane antigen, but may also express GFAP and NFP. They do not express germ cell markers such as α-fetoprotein, placental alkaline phosphatase or β-human chorionic gonadotrophin, nor do they express desmin. Ultrastructually, they are characterized by massive whorls of intermediate filaments. Characteristically, they show homozygous or heterozygous, complete or partial deletion of chromosome 22q and presumably are related to germline and somatic mutation of the *hSNF5/INI1* gene (Biegel *et al.*, 2000). Although ATRTs often contain a PNET component, their distinctive histology, characteristic chromosomal abnormality and aggressive clinical behaviour distinguish them from PNETs. The true nature of ATRT remains to be determined.

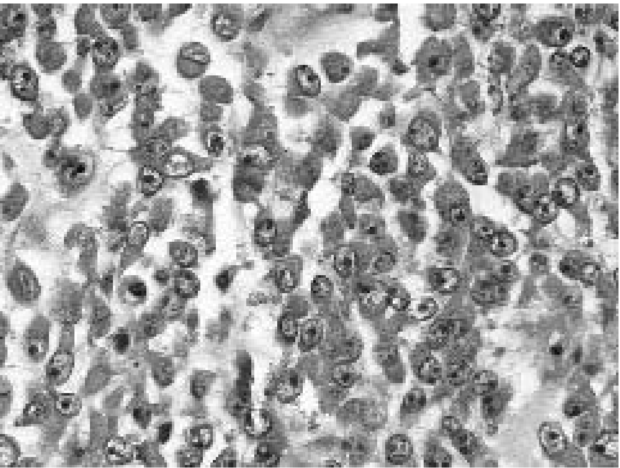

Figure 5 Rhabdoid cells in atypical teratoid/rhabdoid tumours are loosely arranged large egg-shaped cells with eosinophilic cytoplasm, large eccentrically located nuclei containing prominent nucleoli. (Case courtesy of Dr Lucy B. Rorke, Children's Hospital of Philadelphia.)

Primary Tumours of Mature Neuroepithelium

Tumours considered in this section are the most common primary tumours in the CNS. They display features of mature neuroepithelial cells although they do not necessarily arise from such cells. Rather, they may arise from primitive neuroepithelial cells that show differentiation during tumorigenesis. Three major categories will be considered here: glial tumours, glial–neuronal tumours and choroid plexus tumours.

Glial Tumours

Glial tumours, otherwise known as gliomas, are tumours that display features of mature glial cells specifically astrocytes, oligodendrogliocytes and ependymal cells. It is not unusual to have tumours composed of a mixture of these cells. In addition, they may also display a spectrum of biological aggressiveness, often reflected by their histology. In general, low-grade gliomas occur more commonly in younger patients whereas high-grade gliomas are more common in older adults.

Astrocytoma, Anaplastic Astrocytoma, Glioblastoma. Astrocytic tumours are composed of cells that look like astrocytes and are by far the most common of all gliomas. They comprise about one-third of the gliomas in the cerebral hemispheres. Astrocytic tumours are separated into different histological grades that reflect their biological behaviour. Astrocytomas are histologically benign/low-grade tumours, anaplastic astrocytoma has features of a malignant tumour, and glioblastoma is the most malignant version.

Astrocytoma occurs in young adults with a peak incidence in the fourth decade and 15% are seen in children. They are most commonly located in the cerebral hemispheres with frontal and temporal regions as the most common site. They are also common in the spinal cord. In children, the optic nerve, diencephalon, brainstem and cerebellum are the most favoured locations.

Astrocytomas in adults and children behave differently. In adults, the survival rate of astrocytoma is variable and they are notorious for recurring as anaplastic astrocytoma or glioblastoma with a mean time interval of 4–5 years. This occurs more commonly in older patients.

MRI often discloses a poorly defined nonenhancing lesion with oedema. Macroscopically, they are poorly demarcated, soft, grey, expanding lesions that involve mainly the white matter (**Figure 6**). Tumours that arise from the brainstem often diffusely enlarge the latter. Hemispherical astrocytomas may involve the basal ganglia and thalamus. Degenerative changes and cyst formation are common. Histologically, they are composed of neoplastic astrocytes with variable morphology. The architecture ranges from streaming bundles of fibrillary astrocytes to a meshwork-like arrangement. Most often, the tumour cells have poorly defined cytoplasm and small and mature-looking nuclei (**Figure 7**). Some astrocytomas are composed of

fibrillary astrocytes or polygonal to stellate neoplastic cells that arrange themselves into a fine cobweb resembling protoplasmic astrocytes. Gemistocystic forms which tend to be large oval with eosinophilic homogeneous cytoplasm and large nuclei, often binucleated, may also be seen. Often, all morphological subtypes of neoplastic astrocytes can be seen in the same tumour. Degenerative changes and formation of microcysts are very common. Features indicative of aggressive behaviour such as necrosis and mitoses are not present. The low proliferative rate is also reflected by a low Ki-67 labelling index of less than 4% in most cases. Astrocytes strongly express GFAP. These tumours also express other antigens such as S-100 proteins and vimentin, but these markers are not diagnostically useful. Onset at a young age and location at a site that allows gross total resection are two favourable prognostic indicators.

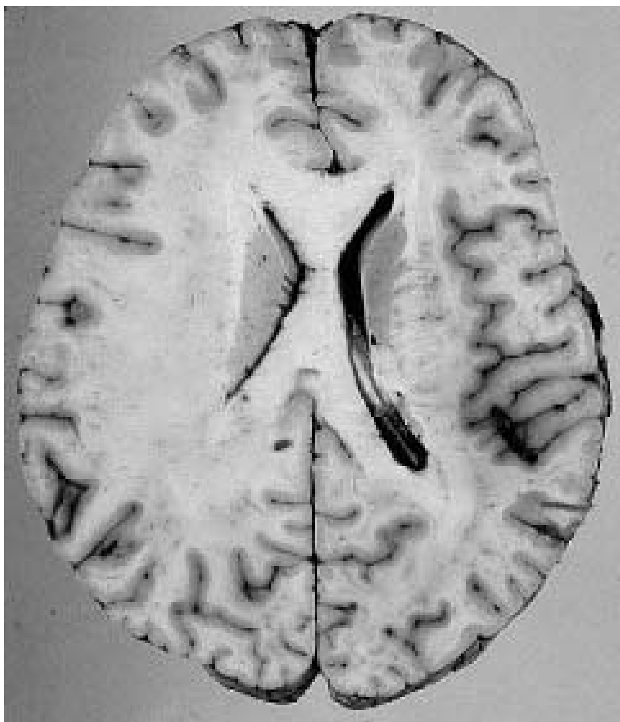

Figure 6 The left side of the brain is expanded by a diffusely infiltrating astrocytoma that also compresses the ventricle. The cut surface of the tumour is similar to normal white matter and no delineation between tumour and normal tissue in appearance. Attenuation of the gyral architecture, however, is obvious.

In contrast to astrocytomas occurring in adults, astrocytoma arising from cerebellum and midbrain in children have excellent prognosis. Childhood astrocytomas arising from pons often carry a grave prognosis.

Anaplastic astrocytomas are aggressive tumours with a peak age of occurrence about 10 years later than that of astrocytomas. MRI usually discloses an enhancing mass with its epicentre in the white matter. These tumours usually enhance with gadolinium. Macroscopically, the tumours have poorly defined borders and are friable, greyish and occasionally haemorrhagic. They are densely cellular, exhibit nuclear pleomorphism, are mitotically active (**Figure 8**) and show endothelial proliferation (**Figure 9**). In some cases, the bulk of the tumour may appear to be a low-grade astrocytoma but microscopic foci of anaplasia may be scattered around. GFAP is usually widely expressed by tumour cells. The brisk proliferative activity is well reflected by the presence of mitotic figures and a Ki-67 labelling index that is usually >5%.

Glioblastoma is the most aggressive astrocytic tumour and unfortunately the most common glial tumour in adults. They also occur in children. The peak incidence is around the sixth and seventh decade and they are 1.5 times more common in men than women. Glioblastoma may be present initially as such or evolve from low-grade glial

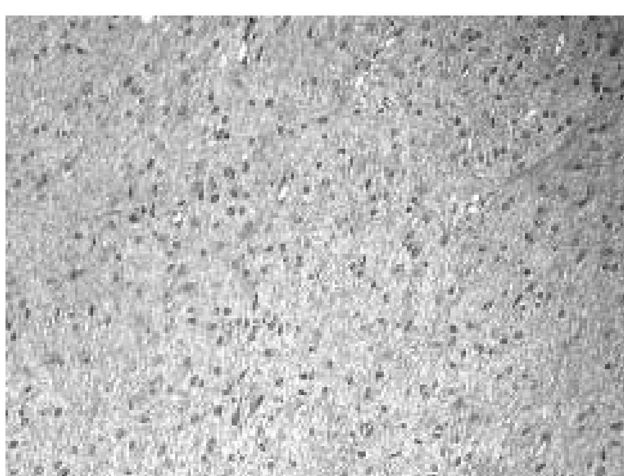

Figure 7 Astrocytoma cells have small hyperchromatic nuclei and a substantial amount of cytoplasm.

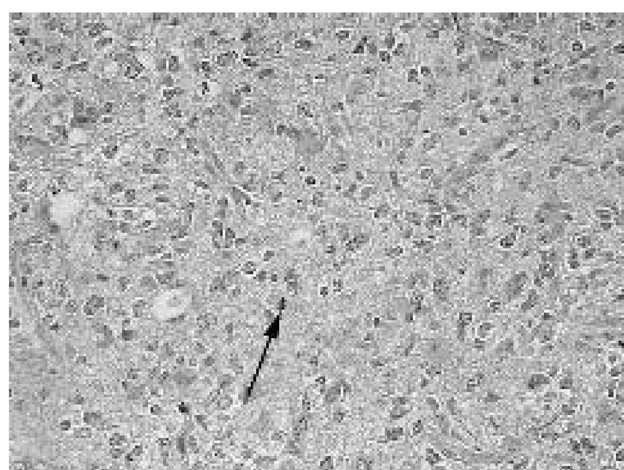

Figure 8 When compared with astrocytomas, cells in anaplastic astrocytocytomas are larger, more pleomorphic and mitotically active (arrow).

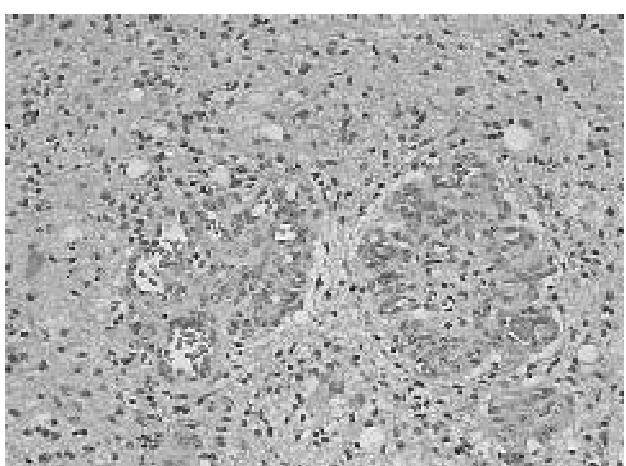

Figure 9 Endothelial proliferation is a hallmark of anaplastic astrocytoma and glioblastoma multiforme. Note glomeruloid architecture of the blood vessels with large and tombstone-like endothelial cells projecting into the lumen.

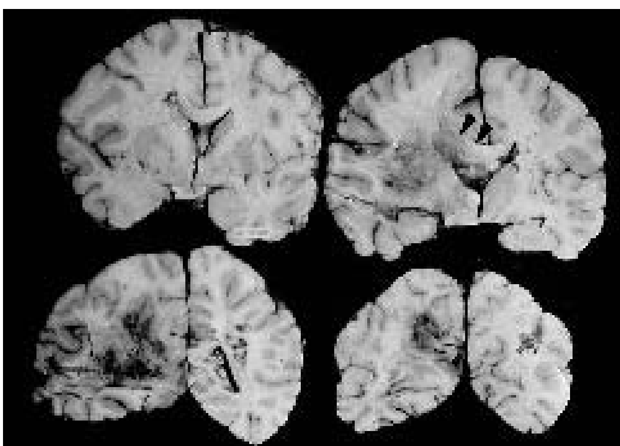

Figure 10 Four coronal sections of cerebrum showing large, poorly demarcated partially haemorrhagic glioblastoma multiforme. Note thickening of the corpus callosum due to tumour infiltration (arrow head).

tumours such as astrocytoma, oligodendroglioma or mixed astrocytoma–oligodendroglioma. The frontal half of the brain is more affected. The tumour may appear as an irregular to multinodular mass with heterogeneous signal and ring enhancement on MRI. They are often associated with a substantial amount of oedema.

Macroscopically, they are typically large hemispherical tumours that extend across the corpus callosum to involve the contralateral hemispheres, the so-called 'butterfly tumour.' They may be poorly demarcated or sharply demarcated; necrosis and haemorrhages are common (**Figure 10**). Histologically, the cellular morphology is highly diversified, as reflected by old term 'glioblastoma multiforme.' The salient histological features of glioblastoma include pseudopalisading necrosis (**Figure 11**),

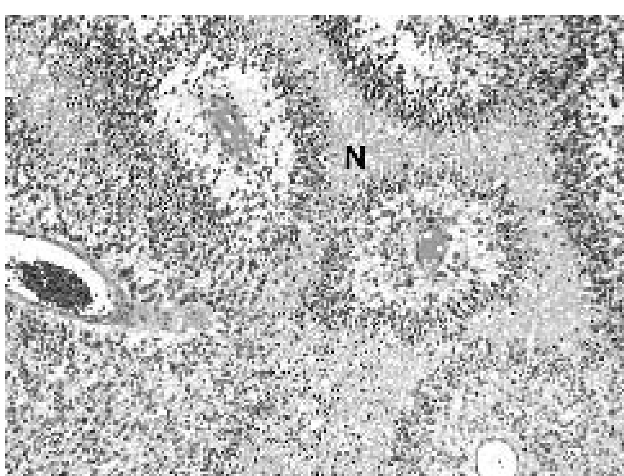

Figure 11 Pseudopalisading necrosis in GBM is composed of necrotic tissue (N) rimmed by viable tumour cells that arrange themselves in a palisading fashion.

striking endothelial proliferation, markedly anaplastic cells and prominent mitotic activity. Bizarre tumour cells and multinucleated giant cells are often seen adjacent to fields of densely packed small anaplastic cells. In general, expression of GFAP is inversely proportional to the degree of anaplasia. Although the majority of glioblastomas express GFAP, it is often expressed in a patchy manner. Ki-67 labelling may vary significantly in different areas of the same tumour and mean values of 15–20% have been reported.

Giant cell glioblastoma is a variant that contains a substantial number of giant cells; it has a slightly better prognosis than regular glioblastoma. Gliosarcoma is a variant that contains a glioblastoma component and sarcomatous component. In rare examples, the latter consist of osteosarcoma or chondrosarcoma.

Astrocytoma with Special Features. Pilocytic astrocytoma, pleomorphic xanthoastrocytoma, desmoplastic infantile astrocytoma and subependymal giant cell astrocytomas are tumours that exhibit distinct clinical and histological features.

Pilocytic astrocytomas are most commonly seen in the first two decades of life. They tend to remain histologically benign, i.e. they do not progress to high-grade gliomas. They are most common in the cerebellum as discrete, slow-growing lesions with or without cystic change. Other preferred sites include optic nerve, optic chiasma/hypothalamus and brainstem. Those that are located in a surgically accessible position can be totally resected and have an excellent prognosis, whereas locations in some sites may preclude such an approach. Hence prognosis in the latter instance is not so sanguine. In contrast to astrocytomas in adults that infiltrate the surrounding brain tissue in a sinister fashion, pilocytic astrocytomas especially in the cerebellum are often well demarcated. Histologically they are characterized by alternating densely packed and loosely packed areas (**Figure 12**). The densely packed

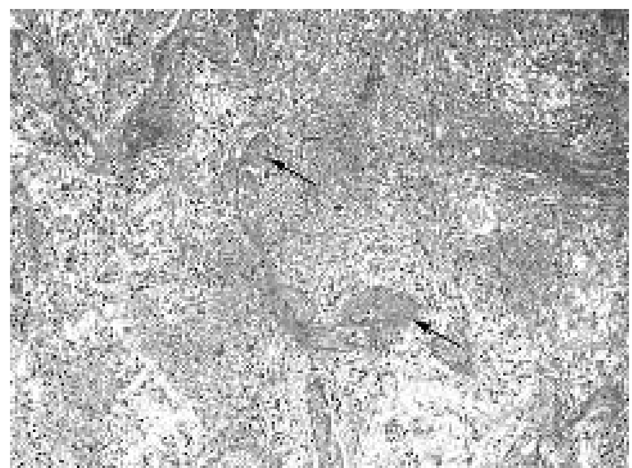

Figure 12 Pilocytic astrocytomas have alternating densely packed and loosely packed areas. Tumour cells in the densely packed areas are reminiscent of bundles of hair. Many thin-walled and dilated blood vessels are typically present (arrow).

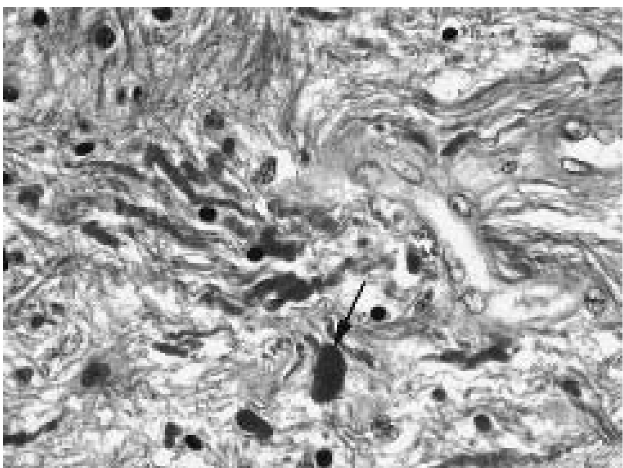

Figure 13 Rosenthal fibres are amorphous to fibrillary hyalinized eosinophilc structures that are intracytoplasmic components of glial processes (arrow). They are typical but not diagnostic for pilocytic astrocytoma.

areas are composed of elongated hair-like (piloid) astrocytes whereas the loosely packed areas are composed of astrocytes with small nuclei and stellate processes that branch and anastomose producing a 'chicken-wire' appearance. Pilocytic astrocytomas are usually vascular and contain peculiar glomeruloids of thin-walled blood vessels reminiscent of wickerwork. They must be distinguished from endothelial proliferation found in anaplastic astrocytoma and glioblastoma. Rosenthal material (**Figure 13**) and eosinophilic granular bodies are common and are most often seen in the densely packed areas. Mucoid and cystic degeneration are common. As expected, the tumour cells strongly express GFAP.

Pleomorphic xanthoastrocytoma and subependymal giant cell astrocytomas are two tumours that are classified as astrocytoma but should probably be in the category of neuronal–glial tumours as they often express both GFAP and NFP that indicate simultaneous glial and neuronal differentiation.

Pleomorphic xanthoastrocytoma is usually seen in children and young adults. They typically occur as supertentorial and superficial tumours that are attached to the leptomeninges and have cystic components. Histologically, they are composed of cells that show extreme variation in size and shape of both nuclei and cytoplasm, hence they are called 'pleomorphic.' Some cells may have foamy or xanthomatous cytoplasm. They contain a dense network of reticulin fibre and multinucleated giant cells are common. Admixed with these cells are also spindly cells. Collections of lymphocytes are often prominent. The large xanthomatous spindle cells express GFAP. Some also express NFPs and synaptophysin. The anaplastic variant exhibits significant mitotic activity and/or necrosis. Most pleomorphic xanthoastrocytomas carry a favourable prognosis but a small proportion of them may progress to high-grade tumours.

Desmoplastic infantile astrocytoma will be discussed later together with desmoplastic infantile ganglioglioma. Subependymal giant cell tumour is almost always associated with tuberous sclerosis and will be discussed together with the latter.

Oligodendroglioma and Anaplastic Oligodendroglioma. Oligodendrogliomas are neoplasms composed of oligodendrocytes and uncommon. Most arise in hemispherical white matter of individuals in the fourth to sixth decades of life. Macroscopically, they display a relatively well-demarcated, soft, greyish pink appearance. Often, mucoid changes in the cells produce a translucent mucoid consistency. Microscopically they are moderately cellular tumours. The cells grow in solid sheets with delicate vascular networks. The cells are round to polygonal cells with a well-defined cytoplasmic membrane, clear cytoplasm and isomorphic round, small nuclei producing the so-called 'fried-egg' appearance (**Figure 14**). Calcified deposits are more common than other gliomas. The proliferation rate is low and mitotic figures are rare, if present at all; the Ki-67 labelling index is <5% (Coons *et al.*, 1997). Oligodendrogliomas may express small amounts of GFAP but no immunohistochemical marker is specific for these tumours. The mean survival time for oligodendrogliomas varies from 3.3 to 7.1 years and the 5-year survival rate varies from 38 to 54% (Dehghani *et al.*, 1998). The biological behaviour is not always predicted by histology and oligodendrogliomas without any anaplastic features can also behave aggressively.

Anaplastic oligodendrogliomas occur in a slightly older age group than do the histologically 'benign' type but the

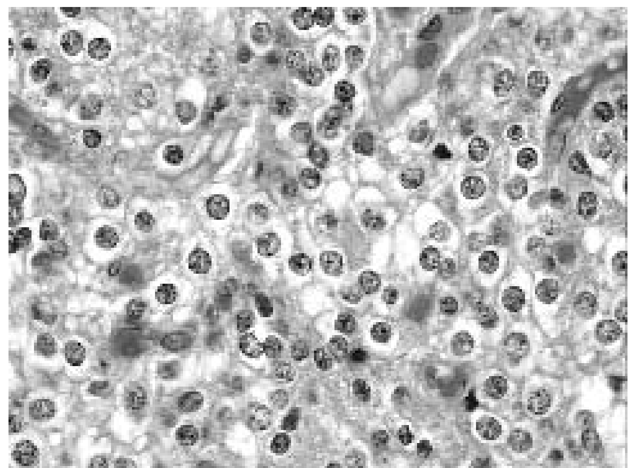

Figure 14 Oligodendrogliomas are characteristically composed of round to polygonal cells with clear cytoplasm and centrally located round nuclei. (Courtesy of Dr Lucy B. Rorke, Children's Hospital of Philadelphia.)

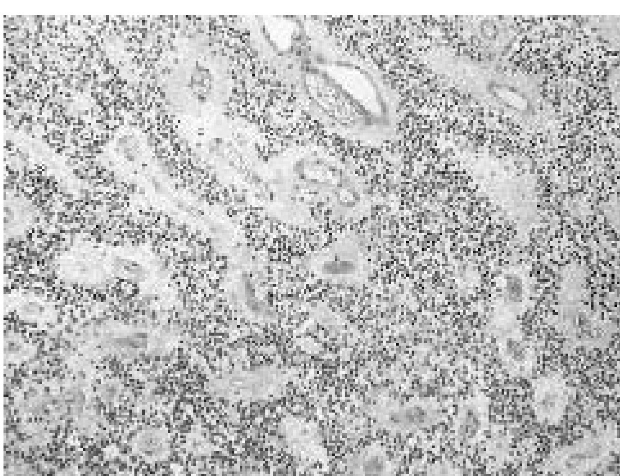

Figure 15 Ependymomas often appear as isomorphic cellular tumours with a rich vascular supply and pseudorosette formation.

preferred locations are similar. The histological features are similar to those of oligodendrogliomas but these tumour cells tend to contain amphophilic rather than clear cytoplasm. There is increased cellularity, a high nuclear-to-cytoplasmic ratio and variation in size and shape of nuclei. Endothelial proliferation and necrosis are often present and mitotic activity is usually brisk. It is not uncommon to find focal anaplastic changes in an otherwise oligodendroglioma, in which case the tumour behaves like an anaplastic oligodendroglioma. The survival rate of patients with anaplastic oligodendroglioma (median survival time 0.87–3.9 years) is overall worse than for its 'benign' counterparts (Shaw *et al*., 1992; Dehghani *et al*., 1998). Recent association of chromosome 1p and 19q deletion with improved responsiveness to chemotherapy in anaplastic oligodendrogliomas may improve survival of these patients (Cairncross *et al*., 1998).

Ependymal Tumours. Ependymal cells are modified glial cells that line the ventricles. Although they have partial features of epithelial cells, they do not have a basement membrane. Ependymal tumours can be segregated into several clinically and pathologically distinct groups on the basis of pathology and clinical behaviour.

Ependymomas are seen in all age groups but most commonly in children, amongst whom they comprise 6–12% of all intracranial tumours in children and about 30% of them occur before the age of 3 years. Ependymomas may occur at any site along the ventricular system and in the spinal canal. In adults they are most common in the spinal cord; in children they are most common in the fourth ventricle. Hydrocephalus and increased intracranial pressure are common manifestations, particularly in tumours that arise in the fourth ventricles.

Ependymomas are grossly well demarcated. Tumours that arise within the fourth ventricle often expand through the foramina of Luschka and Magendie and extend caudally through the foramen magnum, making complete excision difficult. Ependymoma may also have spinal dissemination. They have diverse histological features. Classical ependymomas are composed of densely packed isomorphic cells that have a small amount of cytoplasm (**Figure 15**). The typical architecture is a perivascular distribution of cells forming pseudorosettes (**Figure 16**). Tumour cells have cytoplasmic processes that taper towards the blood vessel wall. Less frequently canals formed by ependymal cells (also known as ependymal

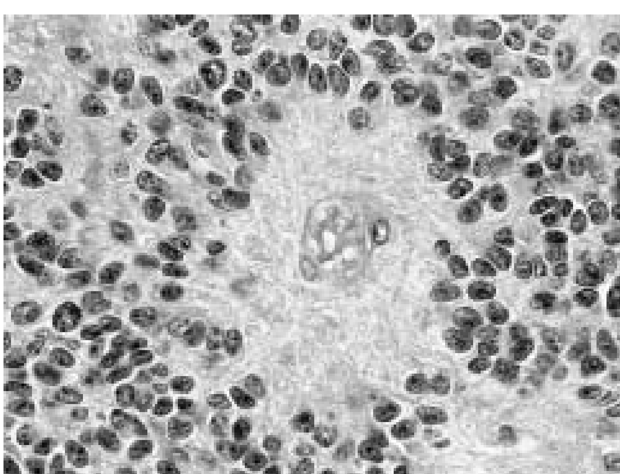

Figure 16 Pseudorosettes, the hallmark of ependymal tumours, are composed of small blood vessels rimmed by a nucleus free mantle of fibrillary cytoplasmic processes that are surrounded by tumour cells.

rosettes) of variable size may predominate in some tumours. A subtype called cellular ependymomas has paucity of pseudorosettes or ependymal canals. Clear cell ependymomas resemble oligodendrogliomas and central neurocytomas. Care must be taken not to confuse them. Papillary ependymoma is a rare variant that is composed of papillae and must be distinguished from choroid plexus papilloma. Tanycytic ependymomas histologically resemble the spindly bipolar tanycytic ependymal cells.

Myxopapillary ependymomas have a distinctive histology and carry an excellent prognosis if completely resected. They can be seen in all age groups but are most common in the fourth decade. These tumours occur almost exclusively in the conus medullaris, cauda equina and filum terminale. Rarely, they can be seen at other levels of the spinal cord or even in sacrococcygeal subcutaneous tissue. These tumours typically have a lobulated, soft, greyish appearance. Histologically, they consist of hyalinized or oedematous fibrovascular cores covered by variable amounts of ependymal cells (**Figure 17**). A mucoid matrix material between tumour cells and blood vessels is typically present. The tumour cells often express GFAP but not cytokeratin, a useful feature to differentiate them from metastatic papillary carcinomas.

Subependymoma is an uncommon, slow-growing, histologically benign periventricular tumour that is composed of cells resembling both ependymal cells and astrocytes. Such tumours are found predominantly in the lateral and fourth ventricles and all age groups are affected. Subendymomas often but not always remain asymptomatic. Clinical manifestations, when present, often result from ventricular obstruction and increased intracranial pressure. Macroscopically, they are sharply demarcated exophytic nodular masses arising from the ventricular wall. Histologically, they display features of both astrocytoma and ependymoma. Sparsely cellular fibrillary astrocytes form a matrix throughout which ependymal cells are unevenly scattered. These cells may form hollow rosettes or perivascular pseudorosettes or may merely consist of small clumps of polygonal cells with no special orientation. Mitotic figures are not usually seen.

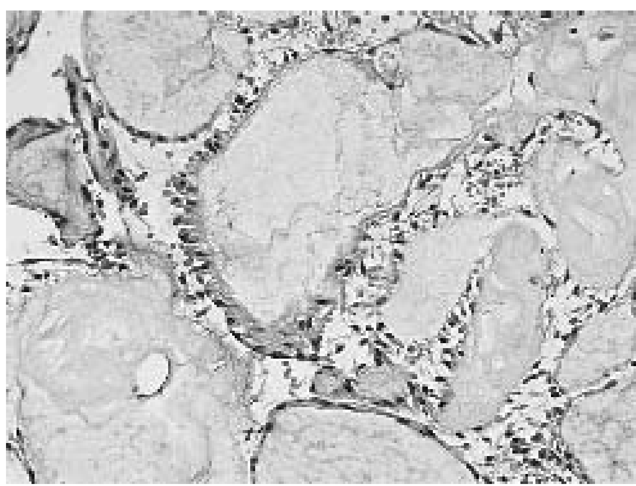

Figure 17 Myxopapillary ependymomas typically contain lakes of myxoid material bounded by a thin layer of cells.

The majority of ependymal tumours express GFAP. EMA is also expressed and most often at the luminal border of the ependymal canal, the internal border of the perivascular pseudorosettes and luminal surface of papillary ependymoma. Cytokeratin is occasionally expressed. The ultrastructural characteristics of normal ependymal cells such as a $9+2$ arrangement of cilia, blepharoblasts and microvilli are well maintained by the tumour cells.

Anaplastic ependymoma is a tumour with histological features suggestive of aggressive behaviour and malignancy. These features included nuclear pleomorphism, high mitotic activity and necrosis.

However, the clinical behaviour of ependymomas is not well correlated with their histological features. In a series of 298 cases, survival of patients could not be correlated with the histopathological features of malignancy (Schiffer *et al*., 1991). On the other hand, Ritter *et al*. (1998) noted that onset at young age, a Ki-67 labelling index of >20% and anaplastic features are associated with aggressive behaviour.

Mixed Gliomas. Some gliomas contain more than one neoplastic component. Oligoastrocytoma, the prototype of mixed glioma, is composed of a substantial mixture of distinct components of astrocytoma and oligodendroglioma. When features indicative of malignant behaviour are present, they are termed anaplastic oligoastrocytoma. The median survival for low-grade mixed oligoastrocytoma is 6.3 years and for high-grade oligoastrocytoma it is 2.8 years (Shaw *et al*., 1994). Other mixed gliomas may contain ependymal and oligodendroglial components, less commonly astrocytic and ependymal components. Rarely, neoplastic components of all three lineages can be found.

Neuronal and Mixed Glial–Neuronal Tumours

Primary neuroepithelial tumours that contain mature neuronal elements are most common in children and young adults. Many are histologically and biologically benign tumours and often have features of hamartomas. While paraganglioma is included in this category of CNS tumour in the WHO Classification, it is best regarded as a neuroendocrine tumour that arises from the nerve roots and hence is discussed in the section 'Tumours of the PNS' (see later).

Ganglioglioma and Gangliocytoma. Ganglioglioma is composed of neoplastic ganglion (neuronal) cells and neoplastic glial cells. Symptoms vary according to location, but intractable epilepsy is the most common clinical manifestation. Indeed, total resolution or significant

improvement for control of epilepsy is often noted following removal of the tumour. They can occur anywhere in CNS but the temporal lobe is the preferred site.

Macroscopically, they consist of a well-circumscribed solid mass or cyst with a mural nodule; they are not usually associated with significant mass effect. Calcification is often present but haemorrhage and necrosis are rare. Neoplastic ganglion cells, the salient feature of these tumours, are moderate to large dysmorphic cells that resemble neurons. They have eccentrically placed, round nuclei containing small but distinct nucleoli; binucleated cells are common. Their cytoplasm is usually basophilic. The ganglion cells may be arranged in clusters in a neuropil-like or glial background.

The amount of glial component is variable. In some tumours there is no significant glial component, in which case the tumour is gangliocytoma (**Figure 18**). Gangliocytomas are almost always benign and can be cured by resection if in an accessible location. Rare anaplastic gangliocytomas have been reported.

Ganglioglioma, a far more common entity than gangliocytoma, is composed of neoplastic ganglion cells admixed with neoplastic astrocytes and enlarged or bizarre-shaped neurons (**Figure 19**). In unusual cases, the glial component may be oligodendroglial rather than astrocytic. Both gangliocytoma and ganglioglioma may contain reticulin around ganglion cells and/or perivascular lymphocytic infiltrations. Neoplastic ganglion cells express NFPs, synaptophysin and other neuronal markers in the neoplastic ganglionic cells, whereas the glial component expresses GFAP. At the ultrastructural level, neurosecretory granules are often seen in the neoplastic neurons; synaptic junctions may or may not be present.

Most gangliogliomas can be cured by resection but a minority of them recur and undergo malignant transformation. Only in exceptional conditions is the product of malignant transformation a high-grade glial neoplasm. Gangliogliomas in the brainstem and spinal cord are 3.5–5 times more likely to recur than cerebral gangliogliomas (Lang *et al*., 1993).

Dysplastic Gangliocytomas of the Cerebellum (Lhermitte–Duclos Disease). This interesting benign cerebellar lesion combines features of hypertrophy, congenital malformation and neoplasm. It is benign and often associated with Cowden disease (see below). Neurological manifestations include ataxia, mild mental retardation and a self-limited seizure disorder. They are most common in young adults and have a marked male preponderance. The lesion is characterized by diffuse hypertrophy of cerebellar folia. Histologically, the normal architecture of cerebellum is effaced. Instead, folia are composed of an outer layer of well-developed radial and more superficially distributed parallel myelinated nerve fibres, and an inner layer of abnormal neurons that contains both small hyperchromatic neurons and large polygonal neurons with prominent nucleoli. The large cells resemble Purkinje cells. The white matter is either absent or greatly reduced. It has been suggested that this is a hamartomatous lesion, a hypothesis supported by its frequent association with other malformations such as megalencephaly and heterotopic grey matter.

Dysembryoplastic Neuroepithelial Tumour (DNET). DNETs are benign glial–neuronal neoplasms that are most commonly seen in children and young adults, often with a history of prolonged drug-resistant seizures. They are superficially located supratentorial tumours that frequently involve the temporal lobe. Macroscopically, they contain a central viscous mass associated with firmer nodules in the periphery. The affected cortex is expanded and foci

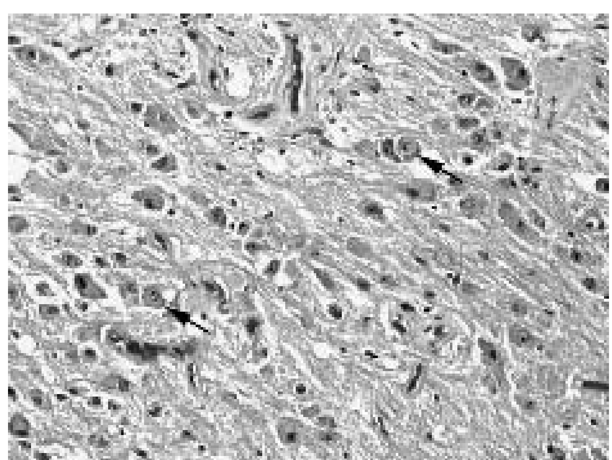

Figure 18 Photomicrograph of gangliocytoma showing tumour composed of abnormal ganglion (arrow) cells scattered through the neuropil.

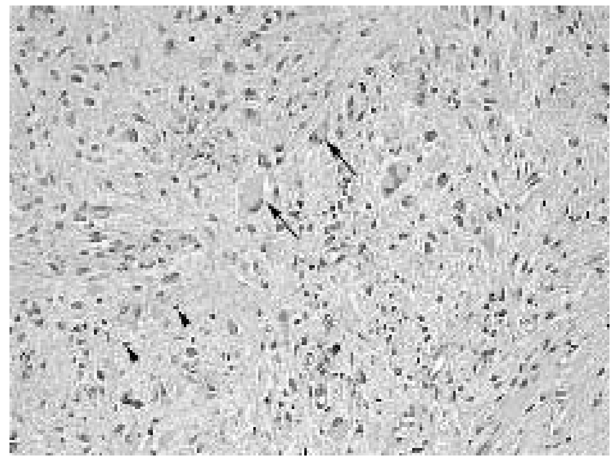

Figure 19 Gangliogliomas have a neuronal (ganglionic) component and an astrocytic component. Ganglionic cells (arrow) are usually much larger than astrocytic cells (arrow head).

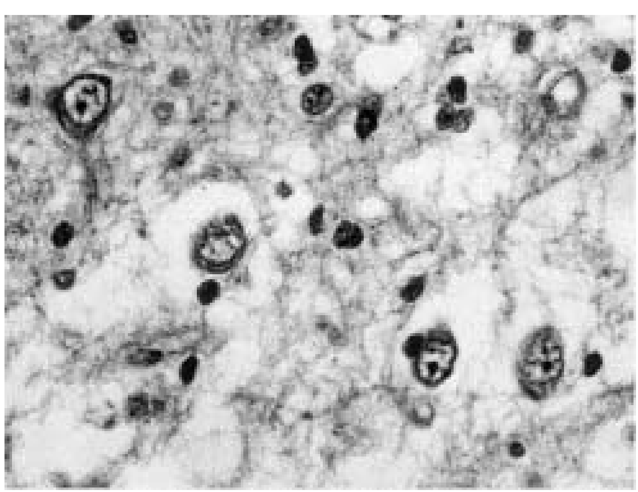

Figure 20 Differences between the neuronal component (large cells) and glial component (small cells) in DNETs are well illustrated here.

of cortical dysplasia (focally disorganized cortex) are invariably seen in the surrounding cortex. Such cortical topography is an important criterion for differentiating between DNETs and other gangliogliomas. Therefore, clinical imaging findings must be seriously examined in conjunction with the histological features. Classical DNETs contain a mucoid component composed of columns of axons perpendicularly oriented to pial surface and lined by small S-100-positive and GFAP-negative oligodendroglia-like cells. Suspended in between these bundles is mucoid material (**Figure 20**) that contains neurons with normal cytology and some GFAP-positive stellate astrocytes. This combination is termed 'specific glioneuronal elements' and is considered the histological hallmark of DNETs (Daumas-Duport, 1993).

Desmoplastic Infantile Ganglioglioma/Astrocytoma (DIG/DIA). Desmoplastic infantile ganglioglioma (DIG) and desmoplastic infantile astrocytoma (DIA) (also known as superficial cerebral astrocytoma or desmoplastic cerebral astrocytoma of infancy) are rare tumours that invariably arise in the supratentorial region and are almost exclusively seen in infants under 2 years of age, although noninfantile cases have been reported. They tend to be large and superficially placed cystic tumours that involve the leptomeninges and are often attached to the dura. The solid part of the tumour is firm or rubbery in consistency and grey or white in colour. Necrosis and haemorrhage are uncommon. They may casue cranial enlargement, tense and bulging fontanelles, downward ocular deviation ('sunset sign') and palsy of the sixth and seventh cranial nerve in infants. Hydrocephalus is common. Despite their large size and some suggestive malignant histological features, prognosis is favourable after surgical resection.

Histologically, DIGs are reticulin-rich astrocytic tumours with a variable neuronal component (DIG). There is an often a sharp demarcation between the cortical surface and tumour. Neoplastic ganglion cells and astrocytes are found within a desmoplastic background. Reticulin stain characteristically discloses deposition of reticulin substance around individual tumour cells. Aggregates of poorly differentiated neuroepithelial cells are often found. The glial cell express GFAP and vimentin; the neuronal component expresses synaptophysin, NFPs and class III β-tubulin. The identity of the poorly differentiated cells is not well defined but is most likely primitive neuroepithelial cells. Mitotic activity in the differentiated component is usually rare, however, the poorly differentiated cases may display mitotic activity. DIA is a reticulin-rich desmoplastic astrocytic tumour with no neuronal component.

Central Neurocytoma. Central neurocytomas are typically seen in young adults with peak incidence in the third decade. They are uncommon tumours that are usually found in the lateral ventricles and/or third ventricle, a feature that often leads to increased intracranial pressure and hydrocephalus. The tumours are greyish and friable and may be calcified and occasionally haemorrhagic. Histological architecture may vary from place to place. Some tumour cells are round to polygonal, contain clear cytoplasm and have well-defined cytoplasmic margins. In fact, they were previously regarded as clear cell ependymoma of the foramen of Monro. They often have a honeycomb appearance that simulates oligodendrogliomas. In other areas, tumour cells may have a substantial amount of neuropils. Ganglioid cells and Homer Wright rosettes are rare findings. Although histologically similar, neurocytoma are separated from oligodendroglioma by immunohistochemical and ultrastructural features. The most useful diagnostic marker is synaptophysin, which is strongly expressed in both the cytoplasm and neuropil of these tumours but not in oligodendrogliomas. If synaptophysin is not detected, electron microscopy may be used to confirm the presence of neurosecretary granules. Synapses are also common but are not required for diagnosis. NFPs are usually not expressed except in ganglioid cells and GFAP is expressed by a small number of tumours. Neurocytomas usually behave in a benign fashion but a small number of them may exhibit increased proliferative activity, necrosis and other features indicative of aggressive behaviour.

Choroid Plexus Tumour

Choroid plexus has features of epithelial cells including tight junctions and basement membrane. Choroid plexus tumours, namely papilloma and carcinoma, are intraventricular tumours. Over 90% arise from the lateral and fourth ventricles while about 5% are found in the third ventricles. Although 80% of these tumours occur before the age of 20 years, most of them occur before the age of 2 years; congenital tumours have been described. They

typically cause hydrocephalus by two mechanisms: obstruction and overproduction of spinal fluid.

Choroid plexus papilloma appears as a cauliflower-like mass that is adherent to the ventricular wall but well demarcated from the brain parenchyma. Histologically, there is recapitulation of normal choroid plexus structure. The tumours are composed of delicate, often oedematous, fibrovascular connective tissue fronds that are covered by single-layered columnar to cuboidal epithelium with basally located nuclei (**Figure 21**). A basement membrane can easily be demonstrated by a periodic acid–Schiff (PAS) stain. Pseudostratification may occur but mulilayered epithelial cells are not seen in papilloma. A few mitotic figures may be present but, unless excessive and atypical, do not indicate malignancy. Brain invasion and necrosis are absent. Like their normal counterparts, the tumours express cytokeratins. Most express vimentin and S-100. Although GFAP is absent in normal choroid plexus, it is focally expressed in about 25–55% of choroid plexus papillomas. Transthyretin (prealbumin), a protein involved in the transport of thyroxine, is expressed in normal choroid plexus and papillomas. Expression of synaptophysin occurs in normal choroid plexus, choroid plexus papilloma and carcinoma but the significance is unclear.

Choroid plexus carcinomas show partial lost of papillary pattern with tumour cells arranged in solid sheets. There are numerous mitoses, nuclear pleomorphism, increased cellularity, necrosis and often extensive brain invasion. The pattern of antigen expression is similar to choroid plexus papillomas. Expression of transthyretin, however, may be reduced. Proliferative activity of the carcinoma (mean 13.8%, range 7.3–60%) is significantly higher than found in papillomas (mean 1.9%, range 0.2–6.0%) (Vajtai *et al*., 1996). Choroid plexus carcinoma is rare in adults. Such a diagnosis should only be made when the possibility of metastatic papillary carcinoma is eliminated through thorough morphological and immunohistochemical study.

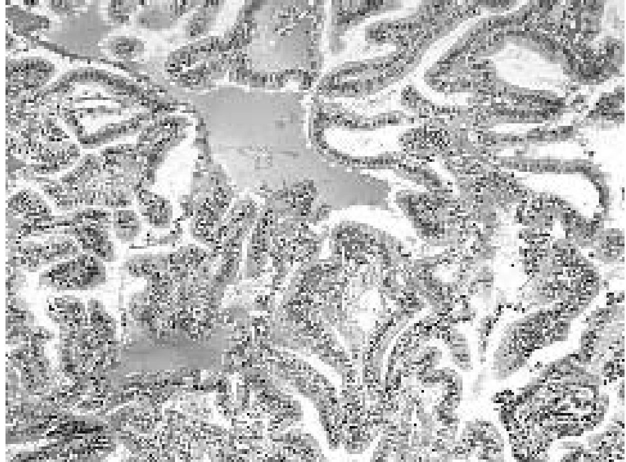

Figure 21 Choroid plexus papilloma show branching papillary structures covered by a single layer of epithelium.

Choroid plexus tumours tend to spread throughout the cerebrospinal fluid. Whereas the carcinomas may produce frank metastases, papilloma with spinal dissemination may remain asymptomatic. The overall 5-year survival rate for choroid plexus papilloma is 100% and for choroid plexus carcinoma 40%. Choroid plexus carcinoma is one of the rare brain tumours that can metastasize to visceral organs.

Pineal Parenchymal Tumour

Pineocytoma is a rare neoplasm that can occur at all ages but older children and young adults are predominantly affected. They tend to be well-defined masses which are composed of solid sheets of small, uniform, mature cells that resemble pineocytes. Some have neuropil or are arranged in a circular pattern that looks like an enlarged Homer Wright rosette. These large rosettes are termed ‘pineocytoma rosettes’ as they are only seen in these tumours. A papillary subtype of pineocytoma has also been described. These tumours strongly express synaptophysin and variably express NFP and other neuronal markers such as class III β-tubulin. Expression of retinal S-antigen and rhodopsin indicating their photoreceptor lineage can often be demonstrated. The 5-year survival of patients with pineocytoma is about 86% (Schild *et al*., 1996).

Pineoblastomas, in contrast, are highly malignant tumours and almost half of them occur within the first 10 years of life. They share many features of PNETs and are better regarded as PNETs with photoreceptor differentiation. Macroscopically, they are soft, friable, haemorrhagic and poorly demarcated tumours. Histologically, they are composed of small primitive cells with hyperchromatic nuclei and scant cytoplasm. Mitotic activity is brisk. They may contain rosettes that resemble those in PNETs in other locations (Homer Wright rosette) or in retinoblastoma (Flexner–Wintersteiner rosette). Dissemination through CSF is common. They are variably immunoreactive for synaptophysin, neurofilament proteins, class III β-tubulin, chromogranin A and retinal S-antigen.

The distinction between pineocytoma and pineoblastoma is blurred in a significant number of cases, in which event they are regarded as pineal parenchymal tumours with intermediate differentiation.

Primary Tumours of Meninges and Mesenchyme

This family of tumours arise within intracranial and intraspinal locations and recapitulate the normal supporting tissue of the CNS such as the leptomeninges and the surrounding mesenchyme.

Meningiomas

Meningiomas are tumours that consist of arachnoid (meningothelial) cells and are most commonly seen in

the areas where arachnoid villi are most abundant, such as the parasagittal region and olfactory groove, and display features of mature meningothelial cells; sometimes they arise from intraventricular locations and are rare in tissue outside the cranium and spinal cord. These are common tumours and comprise 13–26% of all primary intracranial mass lesions. Meningiomas are essentially tumours of middle-aged and elderly individuals, and are only rarely seen in children and infants. They are twice as common in women than in men. These tumours are slow growing and many remain asymptomatic for years. However, local recurrence after surgery is not uncommon. The neurological manifestations are closely related to compression of adjacent structures and the specific neurologic deficits depend on the location of the tumour.

As noted, meningiomas are preferentially found over the cerebral convexity, olfactory groove, sphenoid ridge, parasellar regions, petrous ridge and tentorium cerebelli. Multiple tumours are not infrequent, particularly in patients with neurofibromatosis 2 (see below), and are not necessarily an indication of malignancy. On MRI, meningiomas typically appear as well demarcated masses that enhance homogeneously and may be associated with a variable amount of oedema in the surrounding brain. Grossly, they are well-demarcated, round to lobulated, rubbery to firm masses (**Figure 22**). The cut surface is often homogeneous and tan and can be gritty when substantial calcification is present. Brain tissue is often compressed by the tumour. Intracranial meningiomas are typically attached to the dura whereas those in the vertebral canal are adhered to leptomeninges. These tumours may invade the skull bone and adjacent sinuses or may arise entirely within bone and be associated with osteoblastic activity.

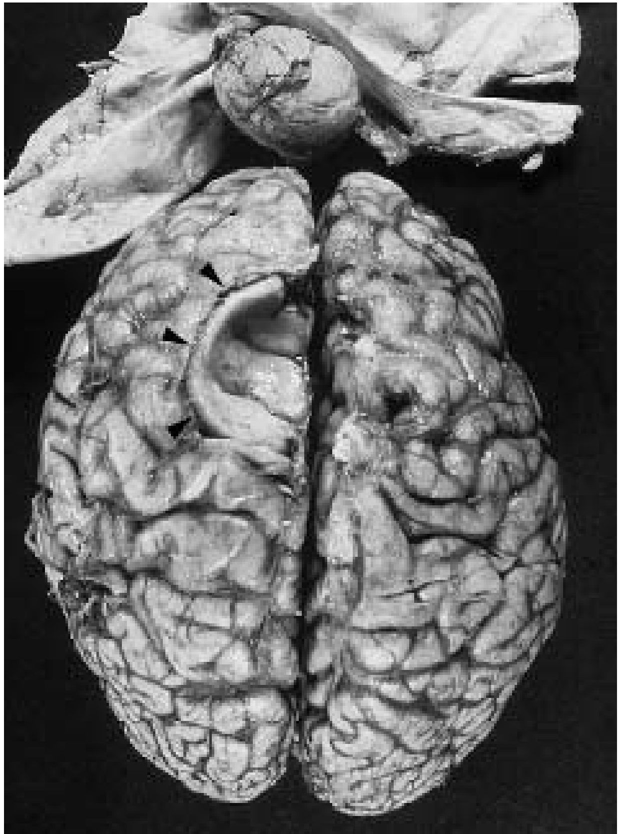

Figure 22 Parasagittal meningioma which has compressed but not invaded the surrounding gyri producing atrophy (arrow head).

Meningiomas are basically histologically benign tumours. They have the most diversified histopathological features and the histology is often variable within the same tumour. Nuclei of the tumour cells are small, round to oval, and display minimal pleomorphism; they may contain nuclear pseudoinclusions. Sporadic large and hyperchromatic nuclei can sometimes be seen. Proliferative activity, as measured by cell cycle labelling, is low; high proliferative activity may be correlated with an increased risk of recurrence. There is no significant pleomorphism, mitotic activity or necrosis.

Histological features of meningiomas are diverse. There are several common histological subtypes of meningiomas. The meningothelial type is composed of tumour cells that are arranged into sheets and lobules that are separated by thin collagenous septae (**Figure 23**). Cytologically they are benign looking and resemble arachnoid cells (**Figure 24**) and very often they arrange themselves into small whorls of cells resembling arachnoid granulations. The fibrous (fibroblastic) meningioma is composed of spindle-shaped cells with elongated cytoplasm that resemble fibroblasts (**Figure 25**). These cells are arranged in parallel and interlacing bundles intermingled with a variable amount of dense collagen. The transitional (mixed) type is essentially a hybrid that has features of both the meningothelial and fibroblastic types. Tumour cells of the psammomatous meningioma tend to arrange

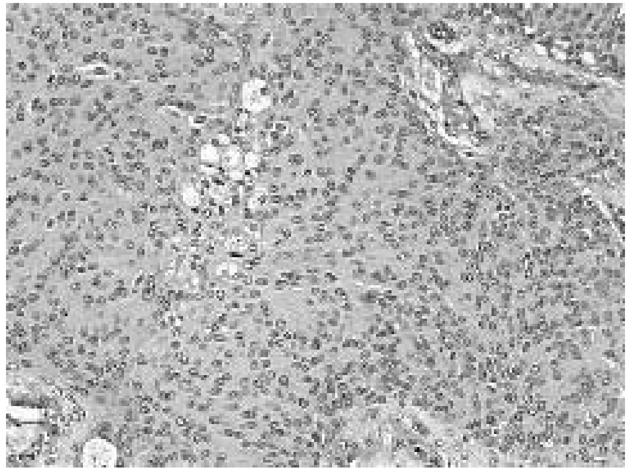

Figure 23 Typical field of meningotheliomatous meningioma showing sheets of arachnoid cells and a small focus of foamy macrophages.

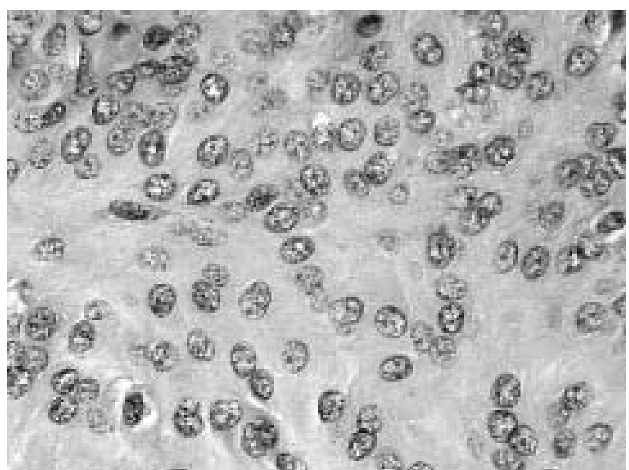

Figure 24 Nuclei of meningioma resemble those of the arachnoid cells and are round to oval and have a speckled chromatin pattern.

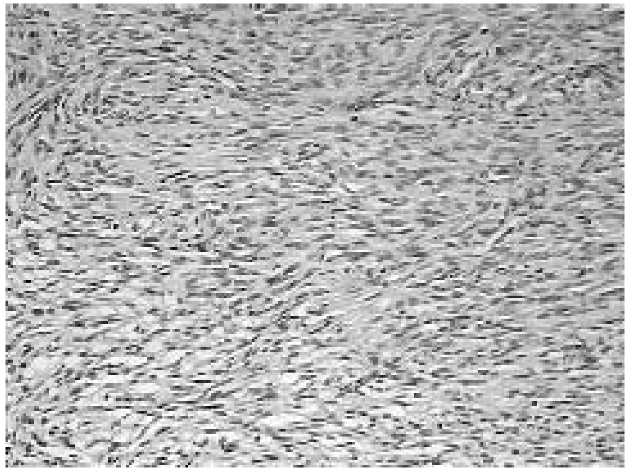

Figure 25 Photomicrograph of fibroblastic meningioma composed of enlarged spindle cells reminiscent of fibroblasts.

themselves into whorls that often contain psammoma bodies, a round to irregular, laminated calcified structure.

Less common types include angiomatous meningioma, microcystic meningioma, secretory meningioma, lymphoplasmacyte-rich meningioma and metaplastic meningioma.

While the aforementioned variants do not exhibit differences in their biological behaviour, papillary meningioma is a variant that behaves aggressively. These tumours are characterized by a perivascular pseudopapillary arrangement of tumour cells. They often have mitotic activity and pleomorphism and tend to recur locally and metastasize to other body regions. Clear cell and chordoid meningioma may also be associated with increased risk of recurrence and aggressiveness.

Immunohistochemically, most meningiomas express EMA in a patchy manner. Expression is less consistent in atypical and anaplastic meningiomas. Vimentin is seen in virtually all meningiomas. These tumours do not express GFAP, a useful feature for differentiating them from desmoplastic gliomas.

Characteristic ultrastructural features of meningiomas include interdigitations of the cytoplasmic membrane, hemidesmosones and desmosomes. They contain abundant amounts of intermediate filaments, sometimes with a pronounced whirling pattern. These filaments are also firmly anchored to the desmosomes, a feature that is also seen in normal arachnoid cells.

Atypical and Anaplastic Meningiomas

Atypical meningiomas display features that suggest aggressive biological behaviour including four mitotic figures per 10 high-power fields, uninterrupted patternless or sheet-like cell growth, increased pleomorphism and necrosis. Such atypical changes can occur with any of the histological variants.

Anaplastic (malignant) meninigiomas display more sinister histological features that far exceed those displayed by atypical meningiomas. Histologically, they are frankly malignant. Both atypical meningiomas and anaplastic meningiomas have a significantly higher proliferation rate than meningioma.

Brain invasion by meningioma is an indication of aggressive behaviour but not an equivalent to frank malignancy as histologically benign meningiomas may invade the brain. On the other hand, atypical and anaplastic meningiomas frequently invade the brain.

Mesenchymal Non-meningothelial Tumours

This is a family of rare tumours that arise within the intracranial and/or intraspinal cavity. They exhibit mesenchymal differentiation of various types including fat, fibrous tissue, muscle, bone, endothelial cells and others. This heterogeneous family includes benign tumours such as lipomas and highly malignant lesions such as mesenchymal chondrosarcomas. Some tumours, such as rhabdomyosarcoma, are preferentially seen in children, whereas other tumours such as chondrosarcoma are often seen in adults; no age group is spared. Only a few will be discussed here.

Vascular Tumours. Vascular lesions of the brain fall into three major groups. The most frequent type is malformative in nature and includes arteriovenous malformations, cavernous angiomas, venous angiomas and capillary telangiectases. These must be distinguished from true neoplastic vascular lesions. Interestingly, these vascular malformations are often associated with familial syndromes that involve malformations of the CNS and blood vessels.

The second type is a true neoplasm with the neoplastic cells displaying histological and immunohistochemical features of endothelial cells. The tumour cells express factor-VIII and CD31 and can also be identified with

Ulex europeus lectin. Haemangiomas are benign tumours. Epithelioid haemangioendotheliomas are rare vascular tumours of intermediate malignancy which arise from the skull base, dura or brain parenchyma. Angiosarcomas are rare but highly malignant vascular tumours. Kaposi sarcomas are only exceptionally encountered and almost always associated with acquired immune deficiency syndrome (AIDS).

In the third type, the tumours have such a rich vasculature to suggest a vascular tumour but the neoplastic cells do not exhibit features of endothelial cells. Examples include haemangiopericytoma and haemangioblastoma.

Haemangiopericytoma. Haemangiopericytoma is an uncommon tumour of intermediate-grade malignancy. The tumours are almost always dural-based and tend to occur in young adults. Macroscopically, they are dural-based solid masses well demarcated from the adjacent brain tissue, almost invariably solitary at initial presentation. Large, thin-walled and dilated blood vessels often with the appearance of a stag-horn are present. Haemangiopericytomas are highly cellular tumours composed of compactly arranged, monotonous polygonal cells with ill-defined cytoplasm and usually mitotically active. There are numerous small vascular channels between the tumour cells. The tumour cells arrange themselves in lobules separated by thin vascular spaces. The neoplastic cells are not immunohistochemically reactive for CD31, factor-VIII or *Ulex europeus*. Characteristically, reticulin material surrounds the individual cells. This is confirmed by ultrastructural demonstration of basal lamina-like amorphous material around the cells. Local recurrence is a rule.

Haemangioblastoma. Haemangioblastoma is a highly vascular tumour but the neoplastic cells do not express features of endothelium. In fact, their nature is poorly understood and, therefore, they are classified as tumours of uncertain histogenesis in the WHO Classification. For practical purposes, they are discussed with other vascular tumours. Haemangioblastomas are relatively common and about 25% of them are associated with von Hippel–Lindau disease. This is a biologically benign tumour and occurs most commonly in young and middle-aged adults; the cerebellum is the preferred site, although they can occur in any part of the CNS. Macroscopically, they are often well-circumscribed cystic tumours, and the strategic position in the posterior fossa often obstructs CSF flow. Histologically, they are highly vascular (**Figure 26**) and are composed of sheets and lobules of vacuolated large stromal cells, the histological hallmark of the tumour. This is combined with a rich capillary network (**Figure 27**). Immunohistochemically, they do not express markers of endothelial cells. The stromal cells contain lipid droplets, a feature best demonstrated by fat stains on frozen sections or electron microscopy, but do not express any marker of endothelial cells. Their nature remains a matter of dispute.

Chordoma. Chordomas are tumours of notochordal tissue that arise mainly at either end of the vertebral column. These tumours may involve the cranial base and extend into the middle and posterior fossae and penetrate the dura. Chordomas in the sacral region are more common, and rarely extend into the spinal canal. Most cases are seen after the age of 50 years (Dorfman and Czerniak, 1998). Although locally invasive, these tumours are histologically benign. Macroscopically, they are grey, bulky, soft to gelatinous masses in consistency. The histological hallmark of chordoma is the large and bubbly physaliferous cell (**Figure 28**) which has pale eosinophilic or amphophilic cytoplasm and a centrally located small-to-medium-sized nucleus. These cells form cohesive sheets or nests and are embedded in a sea of strongly metachromatic acellular substances. Ultrastructurally, the tumour cells contain numerous desmosome-type

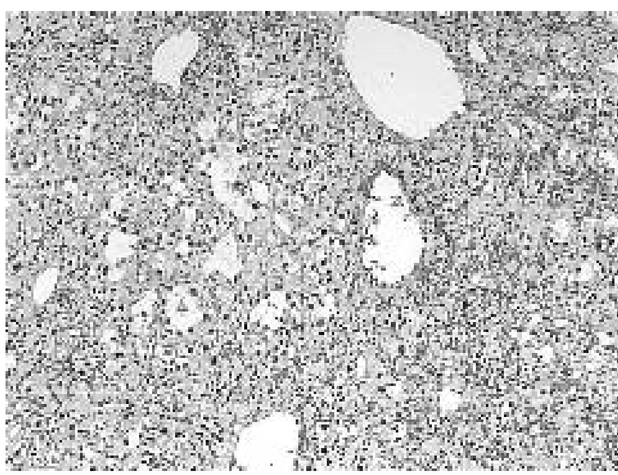

Figure 26 Haemangioblastomas are richly vascular and often have dilated blood vessels.

intercellular junctions which tightly bond them to one another. These cells are immunohistochemically reactive for S-100 protein, EMA, vimentin and cytokeratin. These tumours must be distinguished from chondrosarcoma which they may mimic histologically.

Primary Tumours of Tissue Outside the CNS

These interesting primary tumours have no normal counterparts in the mature CNS. Three families of tumours comprise this group: tumours of the haematopoietic system, germ cell tumours and teratomas, and craniopharyngioma.

Primary Tumours of the Haematopoietic System

The CNS may be involved by both primary and secondary tumours of the haemotopoietic system. A variety of primary lymphoproliferative disorders, including intraparenchymal primary lymphoma, plasmacytoma and mucosal associated lymphoid tissue (MALT) lymphoma of the dura and post-transplantation lymphoproliferative disorder, can be seen in the CNS. Primary non-Hodgkin lymphoma is the most commonly seen entity. In contrast, primary Hodgkin disease of the CNS is exceedingly rare. Primary histiocytic tumours, predominantly Langerhans histiocytosis, are also seen in the CNS.

Primary non-Hodgkin lymphoma of the CNS was a rare disease until the epidemic of HIV infection and wide use of immunosuppression for organ transplantation. In immunocompetent patients, primary CNS lymphoma is seen mainly in elderly patients, but in immunodeficient patients, the age of onset is related to the time of onset of the immunodeficiency and all age groups are affected. Patients with hereditary immunodeficiency disorders have the lowest age of onset, followed by patients with acquired immunodeficiency such as AIDS, and then by patients with organ allograft transplantation. Symptoms and clinical presentation are nonspecific. MRI may reveal solitary or multiple hyperdense or isodense lesions that may or may not enhance. Cystic change is not common. Macroscopically, these tumours are preferentially found in deep-seated brain tissue such as the basal ganglia and periventricular areas. Demarcation from the surrounding tissue can be variable and the consistency varies from soft to firm.

Classification of lymphomas changes frequently. The most recent system in use is the Revised European–American Lymphoma (REAL) classification (Harris *et al.*, 1994), which defines entities on the basis of morphological, immunological, genetic and clinical information. Over 98% of all primary CNS lymphomas are B cell lymphomas, predominantly the diffuse large B lymphoma. T cell lymphomas represent the other 2% of primary CNS lymphoma. Morphologically, the lymphomas are characterized by a multifocal, perivascular (**Figure 29**) and concentric infiltration by large, atypical and monotonous lymphocytes which extensively infiltrate brain tissue. Reticulin fibres around the blood vessels are typically layered and infiltrated by the neoplastic lymphocytes giving an 'onion bulb' appearance. Immunohistochemically, B cell lymphomas express pan-B markers such as CD20 and CD79a. They express monoclonal surface or cytoplasmic immunoglobulins with IgM and kappa light chain being the most common combination. Immunocompetent patients are usually responsive to therapy and the overall 5-year survival rate is about 25–45%. The prognosis in AIDS patients is much more ominous and their median survival rate is only 10–18 months when treated with multimodal therapy.

Germ Cell Tumours

Germ cells are not normal residents of the CNS. However, it is thought that a small number of primordial germ cells are disseminated along the migration trail from the yolk sac to the gonads during embryogenesis. These cells are

the putative origin of germ cell tumours in the CNS. Some tumours are primarily seen in children and are more common in men than women. For unknown reasons, the prevalence in Asian countries is higher than that in the West. They typically occur along the midline with the pineal gland (**Figure 30**) being the most common site, followed by the suprasellar region. The third ventricle, optic chiasma and tectal plate are often affected. In consequence, they often cause hydrocephalus, precocious puberty, visual field defects and Parinaud syndrome.

Like other gonadal and extragonadal germ cell tumours, those arising in the CNS display a spectrum of differentiation. Germinoma, choriocarcinoma, yolk sac tumour, embryonal carcinoma, mixed germ cell tumour and immature and mature teratoma can all occur as primary tumours of the CNS. Pure germinoma and teratoma are, however, the most commonly seen entities. Their pathology is similar to that of other gonadal and extragonadal tumours. Germinomas are generally soft and friable. Histologically, they are composed of large, uniform cells with large vesicular nuclei containing a prominent nucleolus which resemble primitive germ cells. There is an admixture of lymphocytic cells. This is variable but sometimes intense. Placental alkaline phosphatase (PLAP) is expressed by germinoma cells and is helpful in diagnosis. Yolk sac tumours display histological features reminiscent of the embryonic yolk sac endoderm and are composed of primitive-appearing cells that arrange themselves into loosely packed, variably cellular retiform structures. When present, Schiller–Duval bodies are diagnostic. Yolk sac tumours characteristically contain eosinophilic hyaline globules that are PAS positive and immunoreactive for α-foetoprotein (AFP). The histology of embryonal carcinoma may be confused with that of yolk sac tumour. These tumours, however, are more monotonous in their patterns and are composed of sheets of undifferentiated epithelial cells. Embryonal carcinoma expresses cytokeratin and carcinoembryonic antigen (CEA). Choriocarcinoma is a germ cell tumour that differentiates along the trophoblastic lineage and is characterized by the presence of cytotrophoblastic and syncytiotrophoblastic elements. These tumours are immunoreactive for β-human chorionic gonadotrophin.

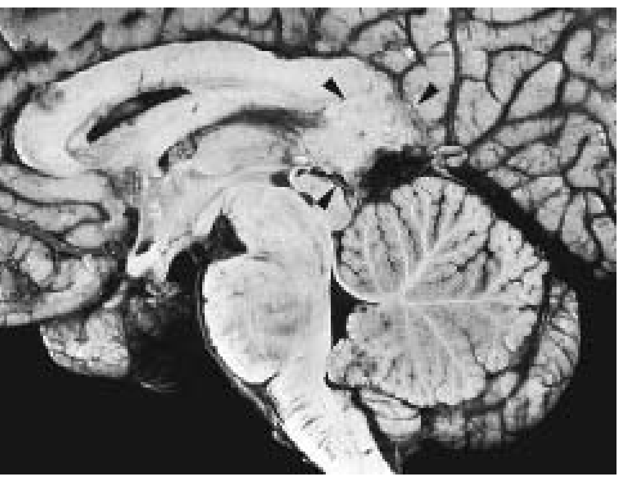

Figure 30 Sagittal section of brain showing yolk sac tumour (arrow head) arising from the pineal gland.

Teratomas, in contrast to the aforementioned germ cell tumours, differentiate along ectodermal, endodermal and mesodermal lineages. Derivatives from all three germ layers such as neural tissue, respiratory epithelium, cartilage, bone, secretory glands and others may be found. In mature teratoma, all elements are fully differentiated 'adult-type tissue.' Immature teratomas contain elements that are not fully developed. Teratoma with malignant transformation refers to tumours that have a frankly malignant component, most often a rhabdomyosarcoma or undifferentiated sarcoma.

Because of the secretion of PLAP, AFP and β-HCG, germ cell tumours currently compose the only class of primary CNS tumours in which detection of primary and recurrent tumour can be easily assayed for oncoproteins in CSF and serum.

Craniopharyngioma

Craniopharyngiomas are biologically benign but locally invasive tumours. They have a bimodal distribution; the bulk of them are seen in children and young adults and the second peak occurs around the sixth decade. They occur in the suprasellar region (**Figure 31**), often have an intrasellar component and are presumably derived from Rathke's pouch. Their proximity to the optic chiasma and pituitary gland make visual disturbance, endocrine abnormalities of the anterior pituitary and diabetes insipidus the

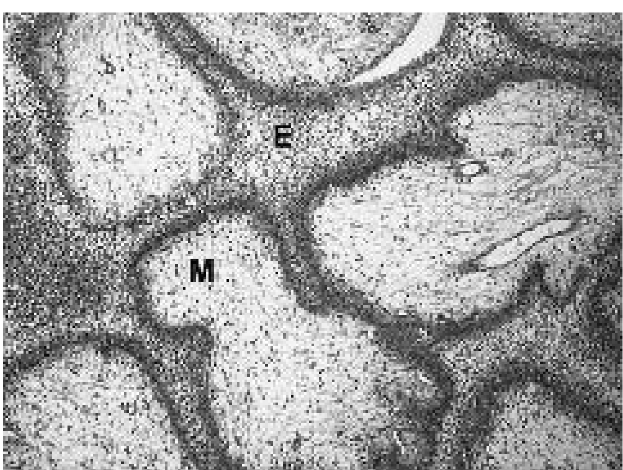

Figure 31 Photomicrograph of an adamantinomatous craniopharyngioma showing a complex pattern composed of anastomosing trabeculae of epithelial cells (E) with peripheral palisading. Supporting the epithelial cells is delicate mesenchymal tissue (M). This field is highly reminiscent of ameloblastomas that occur in the jaw.

most frequent clinical presentations. Compression of the third ventricle often causes hydrocephalus. Craniopharyngiomas are well-demarcated tumours that vary greatly in size and extent. They vary from solid to predominantly cystic. The cystic lesions often contain a cholesterol-rich, thick, brownish yellow fluid that looks like machine oil.

Two major histological variants, namely the adamantinomatous and papillary type, have been described. The adamantinomatous type is histologically very similar to if not identical with ameloblastoma or calcifying odontogenic tumour of the jaw. They are characterized by anastomosing trabeculae of stratified squamous epithelium with peripheral palisading of nuclei. Enclosed within these islands are loosely arranged stellate-shaped epithelial cells and nodular and often calcified masses of 'wet keratin,' a distinctive diagnostic feature of craniopharyngioma. These cell islands are held together and nourished by the vascularized connective tissue stroma. Substantial calcification is often associated with the components that resemble calcifying odontogenic tumour. The papillary craniopharyngioma is composed of pseudopapillae covered by keratinizing squamous cell epithelium. Craniopharygioma is a biologically benign but locally invasive tumour, often associated with substantial gliosis in the surrounding brain tissue. Surgical removal remains the most effective approach and they recur occasionally.

Secondary Tumours

Secondary neoplastic involvement of the CNS falls into two major groups, namely metastatic tumours and secondary involvement of the CNS by haematopoietic tumours such as lymphomas and leukaemias; both involve haematogenous spread. They may present as single or multiple lesions in the brain.

Carcinoma, malignant melanoma and germ cell tumours often produce metastases to the CNS. In contrast, metastatic sarcomas with the exception of alveolar soft part sarcoma are not as common. Metastatic tumours are typically associated with substantial oedema and the clinical symptoms may be disproportionate to the size of the metastases *per se*. The location and size of the metastasis but not the type of tumour dictate the type and nature of neurological abnormalities. Whereas metastases in the cerebral cortex may cause seizures, metastases to the posterior fossa structure often cause hydrocephalus by obstructing the flow of CSF. Metastasis to the spinal cord may compress the spinal cord and produce hemiplegia or quadriplegia, depending on the level of involvement.

Intracranial metastases are most frequently seen in the brain and occasionally in the dura. In the cerebrum, the tumours are most frequently located at the cortical–medullary junction where the calibre of the blood vessels abruptly changes from large to small; most of them are found in the arterial watershed areas of the cerebral hemispheres. In contrast, epidural metastases are most commonly seen in the spinal cord although leptomeningeal and intramedullary (spinal cord) metastases can also occur.

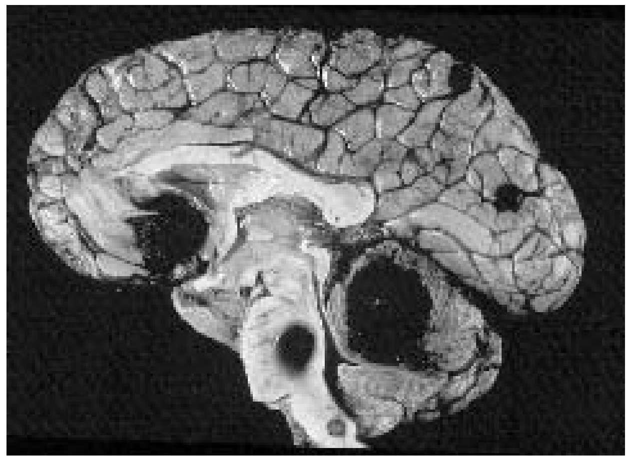

Figure 32 Multiple metastases from a peripheral malignant melanoma. Note the carbon black colour of the tumour.

Over 50% of all metastatic carcinomas originate from the respiratory tract. Adenocarcinoma, small cell and large cell carcinomas are far more likely to generate metastases than squamous cell carcinoma of the lung. Other common origins include carcinoma of the breast and malignant melanoma (**Figure 32**). Renal cell carcinoma has an unexplained high tendency to metastasize to the cerebellum and prostate carcinoma tends to generate epidural metastases that compress the spinal cord. Germ cell tumours of the testis metastasize to the brain in 15–25% of patients and in patients with choriocarcinoma the rate is 83%.

In most cases, the histopathology of the metastatic tumour is similar to the original tumour. The primary tumours in some cases are never found. In these cases, histology and immunohistochemistry may be helpful in identifying the tumour of origin, although this may not always be possible. The survival rate of patients with metastatic tumour in the brain varies greatly but those with single metastasis show the best survival.

Tumours of the PNS

Similar to the CNS, tumours of the PNS can also display features of embryonal and mature features of the PNS. The reader should refer to the Further Reading section for detailed discussion of PNS tumours.

Neuroblastic Tumours of the Adrenal Gland and Sympathetic Nervous System

Neuroblastic tumours are childhood tumours composed of immature neuroectodermal cells derived from the neural crest with or without associated mature ganglionic elements. Neuroblastic tumours are the most common

extracranial malignant tumours during the first 2 years of life and they tend to metastasize widely. About half arise from the adrenal medulla whereas the remainder are associated with ganglia along the sympathetic chain. They typically present clinically as a palpable abdominal mass, hepatomegaly or a thoracic mass. They may compress the spinal cord and/or adjacent nerve roots and present with neurological symptoms. A small number may secrete vasoactive intestinal polypeptide and cause diarrhoea.

The International Neuroblastoma Pathology Classification by Shimada *et al*. (1999) provides a comprehensive approach in correlating the histopathology and clinical outcome of neuroblastic tumours. The neuroblastic cell nests may also display various degrees of differentiation. Neuroblastoma refer to a lesion that is composed exclusively of primitive neuroectodermal cells (**Figure 33**). Ganglioneuroblastoma is composed of nests and islands of neuroblastic cells embedded within a schwannian stroma that contains ganglionic cells (**Figure 34**). Ganglioneuroma is composed predominantly of mature ganglionic cells in a schwannian background, although a small amount of differentiating neuroblasts can be present. Grossly, they are encapsulated, soft, grey–tan tumours. Ganglioneuromas are firmer than neuroblastomas. Histologically, neuroblastomas are composed of neuroblastic cells that have small, hyperchromatic nuclei and minimal cytoplasm. Some of them may display features of differentiating neural cells with neuropil and Homer Wright rosettes. Adrenergic, cholinergic or mixed neurotransmitter enzyme and intracytoplastic catecholamines may be demonstrated histochemically. These tumours may also express chromogranin, gamma-subunit of neuron-specific enolase, neurofilament proteins and neuronal microtubule-associated proteins. The schwannian stroma expresses S-100 protein. The overall prognosis of neuroblastoma correlates with clinical staging, the histological grade of tumour, expression of TrkA and N-Myc amplification.

Olfactory Neuroblastoma (Esthesioneuroblastoma)

Olfactory neuroblastoma is a malignant tumour that is composed of primitive neuroepithelial cells and is assumed to arise from olfactory receptor cells in the nasal cavity. In contrast to neuroblastoma of the adrenal gland and sympathetic ganglia, olfactory neuroblastomas are fairly uncommon and occur predominantly in adults. They are slow-growing tumours and are often associated with long-standing symptoms. Invasion into the adjacent structures and metastasis, often to the cervical lymph nodes, is common. Macroscopically, they are soft and richly vascularized polypoid lesions. Histologically, they are composed of primitive neuroectodermal cells arranged in lobules and often form Homer Wright rosettes. Immunohistochemistry is often necessary to distinguish them from other primitive tumours.

Neurofibroma

Neurofibroma is a benign tumour that may occur in all age groups. The exact incidence of neurofibroma is unclear and they are often associated with neurofibromatosis 1 (NF1). They are most frequently found in the part of the PNS that is most distant from the spinal cord and brain; they are occasionally seen in spinal nerve roots and rarely seen in the cranial nerves. When neurofibromas arise from a small peripheral nerve, they characteristically diffusely infiltrate the nerve. They may be confined by the perineurium when they arise from medium-sized nerves but they tend to infiltrate into the surrounding soft tissue. Neurofibromas usually present as cutaneous nodules (localized cutaneous

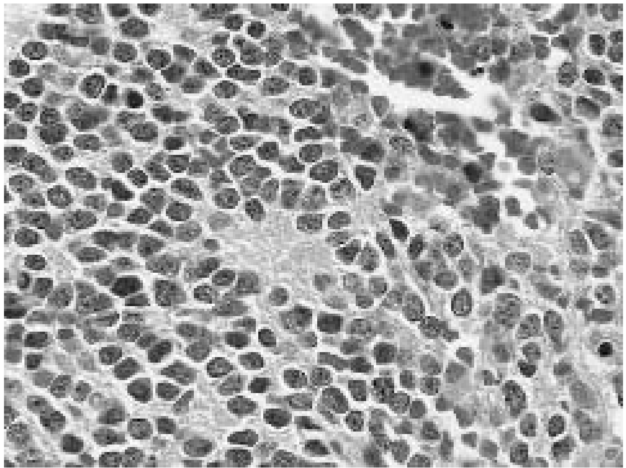

Figure 33 Neuroblastoma arising within the adrenal gland showing a Homer Wright (neuroblastic) rosette (centre of the figure). (Courtesy of Dr David Carpentieri, Children's Hospital of Philadelphia.)

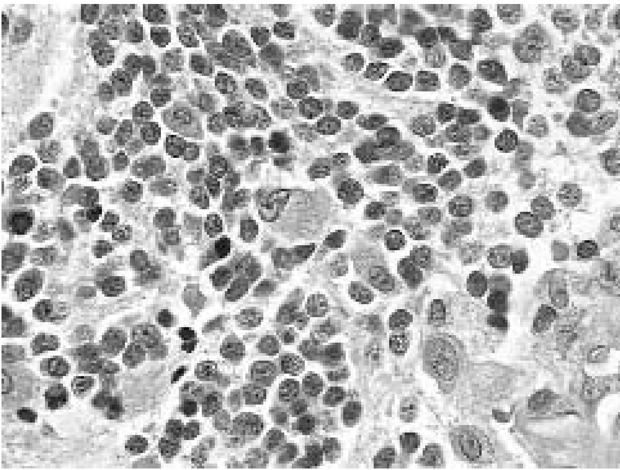

Figure 34 Ganglioneuroblastoma displaying neuronal differentiation (large cells). (Courtesy of Dr David Carpentieri, Children's Hospital of Philadelphia.)

neurofibroma) and less commonly as isolated, well-circumscribed masses (isolated intraneural neurofibroma) within nerves. In patients with NF1, they often present as plexiform neurofibromas that appear as diffuse enlargement of major nerve trunk and their branches. Macroscopically, they are firm and grey–tan tumours. While the isolated intraneural neurofibromas may be well demarcated, the plexiform neurofibroma typically appears like a string of sausages (**Figure 35**). Since they arise within the nerve and become an integrated part of it, they cannot be removed without sacrificing the nerve. Cells composing the tumour are fibroblasts, Schwann cells and perineural cells that are embedded within a collagenous and mucoid matrix (**Figure 36**). Most tumour nuclei are small and hyperchromatic; mitotic figures are rare. Axons and myelin degenerate as a consequence of pressure on nerves by neoplastic cells. S-100 is invariably expressed in these lesions. Ultrastructural examination documents the presence of Schwann cells and perineural cells.

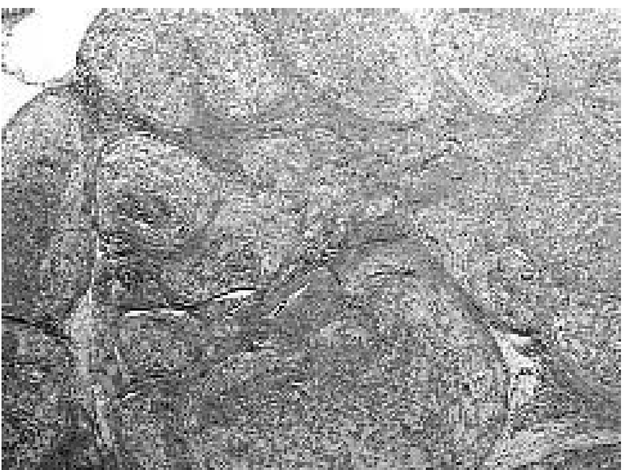

Figure 35 Plexiform neurofibroma showing variable enlargement of nerve bundles which completely obscure normal structure.

Schwannoma

Schwannomas are common benign tumours that are most frequently seen in middle-aged patients (fourth to sixth decades), although they are seen in all age groups. Unless associated with neurofibromatosis 2 (NF2) they are usually solitary. They arise most frequently from sensory branches of peripheral nerves of the head and neck region and extensor aspects of the extremities and are often asymptomatic. When they arise from the spinal nerve roots, they may have a dumbbell shape and compress the nerve root and spinal cord. The cochlear–vestibular nerve is also a common site, causing tinnitis and hearing loss. Rarely, these tumours may be found within the brain and spinal cord.

The majority are well-circumscribed, oval, solid to cystic, tan, rubbery tumours. In contrast to neurofibroma which diffusely infiltrates the nerve, schwannomas compress but do not excessively infiltrate the nerve. Thus, the nerve may be be salvaged during surgical excision of schwannomas. Histologically, schwannomas are composed of elongated spindle-shaped cells that exhibit a variety of patterns. The tumour cells often arrange into Antoni A and Antoni B patterns. The Antoni A pattern is characterized by compact spindle cells that may have nuclear palisading and whorling of cells. Verocay bodies (**Figure 37**) refer to structures formed by two compact rows of palisading nuclei separated by fibrillary cell processes. The nuclei of schwannoma are usually elongated. The Antoni B pattern consists of cells that are loosely arranged in a delicate and reticular pattern (**Figure 38**).

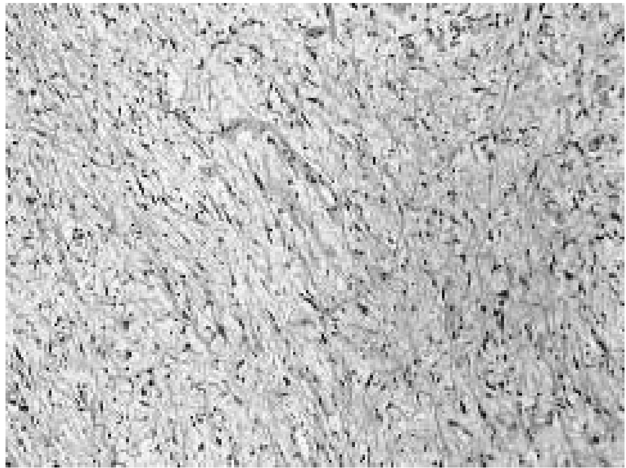

Figure 36 Neurofibromas typically contain delicate spindle cells and mucoid material.

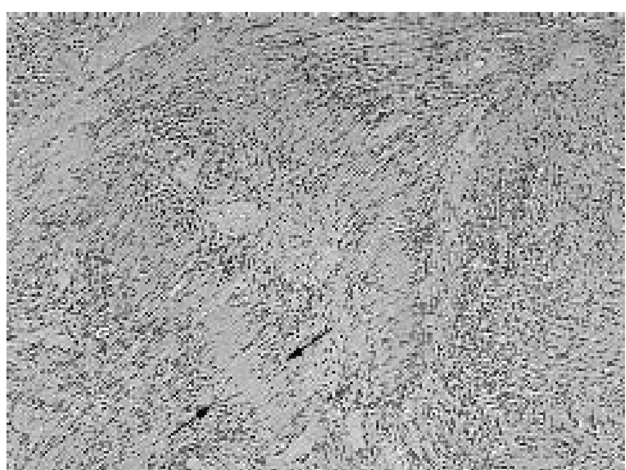

Figure 37 This photomicrograph shows the densely packed Antoni A areas and Verocay bodies formed by alternating palisading bands of nuclei and acellular tumour tissue (arrow).

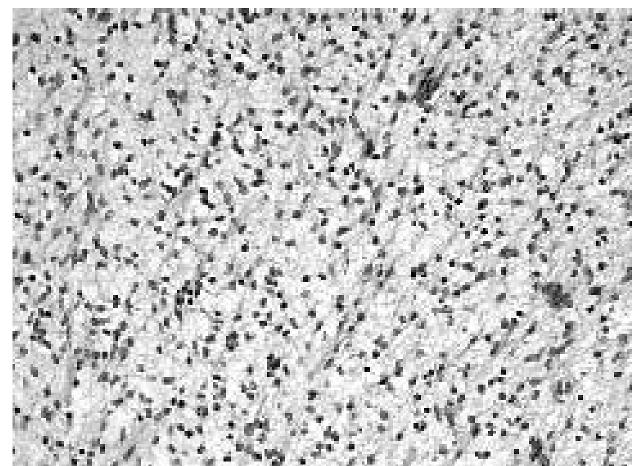

Figure 38 In Antoni B areas, the tumour cells are loosely packed and do not grow in any specific pattern.

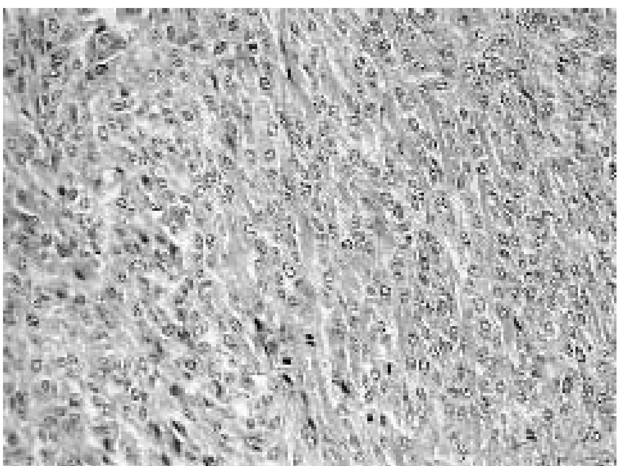

Figure 39 A malignant peripheral nerve sheath tumour can display densely packed and pleomorphic spindle cells. (Courtesy of Dr Paul Zhang, University of Pennsylvania.)

Lipid-laden macrophages and mucoid material are often present. Cellular schwannoma is a variant with increased cellularity. It is a benign variant of schwannoma, although recurrences have been reported. Melanotic schwannomas contain melanin and have immunohistochemical and ultrastructural features of both Schwann cells and melanocytes.

Malignant Peripheral Nerve Sheath Tumour (MPNST)

Malignant peripheral nerve sheath tumours (MPNSTs) are uncommon and over half occur in patients with neurofibromatosis 1. They most commonly arise from plexiform neurofibromas. Many have both features of neurofibroma and schwannoma but the preferred diagnostic classification is MPNST. This has been defined as 'any malignant tumour arising from a peripheral nerve or showing nerve sheath differentiation, with the exception of tumours originating from epineurium or the peripheral nerve vasculature,' according to the WHO Classification. The most common sites of MPNST are deep nerve branches in the buttock, thigh, brachial plexus and paraspinal areas. Cranial nerves are uncommonly involved. On gross examination they are medium-sized, firm, hard, pseudoencapsulated tumours that are adherent to the nerve of origin. Necrosis is common. MPNSTs exhibit the most diverse histological features among all tumours of the PNS and soft tissue tumours. Significant portions may be undifferentiated (**Figure 39**). Diagnosis depends either on demonstration of tumour origin from a peripheral nerve trunk, a benign or malignant peripheral nerve tumour or immunohistochemical or ultrastructural features of Schwann or perineural cell differentiation.

Paraganglioma

This is a benign neuroendocrine tumour that arises in autonomic ganglia (paraganglia) throughout the body or within the adrenal medulla where this tumour is known as a phaeochromocytoma. Within the CNS, paragangliomas are restricted to the cauda equina and filum terminale. Paragangliomas usually occur in adults and some are endocrinologically active. These well-differentiated tumours are composed of large polygonal chief cells (type I cells) arranged in lobules (zellballen architecture) delimited by reticulin fibres and a single layer of inconspicuous sustentacular cells (type II cells). The relationship between these two types of cells is progressively lost with reduction of the sustentacular component as the tumour increases in malignancy. The chief cells are immunoreactive to synaptophysin and chromogranin whereas the sustentacular cells express S-100 protein and GFAP. The chief cells may also express other neuropeptides. Ganglionic differentiation is seen in over half of the paragangliomas arising within the cauda equina.

MOLECULAR GENETICS

Recent advances in molecular genetics have greatly improved our understanding of the aetiology of brain tumours. At the same time, such knowledge has been used to screen high-risk patients, to confirm diagnosis and to plan treatment. Limitation of space allows discussion of only a few examples.

Familial Tumour Syndromes Involving the Nervous System

This is a consortium of syndromes characterized by a combination of malformations, hamartomas and tumours of the nervous system with systemic neoplastic and non-neoplastic conditions. Many are associated with other

conditions which facilitate early clinical recognition (**Table 4**). Some have characteristic skin lesions and are known as neurocutaneous syndromes, phakomatoses or ectomesodermal syndromes, the most common of which are discussed.

Tuberous Sclerosis

Tuberous sclerosis involves multiple organs but the brain is most frequently affected. It is relatively common, the incidence being between 1 in 6000–10 000. Multiple hamartomas or slowly growing tumours involve the CNS, retina, skin, heart and kidney. This is an autosomal dominant condition with high penetrance. It is unusual to observe affected siblings of apparently normal parents. The *TSC1* gene on chromosome 9q34 that encodes hamartin and and *TSC2* gene on chromosome 16p13.3 that encodes tuberin have been identified. Hamartin is strongly expressed in organs that are affected by tuberous sclerosis such as brain, kidney and heart. Tuberin is also widely expressed and its pattern of expression overlaps that of hamargin. Although mutations of both *TSC1* and *TSC2* have been described in patients with tuberous sclerosis, genotype–phenotype correlation has not been well established.

Clinical manifestations are mostly related to the slowly growing tumours or hamartomas, and are highly variable. Severity is related to the extent of involvement and age of onset. In classical cases patients have seizures, are often mentally retarded and have adenoma sebacum; however, clinical manifestations can be extremely variable. Tuberous sclerosis can be separated into definitive, provisional and suspect category on the basis of specific clinical criteria. The pathology of tuberous sclerosis is diverse (**Table 6**), and only features pertinent to the CNS will be discussed.

Table 6 Manifestations of tuberous sclerosis

Brain	Cortical tuber
	Subependymal nodule
	Subependymal giant cell tumour
	Heterotopic grey matter
Skin	Adenoma sebacum (facial angiofibroma)
	Hypomelanotic macule
	Peri- or subungal fibroma
	Shagreen patches (fibrous hamartomas of dorsal surfaces, rarely seen before puberty)
	Poliosis and leucotrichia
Eye	Retinal giant cell astrocytoma
	Hypopigmented iris spot
	White eyelashes
	Hamartomata of eyelids and conjunctivae
Kidney	Angiolipoma
Heart	Single or multiple rhabdomyoma
Other organs affected	Bone, lung, liver, adrenals, gonads, thyroid, teeth and gingival tissue

Cortical tubers consist of pale, firm, cortical nodules that expand the gyri and blur the margin between grey and white matter. Calcification is common and can transform the tuber into a stony-hard structure. The number and location of tubers varies and they are scattered throughout the brain and they often act as epileptic foci. Histologically, the normal cortical architecture is effaced by collections of large bizarre cells that are haphazardly arranged within a gliotic background. These bizarre-looking cells have a amphophilic to slightly eosinophilic homogeneous cytoplasm and well-defined cytoplasmic borders. They also have stout processes, peripheral vacuolation, eccentric nuclei and prominent nucleoli. It is often difficult to determine whether they are glial cells or neurons by routine histological criteria. These cells often express tuberin, vimentin, nestin and some may express GFAP and neurofilament.

Subependymal nodules are often described macroscopically as 'candle-gutterings' which consist of variably sized nodules that protrude into the ventricle, most often the lateral ventricle. Histologically, they are composed of large, bizarre cells with pale amphophilic cytoplasm and large nuclei, often more than one in each cell. Scattered clusters of primitive neural cells may be seen in neonates. Subependymal nodules are often calcified. Vimentin is usually strongly expressed and, since both GFAP and NFP are also expressed in an irregular manner, it is difficult to define these cells as glial cells or neuronal cells. In contrast to the bizarre cells in cortical tubers, cells in the white matter and subependymal nodules express tuberin weakly or not at all. In some cases, these nodules continue to expand and give rise to a true neoplasm called 'subependymal giant cell astrocytoma' (**Figure 40**). Although this tumour is called an astrocytoma, it displays both glial and neuronal phenotypes and should more correctly be simply termed 'subependymal giant cell tumour.'

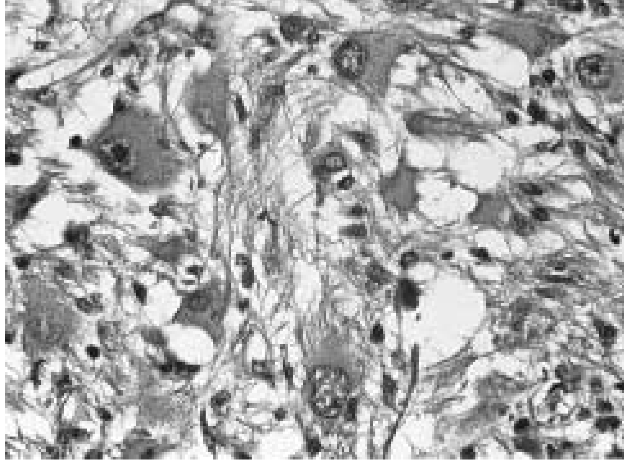

Figure 40 Large atypical cells characteristic of subependymal giant cell tumour. Note the fibrillary component and large cells with a resemblance to ganglion cells.

Table 7 Diagnostic criteria for neurofibromatosis

Neurofibromatosis 1

The criteria for making a diagnosis of NF1 are met if a patient has two or more of the following:

1. Six or more café-au-lait macules that have a maximum diameter over 5 mm in prepubertal patients and over-15 mm in postpubertal patients
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling in the axillary or inguinal regions
4. Optic nerve glioma
5. Two or more Lisch nodules (iris hamartomas)
6. A characteristic osseous lesion, such as sphenoid wing dysplasia or thinning of the long bone cortex with or without pseudoarthrosis and deformity of long bone
7. A first-degree relative (i.e. parent, sibling or offspring) with NF1 by the above criteria

Neurofibromatosis 2

The criteria for making a diagnosis of NF2 are met if a patient has one of the following:

1. Bilateral vestibular schwannomas
2. A first-degree relative with NF2 and either
   - Unilateral vestibular schwannoma or
   - Two of the following: neurofibroma, meningioma, schwannoma, glioma, juvenile posterior lenticular opacity

(Adapted from the National Institutes of Health Consensus Development Conference, 1988, Neurofibromatosis. *Archives of Neurology*, **45**, 575–578.)

Neurofibromatosis Type 1 (NF1)

NF1, also known as von Recklinghausen disease and peripheral neurofibromatosis, is a pleiotropic congenital multiple dysplasia syndrome characterized by multifocal hyperplasia and neoplasia in the supportive tissue throughout the entire nervous system. It is not a homogeneous syndrome and many clinical variants exist. The *NF1* gene is located on 17q11.2 and it encodes neurofibromin, a classical tumour-suppressor gene. Whole gene deletion, single- and multiple-exon deletions and insertions comprise about 50% of all the mutations.

The syndrome is defined by clinical criteria (**Table 7**). Clinical manifestations of NF1 are diverse (**Table 8**) and only those pertinent to the nervous system are discussed. The cardinal sign of NF1 is multiple neurofibromas. Some unusual variants of neurofibromas such as dermal neurofibroma and plexiform neurofibroma are characteristically seen in NF1 patients. Malignant transformation of neurofibromas in NF1 patients most frequently occurs in a preexisting plexiform neurofibroma and they usually do not occur until middle or late adult age. The transformation may occur as a progression in anaplasia over a period of years. The reported incidence of malignant transformation varies widely but a rate of 3–5% may be a good estimate. The resultant malignant tumour is usually a malignant peripheral nerve sheath tumour (MPNST).

Table 8 Manifestations of NF1

Skin	Café-au-lait macules
Neurofibromas	Plexiform
	Dermal
	Nodular
Sarcomas	Malignant peripheral nerve sheath tumour
	Rhabdomyosarcoma
	Triton tumour
Neoplastic CNS lesions	Optic tract/hypothalamic glioma
	Brainstem glioma
	Astrocytoma
	Anaplastic astrocytoma
	Glioblastoma
Non-neoplastic CNS conditions	Unidentified bright objects (UBO) on MRI
	Learning problem
	Epilepsy
	Neuropathy
	Hydrocephalus
	Hamatomatous glial proliferation
Osseous lesions	Sphenoid wing dysplasia
	Pseudoarthrosis
	Macrocephaly
	Scoliosis
Ocular	Lisch nodules
Other tumours	Phaeochromocytoma
	Carcinoid
	Juvenile chronic myeloid leukaemia

NF1 patients are also prone to develop gliomas. Those which develop in the optic nerve, hypothalamic region and brainstem are usually pilocytic astrocytomas and may remain static for many years and, in fact, some may even regress. Astrocytomas that arise in the cerebral and cerebellar hemispheres, however, may progress to anaplastic astrocytomas and glioblastoma multiforme.

Neurofibromatosis 2 (NF2)

Similarly to NF1, the cardinal changes of NF2 are multifocal hyperplasia and neoplasia in the supportive tissue throughout the entire nervous system. The elements being affected, however, are different.

NF2 is also an autosomal dominant disorder but its prevalence is only one-tenth of that of NF1. It is also defined by clinical criteria (**Table 7**). The gene is on chromosome 22q12 and encodes the protein merlin or schwannomin, most likely a tumour-suppressor gene. Nonsense and frameshift mutations are often associated with a more severe phenotype while missense mutations that preserve the carboxyl terminus of the protein result in milder phenotypes.

Schwannoma, particularly arising in the eighth cranial nerve, is the most frequent manifestation but malignant

transformation is extremely uncommon. Schwannomatosis, essentially pathological proliferation of Schwann cells, is often found in the dorsal spinal nerve roots and also in the perivascular space of the spinal cord. Meningiomas are seen in about half of NF2 patients and they are often multiple. Interestingly, they have a tendency to arise from the stroma of choroid plexus, an otherwise unusual site.

Meningioangiomatosis, a rare hamartomatous lesion of the leptomeninges, is far more commonly seen in NF2 patients than in general population. NF2 patients also have an increased incidence of glial tumours. Over 80% of them are in the spinal cord and of the rest 10% are in the medulla. Ependymomas are common and often occur as multiple intramedullary masses. Ependymal ectopias have also been described in NF2 patients and may represent the cell of origin of the ependymomas.

Von Hippel–Lindau Syndrome

Von Hippel–Lindau syndrome is an autosomal dominant heriditary syndrome characterized by multiple cysts and benign and malignant neoplasms involving the brain, retina, kidney, pancreas, adrenal glands, inner ear and other organs. The incidence is about 1 in 36 000 to 1 in 45 000 in the general population. This results from germ-line mutations of the *VHL* tumour-suppressor gene that is located on chromosome 3p25.3; a missense mutation is the most common. The *VHL* gene is involved in cell cycle regulation and angiogenesis.

Haemangioblastomas must be present in order to make a diagnosis of von Hippel–Lindau syndrome. Although haemangioblastomas can occur sporadically, they are seen in younger age groups when associated with von Hippel–Lindau syndrome. Most commonly, they occur in the cerebellum but they can also occur in other parts of the brain and in the retina. Other manifestations of von Hippel–Lindau syndrome include renal cysts and renal cell carcinoma, pancreatic cysts and islet cell tumours, phaeochromocytoma and endolymphatic sac tumour of the inner ear. Other organs may also be affected. The occurrence of phaeochromocytoma and renal cell carcinoma, interestingly, is correlated with specific mutations.

Basal Cell Naevus Syndrome

Basal cell naevus syndrome, also known as naevoid basal cell carcinoma syndrome, is transmitted in an autosomal dominant pattern and is typically caused by a germ-line mutation of the *PTCH* gene on chromosome 9q22.3. The majority of the mutations are frameshift or nonsense mutations that lead to truncated proteins. This gene is involved in the Sonic hedgehog signalling pathway. Mutations of the *PTCH* gene and Sonic hedgehog signal pathway are also related to holoprosencephaly.

Basal cell naevus syndrome is characterized by multiple basal cell carcinomas of the skin, odontogenic keratocysts, palmar and plantar dyskeratotic pits and CNS abnormalities including intracranial calcifications, macrocephaly and PNETs of the posterior fossa (medulloblastoma). Other less common clinical manifestations such as ophthalmic abnormalities, cardiac fibromas and cleft palate may also be present. Histological features of the PNETs that occur in patients with basal cell naevus syndrome are similar to those that occur sporadically, although the majority are the desmoplastic variant.

Cowden Disease

One of the major manifestations of Cowden disease is dysplastic gangliocytoma of the cerebellum (Lehmitte–Duclos disease). It is associated with a variety of mucocutaneous lesions that include verrucous skin changes, fibroma of the oral mucosa, multiple facial tichilemmomas, hamartomatous polyps and cancer of the colon and tumours of the breast and thyroid. It is an autosomsal dominant disorder and is frequently caused by a germ-line mutation of the *PTEN/MMCA1* gene on chromosome 10q23. In addition to dysplastic gangliocytoma of the cerebellum, Cowden disease can also be associated with heterotopic grey matter, hydrocephalus, mental retardation and seizures. (See also chapter *Inherited Predispositions to Cancer*.)

Cytogenetics and Fluorescent *In Situ* Hybridization (FISH)

Cytogenetics is the study of karyotypes and allows the detection of structural changes of chromosomes, namely deletion, inversion, translocation, trisomy and polysomy, and microsatellites. Since all chromosomes are visualized at the same time, it is a good screening test for chromosomal abnormalities. A variety of chromosomal abnormalities have been identified in human brain tumours using cytogenetics. Although cytogenetic techniques allow visualization of the entire karyotype, culture of tumour cells is required. In addition, they cannot detect microdeletions that are beyond resolution by banding techniques. Fluorescent *in situ* hybridization (FISH) can be used in paraffin-embedded tissue and in cultured cells. By using an appropriate fluorescent probe, a particular chromosome can be visualized or the visualization can be limited to a small region that allows the detection of microdeletions. Gene amplifcation in the form of double minutes can also be seen. FISH, however, cannot visualize all chromosomes at the same time and is more appropriate for confirmation of a specific chromosomal change.

Although many genetic abnormalities have been identified in brain tumours, most of them do not have a consistent pattern of chromosomal abnormalities. However, some genetic abnormalities are more often seen than others. One of the best examples is the association of isochromosome 17q with primitive neuroectodermal tumours of the posterior fossa (medulloblastoma) (**Figure 41; see colour plate section**). Another example is atypical teratoid rhabdoid tumour, which is associated with monosomy or

deletion of chromosome 22 (**Figure 42; see colour plate section**) in over 80% of cases, a useful diagnostic feature.

Molecular Genetics and Progression of Brain Tumours

Astrocytic tumours often progress from a low-grade tumour to anaplastic astrocytomas and finally become the highly malignant glioblastoma multiforme, the so-called secondary glioblastoma. This type of tumour progression is a multistep process driven by sequential alternations of specific genes or chromosomal loss. On the other hand, glioblastoma may also arise *de novo* without a precursor low-grade astrocytoma. Interestingly, the genetic changes in these tumours, also known as primary glioblastoma, are not the same as the secondary glioblastoma. Similar sequential genetics have also been observed in the progression of oligodendrogliomas. A variety of mutations have also been observed in other tumours.

PROGNOSTIC FACTORS

It cannot be overemphasized that tumours of the CNS are heterogeneous in clinical and biological behaviour. In general, the type of the tumour and its biological grade dictate the clinical outcome. In the WHO Classification (Kleihues and Cavenee, 2000), CNS tumours are separated into four grades. Grades I and II are low-grade tumours and that behave either in a benign fashion or as slow growing lesions; prolonged survival is possible. Grades III and IV are high-grade tumours, behave aggressively (**Table 9**) and are associated with short survival.

Location of a tumour in an inaccessible site such as the deeper parts of the cerebrum (such as basal ganglia and thalamus) or brainstem often precludes the benefits of surgical resection. The general condition of a patient also affects the clinical outcome. Younger patients with high-grade astrocytic tumours, in general, have a better survival than older patients. Other favourable prognostic factors for prolonged survival for patients with glioblastoma include long preoperative duration of symptoms, high Karnofsky Performance Status score, extensive surgical resection, use of postoperative radiation therapy and use of adjuvant chemotherapy.

Multiple prognostic indices are often present for one particular type of tumour, e.g. PNETs. Diagnosis at over 4 years of age is a favourable prognostic sign in PNETs arising from the cerebellum (medulloblastoma). In addition, limited extent of local disease, extensive surgical resection and no dissemination within the CNS are also good prognostic signs. The large cell variant of PNET has a worse prognosis; c-*myc* amplification and expression of GFAP are unfavourable. On the other hand, expression of Trk C receptor, a high-affinity neurotrophin receptor, is associated with improved survival.

Table 9 WHO grades of different brain tumours

Grade I
Pilocytic astrocytoma
Subependymoma
Choroid plexus papilloma
Ganglioglioma
Desmoplastic ganglioglioma/astrocytoma (DIG/DIA)
Dysembryoplastic neuroepithelial tumour (DNET)
Paraganglioma
Schwannoma
Neurofibroma
Perineuroma
Meningioma (variant dependent)
Grade II
Diffuse astrocytoma
Pleomorphic xanthoastrocytoma
Oligodendroglioma
Oligoastrocytoma
Ependymoma
Ganglioglioma
Central neurocytoma
Pineocytoma
Meningioma (variant dependent)
Grade III
Anaplastic astrocytoma
Anaplastic oligodendroglioma
Anaplastic oligodendroglioma
Anaplastic ependymoma
Choroid plexus carcinoma
Anaplastic ganglioglioma
Malignant peripheral nerve sheath tumour (MPNST)
Meningioma (variant dependent)
Anaplastic meningioma
Grade IV
Glioblastoma
Giant cell glioblastoma
Gliosarcoma
Medulloepithelioma
Primitive neuroectodermal tumour (PNETs)
Atypical teratoid/rhabdoid tumour (ATRT)
Malignant peripheral nerve sheath tumour (MPNST)

OVERVIEW OF PRESENT CLINICAL MANAGEMENT

Surgery, radiation therapy and chemotherapy are the three cornerstones of treatment. Several clinical pathological parameters must be considered before a treatment plan is formulated for an individual patient. The age of the patient, preoperative medical condition, presence of other systemic disease and malignant disease and location of the tumour must all be considered. The type of tumour, as determined by pathological examination of biopsy material, dictates the direction of further treatment. Biologically benign CNS

and PNS tumours are treated surgically unless they are located in an inoperable location. Malignant tumours are often treated with chemotherapy and radiation therapy in addition to surgery. Most primary brain tumours are candidates for surgical treatment except that haematopoietic tumours are often treated with radiation and chemotherapy alone without bulk tumour resection.

Maximum tumour resection and optimum preservation of neurological functions are the two most important treatment goals for patients with brain tumours that should be surgically treated. Tumours located around or within the brainstem, diencephalon and motor cortex are particularly troublesome because damage to these areas will lead to neurological catastrophe. For these tumours, stereotactic biopsy is the diagnostic procedure of choice for the determination of the nature of the lesion. It is a computer-assisted technique that allows three-dimensional coordinated localization of an intracranial lesion. Based on these coordinates, a needle is inserted to obtain a small amount of tissue for pathological examination without producing excessive damage to the critical surrounding brain structures. Tumours located in these difficult locations are generally treated with radiation therapy and chemotherapy alone.

Since the general principles of radiation therapy are discussed elsewhere, discussion here is limited to issues specific for the CNS. In general, toxic effects produced by irradiating the human brain are categorized temporally and pathologically into three major types. The first type are acute reactions that occur during radiation therapy. They are uncommon in patients receiving conventional daily dose fractionation (1.8–2 Gy per day) but are common in patients treated with 10 Gy or above as a single fraction. Subacute reactions (early-delayed reactions) are related to radiation injury sustained by oligodendrocytes and alterations in capillary permeability and present as transient demyelination. The subacute reactions are characterized by a transient syndrome that includes somnolence, anorexia and irritability. The late-delayed reactions occur within several months or up to many years following treatment. They comprise a spectrum of clinical and pathological conditions involving multiple mechanisms. Clinical manifestations includes asymptomatic changes of the white matter and vasculature, change in cognition, hypothalamic–pituitary dysfunction, cranial neuropathy, disseminated necrotizing leucoencephalopathy, radiation necrosis and second malignancy due to radiation.

Chapter 52

Eye and Ocular Adnexa

Arun Jain and Frederick A. Jakobiec
Massachusetts Eye and Ear Infirmary, Boston, MA, USA

CONTENTS

- Normal Development and Structure
- Tumour Pathology

NORMAL DEVELOPMENT AND STRUCTURE

The globe and the ocular adnexa represent a unique compartment, where terminal differentiation from all three germinal layers of the embryo has given rise to very specialized structures not found elsewhere in the body. Owing to this extraordinary collection of different tissues, one encounters tumours unique to this location as well as others found more commonly in distant parts of the body.

The eye is a sensory end organ that develops from the interaction of the primordial optic vesicle with the overlying ectoderm during the fourth week of gestation. The optic vesicle, one on each side, is an out pouching from the rostral end of the neural tube. The neural tube originates from the neural plate, which is a derivative of embryonic ectoderm and precursor of the entire central nervous system. The lens and most of the cornea develop from the inductive interaction of the optic vesicle with the surface ectoderm. The neural crest contributes extensively to the connective tissue of the head and neck region, which is due to the absence of paraxial somites in the head and neck region. These connective tissue contributions of the neural crest are collectively referred to as mesoectoderm or ectomesenchyme. Therefore, in the orbit, the fibrous and fibroadipose tissue, meninges of the optic nerve, sclera and episclera, vascular pericytes and striated extraocular muscle satellite cells, peripheral nerve cellular elements, and osteocytes and cartilaginous elements are all progeny of neural crest anlage. **Table 1** demonstrates the origin of the various structures of the eye from different germinal layers.

The eye is composed of three layers: the outermost sclera with its anterior extension as the cornea, the uveal tract and the innermost layer being the retina. The six extraocular muscles are composed of striated muscle fibres and aid in the fine and gross control of eye movements. Four of these muscles arise from the orbital apex in a concentric fashion surrounding the annulus of Zinn. Intraocularly the iris and ciliary body are composed of smooth muscle and are innervated by autonomic nerve fibres. The retina is a complex multilayered structure, innermost layer of which is formed by the axons of the ganglion cell layer (nerve fibre layer) and the outmost

Table 1 Origin of different structures from germinal layers

Ectoderm		Mesoderm	Endoderm	Neural crest
Surface ectoderm	Neuroectoderm			
Anterior cornea	Neurosensory retina	Vascular endothelium	None	Anterior chamber
Eyelids	Retinal pigment epithelium	Extraocular muscles		(Posterior cornea)
(Holocrine glands)	Pars plana epithelium	Corneal stroma		(Trabecular meshwork)
(Apocrine glands)	(Secondary vitreous)			(Iris stroma)
(Eccrine glands)	(Lens zonules)			Uveal tract
(Pilosebaceous units)	Ciliary epithelium			(Dendritic melanocytes)
Conjunctiva	Iris pigment epithelium			Sclera
(Lachrymal glands)	(Dilator muscle)			Meninges
(Mucous glands)	(Sphincter muscle)			Orbital soft tissues
Crystalline lens	Optic nerve			Facial bones
				Trochlea

layer is formed by the photoreceptors. The neuro-sensory retina and the retinal pigment epithelium (RPE) continue anteriorly as the pigmented and non-pigmented epithelium of the ciliary body and iris.

The conjunctiva is lined by non-keratinized stratified squamous epithelium about 4–5 cell layers thick and has numerous goblet cells. Accessory lachrymal glands of Krause and Wolfring are present in the superior fornix of the conjunctiva. At the mucocutaneous junction of the eyelid, where conjunctival epithelium changes into keratinized stratified squamous epithelium of the skin, there are openings for about 30 sebaceous glands known as meibomian glands in the upper lid and 20 in the lower lid. These glands are embedded in a matrix of dense connective tissue known as tarsus. Anterior to this row of meibomian glands is a row of cilia (eye lashes) which have their own associated sebaceous glands known as glands of Zeiss and apocrine glands known as glands of Moll.

The orbit is compartmentalized into intraconal and extraconal spaces by the intermuscular septa of the extraocular muscles. The intraconal space is by far the larger of the two and is further divided by numerous thin fibrous septa into spaces that are all filled with fat. Through these compartments traverse the nerves and vessels supplying the extraocular muscles and the autonomic nerves and vessels to the choroid, ciliary body and iris. The ophthlamic artery, which later becomes the central retina artery, supplies the optic nerve and the retina. The orbit and the intraocular tissues are devoid of lymphatics, which serves to explain the metastatic pattern of some tumours. Conjunctiva and eyelids, on the other hand, are richly supplied with lymphatics.

The lachrymal gland is present in the supero-lateral recess of the orbit and is divided into two lobes by the lateral extension of the levator palpebrae superioris. The fine ductules of the lachrymal gland then open into superior fornix for the egress of tears. The tears then drain though two canaliculi into the lachrymal sac present in the lachrymal fossa formed by the lachrymal bone and frontal process of the maxilla.

TUMOUR PATHOLOGY

Eye and adnexal tumours can be subdivided into intraocular tumours, adnexal tumours of the eyelid, lachrymal sac and conjunctiva and orbital tumours. There is considerable overlap in this classification scheme, since intraocular tumours can sometimes invade the orbit and adnexal tumours on rare occasions can extend intraocularly.

Eyelid and conjunctival tumours have various counterparts in the skin from other parts of the body. Primary acquired melanosis, although analogous to lentigo maligna in the skin, has different prognostic and therapeutic implications. One of the most important malignancies confined almost exclusively to the skin of the eyelids is sebaceous cell carcinoma.

The differential diagnosis of orbital tumours in children is strikingly different from that of adults. Capillary haemangioma and dermoid cysts are probably the most frequent orbital tumours encountered in children, whereas cavernous haemangioma is more often seen in adults and lymphoproliferative lesions are confined almost exclusively to the sixth and seventh decades of life.

The most important intraocular tumours are retinoblastoma in children and uveal melanoma in adults. However, there is a long list of other intraocular tumours that can arise *de novo* or from metastasis. In the following sections, emphasis will be placed on tumours that are unique to the eye and ocular adnexa.

Epidemiology

Eyelid and conjunctival tumours usually affect the elderly. The median age at diagnosis of sebaceous carcinoma of the eyelid is 64 years and 60–70% of them are females.

Retinoblastoma is the most common intraocular tumour of childhood and the most common tumour of the retina. It is a rare malignant tumour with a prevalence of about 1 in 23 000 live births in the UK, 1 in 16 000 in The Netherlands and 1 in 20 000 in Japan (Albert and Jakobiec, 2000a)

Uveal melanoma is by far the most clinically important intraocular malignancy in adults, owing to its risk of metastasis and subsequent death, even though uveal metastasis has a higher incidence when autopsy eyes are studied for occult intraocular tumours. It is the most common primary intraocular malignancy, occurring in approximately 6–7 cases per million people in the USA.

Aetiology

A variety of known and unknown factors contribute to neoplastic transformation of cells in the eye and ocular adnexa. The risk associated with UV exposure in the development of skin tumours is well established. Conjunctival lesions such as pterygia, pinguecula, and actinic keratosis are also related to prolonged exposure to UV light as documented by their higher frequency in more tropical areas.

Conjunctival papillomas and dysplasias are akin to skin papillomas, and human papillomaviruses 16 and 18 have been implicated in the pathogenesis of some of these lesions.

The presence of genetic mutations is well established in retinoblastoma. The role of specific gene alterations in the pathogenesis of uveal melanoma is less well defined than it is in retinoblastoma (see section on Molecular Genetic Findings).

Certain lesions in the conjunctiva and the uveal tract predispose to the development of malignant melanoma.

These include congenital melanosis and naevi. Congenital melanosis can involve only the sclera (ocular melanocytosis) or it can affect both the sclera and the skin of the lids, in which case it is referred to as Naevus of Ota (oculodermal melanocytosis) (**Figure 1; see colour plate section**). The risk of progression to malignant melanoma in congenital melanosis is primarily in the uveal tract. Naevi, however, in the conjunctiva or the uvea can give rise to malignant melanoma in either location.

The role of racial pigmentation is well established in a variety of skin, conjunctival and uveal malignancies. Individuals with lightly pigmented skin also have less melanin in the RPE and choroid, which leads to less protection from the harmful UV rays of the sun. The incidence of uveal malignant melanoma is 8–9 times higher in whites than in blacks in the USA.

Radiation used for the treatment of childhood retinoblastoma has led to an increase in the development of sarcomas in the field of radiation. Patients with the heritable form of retinoblastoma, however, have an increased incidence of sarcomas within and outside the field of radiation, with osteogenic sarcoma the most prevalent.

Screening and Prevention

Better understanding of the pathophysiology of certain tumours of the eye and ocular adnexa has greatly improved the prognosis of these tumours owing to the increased emphasis on screening and prevention. The risk of development of retinoblastoma in the siblings and progeny of patients with retinoblastoma can be accurately assessed and appropriate screening can be deployed to detect early lesions. Patients with uveal and conjunctival naevi should be evaluated on a yearly basis to detect progression of these lesions to malignant melanoma.

The association of certain tumours of the eye and ocular adnexa with other systemic neoplasms (both benign and malignant) has led to an increased awareness of these genetic syndromes and underscores the importance of the ophthlamologist in making an early diagnosis. Some of these will be discussed in the sections below.

Gross/Histopathology/ Preinvasive Lesions/ Ultrastructure/ Immunohistochemistry

Tumours of the Eyelid and Conjunctiva

Tumours of the eyelid skin are the same as found in other parts of the body and are detailed elsewhere in this book. Basal cell carcinoma of the eyelids is the most frequent of the skin malignancies followed by squamous cell carcinoma (Albert and Jakobiec, 2000b). The lower lid is the most frequently affected area followed by the medial canthus and then the upper lid and lateral canthus. The basal cell naevus (Gorlin–Goltz) syndrome is characterized by the presence of multiple basal cell epitheliomas on the face, and less frequently on the trunk, neck and axilla. The tumours may not become invasive for many years. Associated anomalies include pitted areas in the skin of the palms and soles, odontogenic cysts of the jaw, spina bifida occulta, rib anomalies, skull anomalies, cleft lip and palate and hypogonadism in males. It is inherited in an autosomal dominant fashion with variable penetrance. The specialized glands of Moll, Zeiss, Wolfring and Krause can give rise to adenocarcinoma or a variety of benign lesions such as hydrocystoma, syringoma, eccrine acrospiroma and pleomorphic adenoma. Benign tumours of hair follicle origin include trichoepithelioma, trichofolliculoma, trichilemmoma and pilomatrixoma (calcifying epithelioma of Malherbe). Multiple trichilemmomas are seen in Cowden's syndrome. Melanocytic lesions of the eyelid skin and conjunctiva such as naevi and melanomas are also frequently encountered.

Pinguecula, pterygium and actinic keratosis result from UV damage to the conjunctiva. These lesions are exclusively found in the interpalpebral conjunctiva exposed to sunlight. The characteristic hallmark of all three is the elastotic degeneration present in the substantia propria of the conjunctiva.

Dysplasia and conjunctival intraepithelial neoplasia (carcinoma-*in-situ*) may occur anywhere on the conjunctival surface, but most often starts at the limbus (**Figure 2**). Most lesions have an opalescent papillary rather than a leukoplakic appearance due to lack of keratinization observed microscopically. A benign condition but often confused for malignancy seen in certain Haliwa Indian tribes of North Carolina is benign hereditary intraepithelial dyskeratosis appearing as patches of thickened and injected plaques of conjunctiva on the bulbar surface.

Other rare tumours include choristomas of the conjunctiva and Merkel cell tumours and myxomas of the

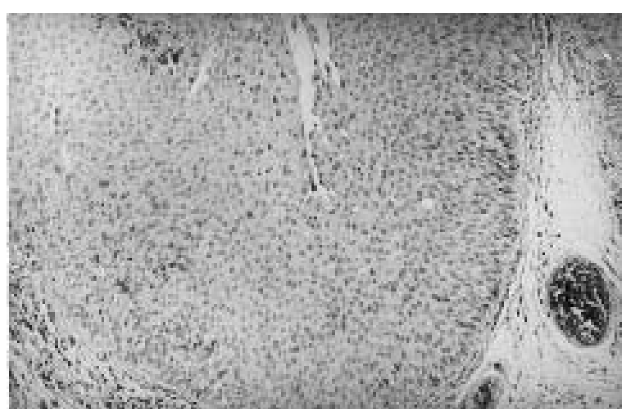

Figure 2 Conjunctival intraepithelial neoplasia demonstrating full thickness involvement of the epithelium with malignant cells.

eyelid. The latter are associated with the Carney complex, a genetic syndrome comprised of cardiac and cutaneous myxomas, spotty skin pigmentation and endocrinopathy. Choristomas such as the limbal dermoid are associated with lid coloboma in the Goldenhar syndrome. Two categories of tumours deserve special focus owing to their exclusive localization to the ocular adnexa and often challenging management. These are the sebaceous cell carcinoma of the eyelid and primary acquired melanosis of the conjunctiva.

Sebaceous Gland Tumours

Sebaceous adenomas are rare and usually solitary lesions not exceeding 1 cm in size. Histologically, they are composed of sebaceous lobules that show an orderly maturation from germinative cells located on the periphery towards the more central sebaceous cells. Muir–Torre syndrome, an autosomal dominant cause of familial cancer, is an association of multiple sebaceous gland neoplasms, other cutaneous neoplasms and multiple visceral carcinomas, especially of the colon. Often, only a single sebaceous adenoma of the eyelid may be associated with internal malignancy.

Most sebaceous carcinomas of the eyelid arise in the meibomian (tarsal) glands, followed by the glands of Zeiss, and, less frequently, sebaceous glands in the caruncle or the skin of the eyebrow. A distinctive clinical feature of many sebaceous gland carcinomas is a persistent unilateral blepharo-conjunctivitis, referred to as the 'masquerade syndrome' (**Figure 3; see colour plate section**). They can also arise in a nodular fashion at the lid margin where they appear as waxy yellowish lesions, sometimes simulating a chalazion. Histologically, the most common pattern is lobular with the degree of differentiation determining the type of cells present. The lobules exhibit basaloid features but lack the peripheral palisading of basal cell carcinoma. Well-differentiated tumours usually have areas of easily identifiable sebaceous cells with the characteristic finely vacuolated cytoplasm. Poorly differentiated neoplasms have anaplastic cells with hyperchromatic nuclei and typical mitotic figures. Frozen section and oil red O stains for lipid may be necessary to establish the diagnosis.

Sebaceous carcinoma can spread by either intraepithelial or direct extension. Intraepithelial spread can occur in a carcinoma-*in-situ* like fashion with the entire epithelium being replaced by neoplastic cells, or individual cells can migrate through intercellular spaces to distant areas in the eyelid skin or conjunctiva (**Figure 4**). This latter phenomenon is termed pagetoid spread, resembling Paget disease of the breast.

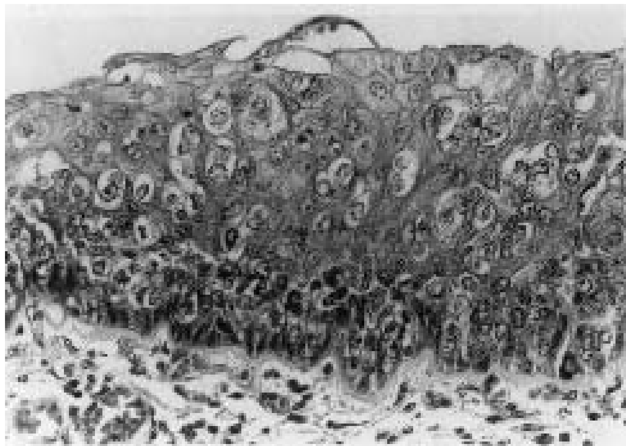

Figure 4 Pagetoid spread of sebaceous carcinoma (cells with clear cytoplasm) in the conjunctival epithelium (courtesy AFIP).

Primary Acquired Melanosis (PAM)

PAM is a unilateral neoplastic melanocytic proliferation within the conjunctival epithelium, observed most often in white patients. They appear as flat areas of increased yellow–brown pigmentation in middle age, mostly on the bulbar conjunctiva, which does not fade towards the fornices like racial melanosis (**Figure 5; see colour plate section**). When the palpebral conjunctiva near the lid margin is involved, the melanosis often extends on to the adjacent epidermis. Elevated lesions developing in PAM is usually an indication of malignancy, i.e. melanoma.

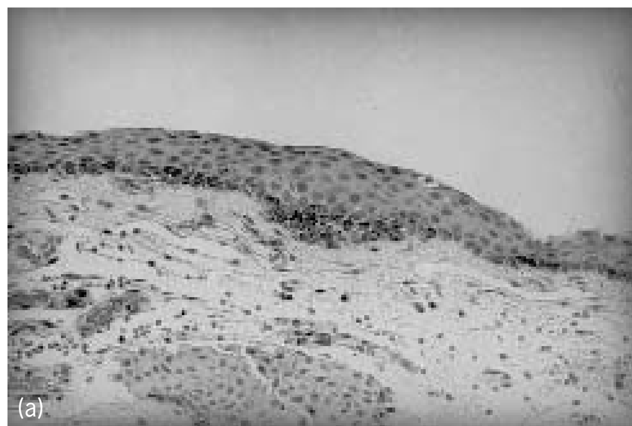
Histologically, their appearance can be variable. There may be small polyhedral cells with no atypia, spindle-shaped cells with moderate atypia or large highly atypical epithelioid cells. The pattern of invasion of the conjunctival epithelium can vary from involvement of the basal layers to pagetoid extension or even full thickness replacement by atypical melanocytes resembling melanoma-*in-situ* (**Figure 6**).

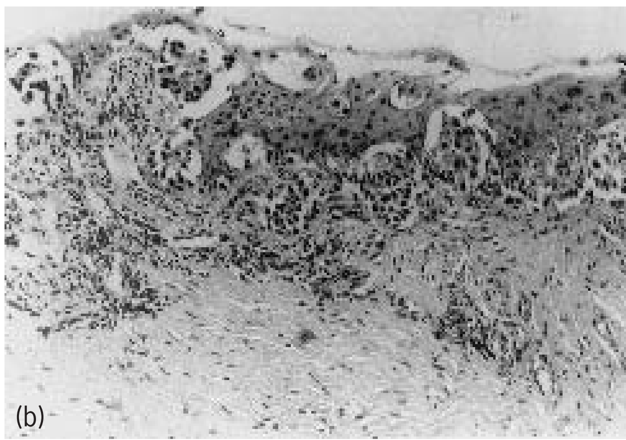
Tumours of the Retina

Retinoblastoma

Five growth patterns are recognized for intraocular retinoblastoma: endophytic, exophytic, mixed endophytic–exophytic, diffuse infiltrating and complete spontaneous regression. The tumour can either arise from one location or be multicentric. Endophytic retinoblastomas grow mainly from the inner nuclear layer of the retina into the vitreous. Endophytic tumours can shed tumour cells into the vitreous, as they become large and friable, where they grow into separate tiny spheroidal masses that appear as cotton balls. Tumour cells in the vitreous may seed on to the inner surface and invade into the retina. It is important to distinguish multicentric retinoblastoma from retinal seeding because the presence of multiple tumours indicates a germ-line mutation. This distinction is frequently difficult or impossible to make.

Exophytic retinoblastomas grow from the outer nuclear layer towards the choroid, producing first an elevation and





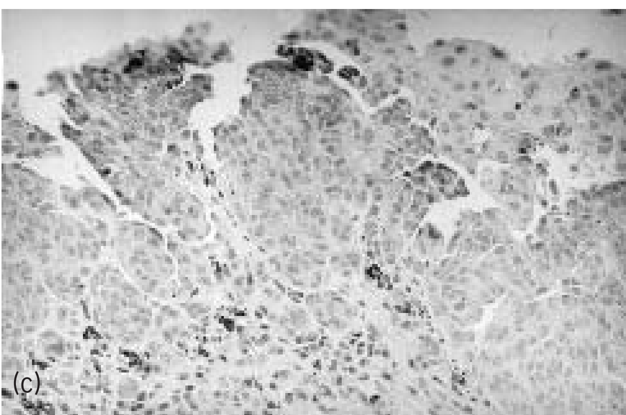


Figure 6 (a) Primary acquired melanosis without atypia. The melanotic hyperplasia is confined to the basilar layer. (b) Primary acquired melanosis with severe atypia. Nests and individual epithelioid melanocytes extend throughout the thickness of the epithelium in a pagetoid fashion (courtesy AFIP). (c) Primary acquired melanosis with invasive melanoma. Besides full thickness involvement of the epithelium with melanoma cells, some have invaded the substantia propria through the basement membrane.

then a detachment of the retina (**Figure 7; see colour plate section**). On ophthalmoscopic examination, the tumour is seen through the retina with vessels coursing over it (**Figure 8; see colour plate section**). Tumour cells can then seed the outer retinal surface or invade into the RPE and Bruch's membrane with subsequent infiltration of the choroid. From the choroid, the tumour cells can escape along the ciliary vessels and nerves into the orbit and conjunctiva and then gain access to blood vessels and lymphatics.

Mixed endophytic–exophytic tumours are the most common form of presentation, especially among larger tumours. They have features of both endophytic and exophytic growth. Diffuse infiltrating retinoblastomas often present the greatest challenge in clinical diagnosis, but fortunately are the least common of all forms. These tumours grow diffusely within the retina without thickening it much. Tumour cells are often shed into the vitreous, which can reach the anterior chamber to create a pseudohypopyon. Because of the absence of a mass, this type of retinoblastoma masquerades as a retinitis, vitritis or Toxocara endophthalmitis.

Complete spontaneous regression is believed to occur more frequently in retinoblastoma than in any other malignant neoplasm. Typically, there is a severe inflammatory reaction followed by phthisis bulbi. The mechanisms by which regression occurs are unknown.

Table 2 illustrates the differential diagnosis of retinoblastoma.

Histologically, retinoblastomas are essentially malignant neuroblastic tumours that may arise in any of the nucleated retinal layers. The predominant cell has a large basophilic nucleus of variable size and shape and scanty cytoplasm. Mitotic figures are typically numerous. The tumour cells have a striking propensity to outgrow their blood supply. Especially in large tumors, cuffs of cells surrounding central dilated vessels form areas of viable tumour that have a characteristic appearance (**Figure 9**). The tumour cells undergo ischaemic necrosis if they are displaced more than 90–110 μm from the vessel. A cuff thickness of approximately 100 μm represents the approximate distance that oxygen can diffuse before it is completely consumed in rapidly growing neoplasms.

The ability of retinoblastomas rapidly to outstrip their blood supply leads to areas of coagulative necrosis. Foci of calcification are frequently seen in these areas. The DNA liberated from necrotic cells can become absorbed preferentially in the walls of blood vessels and by the internal limiting membrane of the retina, giving a deep blue (haematoxylinophilic) or Feulgen-postive stain to these tissues.

Retinoblastomas characteristically form rosettes and flurettes, which are attempts at photoreceptor differentiation. Flexner–Wintersteiner rosettes are highly specific for retinoblastomas, but are also observed in pineoblastoma and medulloepithelioma. Even though these rosettes represent areas of differentiation by the

Table 2 Differential diagnosis of retinoblastoma: conditions simulating retinoblastoma based on clinical diagnoses in a study consisting of 500 patients (From Shields *et al.*, 1996, *Archives of Ophthalmology*, **114**, 1330–1338.)

Condition	%

tumour, they are composed of malignant cells and occur in areas of mitotic activity. The typical Flexner–Wintersteiner rosette (**Figure 10**) is composed of tall cuboidal cells that encircle an apical lumen. The apical ends of the cuboidal cells are held together by terminal bars and the cells may have apical cytoplasmic projections into the lumen of the rosette. Electron microscopy has demonstrated that these projections represent primitive inner and

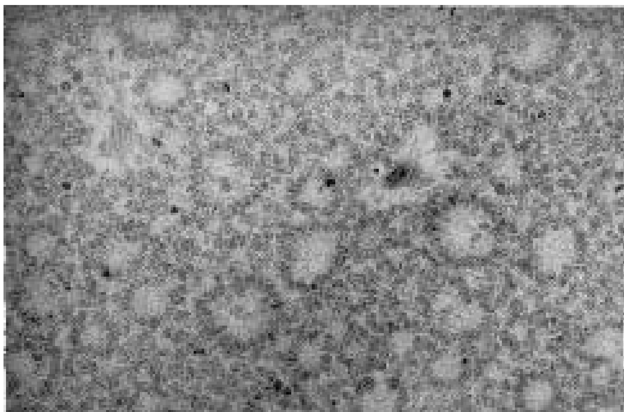

Figure 10 Flexner-Wintersteiner rosettes in retinoblastoma.

outer segments and, therefore, these tumour cells are attempting to form photoreceptor cells. Alcian blue stain reveals the presence of hyaluronidase-resistant glycosaminoglycans in the lumina of the rosettes that have similar staining characteristics to the extracellular matrix of rods and cones. Cells forming Flexner–Wintersteiner rosettes share several other ultrastructural features with retinal photoreceptors: zonula occludens that form a luminal limiting membrane analogous to the external limiting membrane of the retina, cytoplasmic microtubules, cilia with the $9+2$ pattern and lamellated membranous structures resembling the discs of rod outer segments. Immunohistochemical and lectin histochemical studies have also supported the concept that retinoblastomas arise from undifferentiated retinal cells that may differentiate into photoreceptor cells. Homer Wright rosettes are the other type of rosettes found in retinoblastomas, but are less common. They are found in a variety of neuroblastic tumours and are less specific for retinoblastoma. In these rosettes, the cells are not arranged about a lumen but send out cytoplasmic processes that form a tangle in the centre of the rosette. Finally, fleurettes probably represent the highest degree of differentiation of the tumour cells into photoreceptors. Fleurette represents a collection of benign appearing cells with long cytoplasmic processes that stain brightly with eosin. The cytoplasmic processes project through a fenestrated membrane and fan out like a bouquet of flowers (hence the term fleurette).

Extraocular extension and metastasis Retinoblastoma, if left untreated, has a propensity for rapid invasive growth typical of blastic tumours in children. The most common routes for local spread are through the optic nerve (**Figure 11**) and invasion of the choroid. Extraocular extension occurs via scleral canals or by massive replacement of the sclera.

Glial Tumours

Astrocytomas of the retina are rare and almost always benign tumours. The majority of them (over 50%) occur in

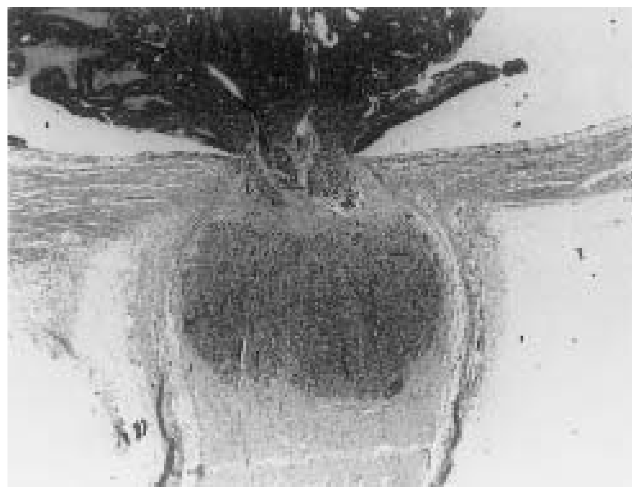

Figure 11 Retinoblastoma. Tumour is invading the optic nerve but not reaching the surgical margin (courtesy AFIP).

patients with tuberous sclerosis and a small proportion develops in patients with neurofibromatosis. They are also described as astrocytic hamartomas. On ophthalmoscopic appearance, early tumours appear flat and translucent. Older lesions tend to calcify and may be confused with retinoblastoma. Histologically, they are composed of elongated fibrous (pilocytic) astrocytes containing small oval nuclei. Rare giant cell (gemistocytic) astrocytomas have also been described.

Vascular Tumours

Retinal capillary haemangiomas are the hallmark of von Hippel–Lindau and are similar to cerebellar haemangioblastomas. Clinically, the tumours progress from small red to greyish appearing lesions with no abnormal vessels, to moderate-sized pink or yellowish lesions with large feeder vessels and retinal haemorrhage and exudation. Fluorescein angiography reveals leakage in the early phase of the angiogram and is diagnostic. Histologically, the tumour is composed of small vascular channels that have the appearance of capillaries. Large foamy cells which are debated to be histocytic, endothelial or astrocytic in origin are present in the stroma. Gliosis of the adjacent retina with massive exudation, haemorrhage and retinal detachment is frequently present.

Cavernous haemangioma of the retina is a rare congenital malformation that differs from capillary haemangiomas in several aspects. The affected retina shows isolated clusters of aneurysmal dilation of retinal vessels with absent feeder vessels. There is no arteriovenous shunting owing to the low flow state of these tumours and there is no disturbance of permeability on clinical examination or fluorescein angiography. Histologically, large vascular channels with normal walls thicken the retina. The inner retinal layers may be discontinuous in the area of the vascular lesions.

Lymphoid Tumours

Retinal involvement may be the initial and only manifestation of primary CNS lymphoma. The retina is usually not involved in a generalized systemic lymphoma and conversely the reticuloendothelial system is not affected by a primary CNS lymphoma. The vitreous is often involved by the presence of lymphoma cells and can masquerade as uveitis. In fact, the the presence of glaucoma, uveitis and neurological symptoms in an elderly individual should raise the suspicion of primary CNS lymphoma and appropriate imaging studies of the brain should be performed. The diagnosis may be confirmed microscopically by cytological examination of cells from the cerebral spinal fluid, vitrectomy, vitreous aspiration, or from biopsy of brain or retina.

The gross findings include placoid or hemispherical mound-like elevations of the retinal pigment epithelium (**Figure 12; see colour plate section**). The optic nerve may be involved with neoplastic cells as opposed to the uvea, which is rarely affected except for the presence of a reactive inflammatory infiltrate. The tumour cells possess varying amounts of cytoplasm with polyhedral or amoeboid outlines. Most of the nuclei exhibit single or multiple nucleoli. Mitotic figures are frequently present along with areas of retinal necrosis.

Neuroepithelial Tumours

Tumours of the neuroepithelium can be divided into congenital and acquired lesions. Congenital lesions usually arise from the medullary epithelium and are called medulloepitheliomas. The medullary epithelium has the capacity to differentiate into retinal pigment epithelium (RPE), nonpigmented and pigmented ciliary epithelium and neurons. They have also been termed diktyomas, since they are composed of a network of neuroepithelial bands. When they contain heterologous tissue elements such as cartilage, skeletal muscle and brain, they are referred to as teratoid.

Clinically, these tumours usually arise from the ciliary body, but on rare occasion may arise from the retina or optic disc. Some ciliary body medulloepitheliomas are cystic and may become detached to be carried into the anterior chamber through the pupil. Histologically, the tumour is composed of cords and sheets of cells ranging from a single layer of columnar epithelium to stratified multilayered structure that resembles embryonic retina. The apical side of the cords has several fenestrations resembling the external limiting membrane of the retina. Malignant medulloepitheliomas contain totally undifferentiated cells and Flexner–Wintersteiner rosettes may occasionally be observed, making differentiation from childhood retinoblastoma difficult.

Acquired lesions arising from the retinal pigment epithelium, non-pigmented and pigmented ciliary pigment epithelium can be categorized either as adenomas or adenocarcinomas. However, a more frequent lesion arising from

the non-pigmented ciliary epithelium is a Fuchs adenoma, which is a hyperplasia rather than a true neoplasm. Grossly, Fuchs adenomas are small, white nodules that usually measure less than 1 mm in diameter and are located on the pars plicata. Histologically, the lesion consists of a nodule of hyperplastic, nonpigmented ciliary epithelium arranged in sheets and tubules, embedded in a matrix of PAS-positive basement membrane-like material. Congenital lesions of the RPE include combined hamartoma of the retina and RPE and congenital hypertrophy of the retinal pigment epithelium (CHRPE). Bilateral and multiple CHRPE lesions have been associated with Gardner's syndrome, an autosomal dominant condition characterized by adenomatous polyps of the colon, which may progress to adenocarcinoma and musculoskeletal anomalies.

Tumours of the Uveal-Tract

Melanocytic naevi and malignant melanoma are by far the most frequent and clinically important tumours of the iris, ciliary body and the choroid. In autopsy studies, metastasis is the most frequent tumour observed in the choroid; however, choroidal melanoma is the most frequent primary intraocular malignancy of adults.

Iris

Tumours of the iris can arise from the iris pigment epithelium, smooth muscle or stromal melanocytes. These include cysts and adenomas of the iris pigment epithelium, leiomyomas, naevi and malignant melanomas.

An iris naevus is a benign tumour that arises from the stromal melanocytes. They appear flat to slightly elevated under slit lamp examination and usually remain stationary in size, although they have the potential for malignant transformation (**Figure 13; see colour plate section**). Histologically, they are composed of low-grade spindle-type cells. Occasionally, when the naevus consists of heavily pigmented, plump polyhedral cells, it is referred to as a melanocytoma (**Figure 14**). In neurofibromatosis type I, the stromal melanocytes undergo a hamartomatous proliferation into small, tan-coloured nodules on the surface of the iris known as Lisch nodules. Juvenile xanthogranuloma, a benign dermatological disorder of children and young adults, can lead to thickening of the iris with neovascularization and haemorrhage. Histologically, it is composed of mildly atypical histiocytes.

An iris melanoma is a malignant neoplasm of the stromal melanocytes. They are nodular, circumscribed and variably pigmented. An iris melanoma can be darkly pigmented or amelanotic or a mixture of the two. An important variant of the nodular type of iris melanoma is diffuse iris melanoma. This type of melanoma presents with diffuse thickening of the iris, acquired hyperchromic heterochromia and glaucoma (**Figure 15**). The histology of

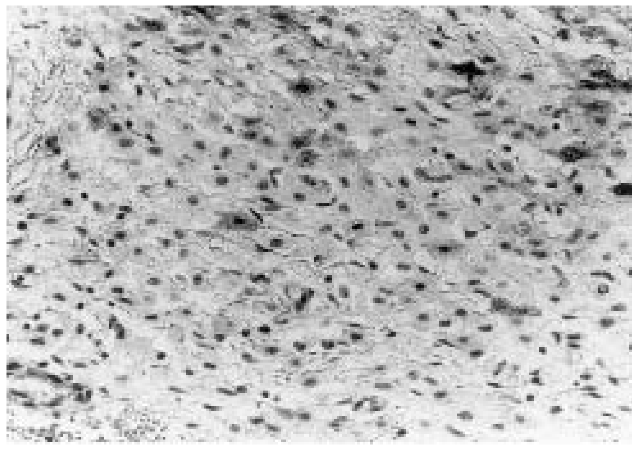

Figure 14 Melanocytoma. Bleached preparation showing plump polyhedral melanocytes with small ovoid nuclei (courtesy AFIP).

Figure 15 Diffuse iris melanoma. The angle of the eye is well shown in the low-power photomicrograph. The higher power photograph shows discohesive epithelioid melanoma cells studded on the anterior surface of iris and the angle structures.

iris naevus and melanoma will be discussed with their choroidal counterparts.

Ciliary Body

Ciliary body tumours include neoplasms of the pigmented and non-pigmented ciliary epithelium as discussed in the section on retinal tumours. Ciliary body melanomas are less frequent than choroidal melanomas but more frequent than iris malignant melanomas. The growth pattern of ciliary body melanomas differs from that of the choroidal variety. The absence of Bruch's membrane in the ciliary body leads to early endophytic growth of the tumour in the posterior chamber, with occasional subluxation or indentation of the lens. Ciliary body melanoma can grow on to the iris, in which case a small hyperpigmented lesion on the iris might appear on the periphery of the iris, representing the tip of the iceberg. Occasionally, they can erode through the sclera and appear on the surface of the globe near the limbus, simulating a conjunctival melanoma. Diffuse ciliary body melanomas have a tendency to grow in a ring-like fashion.

Choroid

Choroidal naevi are benign melanocytic tumours that can occasionally degenerate into malignant melanomas. Ophthalmoscopically, a choroidal naevus is variably pigmented (it may rarely be amelanotic) and is usually less than 2 mm in height. The surface of the lesion often has small yellowish–white deposits known as drusen. Subretinal fluid is not a hallmark of choroidal naevi as is the case with melanomas. Histologically, choroidal naevi are composed of low-grade spindle cells. The proliferation of benign melanocytes throughout the uvea is associated with certain systemic malignancies such as ovarian and uterine carcinoma (Gass *et al*., 1990). This is referred to as bilateral diffuse uveal melanocytic proliferation (BDUMP) and is a paraneoplastic syndrome.

Choroidal melanomas are the most frequent of all the uveal (iris, ciliary body and choroid) melanomas. The use of the indirect ophthalmoscope has dramatically improved the detection and diagnosis of small choroidal tumours. The gross pathological features of choroidal melanoma are characteristic. The tough fibrous sclera prevents the outward growth of the melanoma into the orbit. However, the weaker Bruch's membrane on the inner aspect of the tumour can become stretched and eventually rupture from the expanding sub-retinal pigment epithelial mass. The tumour herniates through the rupture and grows into the subretinal space, giving a 'collar button' or mushroom-shaped configuration (**Figure 16; see colour plate section**). The retina overlying the uveal melanoma undergoes atrophy or cystoid degeneration while the retina surrounding the tumour is detached by the accumulation of serous exudate between the retina and the RPE. Some choroidal melanomas can invade the orbit by growing along the course of perforating nerves and vessels.

In 1913, Calender classified uveal malignant melanoma based on cytological and histological features. Since then, this scheme has been widely accepted owing to its prognostic significance, but has also undergone some modification from the original description of cell types. The cells of the uveal malignant melanoma are now divided into spindle and epithelioid cell types. Spindle-type cells are fusiform shaped and usually arranged in a fascicular pattern (**Figure 17**). They have cigar-shaped nuclei, with prominent nucleoli and frequent mitotic figures. The epithelioid-type cells are larger and more pleomorphic than the spindle type cells. They have abundant cytoplasm with distinct cell boundaries (**Figure 18**). Their characteristic loose intercellular cohesion leads to extracellular space between adjacent cells. The nucleus is larger and rounder with irregular indentations when compared with the spindle cell counterpart. Mitotic activity is also greater than in spindle cell tumours. Based on the presence or absence of each cell type, uveal melanomas can be classified as

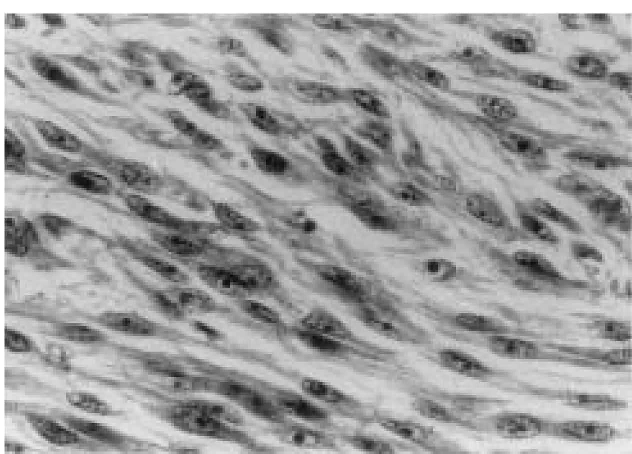

Figure 17 Malignant melanoma. Spindle-type cells (courtesy AFIP).

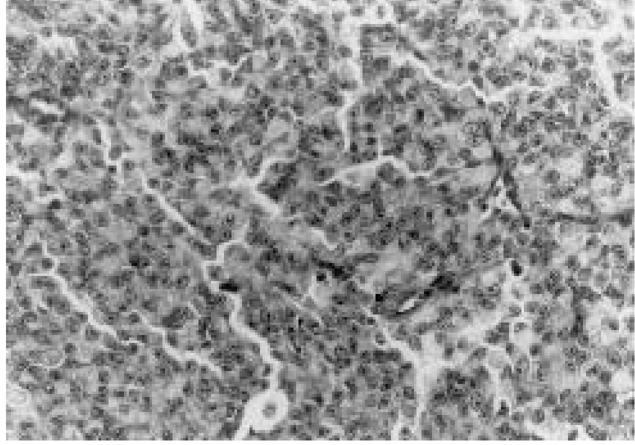

Figure 18 Malignant melanoma. Epithelioid-type cells (courtesy AFIP).

spindle, epithelioid or mixed cell-type tumours, each with different prognostic significance (discussed later).

Since uveal melanocytes are derived from neural crest, they stain positive for HMB-45, S-100 and neuron-specific enolase. Uveal naevi stain with less intensity for all three immunohistochemical markers.

Other tumours of the uvea include leukaemic infiltration, uveal lymphoma with extraocular extension, leiomyosarcoma and neuroepithelial tumours of the ciliary body (discussed under Tumours of the Retina). Choroidal osteoma and haemangioma are relatively rare tumours. The latter when seen in association with the Sturge–Weber syndrome often gives the fundus a 'tomato ketchup' appearance.

Tumours of the Orbit

A variety of benign and malignant tumours of the orbit have been described in adults and children. Capillary haemangioma, lymphangioma, dermoid cysts and rhabdomyosarcoma are most common in children whereas fibrous histiocytoma, cavernous haemangioma, schwannoma and lymphoid neoplasms occur more commonly in adults.

Capillary Haemangioma

In most cases, capillary haemangioma is located in the anterior aspect of the orbit and frequently involves the lid. The appearance of the lesion varies from a striking red 'strawberry naevus' located in the dermis to a more diffuse and light blue discoloration of the skin present in deeper orbital lesions. They have an infiltrative growth pattern and can involve any of the orbital structures. The tumour is composed of plump endothelial cells, which proliferate in solid lobules during the rapid growth phase of the tumour. Although these are benign tumours, they may contain numerous mitotic figures. Electron microscopy has revealed pericytes surrounding the endothelial lobules, indicating the capillary origin of these tumours.

Cavernous Haemangioma

Grossly, cavernous haemangiomas have an intense violaceous hue due to the presence of partially oxygenated venous blood in the vascular spaces. The tumour has a well-formed capsule surrounding vascular channels, which measure 0.5–1 mm in diameter and are filled with blood. Electron microscopy has revealed the vascular spaces to be lined by a monolayer of endothelial cells.

Lymphangioma

Lymphangioma is considered a choristoma since there are no endothelial-lined lymphatic channels in the orbit. In contrast to other encapsulated orbital tumours, a lymphangioma does not possess a capsule and therefore has a tendency to diffusely infiltrate soft tissues of the orbit. It is composed of endothelial lined channels with the ultrastructural features of lymphatics.

Haemangiopericytoma

Haemangiopericytoma is an encapsulated tumour with a grey to red–brown colour on cut section. They are composed of small polyhedral and spindle-shaped cells tightly packed around blood vessels. These vessels range from small capillaries to large sinusoidal spaces, some of which have a typical 'staghorn'configuration. Haemangiopericytoma have been divided into benign and malignant varieties based on histological criteria: cytological atypia, mitotic activity and necrosis.

Fibrous Histiocytoma

Fibrous histiocytoma is one of the most common tumours of the orbit. Grossly, they are encapsulated, rubbery to firm and vary from greyish white to yellow–tan. Microscopically they are composed of a mixture of spindle-shaped fibroblast-like cells and more ovoid, sometimes lipidized histiocytes. Detailed descriptions about the histological variations can be found elsewhere.

Neurofibroma

Of the three types of neurofibromas found in the orbit, plexiform, diffuse and isolated, only the plexiform variant is consistently observed in patients with neurofibromatosis type I. It appears within the first decade of life and grows in an infiltrating fashion that may involve any orbital structure. The enormous overgrowth of the orbital peripheral nerves may sometimes cause excessive redundancy of the lid skin, leading to elephantiasis neuromatosa. This tumour-like lymphangioma is not encapsulated. Histologically, it is composed of numerous proliferating units of the terminal branches of peripheral nerves in a loose stroma of axons, Schwann cells and endoneural fibroblasts.

Schwannoma

Like neurofibroma, schwannoma originates from the peripheral nerves of the orbit, most often the supraorbital nerve. Histopathologically, they are encapsulated by the perineurium of the nerve of origin. The classical feature of a schwannoma is the presence of solid cellular areas, referred to as the Antoni A pattern and other more myxoid areas with stellate or ovoid-appearing cells referred to as Antoni B areas. In Antoni A areas, nuclear palisading is common, which often leads to formation of fascicles of nuclei in a highly regimented fashion known as Verocay bodies.

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common primary malignant tumour of childhood. The average age at time of diagnosis is 7 years. The superonasal aspect of the orbit is the site of predilection for this tumour. When it originates in a submucosal site such as the conjunctival stroma, it is

referred to as the botryoid type. The tumour is not encapsulated and usually invades adjacent structures. Based on histological features, rhabdomyosarcomas are divided into embryonal, alveolar and pleomorphic (differentiated) types.

Dermoid Cyst

Dermoid cysts result from congenital arrest of ectoderm within sutures of the orbital bones. The majority of dermoid cysts become symptomatic within the first decade of life. Nasally located dermoids are often lined by conjunctival epithelium, whereas temporal dermoids are lined by skin and have dermal appendages such as hair and sebaceous glands present in the wall of the cyst.

Lymphoid Neoplasms

Lymphoid neoplasms of the orbit are among the most prevalent of orbital tumours. In patients above age 60 years, they represent >50% of all orbital tumours. Clinically and grossly, lymphoid tumours have a fish-flesh ('salmon patch') or creamy to yellow appearance. They are very friable owing to the absence of fibrous stroma. Histologically, lymphoid tumours should be divided into lymphomas and benign lymphoid hyperplasia. However, this distinction is not always possible and tumours exhibiting intermediate characteristics are referred to as atypical lymphoid hyperplasia (Knowles *et al*., 1990). Benign lymphoid hyperplasia has a follicular organisation with benign-appearing small, dark lymphocytes. However, the follicles can be of irregular size and shape and have high mitotic activity.

Orbital and adnexal lymphomas are almost always of the non-Hodgkins's type. Small cell lymphomas of B cell type originating in the conjunctival substantia propria are referred to as Maltoma (mucosal associated lymphoid tissue).

Other Tumours

Other tumours found in the orbit include teratomas, exclusively in newborns, histiocytic disorders such as unifocal and multifocal eosinophilic granuloma (Langerhans cell histiocytosis), malignant melanoma, blue naevus, fibrous dysplasia, granulocytic sarcoma, osteogenic sarcoma and metastasis. This is by no means an exhaustive list, since other rare tumours in the orbit have been described.

Tumours of the Optic Nerve

Glioma

Most gliomas of the optic nerve are benign pilocytic astrocytomas. They are usually seen in association with neurofibromatosis type I. They are very slow-growing tumours, often enlarging in an episodic fashion and then lying dormant for many years. On imaging studies such as MRI and CT, they appear as fusiform enlargements of the optic nerve. The dura is always intact surrounding the tumour and it is often difficult to determine the margin of the tumour from the normal optic nerve. Histologically, pilocytic astrocytomas of the optic nerve are composed of elongated, spindle-shaped, hair-like astrocytes. They have a benign appearance with the notable exception of mitotic figures. These tumours show positive immunohistochemical staining for glial fibrillary acidic protein (GFAP). Rosenthal fibres, which represent degenerative changes within the astrocytic cell processes, are also frequently seen in these tumours. They appear as cylindrical or spherical eosinophilic bodies. Ultrastructurally, Rosenthal fibres are composed of electron-dense granular material and glial filaments.

Meningioma

Almost all orbital meningiomas either arise from the meninges of the optic nerve or invade the orbit secondarily from an adjacent intracranial site such as the sphenoid wing. The clinical features of meningioma are much different from those of glioma. Meningiomas are associated with type II and not type I neurofibromatosis. The age at diagnosis is considerably greater in patients with meningioma. However, it should be considered in the differential diagnosis of any optic nerve lesion causing exophthalmos and visual loss even in the first few years of life.

Unlike gliomas, meningiomas usually extend through the dura. The tumour does not invade the optic nerve and grows in a sleeve-like manner within the meninges. Meningiomas may infiltrate all of the orbital structures but intraocular invasion through the sclera is rare. Histologically, they are similar to intracranial meningiomas.

Tumours of the Lachrymal Gland and Sac

Lachrymal gland tumours bear a striking resemblance to those of the salivary gland. Approximately half of all lachrymal gland tumours are epithelial and the rest are non-epithelial. Of the epithelial tumours, half are benign and half malignant. They constitute 10% of all orbital lesions in some series.

Pleomorphic Adenoma

Pleomorphic adenomas or benign mixed tumours are the most common tumours of the lachrymal gland. They present as a firm, painless and slowly developing mass in the superolateral orbit. They are pseudoencapsulated and may contain cystic areas. Histological sections reveal an admixture of epithelial and mesenchymal elements that can take a variety of patterns.

Pleomorphic Carcinoma

Also known as malignant mixed tumours, pleomorphic carcinomas arise from malignant transformation of pleomorphic adenomas. Histologically, they can take the appearance of adenocarcinoma, adenoid cystic carcinoma,

squamous cell carcinoma, undifferentiated carcinoma or sebaceous carcinoma in which a pre-existing pleomorphic adenoma can be identified.

Other Tumours

Adenoid cystic carcinoma, mucoepidermoid and adenocarcinoma of the lachrymal gland can arise *de novo* in the lachrymal gland. Their histopathology is similar to that of tumours found in the salivary glands. Lymphomas and benign reactive lymphoid hyperplasia are the most common non-epithelial tumours of the lachrymal gland. **Table 3** lists the different types of tumours that can arise in the lachrymal sac.

Molecular Genetic Findings

Retinoblastoma represents a paradigm in understanding the molecular basis of inherited predisposition to developing malignancy. The retinoblastoma gene, a tumour suppressor gene, is located on the long arm (q14 locus) of chromosome 13 (Dryja *et al*., 1984). Hence each cell carries two copies of this gene and in normal individuals their gene product serves to inhibit the development of retinal tumours. The retinoblastoma gene product (pRB) normally inactivates E2F (a nuclear transcription factor) and halts the normal cell cycle between G1 and S phases. However, in each case of retinoblastoma, an initial mutation inactivates one copy of the gene. The mutation can be caused by a single-base change of DNA, a point mutation, a chromosomal translocation, a small deletion or a large deletion that is observable by karyotyping. The mutation can be germ-line or somatic leading to the hereditary (multiplex) and non-hereditary (simplex) forms of retinoblastoma. The homozygous form of the mutated retinoblastoma gene is probably fatal *in utero*. In the heterozygous form (hereditary form), the individual inherits a mutated gene from one parent and acquires the second mutation sometime after birth. This was Knudson's initial 'two hit hypothesis' and postulates the necessity for both genes to be inactivated for development of retinoblastoma. Loss of all pRB due to homologous deficiency at 13q14 eliminates the 'brakes' and uncontrolled proliferation of retinoblastoma ensues. In the non-hereditary form, the individual acquires both mutations after birth.

The majority of retinoblastomas are of the inherited variety. The defective gene in this instance can be acquired from a parent who is a known carrier or more often they may represent a new germline mutation. Multiple and especially bilateral retinoblastomas almost always signify a germinal mutation. Median age at diagnosis is significantly lower for bilateral retinoblastoma than for unilateral retinoblastoma. An important facet of providing care for patients with retinoblastoma is the assessment of risk of developing the same malignancy in the siblings or progeny of the affected individual. This can be done accurately using modern molecular biology techniques.

Phakomatoses ('birthmarks') are comprised of a group of disparate clinical syndromes, which share certain features in common. These include the presence of multisystem hamartomas, predominantly in ocular, cutaneous and intracranial locations. They may arise at birth or later in life, and can undergo malignant transformation. The term is usually applied to include von Hippel–Lindau (angiomatosis retinae, capillary haemangioma), turberous sclerosis (Bournveille disease), neurofibromatosis (type I and II) and Sturge–Weber sydnromes (encephalo-trigeminal angiomatosis), although some authors also include Wyburn–Mason and ataxia-telangectasia (Louis–Bar syndrome) in this group of diseases. Of the first four conditions, all except Sturge–Weber are inherited in an autosomal dominant fashion. The target locus for von Hippel–Lindau was recently mapped to 3p25–26 and the gene product (pVHL) balances mRNA transcription. The same locus is home to the gene which codes for vascular endothelial growth factor (VEGF). Mutations in 3p25–26 lead to unchecked transcription and upregulation of VEGF. Tuberous sclerosis complex (TSC) has two known disease

loci, on chromosomes 9q34 (*TSC1*) and 16p13.3 (*TSC2*). The TSC1 and TSC2 gene products are known as hamartin and tuberin, respectively, and are expressed in neurons and astrocytes where they physically interact. Neurofibromatosis (NFT), the most common of the phakomatoses, has two forms. The gene responsible for NFT type I (peripheral form) is located on chromosome 17 and NFT type II (central form) on chromosome 22.

The majority (85%) of follicular B cell lymphomas, such as primary ocular–CNS lymphoma, harbour a characteristic translocation (t(14;18)) which is felt to represent an error occurring during physiological gene rearrangement. Genes located at the translocation breakpoint (*bcl-2/ IgH*) are considered putative oncogenes that are deregulated via juxtaposition with an antigen receptor gene. Southern blot analysis is helpful in confirming both the translocation as well as monoclonal IgH expression.

Prognostic Factors

Mortality from choroidal melanoma depends on a variety of factors but has been reported in larger series to be 35% at 5 years and 50% at 10 years. There have been multiple studies to correlate gross and cytopathological features of uveal melanoma with prognosis. Location of the tumour, largest tumour diameter (LTD), height of tumour have all been found to correlate with future mortality. Patient survival is better for LTD less than 10 mm. On the histological side, optic nerve or scleral invasion, cell type (spindle, mixed or epithelioid), standard deviation of the nucleolar area and mean of the largest nucleoli are positively correlated with death from metastatic melanoma. Spindle cell tumours carry the most favourable prognosis, followed by mixed cell lesions. Pure epithelioid cell malignant melanomas have the poorest prognosis, but fortunately are also the most rare.

Retinoblastoma has a much better prognosis than choroidal melanoma. There has been a remarkable shift in the long-term survival of these patients since the early part of the century, when it was uniformly a fatal disease. The overall long-term survival in retinoblastoma in the USA and UK is now 85%. Even though patients with retinoblastoma survive the initial disease, those that have the genetic abnormality are subject to other tumours, most notably osteosarcoma. About two-thirds of the second tumours are in the radiation field used to treat retinoblastoma and the other third are in areas remote from the radiation field.

Retinoblastomas metastasize in four ways: direct infiltration, dispersion, haematogenous and lymphatic dissemination. Direct infiltrative spread occurs along the optic nerve from the eye to the brain. Once the orbital soft tissues are invaded, the tumour spreads directly into the orbital bones, through the sinuses into the nasopharynx, or via the various foramina into the cranium. Dispersion of tumour cells occurs after cells in the optic nerve have invaded the leptomeninges and gained access to the subarachnoid fluid. Flow of cerebrospinal fluid spreads the tumour cells to the brain and spinal cord. The most common sites for haematogenous spread are lungs, bones, brain and other viscera. Extraocular invasion and, to a lesser degree, choroidal invasion increase the risk of haematogenous spread. Lymphatic spread occurs in those tumours that invade the anterior orbital tissues including the conjunctiva, since the orbit is devoid of lymphatics. The spread of retinoblastoma into the optic nerve and into the orbit through the sclera is associated with less favourable prognosis.

When metastasis occurs, it is generally within the first year or two following treatment. The median time to death in patients with metastatic retinoblastoma is 6.4 months in unilateral cases and 14.2 months in bilateral cases. In contrast, the estimated median time to death in uveal melanoma is 7.2 years. Late death from metastasis, which occurs frequently following enucleation for melanoma, is so rare after treatment for retinoblastoma that when metastasis is suspected, the question of an independent new primary tumour must be considered.

All malignant neoplasms of the lachrymal gland with the possible exception of mucoepidermoid carcinoma carry a poor prognosis. Death usually results within 3–5 years from tumour extension along nerves through the superior orbital fissure and invasion through the orbital bones into the middle cranial fossa. Haematogenous metastasis, particularly to the lungs, is the second most common cause of death.

Overview of Present Clinical Management

Tumours of the Eyelid and Conjunctiva

Local excision is usually curative for the majority of skin and conjunctival tumours. Notable exceptions to this are sebaceous cell carcinoma and primary acquired melanosis. Besides growing locally in a nodular fashion, both of these lesions can spread to distant sites of the conjunctiva and epidermis of the skin intraepithelially termed pagetoid extension, rendering local excision unfeasible. Map biopsies are therefore required to assess the extent of neoplastic involvement of the ocular adnexa. In such cases cryotherapy can be used to treat wider areas, but excessive application can lead to dry eye and symblepharon formation.

Squamous cell carcinoma and to a lesser extent basal cell carcinoma can invade the deeper tissues in the orbit, requiring orbital exenteration. Extensive pagetoid spread of sebaceous cell carcinoma to the cornea, all four quadrants of the conjunctiva and the skin of the eyelid may also necessitate orbital exenteration. A variety of composite and myocutaneous flaps and skin grafting techniques from adjacent areas have been described for repair of large defects of the lids in cases where wide local excision is performed.

Primary lymphoid neoplasms of the ocular adnexa may be observed if they are asymptomatic and without evidence of systemic dissemination. Radiation or cryotherapy can be used if they involve extensive areas of the conjunctival fornices or the patient is symptomatic. A thorough evaluation to rule out a systemic lymphoma is mandatory in every patient in whom a lymphoma is suspected.

Tumours of the Retina

It is imperative to make as accurate a diagnosis as possible when a patient in whom retinoblastoma is suspected is encountered. The long list of benign conditions causing leukocoria, one of the cardinal signs of retinoblastoma (see **Table 2**), can cause confusion and lead to misdiagnosis with disastrous consequences. A variety of modalities are available for the treatment of retinoblastomas; however, the type of treatment depends on many factors, such as age of the patient, unilateral or bilateral disease, size and intraocular location of the tumour, and most importantly local or distant spread of the tumour. Enucleation is probably the most widely employed treatment. Other forms of treatment include external beam radiation, cryotherapy and photocoagulation therapy. Invasion of the optic nerve and extraocular extension significantly alter prognosis and mandate the use of chemotherapy in addition to local treatment (Gallie *et al*., 1996; Murphree *et al*., 1996; Shields *et al*., 1996).

Capillary haemangiomas of the retina are most often treated with cryotherapy or photocoagulation, depending upon the location. Treatment of haemangiomas near the optic disc or macula can be challenging. Intraocular lymphoma is treated with radiation and chemotherapy, but it carries a poor prognosis.

Tumours of the Uveal Tract

Iris melanomas can be locally excised by performing a sectoral iridectomy or iridocyclectomy with good results. Juvenile xanthogranuloma responds dramatically to topical steroids and is a self-limited disorder.

The management of choroidal melanoma is controversial (Zimmerman and McLean, 1979). The collaborative ocular melanoma study (COMS) now in progress is comparing enucleation versus plaque radiotherapy for medium-sized tumours (6–10 mm in height) and enucleation versus pre-enucleation radiotherapy for large tumours (>10 mm in height) with 10-year survival as outcome measure. Initial data suggest no statistical difference between enucleation and plaque radiotherapy for medium-sized choroidal melanomas (Collaborative Ocular Melanoma Study Group 1998). Enucleation is generally recommended for large tumours with little hope of salvageable vision (Gragoudas *et al*., 1980). Radiotherapy, with either radioactive plaque or charged particles (proton beam), is recommended for medium-sized and large melanomas when there is a possibility of salvaging some vision. More recently, the use of transpupillary thermotherapy either alone or combined with plaque radiotherapy has been advocated.

Tumours of the Orbit

Capillary haemangiomas grow rapidly after birth and usually appear during the first 6 months of life. They enter a stationary stage during the next 1–2 years followed by spontaneous involution during the next 5–6 years. If the tumour is not judged to be a threat to vision and subsequent amblyopia, it can be observed without treatment. In case of significant functional or cosmetic impairment, intralesional corticosteroid injection is the most common form of treatment.

The surgical management of encapsulated and nonencapsulated tumours of the orbit is different. Encapsulated tumours more easily lend themselves to removal without too much dissection. Even then surgery is usually reserved for progressively enlarging tumours that threaten vision due to compromise of the optic nerve or the ocular surface from progressive proptosis. Lymphangioma and plexiform neurofibroma, on the other hand, are rarely approached surgically with the intent of completely excising the tumour, owing to their infiltrative growth pattern. Rhabdomyosarcoma is essentially treated with systemic chemotherapy.

The mainstay of treatment for ocular and periocular lymphoid tumors is radiotherapy (Char *et al*., 1998). Cryotherapy is often very effective for localized and low-grade conjunctival lymphomas and has much less morbidity when compared with radiotherapy. Local radiotherapy and systemic chemotherapy are recommended for high clinical grade lymphomas, multifocal processes such as angiotropic large cell lymphoma and systemic leukaemia.

Tumours of the Optic Nerve

Both optic nerve glioma and meningioma are slow-growing tumours. Management of these tumours is again controversial. These can often be observed for many years until such time when they extend intracranially to involve the optic chiasm or the contralateral optic nerve. In these instances the tumour can be surgically resected or radiation can be used to retard its growth.

Tumours of the Lachrymal Gland and Sac

Complete excision of pleomorphic adenomas of the lachrymal gland is absolutely essential and usually curative. However, incomplete resection can lead to local recurrence or even malignant transformation in the future. All malignant neoplasms of the lachrymal gland carry a poor prognosis despite aggressive surgical attempts at complete resection. Adenoid cystic and adenocarcinoma of the lachrymal gland are almost uniformly fatal at 5 years.

Chapter 53
Ear

Bruce M. Wenig
The Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY, USA

CONTENTS

- Normal Development and Structure
- Neoplasms of the Ear and Temporal Bone
- Neoplasms of the Middle Ear and Temporal Bone

NORMAL DEVELOPMENT AND STRUCTURE

The ear is represented by three distinct compartments, the external ear, the middle ear and temporal bone, and the inner ear. The external ear develops from the first branchial groove. The external auricle (pinna) forms from the fusion of the auricular hillocks or tubercles, a group of mesenchymal tissue swellings from the first and second branchial arches, that lie around the external portion of the first branchial groove (Moore, 1988). The external auditory canal is considered a normal remnant of the first branchial groove. The tympanic membrane forms from the first and second branchial pouches and the first branchial groove (Moore, 1988). The ectoderm of the first branchial groove gives rise to the epithelium on the external side, the endoderm from the first branchial pouch gives rise to the epithelium on the internal side and the mesoderm of the first and second branchial pouches gives rise to the connective tissue lying between the external and internal epithelia (Moore, 1988). The middle ear space develops from invagination of the first branchial pouch (pharyngotympanic tube) from the primitive pharynx. The eustachian tube and tympanic cavity develop from the endoderm of the first branchial pouch; the malleus and incus develop from the mesoderm of the first branchial arch (Meckel's cartilage) while the incus develops from the mesoderm of the second branchial arch (Reichert's cartilage) (Moore, 1988). The first division of the ear to develop is the inner ear that appears toward the end of the first month of gestation (Dayal *et al*., 1973; Moore, 1988). The membranous labyrinthe, including the utricle, saccule, semicircular ducts and cochlear duct, arises from the otic vesicle (otocyst). The otic vesicle forms from the invagination of the surface ectoderm, located on either side of the neural plate, into the mesenchyme. This invagination eventually loses its connection with the surface ectoderm. The bony labyrinthe, including the vestibule, semicircular canals and cochlea arises from the mesenchyme around the otic vesicle (Dayal *et al*., 1973; Moore, 1988).

The outer portion of the external ear includes the auricle or pinna leading into the external auditory canal with its medial limit being the external aspect of the tympanic membrane. Histologically, the auricle is essentially a cutaneous structure composed of keratinizing, stratified squamous epithelium with associated dermal adnexal structures that include hair follicles, sebaceous glands and eccrine sweat glands. The subcutaneous tissue is composed of fibroconnective tissue, fat and elastic-type fibrocartilage which gives the auricle its structural support. In addition to the dermal adnexal structures, the outer third of the external canal is noteworthy for the presence of modified apocrine glands called ceruminal glands that replace the eccrine glands seen in the auricular dermis. Ceruminal glands produce cerumen and are arranged in clusters composed of cuboidal cells with eosinophilic cytoplasm often containing a granular, golden yellow pigment. These cells have secretory droplets along their luminal border. In the inner portion of the external auditory canal, ceruminal glands, and also the other adnexal structures, are absent. Similarly to the auricle, the external auditory canal is lined by keratinizing squamous epithelium that extends to include entire canal and covers the external aspect of the tympanic membrane. The inner two-thirds of the external auditory canal contains bone rather than cartilage.

The middle ear or tympanic cavity contents include the ossicles (malleus, incus and stapes), eustacian tube, tympanic cavity proper, epitympanic recess, mastoid cavity and the chorda tympani of the facial (VII) nerve. The middle ear, and also the external ear, function as conduits for sound conduction for the auditory part of the internal ear. The anatomic limits of the middle ear include (1) lateral or internal aspect made up by the tympanic membrane and squamous portion of the temporal bone, (2) medial aspect bordered by the petrous portion of the temporal bone, (3) superior (roof) delimited by the tegmen tympani, a thin plate of bone which separates the middle ear space from the cranial cavity, (4) inferior (floor) aspect bordered by a thin plate of bone separating the tympanic cavity from the superior bulb of the internal jugular vein,

(5) anterior aspect delimited by a thin plate of bone separating the tympanic cavity from the carotid canal housing the internal carotid artery and (6) posterior aspect delimited by the petrous portion of the temporal bone containing the mastoid antrum and mastoid air cells. Histologically, the lining of the middle ear is a respiratory epithelium varying from ciliated epithelium in the eustacian tube to a flat, single, cuboidal epithelium in the tympanic cavity and mastoid. The epithelial lining the eustacian tube becomes pseudostratified as it approaches the pharyngeal end. Under normal conditions, there are no glandular elements within the middle ear. The eustachian tubes contain a lymphoid component, particularly in children, that is referred to as Gerlach's tubal tonsil. The ossicular articulations are typical synovial joints.

The internal ear is embedded within the petrous portion of the temporal bone and consists of the structures of the membranous and osseous labyrinthe, and the internal auditory canal in which the vestibulocochlear (VIII) nerve runs. The internal ear is the sense organ for hearing and balance. The anatomy and histology of this region is complex and beyond the scope of this chapter and the reader is referred to specific texts detailing the inner ear anatomy and histology.

NEOPLASMS OF THE EAR AND TEMPORAL BONE

The classification of neoplastic lesions of the ear and temporal bone are listed in **Table 1**. Owing to limitations of space, this chapter will detail those lesions unique to the ear. The most common lesions of the external ear are of cutaneous origin. The reader is referred to the chapter on dermatopathology for a more complete discussion of cutaneous pathology. Numerous non-neoplastic lesions occur in the ear and temporal bone. Although this chapter is limited to neoplasms, for completion the classification of non-neoplastic lesions of the ear and temporal bone are listed in **Table 2**. Along this line, no chapter dealing with lesions of the ear would be complete without a discussion on cholesteatomas. The section on cholesteatoma precedes the discussion on the neoplasms of this region.

Table 1 Classification of neoplasms of the ear

External ear
Benign
Keratoacanthoma
Squamous papilloma
Seborrhaeic keratosis
Ceruminal gland neoplasms
Melanocytic nevi
Dermal adnexal neoplasms
Neurilemmoma/neurofibroma
Osteoma
Chondroma
Others
Malignant
Basal cell carcinoma
Squamous cell carcinoma
Verrucous carcinoma
Ceruminal gland adenocarcinomas
Malignant melanoma
Merkel cell carcinoma
Atypical fibroxanthoma
Others
Middle and inner ear
Benign
Middle ear adenoma
Epithelial papilloma
Jugulotympanic paraganglioma
Meningioma
Acoustic neuroma
Indeterminant biological behaviour
Endolymphatic sac papillary tumour
Malignant
Middle ear adenocarcinoma
Primary squamous cell carcinoma
Rhabdomyosarcoma
Osteosarcoma, chondrosarcoma
Haematolymphoid (e.g. malignant lymphoma)
Others
Secondary tumours

Cholesteatoma (Keratoma)

Cholesteatoma is a pseudoneoplastic lesion of the middle ear characterized by invasive growth and the presence of stratified squamous epithelium that forms a sac-like accumulation of keratin within the middle ear space. Despite their invasive growth, cholesteatomas are not considered to be true neoplasms. The term cholesteatoma is a misnomer in that it is not a neoplasm and it does not contain cholesterol (Ferlito *et al*., 1997). Perhaps the designation of keratoma would be more accurate, but the term cholesteatoma is entrenched in the literature.

Cholesteatomas tend to be more common in men than in women and are most common in the third and fourth decades of life. The middle ear space is the most common site of occurrence. Initially, cholesteatomas may remain clinically silent until extensive invasion of the middle ear space and mastoid occurs. Symptoms include hearing loss, malodorous discharge and pain and may be associated with a polyp arising in the attic of the middle ear or perforation of the tympanic membrane. Otoscopic examination may reveal the presence of white debris within the middle ear which is considered diagnostic.

The majority of cholesteatomas are acquired and either arise *de novo* without a prior history of middle ear disease or arise following a middle ear infection; a small percentage of cases are congenital. The latter have also been referred to as epidermoid cysts (Schuknecht, 1993a). The pathogenesis is thought to occur via migration of

Table 2 Classification of non-neoplastic lesions of the ear

External ear
- Developmental (accessory tragi; first branchial cleft anomalies, others)
- Infectious diseases
- Keloid
- Epidermal and sebaceous cysts
- Idiopathic cystic chondromalacia
- Chondrodermatitis nodularis helicis chronicus
- Angiolymphoid hyperplasia with eosinophilia/Kimura disease
- Autoimmune/systemic diseases (relapsing polychondritis; gout)
- Exostosis
- Others

Middle and inner ear, including temporal bone
- Developmental and congenital anomalies
- Infectious (otitis media)
- Otic or aural polyp
- Cholesteatoma
- Otosclerosis
- Langerhans cell histiocytosis (eosinophilic granuloma)
- Heterotopias (central nervous system tissue; salivary gland)
- Teratoma
- Others

squamous epithelium from the external auditory canal or from the external surface of the tympanic membrane into the middle ear. The mechanism by which the epithelium may enter the middle ear probably is by a combination of events, including perforation of the tympanic membrane (particularly in its superior aspect referred to as the pars flaccida or Shrapnell's membrane following an infection) coupled with invagination or retraction of the tympanic membrane into the middle ear as a result of long-standing negative pressure on the membrane secondary to blockage or obstruction of the eustachian tube. Other theories by which cholesteatomas are thought to occur include traumatic implantation, squamous metaplasia of the middle ear epithelium or congenital.

Cholesteatomas appear as a cystic, white to pearly appearing mass of varying size containing creamy or waxy granular material. The histological diagnosis of cholesteatoma is made in the presence of a stratified keratinizing squamous epithelium, subepithelial fibroconnective or granulation tissue and keratin debris (**Figure 1; see colour plate section**). The essential diagnostic feature is the keratinizing squamous epithelium and the presence of keratin debris alone is not diagnostic of a cholesteatoma. The keratinizing squamous epithelium is cytologically bland and shows cellular maturation without evidence of dysplasia. In spite of its benign histology, cholesteatomas are 'invasive' and have widespread destructive capabilities. The destructive properties of cholesteatomas result from a combination of interrelated reasons, including mass effect with pressure erosion of surrounding structures from the cholesteatoma, the production of collagenase which has osteodestructive capabilities by its resorption of bony structures and bone resorption (Abramson *et al*., 1984). Collagenase is produced by both the squamous epithelial and the fibrous tissue components of the cholesteatoma.

The histological diagnosis of cholesteatomas is relatively straightforward in the presence of keratinizing squamous epithelium. In contrast to cholesteatomas, squamous cell carcinoma shows dysplastic or overtly malignant cytological features with a prominent desmoplastic stromal response to its infiltrative growth. Cholesteatomas do not transform into squamous cell carcinomas. DNA analysis on human cholesteatomas showed the majority of cases analysed to be euploid (Desloge *et al*., 1997). As such, owing to a lack of overt genetic instability, cholesteatomas could not be considered to be malignant neoplasms. Cholesterol granuloma is not synonymous with cholesteatoma. These entities are distinctly different pathological entities and should not be confused with one another.

Complete surgical excision of all histological components of the cholesteatoma is the treatment of choice. If not completely excised, cholesteatomas can have progressive and destructive growth, including widespread bone destruction which may lead to hearing loss, facial nerve paralysis, labrynthitis, meningitis, epidural and/or brain abscess.

Ceruminal Gland Neoplasms

Ceruminal gland tumours arise from the cerumen-secreting modified apocrine glands (ceruminal glands) of the external auditory canal. Ceruminal glands are located in the dermis of the cartilaginous (outer) portion of the external auditory canal. In general, ceruminal gland neoplasms are uncommon but represent one of the more common tumours of the external auditory canal. The generic designation of ceruminoma should be avoided. Ceruminal gland neoplasms should be specifically diagnosed according to tumour type. The classification of ceruminal gland neoplasms includes benign and malignant tumours. The benign ceruminal gland tumours include ceruminal gland adenoma (ceruminoma), pleomorphic adenoma and syringocystadenoma papilliferum (Hyams *et al*., 1988a). The malignant ceruminal gland tumours include ceruminal gland adenocarcinoma, adenoid cystic carcinoma and mucoepidermoid carcinoma.

Ceruminal gland neoplasms tend to affect men more than women and occur over a wide age range but are most frequently seen in the fourth to sixth decades of life. Symptoms include a slow-growing external auditory canal mass or blockage, hearing difficulty and infrequently otic discharge (Wetli *et al*., 1972; Pulec, 1977; Hyams *et al*., 1988a). The gross appearance of ceruminal gland neoplasms includes skin-covered, circumscribed, polypoid or rounded mass ranging in size from 1 to 4 cm in diameter. Ulceration is uncommon and may suggest a malignant neoplasm.

Histologically, ceruminal gland adenomas are unencapsulated but well-demarcated glandular proliferations. The glands vary in size and may have various combinations of growth patterns, including solid, cystic and papillary. A cribriform or back-to-back glandular pattern is commonly seen. The glands are composed of two cell layers, the inner or luminal epithelial cell is cuboidal or columnar appearing with an eosinophilic cytoplasm and a decapitation-type secretion (apical 'snouts') characteristic of apocrine-derived cells; the outer cellular layer is a spindle cell with a hyperchromatic nucleus and represents myoepithelial derivation (**Figure 2; see colour plate section**). A golden yellow–brown granular-appearing pigment can be seen in the inner lining cells and represents cerumen. Cellular pleomorphism and mitoses can be seen but are not prominent. Diastase-resistant, PAS-positive and/or mucicarmine-positive intracytoplasmic and/or intraluminal material may be seen.

Ceruminal gland pleomorphic adenomas are uncommon tumours. The histology is similar to that of pleomorphic adenomas of salivary gland origin. Syringocystadenoma papilliferum is a benign tumour of apocrine gland origin that usually occurs on the scalp and face area. Syringocystadenoma papilliferum may originate in the external auditory canal from ceruminal glands. The histology is similar to that of tumours of the more common cutaneous sites.

The treatment of choice for benign ceruminal gland neoplasms is complete surgical excision, which is curative. Recurrence of the tumour can occur and relates to inadequate surgical excision.

In contrast to ceruminal gland adenoma, patients with ceruminal gland adenocarcinomas more often have associated pain (Wetli *et al*., 1972; Pulec, 1977; Hyams *et al*., 1988a). Histologically, features that may assist in differentiating ceruminal gland adenocarcinomas from the adenomas include a loss of the glandular double cell layer with identification of only the inner or luminal epithelial cell, the presence of cellular pleomorphism with nuclear anaplasia, increased mitotic acitvity and invasive growth. However, well-differentiated ceruminal gland adenocarcinomas may appear similar to their benign counterparts and are differentiated only on the basis of invasive growth. At the other end of the spectrum, poorly differentiated ceruminal adenocarcinomas occur and are recognized on the basis of their localization in external auditory canal. Other types of ceruminal gland malignant tumours include adenoid cystic carcinoma and mucoepidermoid carcinoma. These tumours are morphologically similar to their salivary gland counterparts.

For ceruminal gland adenocarcinoma, *en bloc* surgical resection is the treatment of choice. Middle ear or temporal bone involvement necessitates more radical surgery (Hicks, 1983). Supplemental radiotherapy is recommended (Hicks, 1983). Metastases are rare and include regional lymph nodes and the lung (Pulec, 1977; Hicks, 1983). For ceruminal gland adenoid cystic carcinoma and mucoepidermoid carcinoma, wide surgical resection is the recommended treatment with or without supplemental radiotherapy. The prognosis for ceruminal gland adenoid cystic carcinoma generally is similar to that for their salivary gland counterparts, including relatively good short-term (i.e. 5-year) survival but poor long-term (i.e. 10–20 years) survival (Perzin *et al*., 1982).

NEOPLASMS OF THE MIDDLE EAR AND TEMPORAL BONE

Benign Tumours

Middle Ear Adenomas (MEA)

MEA are benign glandular neoplasms originating from the middle ear mucosa (Hyams *et al*., 1988b; Batsakis, 1989). MEA occur equally in both genders and occur over a wide age range but are most common in the third to fifth decades of life. MEA are found in any portion of the middle ear including the eustachian tube, mastoid air spaces, ossicles and chorda tympani nerve. The most common symptom is unilateral conductive hearing loss but fullness, tinnitus and dizziness may also occur. Pain, otic discharge and facial nerve paralysis rarely occur and, if present, may be indicative of a malignant process. Otoscopic examination in the majority of cases will identify an intact tympanic membrane with tumour confined to the middle ear space with possible extension to the mastoid. Occasionally, the adenoma will perforate through the tympanic membrane with extension into and presentation as an external auditory canal mass. There are no known aetiological factors related to the development of MEA. MEA are not associated with a prior history of chronic otitis media. Concurrent cholesteatomas may be seen with MEA but there is no known association between these two lesions.

An MEA is a grey–white to red–brown, rubbery to firm mass free of significant bleeding on manipulation. Histologically, MEA are unencapsulated lesions with glandular or tubule formation, as well as solid, sheet-like, trabecular, cystic and cribriform growth patterns (**Figure 3; see colour plate section**). Rarely, MEA may show a predominant papillary growth. The neoplastic glands occur individually or have back-to-back growth. The glands are composed of a single layer of cuboidal to columnar cells with a varying amount of eosinophilic cytoplasm and a round to oval hyperchromatic nucleus. Nucleoli may be seen and are generally eccentrically located. The cells may have a prominent plasmacytoid appearance, particularly evident in the more solid areas of growth but also in the cells forming the glandular structures (**Figure 4; see colour plate section**). A paranuclear clear zone is not present. Often, adjacent to or intimately admixed with the

glands is a more solid or sheet-like growth of similar-appearing neoplastic cells. The cells may have a more dispersed or stippled nuclear chromatin with the 'salt and pepper' pattern suggestive of neuroendocrine differentiation. Cellular pleomorphism may be prominent but mitoses are uncommon. The stromal component is sparse and may appear fibrous or myxoid.

Histochemical stains show the presence of intraluminal but not intracytoplasmic mucin-positive material. Periodic acid Schiff (PAS)-positive material is not present. By immunohistohemical evaluation, the neoplastic cells are cytokeratin positive but are not reactive with chromogranin, synaptophysin, S-100 protein, desmin, actin or vimentin. Some MEA may have immunoreactivity with one or more neuroendocrine markers, including chromogranin and synaptophysin. These MEA with neuroendocrine differentiation have been termed carcinoid tumours of the middle ear (Latif *et al.*, 1987; Stanley *et al.*, 1987; Manni *et al*., 1992). However, these 'carcinoid tumours' are better viewed as part of the histologic spectrum of MEA (El Naggar *et al*., 1994), albeit one with neuroendocrine differentiation, rather than representing a distinct middle ear neoplasm separate from MEA.

MEA should be differentiated from glandular metaplasia that may occur in the setting of chronic otitis media (COM). These metaplastic glands may be misdiagnosed as neoplastic. In contrast to MEA, the glandular proliferation in COM is focal or haphazardly arrayed and occurs in the presence of histological features of COM, including chronic inflammation with fibrosis and calcifications (tympanosclerosis). MEA may perforate the tympanic membrane and appear to represent a neoplasm of the external auditory canal, such as a ceruminal gland adenoma. The histological features of these two tumour types are distinctly different and should allow for easy distinction. In contrast to the rare middle ear adenocarcinoma, MEA lack marked cellular pleomorphism, increased mitotic activity, necrosis or invasion of bone and other soft tissue structures.

The treatment for all MEA is complete surgical excision. Surgery may be conservative if the lesion is small and confined to the middle ear or more radical (mastoidectomy) for larger lesions associated with more extensive structural involvement. Recurrent tumour may occur and is a function of inadequate excision. Some MEA may be locally aggressive and rarely may invade vital structures causing death, but metastatic disease does not occur. In general, the clinical, radiological and pathological findings are indicative of a benign tumour. Nevertheless, the histological appearance is not always predictive of the clinical behaviour.

Jugulotympanic Paragangliomas (JTP)

JTP are benign neoplasms that arise from the extraadrenal neural crest-derived paraganglia specifically located in the middle ear or temporal bone region. Synonyms include glomus jugulare tumour and glomus tympanicum tumour. JTP are considered the most common tumour of the middle ear (Hyams *et al*., 1988b). JTP affect women more often than men and are most common in the fifth to seventh decades of life. The majority (85%) of the JTP arise in the jugular bulb resulting in a mass lesion in the middle ear or external auditory canal (Hyams *et al*., 1988b). Approximately 12% take origin from Jacobson's nerve (tympanic branch of the glossopharyngeal nerve) and present as a middle ear tumour (Hyams *et al*., 1988b). Approximately 3% arise from Arnold's nerve (posterior auricular branch of the vagus nerve) and arise in the external auditory canal (Hyams *et al*., 1988b). The most common symptom is conductive hearing loss. Other symptoms include tinnitus, fullness, otic discharge, pain, haemorrhage, facial nerve abnormalities and vertigo. JTP are often locally invasive neoplasms with extension into and destruction of adjacent structures including the temporal bone and mastoid. CT scan will show a soft tissue mass often with evidence of extensive destruction of adjacent structures. JGP are vascularized lesions that are fed by branches of nearby large arteries.

The gross appearance of JTP include a polypoid, red, friable mass identified behind an intact tympanic membrane or within the external auditory canal, measuring from a few millimetres to a large mass completely filling the middle ear space. Irrespective of the site of origin, the histological appearance of all extra-adrenal paragangliomas is the same. The hallmark histological feature is the presence of a cell nest or 'zellballen' pattern (**Figure 5; see colour plate section**). The stroma surrounding and separating the nests is composed of prominent fibrovascular tissue. While this pattern is characteristic of paragangliomas it is not unique to paragangliomas and can be seen in other tumours, including neuroendocrine carcinomas (carcinoid and atypical carcinoid tumours), melanomas and carcinomas. Paragangliomas are predominantly composed of chief cells which are round or oval cells with uniform nuclei, dispersed chromatin pattern and abundant eosinophilic, granular or vacuolated cytoplasm. The sustentacular cells, represent modified Schwann cells, are located at the periphery of the cell nests as spindle-shaped, basophilic appearing cells but are difficult to identify by light microscopy. Cellular and nuclear pleomorphism can be seen but these features are not indicative of malignancy. Mitoses and necrosis are infrequently identified. Paragangliomas lack glandular or alveolar differentiation.

Paragangliomas are often readily identified by light microscopic evaluation. However, in certain instances paragangliomas may be difficult to differentiate from other tumours that have similar histomorphological features. Not infrequently, middle ear and temporal paragangliomas do not show the characteristic cell nest appearance that occurs in other sites. This 'loss' of the organoid growth may be

artifactually induced by surgical manipulation ('squeezing') of the tissue during removal. The absence of the typical growth pattern may result in diagnostic confusion with other middle ear tumours.

Histochemical stains may be of assistance in the diagnosis of paragangliomas. Reticulin staining may better delineate the cell nest growth pattern with staining of the fibrovascular cores surrounding the neoplastic nests. In addition, the tumour cells are argyrophilic (Churukian–Schenk). Argentaffin (Fontana), mucicarmine and PAS stains are negative. The diagnosis of JTP is facilitated by immunohistochemical stains. The immunohistochemical antigenic profile of paragangliomas includes chromogranin and synaptophysin positivity in the chief cells and S-100 protein staining localized to the peripheral located sustentacular cells. Vimentin is variably reactive in both the chief cells and sustentacular cells. In general, epithelial markers, including cytokeratin, and also HMB-45 and mesenchymal markers (desmin and other markers of myogenic differentiation), are negative. Ultrastructural evaluation shows the presence of neurosecretory granules (Kliewer *et al*., 1989). DNA ploidy studies by image analysis are not predictive of the behaviour of paragangliomas (Barnes and Taylor, 1990).

Complete surgical excision is the treatment of choice, but the location and invasive nature of these lesions often preclude the ability to resect JTP completely. In such cases, radiotherapy is a useful adjunct to surgery. Radiotherapy results in a decrease or ablation of vascularity and promotes fibrosis. Preoperative embolization is useful in decreasing the vascularity of the tumour and facilitating surgical resection. Local recurrence of the tumour can be seen in as high as 50% of the cases. The histological appearance of paragangliomas does not correlate with the biological behaviour of the tumour. JTP are slow-growing tumours but may be locally invasive with extension into and destruction of adjacent structures, including the temporal bone and mastoid (Larson *et al*., 1987). Intracranial extension may occur in up to 15% of cases (Spector *et al*., 1975). Neurological abnormalities, including cranial nerve palsies, cerebellar dysfunction, dysphagia and hoarseness, may be seen and correlate with the invasive capabilities of this neoplasm. Functioning JTP as evidenced by endocrinopathic manifestations occur, but are extremely uncommon. Malignant JTP occur, are associated with histological criteria of malignancy, including increased mitotic activity, necrosis usually seen within the centre of the cell nests and vascular invasion, and may metastasize to cervical lymph nodes, lungs and liver.

Acoustic Neuroma (AN)

AN is a benign neoplasm that originates from Schwann cells specifically from the VIIIth cranial nerve. Synonyms include neurilemmoma, acoustic Schwannoma and benign peripheral nerve sheath tumour. AN accounts for up to 10% of all intracranial neoplasms and represent up to 90% of all cerebellopontine angle tumours (Hyams *et al*., 1988b). AN are more common in women than in men and may affect any age but are most common in the fourth to seventh decades of life. The majority of AN involve the superior or vestibular portion of the VIIIth nerve as compared with involvement of the cochlear portion of the VIIIth nerve. Symptoms include progressive (sensorineural) hearing loss, tinnitus and loss of equilibrium; with progression the tumour enlarges and may compress adjacent cranial nerves (V, VII, IX, X, XI), the cerebellum and the brainstem leading to facial paraesthesia and numbness, headaches, nausea, vomiting, diplopia and ataxia. Up to 8% of ANs may be bilateral (Erickson *et al*., 1965; Kasantikul *et al*., 1980; Martuza and Ojemann, 1982; Anand *et al*., 1993; Moffat and Irving, 1995). Bilaterality of ANs may represent a potential indicator of neurofibromatosis type 2 (Moffat and Irving, 1995; Rietz *et al*., 1983). Symptoms of neurofibromatosis may be seen in up to 16% of patients and those with neurofibromatosis who develop AN generally are symptomatic at an earlier age (second decade). The radiological appearance of AN include flaring, asymmetric widening or erosion of the internal auditory canal by CT or MRI. Tumours as small as 1 cm or less are capable of being detected by CT or MRI analysis.

The gross appearance of AN includes a circumscribed, tan–white, rubbery to firm mass which may appear yellow and have cystic change. Tumour sizes range from a few millimetres up to 4—5 cm in greatest diameter. Histologically, the tumours are unencapsulated and similar in appearance to benign Schwannomas of all other locations (**Figure 6; see colour plate section**). The cellular component includes elongated and twisted nuclei with indistinct cytoplasmic borders. The cells are arranged in short, interlacing fascicles and whorling or palisading of nuclei may be seen. Nuclear palisading with nuclear alignment in rows called Verocay bodies can be seen. The cellularity may vary and some benign Schwannomas can be very cellular (so-called cellular Schwannoma). Mitoses are usually sparse in number, and cellular pleomorphism with hyperchromasia can be identified but are not features of malignancy. Retrogressive changes, including cystic degeneration, necrosis, hyalinization, calcification and haemorrhage may be seen. Schwannomas have prominent vascularity composed of large vessels with thickened (hyalinized) walls.

Immunohistochemistry shows the presence of diffuse and intense S-100 protein reactivity. There is no immunoreactivity with cytokeratin or the neuroendocrine markers chromogranin and synaptophysin.

Complete surgical excision is the treatment of choice. Complete removal usually is curative. AN may result in death secondary to herniation of the brainstem in untreated and/or large neoplasms. Malignant AN are exceedingly rare and, if present, neurofibromatosis should be suspected.

Meningiomas

Meningiomas are benign neoplasms arising from arachnoid cells forming the arachnoid villi seen in relation to the dural sinuses. Meningiomas represent 13–18% of all intracranial tumours and are the second most common tumour to AN of the cerebellopontine angle (Hyams *et al.*, 1988b). Meningiomas are more common in women than in men and are most commonly seen in the fifth decade of life. Meningiomas infrequently occur in children. The occurrence of a meningioma outside the central nervous system is considered ectopic and can be divided into those meningiomas with no identifiable CNS connection (primary) and those with CNS connection (secondary). The development of primary meningiomas in the middle ear and temporal bone results either from direct extension or from the presence of arachnoid cells ectopically located. The most common sites of occurrence of the 'ectopically' located meningiomas is the head and neck region, specifically the middle ear and temporal bone, including the internal auditory canal, jugular foramen, geniculate ganglion, roof of the eustachian tube and sulcus of the greater petrosal nerve (Hyams *et al.*, 1988b). The clinical presentation of middle ear meningiomas includes progressive hearing loss, loss of equilibrium, headaches, cerebellar dysfunction and cranial nerve abnormalities. Patients with neurofibromatosis have an increased incidence of developing a meningioma. In addition, patients with neurofibromatosis also experience increased incidence of multiple, separate occurring meningiomas in intra- and extracranial sites. Radiological findings include a soft tissue mass with variable vascularity. A pathognomonic feature for meningioma in this location is the presence of speckled calcification in a soft tissue mass.

The histological features of middle ear and temporal bone meningioma are similar to those of their intracranial counterparts (**Figure 7; see colour plate section**). The immunohistochemical antigenic profile of meningiomas includes reactivity with epithelial membrane antigen (EMA) and vimentin. In contrast to middle ear adenomas, meningiomas are generally nonreactive with cytokeratin, and in contrast to jugulotympanic paragangliomas, meningiomas are nonreactive with neuroendocrine markers (e.g. chromogranin and synaptophysin).

Complete surgical excision is the treatment of choice and is curative. Local recurrence relates to inadequate excision. Malignant change rarely, if ever, occurs. A diagnosis of middle ear meningioma should be made only after clinical evaluation is made to exclude secondary extension from an intracranial neoplasm (Rietz *et al.*, 1983).

Endolymphatic Sac Papillary Tumour

The endolymphatic sac papillary tumour (ESPT) is an uncommon but distinct neoplasm possibly representing a manifestation of von Hippel–Lindau (VHL) syndrome (Megerian *et al.*, 1995; Manski *et al.*, 1997). ESPT has been referred to by a variety of names, including adenoma of endolymphatic sac, adenoma/adenocarcinoma of temporal bone or mastoid, low-grade adenocarcinoma of probable endolymphatic sac origin, papillary adenoma of temporal bone, aggressive papillary tumour of temporal bone, aggressive papillary middle ear tumour and, more recently, as the Heffner tumour (Batsakis and El-Naggar, 1993; Wenig and Heffner, 1996). An endolymphatic sac origin for these tumours is supported by a combination of findings, including the early clinical manifestations of vestibular disease (e.g. sensorineural hearing loss, tinnitus and episodic vertigo), radiographic features showing the tumour to grow in the region site where the endolymphatic sac is located (i.e. posterior–medial petrous ridge), intraoperative identification of an *in situ* tumour originating from within the endolymphatic sac and morphological similarities and shared immunohistochemical and ultrastructural features of the tumour with the normal endolymphatic sac epithelium (Wenig and Heffner, 1996). The diagnosis of this tumour is based on clinical, radiographic and pathological correlation. A diagnosis of ESPT should prompt the clinician to exclude the possibility that the patient has VHL syndrome (Megerian *et al.*, 1995; Manski *et al.*, 1997).

The histopathological appearance of ESPT is variable. ESPTs are papillary and focally cystic tumours. The papillary structures are generally not complex in their growth. The neoplastic cells vary in appearance from flattened or attenuated appearing cells to columnar appearing cells (**Figure 8; see colour plate section**). Most often there is only a single row of cells. Occasionally, the surface epithelial cells may have the appearance suggesting a double layer of cells (epithelial and myoepithelial); however, the 'outer' row of cells, in all probability, represent a stromal element as they have not been shown to be immunoreactive with epithelial markers (Heffner, 1989). The epithelial cells have uniform nuclei that are usually situated either in the centre of the cells or toward the luminal aspect, and have a pale eosinophilic to clear appearing cytoplasm. The latter may predominate in any given tumour. Cell borders may be seen but, not infrequently, the neoplastic cells lack a distinct cell membrane. In some cases, there are hypercellular areas with crowded, variably sized cystic glandular spaces that contain eosinophilic (colloid-like) material (**Figure 9; see colour plate section**). The latter appear remarkably similar to thyroid tissue. In all cases, pleomorphism is minimal, and mitotic activity and necrosis are rarely present.

A granulation tissue reaction is seen in association with the neoplastic cells and includes small vascular spaces lying in close proximity to the surface epithelium and/or within the stroma of the papillary fronds. Owing to the absence of a distinct cell membrane around the neoplastic cells, a sharp demarcation separating the neoplastic cells from the subjacent granulation tissue is not present. This appearance may create diagnostic confusion so that the

neoplastic proliferation is not appreciated, and the entire process is viewed as reactive. This interpretation is further enhanced by the presence in the stroma of a mixed inflammatory cell infiltrate, fibrosis, vascular proliferation, fresh haemorrhage and/or haemosiderin (within the neoplastic cells or within macrophages), cholesterol granulomas and dystrophic calcification. The latter does not include laminated calcific concretions (psammomatoid bodies).

Intracytoplasmic diastase-sensitive, PAS-positive material can be seen. The colloid-like luminal material stains strongly with PAS reagent with and without diastase digestion. Intracytoplasmic and intraluminal mucin staining is rarely positive. Iron stains are positive. ESPTs are diffusely cytokeratin positive and also show variable reactivity with epithelial membrane antigen (EMA), S-100 protein, vimentin, neuron-specific enolase (NSE), glial fibrillary acidic protein (GFAP), Ber-EP4, synaptophysin and Leu-7. Thyroglobulin immunoreactivity is not seen. Ultrastructurally, ESPT shows the presence of intercellular junctional complexes, microvilli, basement membrane material, rough endoplasmic reticulum and intracytoplasmic glycogen and secretory granules (Heffner, 1989).

The differential diagnosis includes middle ear adenoma. However, the clinical, radiographic and pathological features that are unique to ESPT should allow for its distinction from middle ear adenoma. The same would apply for the other common neoplasms of the middle ear and temporal bone. The differential diagnosis also includes choroid plexus papilloma and metastatic carcinoma of thyroid gland or renal origin. Choroid plexus papillomas are intracranial (i.e. intraventricular) tumours with histological features different from those of ESPT (Wenig and Heffner, 1996). The absence of thyroglobulin reactivity would differentiate ESPT from metastatic thyroid papillary carcinoma. Metastatic renal cell carcinoma would not have the immunohistochemical antigenic features seen in ESPT.

Radical surgery, including mastoidectomy and temporal bone resection that may necessitate sacrifice of cranial nerves, is the treatment of choice, and is potentially curative. Local recurrence will result following inadequate surgical removal; operative morbidity may be high. Despite their relatively slow growth, these neoplasms are capable of widespread infiltration and destruction, and may be lethal (Heffner, 1989). The prognosis is dependent on the extent of disease and the adequacy of resection. Earlier detection when the tumours are relatively small and confined may decrease the operative-associated morbidity and be curative.

Malignant Neoplasms of the Middle Ear

Primary malignant neoplasms of the middle ear are extremely rare. **Table 1** lists some of these malignant neoplasms. The discussion of malignant neoplasms of the middle ear will be limited to epithelial malignancies, including squamous cell carcinoma and adenocarcinoma, and a brief discussion on rhabdomyosarcoma of this region.

Middle Ear Squamous Cell Carcinoma (ME-SCC)

Primary malignant neoplasms with squamous differentiation originating from the middle ear mucosal epithelium are rare (Kenyon *et al*., 1985; Hyams *et al*., 1988c). ME-SCC is most common in the sixth and seventh decades of life. The majority of patients have a long history of chronic otitis media usually greater than 20 years in duration. The development of ME-SCC is also linked to radiation treatment for intracranial neoplasms and, although no longer used, radiotherapy for middle ear inflammatory conditions. Concomitant cholesteatomas can be seen in up to 25% of cases but there is no correlation between cholesteatomas and the development of a middle ear squamous cell carcinoma (Hyams *et al*., 1988c). ME-SCC should be suspected in patients with a long-standing chronic otitis media who present with sudden onset of pain out of proportion to the clinical extent of disease, onset or increase of otorrhea which is often haemorrhagic and/or a lack of clinical resolution following therapeutic doses of antibiotics.

The histology of ME-SCC is similar to that of squamous carcinomas of other sites. The tumours vary from well to poorly differentiated and include infiltrative malignant cells with associated keratinization and/or intercellular bridges.

The differential diagnosis includes a cholesteatoma and metastatic squamous cell carcinoma. Cholesteatomas do not have the dysplastic cytological changes seen in squamous carcinoma. Secondary involvement of this area by squamous cell carcinoma may originate from a distant site and metastasize to the middle ear and temporal bone. Alternatively, a cutaneous squamous cell carcinoma from an adjacent site (external ear, nasopharynx, parotid gland or skin) can directly invade into the middle ear or temporal bone. Detailed clinical history or physical examination would assist in identifying a squamous carcinoma that is metastatic to this site or extends to the middle ear from an adjacent primary tumour.

Radical surgery with radiotherapy is the treatment of choice. In advanced disease, chemotherapy may be of benefit. Prognosis is poor with 5- and 10-year survival rates of 39% and 21%, respectively (Hyams *et al*., 1988c). Metastases may occur but are considered uncommon.

Middle Ear Adenocarcinoma

Middle ear adenocarcinoma is a malignant glandular neoplasm arising from the middle ear mucosa. Middle ear adenocarcinomas are rare (Hyams *et al*., 1988d). In the presence of a malignant glandular neoplasm of the middle

ear and temporal bone, secondary metastasis to this region should be excluded. Middle ear adenocarcinomas may attain large sizes, filling the middle ear space and encasing the ossicles. Symptoms are typically present for many years and include progressive hearing loss and a unilateral draining ear; pain and vestibular manifestations are uncommon. Otoscopic examination in the majority of cases will identify an intact tympanic membrane with tumour confined to the middle ear space with possible extension to the mastoid. Occasionally, the adenocarcinoma will perforate through the tympanic membrane with extension into and presentation as an external auditory canal mass. There is no known association between chronic otitis media and the development of these adenocarcinomas.

Histologically, middle ear adenocarcinomas are in many respects similar to adenomas. In contrast to adenomas, adenocarcinomas have increased cellular pleomorphism, increased mitotic activity and extensive infiltration of surrounding soft tissue structures involving nerves, lymph-vascular spaces and bone.

Complete surgical excision is the treatment of choice. In general, these are slow-growing neoplasms that are locally aggressive but do not metastasize. Death may occur as a result of direct intracranial extension. Confinement to the middle ear space and association with the middle ear mucosa are supportive evidence of origin from the middle ear; nevertheless, metastatic adenocarcinoma from a separate site must be excluded prior to treatment.

Rhabdomyosarcoma (RMS)

In the head and neck, RMS is primarily but not exclusively a disease of the paediatric population. In children and adolescents, RMS represents the most common aural-related malignant neoplasm. There is no gender predilection. RMS of the middle ear and mastoid presents as painless unilateral otitis media unresponsive to antibiotic therapy. According to the WHO classification, RMS is divided into six histological subtypes, including embryonal, botryoid, spindle cell, alveolar, pleomorphic and RMS with ganglionic differentiation (so-called ectomesenchymoma) (Weiss, 1995). The International classification of RMS proposed four groups based on prognosis: I, superior prognosis (botryoid RMS and spindle cell RMS); II, intermediate prognosis (embryonal RMS); III, poor prognosis (alveolar RMS and undifferentiated RMS); and IV, subtypes whose prognosis is not presently evaluable (RMS with rhabdoid features) (Newton *et al*., 1995).

The majority of RMS of the middle ear and mastoid are of the embryonal type that includes botryoid RMS. The next most common histological type is alveolar RMS. The other histological types may occur in the head and neck but are considered uncommon. RMS of the middle ear and mastoid most often appears as an aural (external or middle ear) polypoid lesion similar in appearance to an aural polyp.

RMS is treated by a combination of surgery, radiation and chemotherapy. This combined therapeutic approach has greatly enhanced survival with an overall 5-year survival of 74% for paediatric head and neck RMS (Kraus *et al*., 1997). A problem with middle ear and mastoid RMS is the delay in diagnosis due to misinterpretation of the biopsy specimen as inflammatory polyps or as granulation tissue. This delay in diagnosis may result in more advanced stage disease, placing patients at greater risk of treatment failure owing to uncontrollable local disease. Poor prognostic findings include meningeal involvement (Raney *et al*., 1987). Regional lymph node metastasis and distant haematogenous metastasis to the lungs and bones may also occur.

Secondary Tumours

Metastatic tumours secondarily involving the middle ear and temporal bone originate from virtually every site. The more common malignant tumours to metastasize to this region originate from the breast, lungs and kidneys (Hill and Kohut, 1976; Schuknecht, 1993b). Other tumours that may metastasize to this region include malignant melanoma and prostatic adenocarcinoma. While metastases to the temporal bone often occur late in the disease course, metastatic involvement of the temporal bone may represent the initial presentation of a distant malignant disease. Metastatic disease to the temporal bone occurs via haematogenous spread but may also occur by direct extension from a nearby primary tumour (e.g. squamous cell carcinoma), meningeal carcinomatosis or leptomeningeal extension from an intracranial primary neoplasm (Berlinger *et al*., 1980).

CONTENTS

- Introduction to Cancer Models
- The Use of Breast Cancer Models to Study Tumour Progression
- Oncogenes and Suppressor Genes in Tumour Progression
- Host Surveillance Mechanisms and Tumour Progression
- Cancer Progression and Breast Cancer Gene Expression
- Intercellular Communication and Tumour Cell Diversification
- Cancer Progression and Cellular Diversification

INTRODUCTION TO CANCER MODELS

Since the beginning of studies on the pathogenesis of various cancers, it was recognized that little progress would be made in understanding the molecular and genetic events that define the precancerous states, the inception of cancers, sometimes called transformation, and its further progression to invasive and metastatic phenotypes, unless these events could be duplicated in some reproducible way. Thus the need for cancer models was born. There are many different types of cancer models, and our purpose here is not to review them. Rather, we will summarize the various scientific and medical needs for cancer models and what has been accomplished with them and use as an example some models for breast cancer. This in no way is meant to overemphasize the importance of breast cancers over other types of cancers. It simply reflects an example of an important need to understand various molecular and genetic aspects of an important class of cancers because it is a leading cause of death of women in the Western world.

Cancer models are useful for accurately and reproducibly studying a variety of pathogenic, biochemical, immunological, pharmacological, genetic and other properties of cancer cells. Although it would be useful if we all agreed on using one appropriate model system, with the use of only one model it is extremely difficult to study accurately all of the above properties. This is due to the obvious fact that cancer models are ‘models’ and not ‘real’ cancers obtained directly from cancer patients. As such, they are only approximations of reality, and they should not be confused with the real world, although they may have been directly derived from real cancers growing in patients. In addition, certain models are particularly useful for certain types of experiments but not for others, and it is particularly difficult to find one model that can substitute for the number of models that are currently in use to study the properties of breast cancers or any other type of cancer. For hundreds of years pathologists have warned us of the diversity and heterogeneity of clinical cancers, and this diversity cannot be easily reflected in one or even a few models of clinical cancers (Nicolson and Poste, 1983).

The worth of a cancer model is reflected in how accurately and reproducibly the model is able to mimic the ‘real world,’ with the understanding that it may not accurately reflect all of the properties of the *in situ* cancer in its natural human host. In addition, one of the commonly found properties of malignant cancers is that they tend to be quite heterogeneous at the cellular level, and the known instabilities of cancers and cancer cells can result in the continuous diversification and evolution of cancers and, in particular, the cells that comprise them (Nowell, 1976; Poste, 1982; Nicolson, 1986, 1987). Fortunately, or unfortunately depending on the need for exacting reproducibility, most if not all cancer models share with legitimate clinical cancers the properties of cellular instability and diversification into heterogeneous cellular populations during growth, and this is even more apparent in malignant cancers that have progressed to the metastatic phenotype. This instability, although a critical property for any model of human cancers, is also the bane of the experimentalist.

Thus some of the most important properties of cancers, such as their abilities to undergo change, progression, diversification and evolution, are also properties that make the reproducible study of cancers and especially cancer cells so difficult (Poste, 1982; Nicolson, 1987).

Notwithstanding the problems associated with the development and use of cancer models and also the interpretation of data obtained using them, they have proved their worth over the years. In fact, we would know considerably less about the detailed biochemical and immunological and other properties of cancers if we were entirely dependent on using clinical biopsies for experimental studies. Thus cancer models have proved to be an essential element in our research programmes, and without them our knowledge of human cancers, particularly their molecular properties, would be significantly less than it is today. But even with that it should be obvious even to the casual observer that knowing the limitations of cancer models is essential, and cancer models are likely to be as heterogeneous and thus problematic in their utility and usefulness as the cancers from which they were derived (**Table 1**).

It has been said that not all cancer models are useful because they do not closely mimic all of the properties of human cancers. On the other hand, even a model that does not closely mimic human cancer can be useful for some experimental uses, particularly those that are not designed to be applied eventually to clinical use (**Table 1**). Thus it depends greatly on the use for which the model is to be employed. One model may be useful as a cellular repository of certain critical molecules or biochemical platform for certain types of experiments but not entirely useful for other purposes. Hence it depends greatly on the use of the model. The trend in recent years, however, has been to try to develop and use models that reflect as accurately as possible the *in vivo* and *in vitro* characteristics of human cancers so that the information gathered may at some later date be applied to clinical cancers. Of critical need is the use of models to develop new therapeutic approaches for treating highly malignant tumour cells (Frei, 1982).

Cancer models are especially useful for studying certain specific aspects of the individual steps of the cancer progression process, and these models for the most part are *in vitro* and animal models. For example, various models have been developed to study specific properties of cancer cells that are related to progression to the metastatic phenotype. For example, malignant cell adhesion, invasion, survival and growth have been successfully studied *in vitro* and in animal models (**Table 2**). The utility of these *in vitro* models is that detailed biochemical studies can be performed that could not be easily done with *in vivo* systems. Although such models do not exactly mimic the events that occur *in vivo* during the process of metastasis, they are extremely useful for obtaining detailed biochemical information on cellular processes that are related to cancer progression and metastasis.

Models for human cancers have proved useful in a variety of settings where comparisons are necessary. For example, we developed an animal model for breast cancer that was based on a transplantable rat mammary 13762NF adenocarcinoma (Neri *et al*., 1982). This model not only fulfills the criteria that it displays similar pathogenic properties to human breast adenocarcinomas, but it also possesses similar biochemical, immunological and enzymatic properties, cytocellular structures and other characteristics, such as dynamic heterogeneity in drug, radiation and heat sensitivities associated with tumour cell heterogeneity and instability (review: Nicolson, 1994). (See also chapter on *Mammary Tumour Induction in Animals as a Model for Human Breast Cancer*.) When cells from this adenocarcinoma model were injected into the mammary fat pads of syngeneic rats, they first metastasized regionally to axial lymph nodes and then to lungs in a relatively reproducible pattern (Neri and Nicolson, 1981). Interestingly, when the properties of metastatic clones derived from this model

Table 1 Models for cancer and cancer progression: which models are best?

1. What questions are being asked? Do these involve eventual application to the clinic?
2. Should human cancers or cancer cells be used, or will animal tumours or cells suffice?
3. If human cancers/cells are being used, are these representative of the original cancers?
4. If animal tumours/cells are being used, are they of similar histology, natural history, etc., to the human tumours/cells?
5. If animal tumours/cells are being used, do they grow and undergo progression similar to human tumours/cells?
6. If animal tumours/cells are being used, do they have similar changes in molecular genetics?
7. If the tumours/cells are to be assayed *in vivo*, is a syngeneic tumour/host system required?
8. Can human cancers/cells be assayed effectively in immune-compromised animal hosts?
9. Are counterpart normal, preneoplastic, benign or invasive/metastatic tumours/cells necessary for comparison?
10. Are counterpart tumours/cells of similar genetic background necessary for comparison?
11. Will *in vivo* or *in vitro* assays, or both, be used? Is *in vitro* growth required?
12. Are the cancer/tumour cells relatively stable during growth *in vivo* and/or *in vitro*?
13. Are the cancer or tumour cells of similar biological phenotype to the original tumour?
14. Are the cancer or tumour cells of similar biochemistry, immunology, drug sensitivity and other properties to the original tumour?
15. Is the pathogenesis of progression and metastasis similar to the original tumour?
16. Can the model be used to develop relevant new therapies that can be applied to the clinic?

Table 2 Use of models to study individual steps of the metastatic process

1. Tumour growth at a primary site
    - A. Cell cultures (single or mixed cell)
    - B. Cell aggregates (single or mixed cell)
    - C. Implantation at a primary site (animal)
2. Primary tumour invasion
    - A. Invasion of extracellular matrix
    - B. Invasion of thrombin clot
    - C. Invasion of tissue fragments
    - D. Invasion of cell aggregates
    - E. Implantation at a primary site (animal)
3. Tumour cell intravasation
    - A. Invasion of isolated blood vessel
    - B. Invasion of endothelial cell monolayer
    - C. Intravasation of blood vessels (*in vitro*)
    - D. Intravasation of blood vessels (animal)
4. Tumour cell transport
    - A. Transport in a flow cell
    - B. Transfilter migration in a Boyden chamber
    - C. Dynamic stress in a parallel plate chamber
    - D. Transport after i.v. injection (animal)
5. Tumour cell arrest
    - A. Adhesion to endothelial cells
    - B. Adhesion to endothelial cell monolayers
    - C. Adhesion to blood vessel (*in vitro*)
    - D. Arrest after i.v. injection (animal)
6. Tumour cell extravasation
    - A. Invasion of endothelial cell monolayers
    - B. Invasion of blood vessels (*in vitro*)
    - C. Invasion of blood vessels (animal)
7. Tumour cell survival
    - A. Survival in depleted medium
    - B. Survival in organ-conditioned medium
    - C. Survival in immune cell cultures
    - D. Survival after i.v. injection (animal)
8. Tumour cell growth at secondary sites
    - A. Growth in depleted medium
    - B. Growth in organ-conditioned medium
    - C. Growth in immune cell cultures
    - D. Growth after i.v. injection (animal)
    - E. Growth after injection at secondary organ site (animal)

were compared with nonmetastatic cell clones, differences in various biochemical and immunological properties were found to be similar to the molecular differences found in human breast carcinomas derived from primary and metastatic sites (Nakajima *et al*., 1987; Steck *et al*., 1987a,b). Hence this model can be used for a variety of experiments that cannot be done easily with human cancers or biopsies. Similarly, rat mammary tumour models have proved to be very useful in studying the process of development and differentiation of mammary gland tissue (Rudland *et al*., 1998). In this case the interactions of epithelial, myoepithelial and other cell types in the developmental formation of glandular structures were studied *in vitro* and *in vivo* and then related to similar events that occur in human mammary tissues.

Models for breast cancer have also been developed based on murine mammary tumour cell lines (Heppner, 1989). Using various cloned cell lines developed from the same mammary tumour clonal interactions influenced such properties as growth, drug sensitivity and malignancy (Miller and Heppner, 1990). Although these mouse models do not spread regionally before haematogenous colonization, they have other attributes that make them useful as models for breast cancer. The rat and mouse mammary tumour models show many similarities to human breast cancer cells that have been sequentially selected for invasive properties (Thompson *et al*., 1993).

Of course, not all of the properties of human and animal mammary cells will be the same, and not all properties of *in situ* tumours can be mimicked by the same tumour cells growing *in vitro*. The reasons for this are probably related to differences in the cellular compositions of tumours compared with cell populations growing *in vitro* and differences in environment that can affect many of the cellular properties of tumour and normal cells (Miller and Heppner, 1990; Rudland *et al*., 1998). (See also chapter on *Modelling Tumour–Tissue Interactions*.) Important in this consideration is when human cancer cells are grown in animals (usually in nude mice) that they are implanted into the appropriate site (orthotropic implantation) (Fidler *et al*., 1990). For breast cancer cells or tissue, this would usually be the mammary fat pads of rodents, but for other cancers arising in other tissues the tissue of origin would apply. Unfortunately, for human breast cancer cells growing in the mammary fat pads of rodents the microenvironment is not the same as in the human breast, and differences may ensue. In this brief introduction we will discuss the use of breast cancer and other models in ascertaining the critical molecular determinants of various steps of the metastatic process and some of the general properties of malignant breast tumours.

THE USE OF BREAST CANCER MODELS TO STUDY TUMOUR PROGRESSION

There are many important questions in cancer research that can best be answered with the use of tumour models. One of most important is explaining the process of tumour progression or the tendency of tumours to undergo gradual change to more malignant phenotypes, and the use of cancer models to study this process will be summarized. Tumour progression is characterized by specific genetic changes, and these can be studied using animal tumour models that undergo progression. The accumulation of rare qualitative genetic changes is thought to drive tumour progression (Nowell, 1976; Nicolson, 1986, 1991; Moustafa and Nicolson, 1998). These changes include but are not exclusive to DNA sequence alterations, such as gene amplifications, mutations, deletions, translocations and other changes. The accumulation of genetic changes or alterations

may initiate important events that eventually lead to tumour progression, but it is likely that other events are also involved that do not depend on genomic DNA sequence changes (Nicolson, 1986, 1991; Moustafa and Nicolson, 1998). One of the uses of cancer models is to be able to determine the importance of specific genetic events in transformation and progression by replicating these events in an experimental setting. In addition, once candidate genes have been identified, their role in the pathogenesis of cancer can be confirmed using transgenic and gene knockout mice to model the changes associated with specific genes (review: Viney, 1995). (See also chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*.)

The progression of breast cells to the malignant phenotype is mainly typified by quantitative changes in gene expression rather than many qualitative changes (mutations, translocations, truncations, etc.) in gene structures, although the latter changes are known to occur with progression (Nicolson, 1991; Moustafa and Nicolson, 1998). In breast cancer models such qualitative changes have also been documented, especially in genes associated with hereditary breast cancer, such as *BRCA-1* and *BRCA-2* (Lynch *et al*., 1998). Using breast cancer models, parallel studies can be used to examine the role of multiple qualitative cytogenetic and genetic changes and determine if they are important in the process of transformation and progression (Pearce *et al*., 1984).

Qualitative genomic modifications may occur only rarely in tumours, and the rates of appearance of qualitative alterations may vary widely among different tumours. Hence it is important to determine if there are (multiple) critical changes in specific genes that must occur in order for transformation and progression to occur. If qualitative genomic changes are critical to tumour transformation, progression and clonal dominance, then it is likely that the most successful cells in a tumour that have these changes will overgrow the other cells and eventually almost all of the tumour cells within a tumour would display similar genomic modifications (Nowell, 1976). Probably not all genes that undergo change are important in the process of tumour progression, and the types of genes that are most likely to be important have been found to be the genes that encode oncogenes, suppressor genes, differentiation genes and genes associated with growth, invasion, survival and metastasis (Nicolson, 1991; Moustafa and Nicolson, 1998). These are also the genes that are likely to also be changed in their expression (Volpe, 1988; Moustafa and Nicolson, 1998). Often important qualitative changes that are associated with early states of oncogenesis, such as cellular transformation and tumour initiation, are not the same changes that are associated with progression to more malignant states (Nicolson, 1986, 1991; Volpe, 1988; Moustafa and Nicolson, 1998).

The changes in gene expression and gene structure that occur in breast cancer cells as they progress are not the only important events that typify tumour progression. There are also signals from the host tissue microenvironment (cells, extracellular matrix, soluble glyoproteins and other signals) that are important in this process (Nicolson, 1986; 1991; Volpe, 1988; Moustafa and Nicolson, 1998). These signals provide tumours with soluble and insoluble mediators that can modulate tumour cell properties and responses to host tissue, cell and extracellular matrix signals (Bissell and Barcellos-Hoff, 1987). In some tissues, such as breast eipthelium, there are also unique regulators, such as the ionic and metabolic signals that are presented to adjacent cells, either at their surfaces or through junctional communication in epithelium. There are both external and cellular signals that elicit both positive and negative signals that usually control the normal aspects of epithelial tissue differentiation, proliferation and death, and these are important in tumour progression and growth (Nicolson, 1989, 1993; Trosko *et al*., 1993).

As tumours progress, particularly breast and mammary tumours (Foulds, 1975), they are thought to be less responsive to host microenvironments and cellular controls. The end result of this is that they eventually gain autonomy from cell and tissue regulation as they progress to the late or end stages of their life histories (Nicolson, 1986, 1987, 1993). An important property of malignant tumours is their ability to undergo cellular diversification into heterogeneous phenotypes. Heterogeneity in cellular properties is found in virtually all malignant tumour cell populations, but in highly malignant tumours, such as invasive breast carcinomas, it is usually more pronounced than that found in the cells of benign or normal breast tissues. In normal tissues intercellular, cellular and matrix interactions probably combine to stabilize cellular phenotypes into more narrow states of diversity than seen in isolated single cells or tumour cells derived from the same tissue (Nicolson, 1986, 1987, 1993). Once normal cells have been removed from their normal interactions, they show increased diversity in their cellular properties (Rubin, 1990). Such diversity may be due to adoptive changes that individually affect each cell and result in individual quantitative differences in gene expression. In malignant cell populations diversification occurs irrespective of or at least less dependent on the host microenvironment. Eventually, heterogeneous cellular phenotypes arise that are less regulated by normal host cell, matrix and other interactions (Nicolson, 1987, 1993).

In mammary as in other tumour cell populations, single cells or a few cells undergo diversification to more heterogeneous phenotypes, and as this happens these cell populations also face host immune and nonimmune selection pressures. Eventually differences in cellular responses to host mediators, growth stimulators or inhibitors allow certain subpopulations to become dominant in the tumour cell population, or by active processes, such as immune or nonimmune host responses, certain subpopulations arise in the population to become the predominant cellular type (Nowell, 1976; Nicolson, 1987, 1991; Kerbel *et al*., 1988;

Frost and Chernajovsky, 1990). This can result in multiple cycles of diversification and subsequent host selection of tumour cells until dominant malignant cell subpopulations emerge that display highly malignant and autonomous phenotypes. Thus tumour progression probably results in waves of cellular diversification and then restriction of diversity (clonal dominance) (Kerbel *et al*., 1988; Nicolson, 1991) until malignant cell subpopulations become dominant that contain the essential properties to be highly self-sufficient and malignant (**Figure 1**).

The malignant cell progression process, although ominous, is not abnormal. It is probably a normal adaptive process that is important in homeostasis. This may explain why malignant cell characteristics are not restricted to cancer cells. In normal tissues there are some highly motile, invasive normal cells, usually embryonic in origin, that are capable of autonomous survival and growth in different tissues (Armstrong, 1984). In normal adult tissues, moreover, there is evidence that injury can initiate the events necessary for converting sessile, quiescent cells into motile, invasive cells capable of autonomous cellular division, e.g. during angiogenesis or the development of a new vascular system to feed the injured tissue (Folkman and Shing, 1992).

ONCOGENES AND SUPPRESSOR GENES IN TUMOUR PROGRESSION

Qualitative changes in certain oncogenes and suppressor genes are often found in mammary and other tumours. For example, in breast and colorectal cancers the accumulation of multiple, different qualitative genetic changes in oncogenes and suppressor genes typifies cancer progression (Fearon and Vogelstein, 1990), but the range of genetic alterations found in each state suggests that other changes, among them quantitative differences in gene expression, may also be important. This is especially apparent in the most progressed malignant states (Moustafa and Nicolson, 1998). Oncogenes encode proteins that function

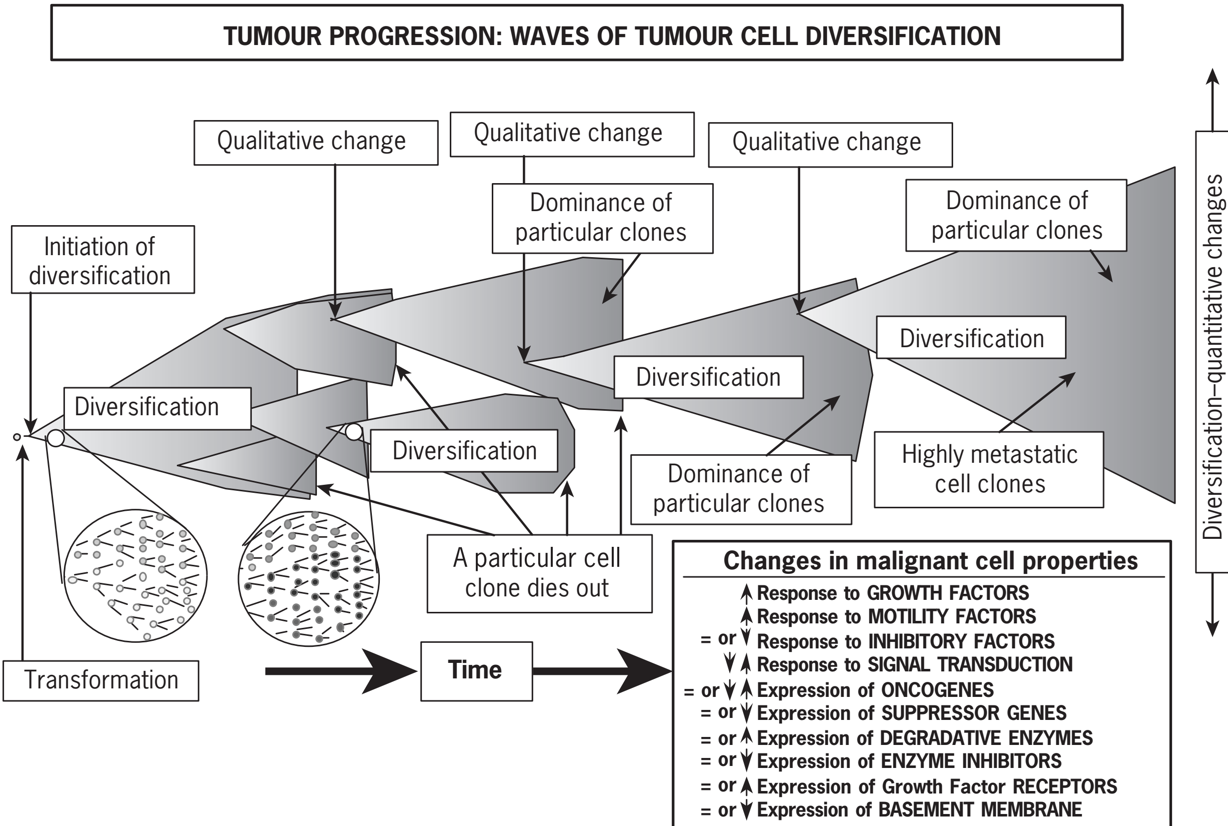

Figure 1 Example of how qualitative alterations in gene sequence and quantitative changes in gene expression could be related to tumour cell diversification and progression. In this diagram a single cell is transformed, proliferates and the progeny undergoes diversification due to quantitative changes in gene expression. As the tumour cells diversify, particular cell clones begin to dominate the cell population owing to growth advantages and host selection. At some point in time in one cell clone a qualitative change in a gene occurs that gives this clone an advantage over other clones in the population, and it proliferates and diversifies until clonal dominance again occurs. After several cycles of qualitative genetic changes, proliferation, and extensive quantitative changes in gene expression that drive diversification, a tumour cell subpopulation has progressed to a highly malignant state. (From Moustafa and Nicolson, 1998, *Oncology Research*, **9**, 505–525.)

abnormally, inappropriately or at improper concentrations, resulting in the circumvention of the normal cellular controls that regulate cellular proliferation and the state of differentiation (Klein and Klein, 1986; Nicolson, 1987). Although qualitative changes in oncogenes have been found in transformed cells, a more common finding is a change in oncogene expression due to chromosome translocations, gene amplifications and other changes, particularly in breast cancer (Yokota *et al*., 1986). Such single events by themselves are unlikely to be the underlying cause of neoplastic transformation, because further cellular changes are usually necessary.

Specific changes in oncogenes are often important in tumour progression. For example, oncogene amplification is an important mechanism (Gitelman *et al*., 1987). Although amplification of oncogenes has frequently been seen in various cancers, it is not universally seen in all tumours (Yokota *et al*., 1986). Oncogene amplification may be indicative of other, unrecognized genetic changes, or the amplification of oncogenes and other genes could contribute more directly to cancer progression (Nicolson, 1991; Moustafa and Nicolson, 1998). Since the expression of oncogenes can differ between primary breast cancers and their metastases, oncogene expression has been proposed to be important in breast tumour progression. However, examination of a variety of primary and secondary tumours reveals that oncogenes can be overexpressed, underexpressed or equally expressed in metastases compared with primary tumours (Yokota *et al*., 1986; Nicolson, 1987). Hence, the qualitative changes seen in oncogenes or the quantitative changes in their expression may contribute to progression, but they are unlikely to be the universal determinants.

Although oncogenes are important in tumour progression, the data are not convincing in support of a universal causative role for oncogenes in the progression of breast and other tumours to the metastatic state. In most studies metastases were compared with advanced primary tumours that may have already undergone all of the changes necessary to become metastatic (Yokota *et al*., 1986; Nicolson, 1987). Experimentally, the insertion of dominantly acting oncogenes into a suitable recipient cell can result in acquisition of the metastatic phenotype (Kerbel *et al*., 1987; Nicolson *et al*., 1990; Tuck *et al*., 1990). Often such experiments have been performed using aneuploid, unstable, easily spontaneously transformable animal cells as recipients, like unstable mouse fibroblast cell lines. In some untransformed cells conversion to the metastatic state only occurred when two different dominantly acting oncogenes were simultaneously inserted, an event rarely seen in spontaneous tumours. These rapid qualitative changes are unlike the slow, sequential changes that characterize spontaneous transformation and tumour progression to the metastatic state *in vivo*.

Some normal cells or even benign tumour cells are highly resistant to oncogene-mediated conversion to the metastatic phenotype (Kerbel *et al*., 1987; Nicolson *et al*., 1990; Tuck *et al*., 1990). Even within the same cell type there appears to be heterogeneity in the ability of dominantly acting activated oncogenes to cause metastatic conversion. For example, in rat mammary cells there was a considerable difference in the ability of an activated ras oncogene to convert benign cells to the metastatic phenotype (Muschel and Liotta, 1988; Nicolson *et al*., 1990). Moreover, in some systems the gene transfer techniques themselves may be as important as the transferred gene in causing metastatic conversion (Kerbel *et al*., 1987; Nicolson *et al*., 1990). (See also chapter on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*.) Often multiple gene copies are inserted, and the effects of their accompanying strong promoter/enhancer elements are not considered. It is usually assumed that oncogene constructs are randomly incorporated into the genome, but just the opposite is likely to be the case. In addition, non-random cytogenetic changes may occur concomitant with gene transfer (Muschel and McKenna, 1989). Hence it is difficult to conclude from experimental studies that the insertion of an oncogene is the only event required for conversion of benign cells to the invasive, metastatic state. In some cases oncogene-mediated conversion of a cell to the invasive, metastatic state may be dependent on the resulting concentration of an oncogene-encoded product (Muschel and Liotta, 1988; Greenberg *et al*., 1989); however, there was no obvious correlation between the expression level of an oncogene-encoded product and metastatic conversion in mammary cells (Nicolson *et al*., 1990). In addition to oncogene insertion and expression, other changes are probably necessary. Some of these changes may involve other oncogenes, suppressor genes, chromosomal structural alterations, and eventually cellular diversification.

Suppressor genes can affect mammary tumour progression and malignancy (Muschel and McKenna, 1989; Sobel, 1990). Metastasis suppressor genes were originally identified on the basis of cell fusion experiments that resulted in suppression of metastatic properties (Sidebottom and Clark, 1983). By examining differences in gene expression in nonmetastatic and metastatic cell lines, several candidate metastasis suppressor genes were identified and eventually isolated (Sobel, 1990). The best known of these in breast cancer is the *nm23* gene family. Steeg *et al*. (1988) cloned the *nm23* candidate metastasis suppressor gene, and low expression of this gene was associated with lymph node metastasis of breast cancers (Bevilacqua *et al*., 1989). The encoded product of the *nm23* gene is known. The predicted sequence of the nm23 protein was found to be identical with the *Drosophila* developmental gene *awd* product (Rosengard *et al*., 1989). The *awd* gene, in turn, was found to have a high degree of homology with nucleotide diphosphate kinase (Kimura *et al*., 1990), suggesting a possible role for the *nm23* gene product in microtubule assembly/disassembly, signal transduction and/or regulation of G proteins. An altered nm23 protein or changes in its expression could result in

modified signal transduction, gene expression and possibly progression in breast cancer.

HOST SURVEILLANCE MECHANISMS AND TUMOUR PROGRESSION

Other differentially expressed genes have been found in highly metastatic cells. For the most part, the precise roles of most of these differentially expressed genes or their gene products in tumour progression have yet to be determined. Some differentially expressed genes could be involved in tumour progression by acting on intracellular signalling in a manner that results in an increase in cell survival or an inhibition of apoptosis or programmed cell death. Gene products that act on host surveillance of tumour cells could also affect tumour progression. As tumour cells proliferate and diversify, they are under host surveillance pressures that continuously seek to inhibit or kill aberrant cells. Components that allow malignant cells to escape host surveillance mechanisms could be important in tumour progression by allowing more malignant cells to become dominant in a tumour cell population. For example, the cells that escape macrophage surveillance mechanisms might be expected to be more malignant by virtue of their ability to grow in the face of host antitumour responses. These less host-sensitive cells could then overgrow the more host-sensitive tumour cells and become the dominant cell population in the tumour. In breast cancer models the most malignant cell populations are also apparently those which are less susceptible to host surveillance systems, suggesting that *in vivo* selection occurs during the progression of mammary tumours to more malignant states (North and Nicolson, 1985). Moreover, in contrast to what has been seen in primary tumours, as metastases grow there are fewer host effector cells that infiltrate into the secondary tumour mass (Bugelski *et al*., 1987). This suggests that metastases may appear to be more resistant to host defences by virtue of the fact that fewer host effector cells can apparently penetrate into metastases.

CANCER PROGRESSION AND BREAST CANCER GENE EXPRESSION

Several differentially expressed genes associated with mammary tumour metastasis have been identified. Highly metastatic cells appear to over or underexpress a number of genes, including the overexpressed *mts1* gene (Ebralidze *et al*., 1989). The *mts1* gene has a high homology with calcium-binding proteins but is of unknown function. This gene has been found to be part of the *S100* gene family that encodes calcium-binding, cytoskeletal-binding proteins. Transfection of the *S100A4* gene into benign mammary cells resulted in these cells acquiring the metastatic phenotype (Davies *et al*., 1993). The *mts1* gene may be related to signal transduction systems, and its overexpression may lead to increased signalling of cell movement and growth.

Other differentially expressed genes have been found in mammary adenocarcinoma cells (Pencil *et al*., 1993). The most differentially expressed genes could, for the most part, be identified as known genes that had already been identified in the metastatic process, e.g. some encoded degradative enzymes, such as type IV collagenases, that are known to be differentially expressed in highly metastatic cells. Other genes encoded transcription or translation protein factors that could be involved in the metastatic process by increasing the ability of more malignant cells to proliferate under limiting growth conditions (Pencil *et al*., 1993). One of the overexpressed novel genes, *mta1*, was identified as overexpressed both in spontaneous rat mammary tumour metastases and in human breast cancer cells of high metastatic potential (Toh *et al*., 1994). This gene appears to function in signal transduction mechanisms but its exact role in maintenance of the malignant phenotype is not known. We have now identified and cloned the human *MTA1* gene, also a novel gene that appears to be involved in human breast epithelial cell motility and growth regulation. We sought to investigate the role of the *MTA1* gene by blocking its expression using an antisense oligonucleotide to the precise sequence at the transcription start site in the gene. In preliminary experiments, the antisense oligonucleotide but not a sense oligonucleotide blocked expression of the gene and inhibited human breast cancer cell motility and proliferation. The *mta1/MTA1* gene has as a part of its structure a Src homology or SH3-binding domain at its C-terminal region. This domain may function in Src and other related signal transduction pathways. The *mta1/MTA1* gene may act to modulate signal transduction pathways, and its overexpression in highly metastatic cells could result in an increased ability to circumvent host controls on cell growth and movement.

INTERCELLULAR COMMUNICATION AND TUMOUR CELL DIVERSIFICATION

The communication via intercellular junctions is an important cellular controlling mechanism in epithelial cells. These structures, in particular gap junctions, allow adjacent epithelial cells to be metabolically and electrically coupled, and this could be important in their normal maintenance of cellular proliferation and diversity. Using nonmalignant epithelial cells in culture we have found that cellular diversification and heterogeneity can be stimulated by oncogene transfer (Nicolson *et al*., 1992). This was demonstrated by transfecting relatively stable benign cell clones with the dominantly acting oncogene construct and observing the diversification of subclones derived from single transfected

cells. We found that stable, benign mammary epithelial cell clones that acquired an oncogene construct diversified rapidly concomitant with the cells acquiring the metastatic phenotype. In addition to increased diversity in metastatic properties, the transfected cells also showed increased diversity in the expression of a metastasis-associated cell surface mucin-like glycoprotein that may be involved in cell adhesion. In contrast, most of the cell clones that received the control gene construct remained relatively more stable and their subclones were for the most part nonmetastatic. The results suggest that rapid cellular diversification is an important property of highly malignant cells. A qualitative genetic change, such as sequence alteration of a dominantly acting oncogene, would be expected to occur at a low rate *in vivo*; however, the results demonstrated the relationships between qualitative gene changes, cellular phenotypic diversification and malignancy. This suggests that stimulation of cellular diversification could be an important step in tumour progression.

Environmental signals can also regulate cellular diversification and heterogeneity (see chapter on *Modelling Tumour–Tissue Interactions*). The dynamic regulation of electrical, ionic and metabolic coupling between epithelial cells is mediated by gap junctions. This form of cellular communication plays an important role in cell proliferation, differentiation, physiological responses and carcinogenesis (Dotto *et al*., 1989). Overexpression of oncogenes can disrupt gap junctional communication, and overexpression of tumour-suppressor genes is associated with an increase in gap junctional communication. When we examined the ability of a dominantly acting oncogene to cause diversification in the junctional communication properties of transfected benign mammary cells, we found that similar to their metastatic properties, their gap junctional communication was inhibited and more diverse among subclones obtained from single cell clones at various times during subculture (Nicolson *et al*., 1992). Intercellular junctional communication and its interference during tumour progression may be important in releasing cells from microenvironmental controls that regulate cellular diversification.

CANCER PROGRESSION AND CELLULAR DIVERSIFICATION

Highly progressed malignant cells exhibit rapid rates of diversification and phenotypic change, mainly due to quantitative differences in gene expression. This probably results in tumours that express a diversity of different immunological, biochemical, enzymological, structural and other cellular phenotypes. The cellular and extracellular mechanisms that control tumour and normal cellular stability and diversity have not been readily appreciated or extensively studied, hence it is difficult to ascribe precise molecular mechanisms for this process. Volpe (1988) proposed that certain genes are present in the genome that control cellular stability, and these may be altered during tumour progression, resulting in extensive tumour cell diversity, evolution and eventually acquisition of more malignant and metastatic cellular phenotypes. He termed these 'stability genes,' and such genes could be involved in karyokinesis and the repair, recombination and replication of DNA. These genes would be good candidates as genes controlling mechanisms that regulate cellular diversification. In addition to stability and other genes, a wide variety of epigenetic factors, such as those that control tissue and stromal organisation, could also control cellular diversification mechanisms (Nicolson, 1987; Moustafa and Nicolson, 1988; Miller and Heppner, 1990). The removal of cells from their usual microenvironments could also result in loss of tissue-specific controls. In this scheme cells are in a constant dynamic flux due to changes in their microenvironments.

There are apparently complex mechanisms that control cellular differentiation and the diversity of cells within tissues. Both normal cells and tumour cells are exposed to variations in the concentrations of various regulatory factors. Although normal cells may be more stable than tumour cells in their microenvironments, under certain conditions normal cells can undergo rapid change and diversification. In contrast, malignant cells can be made more stable in their cellular phenotypes. Thus, as malignant cells progress, they can reach states where they are no longer regulated by paracrine growth factors and inhibitors. Once this occurs, they can grow in a variety of microenvironments that would usually not be permissive for growth (Nicolson, 1993).

Chapter 55

Basic Tissue Culture in Cancer Research

Philip Cavanaugh
Institute for Molecular Medicine, Huntington Beach, CA, USA

CONTENTS

- Biological Background
- Principles of Model Establishment
- Technical Considerations
- General Applications
- Biological Limitations
- Perspectives

BIOLOGICAL BACKGROUND

The maintenance of tissue or cell viability and function *in vitro* was first performed in the late 1800s. Initial attempts at cell culture used crude plasma extracts, chick embryos and ascites fluid as growth media. Most attempts at maintaining tissues *in vitro* were performed to use those tissues as a growth platform for viruses. The move to defined media supplemented with serum as a growth environment was not perfected until the late 1950s (Whitaker, 1972). The basic media used today were developed at around that time. The use of tissue culture to raise cells strictly for studies of the cells themselves then accelerated. It was only natural then for those interested in cancer research to take advantage of the system so that an unending supply of those cells could be grown and harvested to investigate multiple tumour cell properties.

PRINCIPLES OF MODEL ESTABLISHMENT

This chapter is actually devoted mostly to cell culture, which is a subset of tissue culture. For the purposes here, cell culture includes all studies were animal cells are maintained outside the donor in a viable state for long periods of time, encompassing many generations of cell life (Murrell, 1979). Tissue culture is so routinely used that it is not really thought of as a model, but an established dyed-in-the-wool technique. Cell culture is a valuable tool for cancer researchers as it enables investigators to tap a renewable source of stable tumour cells for various experiments. Tissue culture poses a number of drawbacks such as the inevitable *in vitro* alteration of certain cellular characteristics. However, it is an irreplaceable mechanism for the repeated acquisition of standardized cells for study, especially when one is concerned with exploration of human cancer cell properties. An orientation to the use of tissue culture is undertaken by examining the properties of the major tools required, the solutions required, the techniques needed to merge these two and finally special considerations needed to be taken into account when preparing cultured cancer cells for certain studies.

TECHNICAL CONSIDERATIONS

Major Equipment

The major equipment listed are items which one would want to consider obtaining if constructing a new tissue culture laboratory, or to find and acquaint one self with if one is suddenly found to be positioned in an existing facility.

Biological Safety Cabinet

The most vital piece of equipment in a tissue culture laboratory is the biological safety cabinet (BSC). These cabinets are constructed to provide an environment which is continuously flushed with sterile, particulate-free air; thus they provide the sterile environment where the bulk of tissue culture manipulations occur. These cabinets are equipped with high-efficiency particulate air (HEPA) filters which filter out any material $>0.3\ \mu m$ from an air stream. The type of cabinet usually used in tissue culture applications is a type II class A BSC, where the user is protected from biological agents arising from the material being manipulated and that material is protected from similar agents arising from outside the cabinet (Richmond and McKinney, 1995). Thus, air entering the work area and all air exhausting the cabinet pass through a HEPA filter. A diagram of a type II class A BSC is shown in **Figure 1a**. With these cabinets, workers are not protected from HEPA-passable airborne hazardous chemicals being used inside the cabinet. A type II class A cabinet can be ducted

to the outside to help prevent this, but work requiring the use of such hazardous materials is usually performed in a class II type B1 BSC, where all air drawn into the rear grille of the cabinet is vented to the outside through a hard duct (Richmond and McKinney, 1995) (**Figure 1b**). Type B cabinets also possess a greater air flow and direct a greater percentage of cabinet air to the rear. Users must aquaint themselves with the requirements and hazards of protocols and choose the proper cabinet. Other types of BSCs exist which provide additional protections, but these

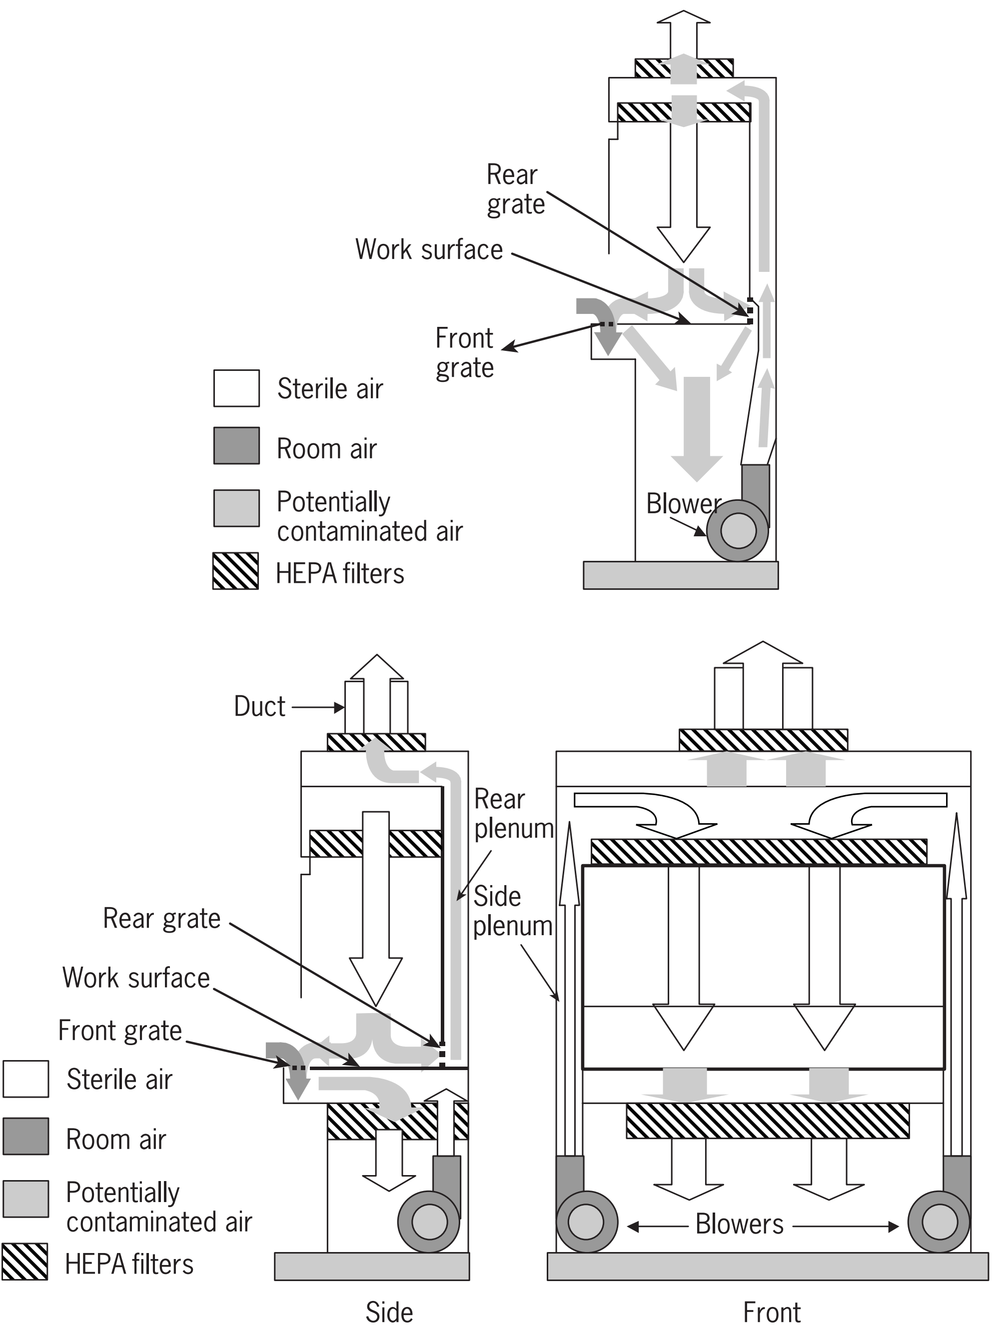

Figure 1 (a) Schematic of a class II, type A biological safety cabinet (BSC). Nonsterile air is drawn through the front and rear grates to the bottom via the blower motor. This air is directed up through the rear plenum where it is forced through one of two HEPA filters and either exits as sterile air through the top or returns into the interior through the bottom filter. (b) Schematic of a class II, type B1 biological safety cabinet. Nonsterile air is drawn through the front and rear grates. Air drawn in through the rear grate is pulled up through the rear plenum, through an HEPA filter and to the outside through a hard duct. Air drawn through the front grate passes through a HEPA filter, is blown up side plenums to the top, where it is passed through another HEPA filter and down on to the work surface.

are rarely found in ordinary tissue culture laboratories. Horizontal and vertical laminar flow clean benches also exist; however, these do not filter exhaust air and afford no user protection from the culture material; these are not BSCs and their use should be avoided in tissue culture operations (Richmond and McKinney, 1995).

Biological safety cabinets direct a flow of sterile air vertically straight downward from the inner top of the cabinet directly onto the working surface (Richmond and McKinney, 1995; Freshney, 2000) (**Figure 1**). At approximately 15 cm above the work surface, air flow is split and diverted horizontally to the front and rear grilles. The split point is typically half way from the rear of the cabinet (Richmond and McKinney, 1995). Since the flow of sterile air in a BSC is from the top down, it is imperative that any non-sterile items be kept away from the top of sterile items which are open, i.e., open bottles of media or open tissue cultures can only be approached from overhead by sterile items. Nonsterile entities such as hands and pipetters should always be positioned to the side of open flasks and bottles (**Figure 2**). Also, work should be performed a respectable distance (at least 10 cm) from the front of the cabinet so as to avoid chance room air contamination. Any object can divert the flow of sterile air, so the working surface of the cabinet should be occupied only with items that are necessary for a particular operation. Care should be taken not to place large objects in front of the rear grille, especially not to the rear of where one is working. The use of a flame in a BSC should be avoided. Air currents formed by the flame will disrupt the flow of sterile air and create unpredictable sterile air directions (Richmond and McKinney, 1995). Likewise, strong air movement outside the cabinet can interfere with uniform sterile air flow, so things such as fans should not be operated in the area of a BSC.

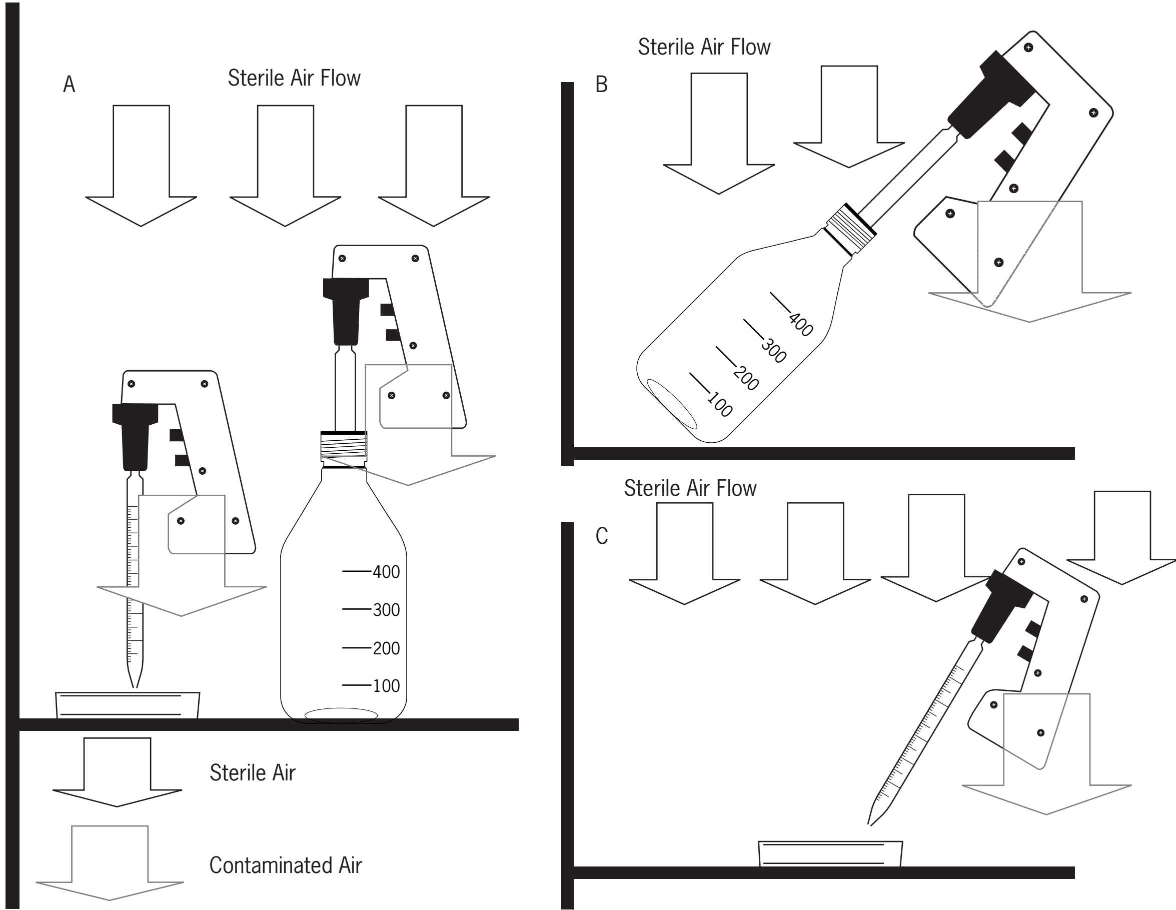

Figure 2 An illustration of a common error made when pipetting into/out of sterile containers or dishes in a tissue culture BSC. In **A**, many first time users will position a non-sterile pipettor (with associated non-sterile user hands) directly over open bottles of sterile media or tissue culture dishes, etc. The straight down vertical flow of sterile air will cause an array of microorganisms to be blown off these non-sterile items directly down into the sterile vessel. All approaches to sterile containers must be made at an angle (**B** and **C**), so that the vertical flow of contaminated air is off to the side of sterile open containers. A rule of thumb is that no sterile bottle can be pipetted into or out of when it is standing upright on its own. If you are not supporting said bottle with your hand while pipetting into/out of it, the approach to the inside will likely cause contaminants to fly in.

These cabinets usually feature side ports for vacuum and gas supply. Vacuum source in a BSC is highly recommended. Cabinet vacuum is required for many tasks, such as aspirating spent media from cultures and for filter sterilizing. A filter flask placed outside the cabinet and connected between the laboratory vacuum source and the hood's vacuum port is used to collect aspirated liquids. This flask usually contains bleach or some other strong disinfectant. An additional empty filter flask can be plumbed between the first flask and the vacuum source, to act as an emergency overflow reservoir. To protect fully the wanderers outside the cabinet, an in-line HEPA filter can be installed in the vacuum line between the vacuum supply and the overflow flask (Richmond and McKinney, 1995) (**Figure 3**).

Biological safety cabinets should be kept clean and all interior stainless-steel surfaces wiped down with 70% ethanol (Richmond and McKinney, 1995) and/or an additional disinfectant (e.g. 0.05–0.1% (w/v) cetylpyridinium chloride) on a regular basis. BSC maintenance and practice vary with the types of living things being handled. Performing routine tissue culture in a BSC and handling hazardous pathogens in a BSC are two separate issues. With the latter, all surfaces prior to the HEPA filters that are impinged upon with air that has buffeted off pathogenic material can be considered hazardous and should not be approached until the entire unit has been decontaminated with formaldehyde. Hence cleaning up under the grilles or spelunking underneath the work area is not a good idea. If one trusts the work materials to be safe, then the areas underneath the front and rear intake grates could be cleaned as this will diminish the flow of large particulates on to the filter. Since airborne particulates impinge upon the HEPA filters and do not really come off, and the filters eventually clog up. Therefore, all hoods should be monitored routinely by qualified technicians to verify adequate air flow and delivery of sterile air (Freshney, 2000).

Autoclave

A second vital piece of equipment is an autoclave (Whitaker, 1972; Paul, 1975; Freshney, 2000). Autoclaves are pressurized heat chambers which are able to kill all known living organisms via a combination of heat and pressure. Autoclaves utilize steam to achieve both of these ends, achieving internal pressures of 15–20 psi and temperatures of 110–140 °C. Autoclaves vary in their design and can be fed by an in-house steam system or can generate

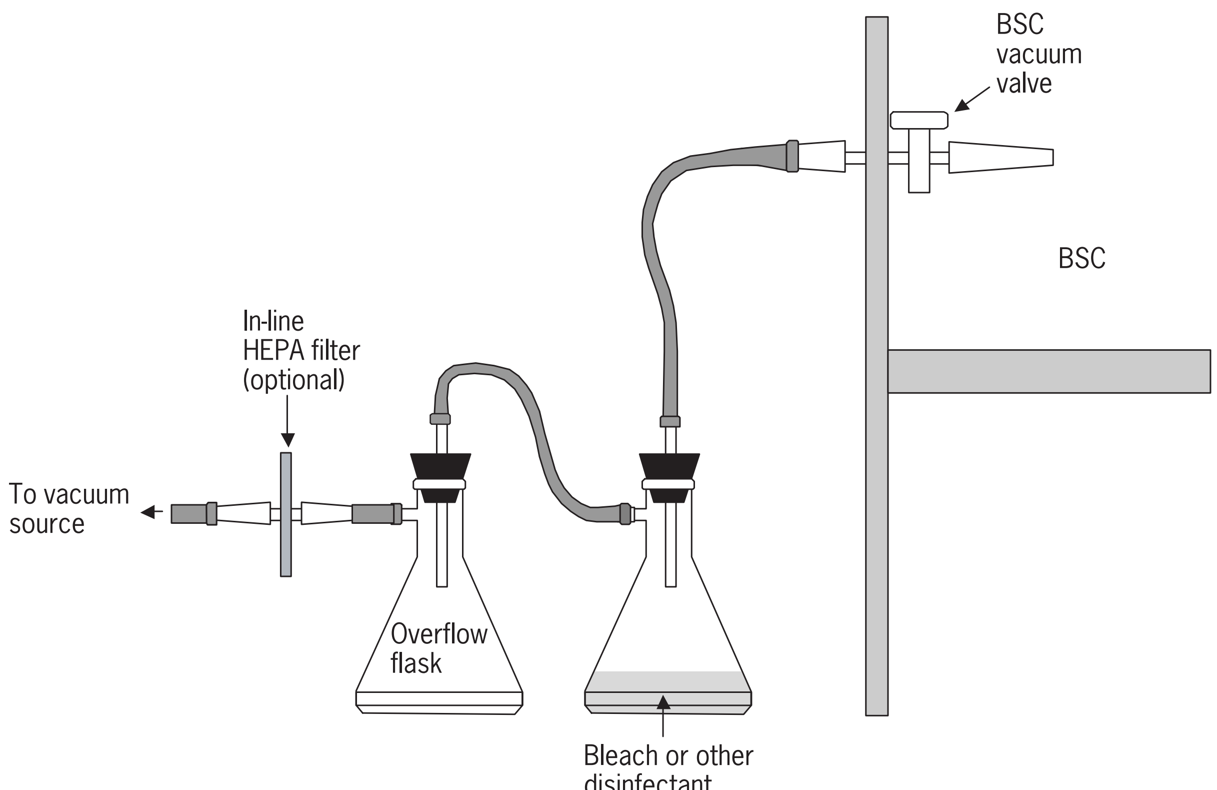

Figure 3 Schematic of a typical vacuum flask arrangement in connection with a BSC. The first flask contains some type of solution which can kill most everything. It serves as the primary reservoir of aspirated liquids. The second flask serves as an emergency overflow reservoir to protect the vacuum pump in graduate student-rich situations where flask number 1 is forgotten about. The in-line HEPA filter is to prevent pathogenic microorganisms from being distributed throughout the room via the vacuum pump or throughout the building via the building vacuum system.

steam from their own internal water supply. As such, manufacturers' instructions on operations specific for a given brand autoclave should be adhered to. The steam used must always originate from deionized water. Most autoclaves feature preset cycles for various items to be sterilized. Knowledge of the materials being autoclaved and the ability to push the proper button are all that is required to kill everything. A basic cycle consists of a rapid pressure build-up and a preset high-pressure incubation time, followed by a rapid depressurization. Typical additions to basic sterilization cycles include a drying step for wrapped or boxed materials, and a slow exhaust cycle for the sterilization of liquids. The latter allows for depressurization to occur slowly enough so that liquid samples do not boil and overflow their container. If a new autoclave is being considered, then examine models which pump sterile air through the chamber during the drying step. This shortens this cycle's time and ensures more uniform drying.

Paper, nylon and polypropylene wrappings and autoclave bags can be purchased which are specifically made for wrapping or enclosing items to be autoclaved. Items can also be autoclaved in stainless-steel, polypropylene or aluminium boxes, a number of which are particularly made for this purpose. Autoclave tape can be obtained which is provided with indicator stripes which turn from white to black when sterilization conditions and proper autoclaving have been achieved, hence this tape makes for a convenient sealer for the aforementioned wrapped or boxed items. The strategy is to wrap or enclose articles to be sterilized so that the steam in the autoclave has free access to all surfaces (Whitaker, 1972), but when removed, the wrappings or containers will be such that airborne contaminants will not be able to enter the sterilized inner sanctum. Nonsteam permeable autoclave containers cannot be totally sealed when put in the autoclave, since contents in the interior will not be exposed to the high pressure. Steam in the autoclave must be free to enter all vessels, so no container placed in the autoclave should be air-tight. Hence all rigid autoclave boxes or tray–cover combinations feature loose-fitting lids. Paper allows the passage of steam in the autoclave, but when dry, acts as a good microbial barrier, so items wrapped in paper can be totally sealed. Glass, stainless steel, aluminium foil, paper, rubber, polypropylene, nylon and polysulfone are all autoclavable. Other common laboratory materials such as polystyrene and polyethylene are not. Nalgene maintains a list of resistance properties (including autoclave resistance) of various plastics at http://nalgenelab.nalgenunc.com/tech.html. Any non-standard items to be autoclaved should be examined for the presence of materials which will undergo significant morphological changes upon undergoing an intra-autoclave experience.

Bottles act as their own autoclave container and should therefore always be autoclaved with the caps on loose, especially when containing liquids. Tight caps mean a sealed system and bottles will not only not be sterilized, but might implode. Some practitioners place a small amount of water in empty bottles or like vessels to be autoclaved, as this ensures adequate steam build up in the vessel interior (Whitaker, 1972). To ensure postautoclave sterility, one can place just-autoclaved bottles in a biological safety cabinet, wait for them to cool and then tighten the caps.

It seems that no matter how slow the depressurization, some liquids can be lost from their containers during autoclaving, hence these should always be placed in a tray when being autoclaved. The initial volume of liquids to be autoclaved should be marked on their bottle so that any loss can be noticed. Certain liquids such as microbiological media tend to foam up in the autoclave; these require more head room, i.e., their container should be twice the volume of the liquid. Many autoclave manufacturers recommend that liquid to be sterilized should occupy no more than two-thirds of the volume of the container.

Incubator

A third major item required for tissue culture is an incubator. Tissue culture incubators possess a number of features for successful culture. All should have a CO_2 feed, monitoring, and adjustment system. Ideally, incubators heat the interior through a water jacket, a water reservoir that surrounds the culture chamber. Water in the jacket is heated to 37 °C and acts as a heat reservoir and temperature stabilizer for the interior. The interior of any incubator should be all stainless steel with as many rounded surfaces as possible, for easy maintenance. Maintenance of a humidified atmosphere in the incubator is performed by the simple inclusion of a tray of deionized water at the bottom of the incubator chamber. Water should not be placed directly on the bottom of the incubator's chamber.

Inverted Microscope

A microscope is essential for monitoring of cell cultures and the performance of certain tasks such as cloning and manual cell counting. An inverted microscope is required to focus in on the bottom of cell culture dishes or flasks in such a way so that the physical same-space intersection of objective and culture vessel is avoided (Freshney, 2000).

Frozen Cell Storage Facilities

Liquid nitrogen is the traditional cooling agent for establishing an environment for frozen cells. A number of liquid nitrogen containers specifically designed for cell storage are commercially available. Any of those with narrow-neck tops are far more efficient at conserving liquid nitrogen than those with flush-diameter tops. Electric freezers which can achieve an internal temperature of −135 to −150 °C are available. These are suitable for cell storage and many laboratories will utilize these in place of liquid nitrogen freezers.

Warm Room

A room or large walk-in chamber kept near 37 °C is necessary for large-scale tissue culture operations. Large-volume roller bottle or spinner tissue cultures for cell or conditioned media harvesting usually cannot be kept in incubators. These facilities do not require humidification or CO_2 addition, as large-scale cultures are usually self-contained (Freshney, 2000).

Cell Counter

Cell counting can always be accomplished on a microscope via the use of a haemocytometer slide. However, this process is tedious and cell enumeration of a large number of samples in this way is awkward. Automated cell counters such as those made by Coulter (Luton, UK) (Paul, 1975; Freshney, 2000) aid in the accurate counting of cell suspensions, provided that the cells are relatively well dispersed. Manual inspection of cells to be counted is always recommended as automated counters do not discern between living and dead cells.

Minor Equipment

A 37 °C water bath is useful for prewarming media, thawing cells, etc. Another instrument convenient to the immediate tissue culture area is a low-speed centrifuge capable of around 3000 *g* and of holding 15- and 50-mL centrifuge tubes. This is used for spinning down cells after various washings, dissociations, etc.

Some type of small-volume hand-operated pipettors are required. Many laboratories use pipettors operating in only two volume ranges: those capable of delivering 20–200 μL and those capable of delivering 200–1000 μL. On occasion, a unit handling 0.5–10 μL may be necessary. An eight- or 12-channel multichannel pipettor will be required if culture in 96-well plates is to be performed. Also required is a pump-operated pipetting device for aspirating and delivering liquid from conventional larger-volume glass or disposable plastic pipettes.

Sterile equipment kept on hand for tissue culture laboratories is fairly similar and includes large and small pipette tips; 1 (or 2), 5 and 10-mL pipettes (with cotton plugs); Pasteur pipettes (with and without cotton plugs); various sized bottles; cell freezing vials; 15- and 50-mL centrifuge tubes; 0.22-μm filters with holders, or disposable 0.22-μm filter units; 0.22-μm syringe filters; various sized syringes; centrifuge micro filter units; etc. All of these can be purchased as presterilized diposables. However, one can also make use of reusable items that are sterilized in house. This offers certain advantages in long-term cost, ease of use and ability to monitor sterility and resterilize when necessary. All pipette tips for common pipettors are made of polypropylene and can be packaged into covered polypropylene racks and sterilized in any autoclave. The most practical glass pipettes for tissue culture use are the short variety. Tissue culture varieties of these accept cotton plugs and are usually sterilized in stainless-steel canisters. Likewise, glass Pasteur (transfer) pipettes can be placed into and sterilized in steel canisters. These can also be plugged with cotton, if needed. Bottles commonly used for tissue culture are the 45-mm wide-mouth variety manufactured by a number of companies. These offer a secure, well-sealed cap, and a drip-proof wide mouth for ease of filling, dispensing and washing. The most affordable reusable filter sterilizing units available are NALGENE® Brand units from Nalge Nunc International (Rochester, NY) and are manufactured from polysulfone. These are available as stand-alone or bottle-top units (**Figure 4**). They are typically fitted with cellulose acetate or nylon 0.22-μm filters and can be repeatedly autoclaved. Disposable filters cost $4–5 per unit, so the $60 reusable Nalgene filter pays for itself after 15–20 rounds of use.

Culture dishes, flasks and plates in virtually all laboratories are disposable polystyrene types. Polystyrene is not autoclavable so the use of these is a one-shot deal. Polystyrene is naturally hydrophobic and untreated vessels are only suitable for the growth of nonadherent cells. Polystyrene is treated under vacuum in the presence of an oxygen-rich plasma and an electrical discharge to create charged hydroxyl, carbonyl and carboxyl functional groups on the plastic (Vitesse-Dadey, 1999). These dishes are now said to be ‘tissue culture treated’ and will permit the adhesion and spreading of adherence-dependent cells. Many different types of treated polystyrene tissue culture flasks and dishes are available. A nomenclature which has developed around flasks is to precede their surface cell growing area in square centimetres with a T, so a 75-cm^2 growth area flask is referred to as a T-75.

The use of Petri-type tissue-culture treated dishes is more awkward than that of screw-top flasks; however, they are more economical, exchange gases more easily and are utilized by many laboratories successfully. Greiner (Bel-Air, MD, USA) sell these dishes and certain flasks and multi-well tissue culture plates at prices significantly less than other suppliers.

This concludes the equipment section and has mentioned most of the basic tools needed for tissue culture. Particular laboratories will possess a number of other items not mentioned here, depending on their own field and requirement for ‘special needs’. We now proceed to the liquid part of tissue culture laboratory requirements.

Solutions

Water

High-purity water is essential for the final rinsing of glassware and the making of tissue culture solutions.

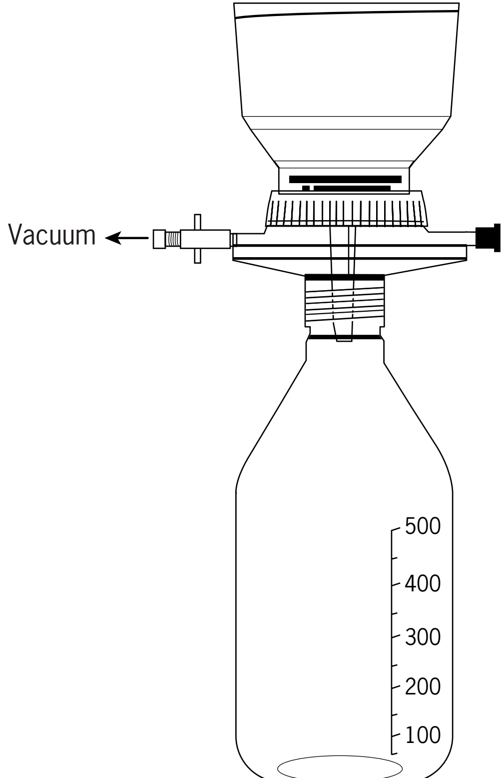

Figure 4 Schematic of the Nalgene 47-mm reusable polysulfone bottle-top filter. The model shown is fitted on to a commonly used 45-mm neck diameter tissue culture bottle. Solutions to be filtered are placed in the upper reservoir and are filtered by vacuum directly into the bottle. These filters are supplied with gas-tight lids (not shown) with fittings for tubing so that continuous filtration of large volumes can be performed. These are usually equipped by the user with nylon 0.22-μm filters and are autoclaved in paper autoclave bags. With the bottle-top design, both sides of the filter are exposed to equal amounts of pressure in the autoclave, with the result being that filter tears are uncommon. Filtration directly into sterile bottles eases handling and reduces the chances of contamination.

Most laboratories have access to water purified by deionization or reverse osmosis. This is adequate for glassware rinsing. Typically, this water is then further purified using commercially available systems which use additional ion-exchange and charcoal filtration (Freshney, 2000). More rarely, distillation is used. Names for high-purity water vary but usually reflect the name of the unit used to do the job. So names such as Nano-pure, Milli-pure, Milli-Q or doubly distilled (DD) water are added to the vocabulary of various laboratories. An article by Brush (1998) is a practical Internet-based reference which summarizes various water-purification systems.

Liquid Sterilization

For the most part, all solutions used in tissue culture are cold filter sterilized. Filter sterilization is achieved by passing the liquid through a sterile membrane which possesses pores of 0.22 μm or smaller. The vessel to hold the sterile material is first sterilized (autoclaved) as is the filter and filter holder assembly. Many facilities use disposable preassembled sterile filter units for this. Disposable 250-mL filter units cost $4–$6 each. Permanent 250-mL autoclavable polysulfone filter holders can be acquired for $60 and the 47-mm diameter 0.22-μm membranes to fit them are around $0.60 each. In the long run, significant savings can be made in purchasing permanent units, if one is not afraid of autoclaving.

A high-purity water system is essential in preparing tissue culture solutions as water from these systems is not only free of contaminants, but also has often been passed through a filter during its production. If a large volume of a particular solution is to be filtered, then an advantageous preliminary (but not necessary) step is first to pass the prepared solution through a glass-fibre and/or 1.0-μm filter on the bench top, prior to entering the hood for final sterile filtering. Certain disposable filter units are equipped with a large-pore prefilter which does the same thing. Sterilization of liquids in an autoclave is performed for certain tissue culture applications. Liquids require some head room when being autoclaved: the container should be 1.2–1.3 times the volume of the solution being sterilized. Still, some water can be lost when liquids are autoclaved, and therefore the use of a graduated container helps, with lost water replaced up to the original mark with sterile water. Water itself may be autoclaved to act as a sterile diluent for sterile 10× concentrated stock solutions such as 10× PBS or 10× liquid media, etc. Certain types of media are autoclavable, but the use of these seems to be rather uncommon.

Salt Solutions

Reproduction of media and salt solution ingredient tables with a listing of all components is not done here. To find such tables and view common media ingredients, do not go to the library. The best references for media component listing are the catalogues of companies (e.g. Invitrogen (Life Technologies Gibco), Carlsbad, CA; Sigma Chemical, St. Louis, MO, USA) which sell them. The Sigma cell culture catalogue is a convenient reference which offers a number of informative tables and methods. The Gibco catalogue contains a helpful reference section which is available on-line at http://www.lifetech.com (Tech Online).

Balanced or isotonic salt solutions are used as a base for media formulation and as a base for other reagents such as trypsin–EDTA solution, or used on their own for various purposes such as cell washing (Kuchler, 1977; Freshney, 2000).

Dulbecco's phosphate-buffered saline (PBS, DPBS or D-PBS) is the simplest formula. It is buffered with sodium and potassium phosphate and can be used in a plain air environment. It contains sodium, potassium, calcium and magnesium as anions and chloride and phosphate as cations. Glucose- and pyruvate-containing versions are available. With Earle's balanced salt solution, the phosphate concentration is lowered 10-fold and bicarbonate is added as the buffering agent. Sulfate is added to the cation list. This is used primarily as a media base or for incubator use since it contains 26 mmol L^{-1} sodium bicarbonate as a buffering agent and requires a 5% CO_2 environment for pH stabilization. Earle's solution always contains glucose as an energy source. Hank's balanced salt solution (HBSS) is similar to Earle's solution but contains less bicarbonate, resulting in an air-utilizable solution. Many laboratories supplement Hank's balanced salt solution with 20–25 mmol L^{-1} HEPES (*N*-2-hydroxyethylpiperazine-*N′*-2-ethanesulfonic acid; final pH 7.4–7.5), to provide additional buffering capacity. All of these salt solutions can be obtained calcium and magnesium free. The calcium-, magnesium-free version of DPBS is sometimes referred to as Dulbecco's phosphate buffered saline A (PBSA). These calcium-, magnesium-free versions are ideal as a base for reagents which require a lack of divalent cations such as trypsin–EDTA solution (for cell dissociation).

Media

Common Media

It seems that the simplest medium is Basal Medium Eagle (BME). Eagle further modified BME, including adding larger amounts of amino acids, to make Minimum Essential Medium Eagle, also known as Minimum Essential Medium (MEM). Dulbecco modified this by adding iron, fourfold more amino acids and vitamins to produce Dulbecco modified MEM (DME). Some DME formulations feature higher glucose concentrations also.

Tissue culture media are complex mixtures of various compounds found to be essential by various investigators for various cell types to survive and proliferate. A number of different types of media exist with various sets of ingredients and uses. Most suppliers classify tissue culture media ingredients into four divisions: salts, amino acids, vitamins and 'other' components. Kuchler (1977) divides media types into four groups. In order from basic to exotic, the ingredient list rises from 28 in group I to 50–60 in group IV. A major difference in the jump from group I to II is the inclusion of nonessential amino acids (Kuchler, 1977). Whitaker (1972) divides media components into nine categories: inorganic salts, amino acids, vitamins, glucose, nonglucose carbohydrate sources, coenzymes, reducing agents, nucleic acid derivatives and lipid sources. The Whitaker system gives one a better understanding of media components and allows for obvious discrimination of the differences between simple and complex media. By and large, the addition of more exotic items was performed in an effort to develop media that would support cell growth in the absence of serum. Those categories and example contents are as follows (Whitaker, 1972).

Inorganic Salts

The basic 'core' salts employed in media are those found in the aforementioned balanced salt solutions. Additional salts are added for various purposes. A major difference in additional salt composition among media is the addition of iron. Many media (e.g. BME, MEM) lack an iron salt whereas others (e.g. DME, Ham F12, Medium 199) are iron supplemented. Other minor metal salts such as zinc, selenium and copper are found in certain media (Ham F12) and others yet are supplemented with rarer salts such as molybdenum and vanadium (MCDB 131).

Amino Acids

Certain media contain only the essential amino acids (BME, MEM, DME) whereas others contain all amino acids (Ham F12, IMDM, NCTC 109). Amino acid concentrations can vary and tend to increase from lower levels in basic media to much higher levels in specialized media such as Waymouth and NCTC 109 (Whitaker, 1972). Close attention should be paid to glutamine concentrations in media as it has a half-life of about 3 weeks at 4 °C and 1 week at 37 °C. Many researchers obtain media glutamine free and add it from a 200 mmol L^{-1} 100× concentrate just prior to use.

Vitamins

A core group of vitamins is present in all media, typical of that found in BME. Additional vitamins such as *p*-aminobenzoic acid and vitamins A, D, E and K are present in others, such as NCTC 109.

Glucose

Glucose is found in nearly all media. Most media contain a minimum of 1000 mg L^{-1}. This rises to 3000 mg L^{-1} in media such as McCoy 5A, to 4500 mg L^{-1} in IMDM and certain formulations of DME and to 5000 mg L^{-1} in Waymouth medium 752/1. Exceptions to this exist, e.g. L-15 medium contains no glucose and substitutes it with galactose.

Carbohydrate Sources Other than Glucose

These are found in specialized media and include compounds such as sodium pyruvate, galactose, ribose and glucoronolactone.

Coenzymes

This category includes compounds that can act as enzyme cofactors and includes things components such as ATP, FAD and coenzyme A, etc., all found in NCTC 109.

Reducing Agents

Ascorbic acid is placed here, although in many tables it is listed as a vitamin. Other agents include glutathione and L-cysteine.

Nucleic Acid Derivatives

This does not include ribose but includes compounds such as hypoxanthine, xanthine, adenine, guanine, cytosine, uracil, etc. Medium 199 is an example of a medium with additional nucleic acid derivatives.

Lipid Sources

These are just plain fats, including cholesterol (medium 199), lipoic acid (Ham F-12) and Tween 80 (medium 199, NCTC 109).

The choice of medium for a certain cell type should be indicated by the supplier and adhered to. Changes in medium for any reason should be accompanied by rigorous examination for any changes in cell behaviour. On occasion, we have had need to switch cells to an iron-deficient medium and this dictated a change in basic medium type, which was kept constant for tests and controls to eliminate media-created changes.

Tissue culture media is usually buffered using a sodium bicarbonate/gaseous CO_2 combination. The buffering system is based on physiological ones and is only effective when an excess of gaseous CO_2 is present. In a $HA \leftrightarrow H^+ + A^-$ acid/base system, at a pH where A^-/HA ratio is high, the presence of an exogenous limitless amount of HA will result in an efficient buffering system, as the excess HA maintains H^+ and A^- at a given ratio, however, the maximum concentration of HA in solution must be limited. A gaseous source of HA can do this: act as a limitless supply, but still exist in a way where the maximum concentration existing in the aqueous phase can be restricted. Most media contain sodium bicarbonate or direct its addition upon preparation. Sodium bicarbonate readily dissociates in aqueous solution forming Na^+ and HCO_{3^-} (carbonate). Carbonate will complex with H^+ to form carbonic acid: H_2CO_3, an acid with a pK_a of 6.1. At a pH of 7.4, carbonate will function as a weak base, as this pH is distant from the pKa, and only about 5% of the added HCO_{3^-} will exist as H_2CO_3. Gaseous CO_2, readily goes into aqueous solution and reacts with water to form H_2CO_3, the concentration of which can be adjusted by adjusting the partial pressure of CO_2 gas in the surrounding atmosphere. At a pH of 7.4, if the concentration of carbonate is 25 meq/L, then the concentration of H_2CO_3 is 1.25 meq/L. If the partial pressure of gaseous CO_2 is set so that H_2CO_3 is maintained at 1.25 meq/L maximum, then the system will buffer at pH 7.4, since H_2CO_3 lost in any way will be replenished by H_2CO_3 formed from gaseous CO_2. Thus, the excess gaseous CO_2 maintains H_2CO_3 and HCO_{3^-} at a given ratio (White *et al.*, 1978). This results in a buffering system which imitates physiological buffering systems to great extent. This system also neutralizes the propensity of CO_2 generated by cellular metabolism to form carbonic acid and lower media pH. To maintain this system, most tissue culture incubators are CO_2 incubators, with a gaseous CO_2 feed line delivering CO_2 from a pressurized tank to the interior, an internal CO_2 monitor, and an automatic gas feed system which will continuously maintain the internal CO_2 monitor, and an automatic gas feed system which will continuously maintain the internal CO_2 at 5–10% (or whatever is set). Confluent cultures will produce other acids such as lactic acid and will utilize carbonate for carboxylation reactions. Therefore, the buffering system will eventually fail in crowded cultures unless media is frequently changed.

Additional buffering capacity is provided in many tissue culture situations by the addition of HEPES to the media. This is a non-toxic zwitterionic buffering agent with a pK_a of 7.3, hence it buffers well at the usual tissue culture pH of 7.4. These media still contain carbonate, for buffering and for synthesis processes. As mentioned, most media contain or direct the addition of sodium bicarbonate as a buffering agent in atmospheres supplemented with 5% CO_2. However, certain media are formulated to buffer adequately in air only and contain no bicarbonate. An example is L-15 (Leibovitz 15) medium. Cells growing in this medium would require a CO_2-free incubator. Other media, such as DMEM, may direct the addition of sodium bicarbonate, which is in keeping with an atmosphere supplemented with 10% CO_2. Care should be taken to maintain awareness with regard to the type of medium and atmosphere required for a particular cell type.

Serum

A medium alone will not usually support the growth of most mammalian cells. The medium is supplemented with serum at 5–20% (v/v), in order to support cell growth. In many cases, excess serum can be toxic, and it is rarely used at >20% (v/v). Serum provides a multitude of growth factors, nutrient transport factors, hormones, lipids and other components required to maintain cells. The most common serum used to supplement media in tissue culture is fetal bovine serum (FBS). This is available from many suppliers and is usually tested for tissue culture use and for the presence of many viral and other microbial agents. FBS from most suppliers is supplied sterile and is thoroughly tested for tissue culture use. The only precautionary note to keep in mind is to have on hand enough serum from the same supplier of the same lot number to last through an entire experiment. Other sera commonly used are calf serum and horse serum. These are also usually supplied sterile and again the only concern is to maintain serum consistency throughout an experiment.

When defined growing conditions are required, or for harvesting of secreted cell products, many investigators utilize serum-free media. Serum-free media are available

in two basic different types of preparations. The first are those containing protein supplements, examples being AIM-V, CHO-A-SFM and endothelial-SFM media (Invitrogen/(Life Technologies/Gibco)). These have a restricted list of cells of which they are advertised to support the growth of. Proteins commonly found in these types of media are albumin, transferrin and insulin. The second type of premade serum-free media are the protein-free variety, examples being PFHM-II and CHO III PFM (Invitrogen/(Life Technologies/Gibco)) and serum-free and protein-free hybridoma medium (Sigma). These are even less universally applicable than the protein-containing type. Serum substitutes are available which can be used to custom augment one's own base medium to achieve serum-free cell growth. The simplest of these is ITS, a supplement containing insulin, transferrin and selenium. More complex mixtures such as controlled-process serum replacements (CPSR, Sigma) are available for custom formulations using one's own medium. The Invitrogen/(Life Technologies/Gibco) catalogue reference guide contains sections on serum-free media and applications and on the adaptation of cells to serum-free conditions.

Antibiotics/Antimycotics

Many researchers avoid the use of these as much as possible. In these cases, their use is avoided in routine culture with established and tested cell lines. Other laboratories place antibiotics in media as a matter of course. In this case, the antibiotics of choice are penicillin and streptomycin. Their concentrations as preventative bacterial inhibitory agents are 100 000 units L^{-1} and 100 mg L^{-1}, respectively. A combination of these two is available commercially as a 100× stock solution. The antifungal/antiyeast agent most commonly used is amphotericin B. It is also available as a 100× stock solution and the final concentration used in media is 2.5 mg L^{-1}. All three of the above are also available as a combination antibiotic/antimycotic solution which is supplied as a 100× preparation. Penicillin and streptomycin are readily soluble in solutions such as PBS or HBSS and in-house sterile filtered preparations of these can easily be produced. Amphotericin B is difficult to solubilize and requires a detergent such as sodium deoxycholate to achieve this. For this reason, amphotericin B is best purchased ready to use as the detergent complex, which is known as fungizone. Other antibiotics are also useful in tissue culture. Gentamicin and kanamycin can be used and both exhibit a broader range of activity than do penicillin and streptomycin, including activity against mycoplasma. The Sigma tissue culture catalogue contains a usefeul table on the actions, activity and recommended concentrations for many tissue culture antibiotics. Antibiotics/antimycotics are usually used when primary cultures are established and are often placed in media after extensive out-of-hood manipulation of cells has occurred, such as with FACS sorting. Antibiotics can sometimes be used to resolve contaminated cultures, in which case the concentrations used can be significantly higher than those listed above, e.g. the cytotoxic concentration of streptomycin is >20 000 mg L^{-1} (Paul, 1975). We have found kanamycin to be particularly nontoxic and have used concentrations as high as 5 mg mL^{-1} to eliminate contamination. The Invitrogen/(Life Technologies/Gibco) catalogue reference guide contains a section on the decontamination of cultures using antibiotics. Elimination of fungal or yeast contamination with amphotericin B is more problematic as this agent is useful as a preventative but is not nearly as effective as a cure. Novel methods to decontaminate yeast-ridden cultures have been described with one (Behrens and Paronetto, 1984) using added macrophages to clear up this type of contamination.

Cell Removal Solutions

Cells are usually removed from tissue culture plates or flasks using 0.25% trypsin and 0.53 mmol L^{-1} EDTA, made in a basic salt solution. Trypsin–EDTA solution can be purchased ready to use or as a 10× solution containing 2.5% trypsin and 5.3 mmol L^{-1} EDTA. The latter is diluted 1:10 in sterile Ca^{2+}-, Mg^{2+}-free PBS or Ca^{2+}-, Mg^{2+}-free HBSS to produce a working solution. Either trypsin or EDTA alone can be used to remove certain cells from surfaces. We have found that Ca^{2+}-, Mg^{2+}-free HBSS containing 0.5–1.0 mmol L^{-1} EDTA can remove many cell types from culture plates, and with certain cells, exposure to 4 °C enhances the effect. Other enzymes such as collagenase or dipase are used on occasion. For simple subculturing and passaging of cells, trypsin–EDTA is used in most cases. The Invitrogen/(Life Technologies/Gibco) catalogue reference guide contains a section on various methods and reagents for the dissociation of cells from culture vessels.

Cell Freezing Solutions

Freezing solutions contain a cryoprotectant which lowers the solution's freezing point and protects cell membranes from freeze-related injury. Cells suspended in these are cooled slowly, and when the freezing point is reached, ice crystals initially form outside the cells. This causes the osmolarity of the extracellular solution to rise and water to diffuse from the cells, resulting in stabilization of the cells in a supercooled dehydrated state. Anyhow, the intracellular crystallization of water is prevented. Glycerol and dimethyl sulfoxide (DMSO) are the usually used cryoprotectants for freezing-point depression. The most prevalent formulation uses DMSO. These solutions are usually made up of the cell's usual growth medium with the addition of the cryopreservative. Thus, a typical freezing solution is 70–80% (v/v) medium, 10–20% (v/v) FBS and 10% (v/v) DMSO. Serum- and/or DMSO-free

solutions are available for special needs such as the cryopreservation of cells grown in serum-free media. Freezing solutions are available premade and presterilized from many suppliers.

Cells

Various cell lines are usually obtained from colleagues or collaborators. Certain companies, such as Clonetics (Walkerton, MD, USA), PromoCell (Heidelberg, Germany) and Cytotech (Copenhagen, Denmark) sell a number of cell lines, mostly normal. The most plentiful source of low-cost (although their costs have risen dramatically from 1995 to 2000) normal and tumour cell lines from various species is the American Type Culture Collection (ATCC) (Rockville, MD, USA) (www.atcc.org). Cells from this source are rigorously checked for contamination and are verified to be of the species stated. Also, the history and growth conditions of the lines are well documented. Any cell lines obtained from a private source should be checked for mycoplasma contamination and, if possible, tested for species verification and the presence of viral agents. Some of this can be accomplished by sending out samples to for-fee providers of these services, e.g. the ATCC offers a mycoplasma testing service. Cross-cellular contamination of cultures has been found frequently, with HeLa cell contamination of numerous cell lines having been reported (Stulberg *et al*., 1976; Ogura *et al*., 1997). Specific instances of other types of cross-species contamination have been noted (Muir and Gunz, 1977; Price *et al*., 1998). If not detected prior to the start of an experiment, this will play havoc with intended studies. Methods for monitoring such contamination are cumbersome, but worthwhile, with fluorescence *in situ* hybridization being a current suggested protocol (Multani and Pathak, 1999), with the indication that the earlier recommendation of the use traditional cytogenetic methods (Pathak and Hsu, 1985) may not be foolproof. Certain other multiparameter comparisons can be performed (Gignac *et al*., 1993), depending on the cell type and available assay techniques. Other preliminary methods can be devised depending on the species being used and the expertise available. For instance, we have found that most antihuman transferrin receptor antibodies will not react with rat (Cavanaugh *et al*., 1999) or mouse transferrin receptors. Simple treatment of rat, mouse or other nonhuman cultured cells with a fluorescent-tagged antibody of this nature followed by fluorescent microscopy will provide evidence of human cell contamination.

Mycoplasma Contamination

Mycoplasma are cell wall-deficient intracellular-dwelling parasitic bacteria which can infect a cultured cell line without causing any apparent morphological changes. Mycoplasma consist of only a plasma membrane, ribosomes and a genome of approximately 580 kb. Mycoplasma can exist during their life cycle as single cells smaller than 0.2 μm in diameter (Raab, 1999). A number of detection methods for mycoplasma are available, with the most recent being polymerase chain reaction-based detection of mycoplasma DNA in culture media (Tang *et al*., 2000). A number of commercially available services exist to which one can send samples for paid mycoplasma testing (Raab, 1999). Mycoplasma contamination can be controlled with antibiotics; however, the proper antibiotic must be chosen (Drexler *et al*., 1994; Freshney, 2000). The Sigma tissue culture catalogue antibiotic table indicates which of these are useful against mycoplasma. Kanamycin and gentamycin are often used. Cell cultures should be tested for mycoplasma on a routine basis, and any new cultures arriving in a particular laboratory should be tested. Trust no-one.

Techniques

Basic Culture

Initiating Cultures from Donated or Purchased Starting Cultures or Frozen Cell Vials

Cell Culture as a Start. Volumes are based on starting with and using a 10-cm diameter dish. In the BSC, aspirate the medium from the source cell culture, using a sterile transfer pipette. Rinse the cells once with 5–10 mL of Ca^{2+}-, Mg^{2+}-free HBSS and aspirate. Add 5–10 mL of sterile trypsin–EDTA and incubate in a tissue culture incubator until the cells detach. Pipette the cells into a sterile centrifuge tube. Centrifuge at 1000 *g* for 5 min, aspirate out the spent trypsin–EDTA solution and suspend the cell pellet in 2–5 mL of sterile growth medium (media plus serum). Add an aliquot of the suspension to waiting sterile fresh tissue culture dishes or flasks containing sterile fresh growth medium (e.g. 10 mL of medium per 10-cm dish). Place the dishes in a humidified 37 °C, 5% CO_2 incubator.

Frozen Cells as a Start. Thaw the cell vial rapidly in a 37 °C water bath. In a BSC, using a sterile pipette, dilute the thawed cell suspension in at least 10 volumes of prewarmed sterile growth medium and add to a fresh sterile culture dish or flask. To reduce the concentration of DMSO, the vial can be centrifuged once thawed, the freezing solution aspirated off and the cell pellet resuspended in growth medium; however, this is not usually necessary. Place the dish in a humidified 37 °C, 5% CO_2 incubator.

Subculturing

Attached Cells

Subculturing is the act of removing cells from a given dish or flask and replating them into additional vessels. This is

synonymous with passaging. This is done to maintain the cells in a viable state and/or to expand the population into additional dishes or flasks for experimental purposes. Each time a cell line is subcultured, the cells are said to have been passaged. Thus, the passage number indicated on a cell culture or vial represents the number of times that they have gone through trypsinization and reapplication to another dish or flask. The method is essentially the same as described above for initiating cultures from cultures.

Suspension Cultures

Many hybridoma cell lines and also leukaemia and lymphoma lines will grow unattached to a dish or other substrate. These cells will not require tissue culture-treated plasticware and can be grown in un-treated Petri dishes. For subculturing, trypsin is not required and an aliquot of cells from an old overgrown culture is pipetted sterilely into a sterile new dish replete with sterile fresh growth medium. Since subculturing is merely a dilution of cells into a new dish, the concept of passaging is hazy here and many investigators do not regard these cells as being passaged in the conventional sense. On occasion, suspension culture cells will be encountered with no passage number.

Cell Counting and Viability

Counting relatively monodispersed cells with an automated cell counter such as a Coulter Counter is the most convenient and accurate method for cell density determination. For this, we usually pipette 100 μL of a cell suspension into 10 mL of Coulter isoton, and count 100 μL of that diluted suspension in the counter. So, the result provided by the instrument is cells per 100 μL of a 1:101 diluted preparation; this value is multiplied by 1010 to provide cells per millilitre in the original suspension. Most cell counters can be programmed to correct for dilution and will present data in terms of cells per millilitre directly. One should make sure that the correction factor fits in with your current state of dilution.

A Coulter Counter has to be set up for particular cell counting operations. For most tumour cells, a 100-μm aperture tube is used and a lower threshold which eliminates counts due to anything with a diameter of less than 4–5 μm is set. A counting instrument such as a Coulter Counter detects particle numbers and sizes. It cannot discriminate between viable and nonviable cells and cannot discriminate like-sized debris from cells. For examination of a cell suspension for viability, debris and degree of cell aggregation, one must visually examine the cells directly under a microscope. Examination, counting and viability are all done at once by adding one volume of 0.4% trypan blue (in PBS) into one volume of a dilute cell suspension. An aliquot of the suspension is placed into a cover-slipped haemacytometer slide and examined under a microscope. Nonviable cells will take up the dye and appear blue. A haemacytometer counting area is divided into nine major squares which are 1 mm per side (**Figure 5**). With an official haemacytometer cover-slip in place, the depth of the counting area is 0.1 mm. All of the cells counted in one of the squares represents cells per 0.1 mm^3. Most individuals count the live and dead cells in four corner squares to acquire cells per 0.4 mm^3. This is multiplied by 2500 to produce cells per millilitre in the dye-treated suspension. The divisions inside the major squares are used as guides; the finer divisions in the side and centre squares are not usually needed for normal tumour cell examination and counting.

Cell Freezing

The process of cell freezing has been made much easier with the development of propan-2-ol-filled freezing chambers, the interior of which will cool from room temperature to −70 °C at a rate of 1 °C min^{-1} in a −70 °C freezer. Cells to be frozen are first removed from a culture dish using sterile trypsin–EDTA as described above, the removed cells are centrifuged and the spent trypsin–EDTA solution is aspirated off the pellet sterilely. The cell pellet is suspended in sterile freezing solution at 37 °C. Some investigators resuspend at no more than 1×10^6 cells ml^{-1}; however, many practitioners use higher densities with no apparent ill effects. The cell suspension is aliquoted into sterile screw-capped freezer vials and placed in a room-temperature freezing chamber. The chamber is placed in a −70 °C freezer overnight. The cell vials are then placed into a liquid nitrogen-cooled permanent storage facility.

Large-scale or High-density Cultures

A number of methods exist to increase cell culture surface area without using billions of dishes (Meisenholder, 1999). A common technique is to use roller bottles. This requires a roller-bottle rolling apparatus, which could be considered as major equipment. The roller is placed in a 37 °C chamber or warm room. Large cell culture equipment of this nature is often not located in a CO_2 environment, and therefore non-CO_2 buffering systems are used, or the bottle interiors are flushed with sterile 5% CO_2 prior to placement in the incubator. Roller bottles with interior pleats are available, which offer an additional increase in surface area. Roller-bottle cultures are often used when cell secreted products are collected (Wakabayashi *et al*., 1995), as the medium to cell surface culture area can be reduced significantly. Another method for establishing large surface area cultures in a small place is to use microcarrier beads (Meisenholder, 1999). A number of different beads with various surface functionalities are available. Cells are subcultured on to or 'plated' on to the beads similarly to how they are plated on to dishes in subculturing. Procedures for the different beads available vary, so the manufacturer's recommendations should be followed for rehydration, sterilization and plating techniques. These

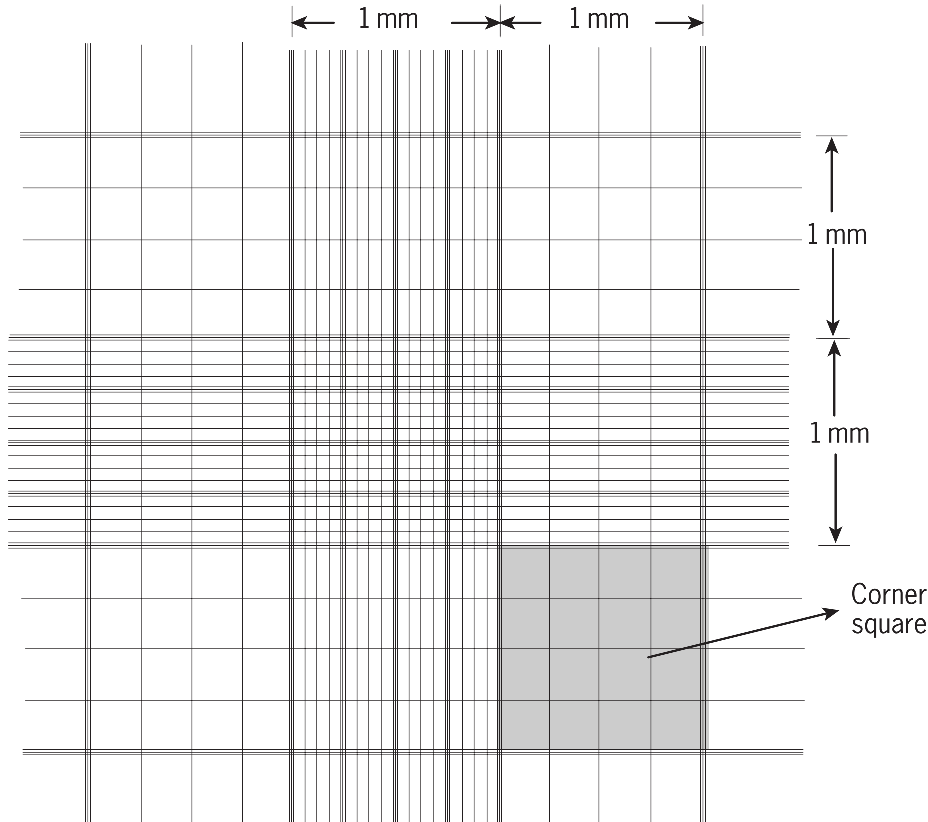

Figure 5 Schematic of a haemocytometer slide. Each major square is 1 mm per side. The depth throughout the entire counting area when the slide is equipped with a haemocytometer cover slip is 0.1 mm. Hence the total cells in one major square represents the number per 0.1 mm^3 in the suspension that was applied to the slide. Usually, corner squares are used since they are the least subdivided. The centre, side, top and bottom squares can be used to count additional 0.1-mm^3 volumes.

cultures are stirred at a slow rate using specialized vessels and stirrers. The stirrers used rotate at extremely low speeds and can often be set to rest at certain time intervals. Once again, the placement of a culture of this nature in a CO_2-supplemented environment is difficult, so these are usually buffered using HEPES or some other agent.

Primary Cultures

For this, cells are dissociated from viable tissue, usually a surgical explant, and are established as growing populations in normal tissue culture environment (Murrell, 1979).Tumour cells will frequently plate out and grow in tissue culture from surgical explants. Tumour cells often readily dissociate from a tumour mass and their transformed nature often results in successful tissue culture growth. For the establishment of tumour cell culture from animals, a section of tumour surgically removed from an anaesthetized host is suspended in the medium of choice. Mechanical manipulation of the tissue with forceps and scissors will often release enough cells to initiate a culture. If necessary, tissue-disrupting enzyme preparations such as collagenase/dispase can be used to dissociate cells. In either case, cells are initially washed 2–4 times by centrifugation and resuspension in fresh media, and then an aliquot is placed in growth medium in a fresh tissue culture dish or plate and placed in the incubator. If contamination with normal cells is seen, then the tumour cells can be further isolated by cloning. In this case, the initial disrupting media, dissociation medium and growth media all usually contain antibiotics and antimycotics.

Cloning

Cloning essentially involves establishing a culture from one cell. One can dilute a monodispersed cell suspension to exceedingly low cell densities (e.g. 10 cells mL^{-1}) and plate this on to a 96-well tissue culture plate at 100 μL per well. Individual cell colonies that arise in given wells can be assumed to have started from one or two cells. These are harvested, recultured and recloned to ensure single-cell origin status. Dilute cell suspensions can also be plated on to 10-cm tissue culture dishes and colonies arising can be harvested using cloning rings. These are ~3–5-mm diameter open-ended glass cylinders which are coated on one rim with sterile silicone grease. Medium is aspirated from

the dish and a ring is placed grease-side down over the colony of choice. Trypsin–EDTA solution is added inside and removed cells are aspirated out and recultured. A good substitute for cloning rings is sterile 3–5-mm Whatman No 1 filter-paper discs that are soaked in trypsin–EDTA. A disc of this nature is placed over the colony of choice and released cells are 'entrapped' by the paper. After the trypsin had done its work, the disc is removed and placed with its captive cells into a fresh dish with fresh growing medium. Many cells do not grow well at low density. Minimizing the increase in culture surface area and media volume when subculturing harvested colonies can help, in addition to the addition of pyruvate to the medium. For hybridomas, commercially available hybridoma cloning factors or supplements can be added to enhance low-density cell survivability.

GENERAL APPLICATIONS

Tissue culture-raised tumour cells have their use in a number of *in vitro* and *in vivo* assays. This chapter is not intended to discuss particular assays, but to warn new investigators of tissue culture manipulations that may have to be performed to make assays work.

Intact cultured cancer cells are used for *in vivo* tumorigenesis and metastasis assays, *in vitro* invasion assays, migration assays, transfection studies, drug sensitivity assays, FACs analysis, adhesion assays, etc. Lysates made from tissue-cultured cancer cells are used for enzyme assays, Western blot analysis, DNA analysis, RNA analysis, signal transduction assays, etc. Any manipulation of the culture system must be done so as not to interfere with the assay system and to ensure that all cell lines being analysed and compared are treated identically.

Usually, fellows, post-docs and graduate students are situated in a laboratory and have to work on established cancer types and their corresponding cell lines as dictated by the laboratory's director and tasks to be accomplished for certain grants. In the rare case that one is presented with a wide-open prospective research situation, and a cell culture-dependent study has not yet been committed to a certain tumour line or species, a decision as to what to use as models must be made. The first of these perhaps is to decide whether or not to work with human or animal lines. If one is not going to extend studies into the *in vivo* arena, then the more human disease state-relevant human lines would probably be the ideal choice. Raising human and raising animal tumour lines in culture are almost identical processes and no major differences in difficulties in propagating either are likely. The handling of human tumour lines does not require any special barrier devices as they are not recognized to pose a threat to researchers manipulating them. If cells are eventually to be injected into host animals and assessed for tumorigenicity, metastatic capability, drug sensitivity, etc., then another set of decisions must be made. Human lines are usually tested in this regard in nude mice, an immunocompromised host which requires special housing and the donning of protective paper pyjamas by the workers. The protective gear needed to be worn to work with nude mice does not make any kind of fashion statement, result in a physically awkward work situation. Animal lines present the advantage of a more ideal *in vivo* testing system, where a tumour line's *in vivo* behaviour can be assessed in fully immunocompetent syngeneic hosts. These latter studies do not require special housing, present a more amiable animal/tumour cell/reagent manipulation system, do not require the wearing of special suits and are much cheaper. Other considerations must be kept in mind, e.g. if one is contemplating the use of certain reagents in an upcoming experiment, then the choice of species of cell line to be used may be limited by the reagent itself. For example, if analysis of certain cell antigens via Western blotting is to be performed, then the antibody to be used must be verified to recognize the antigen in the species of cell line contemplated.

Many studies require the comparison of tumour cells to corresponding normal cells. The culture of certain normal cells can require significantly different conditions than tumour cells. Many normal cells will only go through a limited number of cell divisions prior to a final exit from known reality, whereas their transformed counterparts will keep on ticking. The acquisition and maintenance of normal cells has been made easier by the commercial availability of many of these. Companies such as Clonetics, PromoCell and Cytotech supply normal cell types although these are in many cases restricted to human varieties. Clonetics will supply detailed instructions and media specific for the various normal cells offered. The downside of these sources is that they tend to be rather expensive.

An example of a system where great differences in handling occurs is with normal mammary epithelial cells. These require low concentrations of calcium for optimal cell division (McGrath and Soule, 1984), depending on the reference (Emerman and Wilkinson, 1990). Certain immortalized normal cell types such as normal rat kidney cells will grow readily in culture and handle similarly to tumour cells. Whether or not these types of lines constitute precise normal cell behaviour is not always accepted. Many normal endothelial cell lines are available or have been isolated (Belloni *et al*., 1992), and these often appear to culture and subculture as easily as many tumour cell lines. When dealing with normal cells, three things should be kept in mind (1) unusual media requirements such as low Ca^{2+} for normal mammary epithelial cells; (2) limited number of divisions in culture–experiments may have to be designed so that any normal cell types do not exceed their probable life span; (3) certain handling characteristics such as subculturing at a high density may have to be performed.

BIOLOGICAL LIMITATIONS

Procedures and reagents listed above were developed for day-to-day tissue culture cell maintenance. However, not all routine practices can be immediateley transferred to the experimental situation. All reagents and procedures must be examined for their ability to affect one's own field of study.

Trypsin-induced Artifacts

Cell removal from plates must be done so as not to interfere with subsequent tumour cell action. Trypsinization of tumour cells can inhibit a number of processes. For instance, trypsin exposure can inhibit the ability of tumour cells to aggregate platelets (Gasic *et al*., 1977), so if an assay of this nature is planned, then EDTA removal would be a preferred alternative. Trypsin may cleave cell surface antigens, e.g. the transferrin receptor is known to have a trypsin-sensitive site (Larrick and Creswell, 1979). Analysis of removed cultured cells for cell surface transferrin receptor levels would dictate an avoidance of the use of trypsin.

Media and Serum Effects

As mentioned earlier, FBS used in an experiment should be a constant. The lot number of FBS used should remain the same for the length of the experiment and should be the same used across all cells being compared. Likewise, if two different cell types are being compared in a given assay, the effect on the assay of different sera, different sera concentrations and different media types used must be taken into account. If possible, all of these should be the same. For example, if two different cell types were being analysed for internalized transferrin content, then one might want to be wary of the medium used and consider whether one cell type was grown in a medium containing iron salts whereas the other was not.

FBS is very useful for growing cells, but might present problems when it comes to analysing those cells for a particular activity. The binding of residual serum proteins on to tumour cell surfaces might effect *in vivo* assays, e.g. remaining bovine serum proteins might instigate tumour cell rejection. FBS proteins have been known to be retained by cultured cells for prolonged periods (Johnson *et al*., 1990), and cell-bound FBS proteins have been observed to induce immune responses in cell-injected animals (Mizushima and Cohen, 1985). One might want to substitute the serum of the animal host species into cultures for 1–2 days prior to harvesting those cells for a metastasis assay. On occasion, investigators have avoided FBS altogether, to circumvent possible artifacts (Emerman *et al*., 1990). Bovine serum might influence cell behaviour in ways not necessarily reflective of that shown *in vivo*. If one is analysing human cultured cancer cells for any activity, the replacement of FBS with human serum should be considered. A move to serum-free conditions for any postculture assay (McKenzie *et al*., 1990) could preclude FBS induced artifacts. Culture of cells in same-species serum for particular assays may be the most appropriate growth conditions (Emerman *et al*., 1987).

It is difficult to monitor all media additives and assess the possible contribution of all to artifactual effects. The best practice is to keep abreast of recent developments in a particular area and to be aware of any reports of negative effects of particular media components. A good example is the discovery that phenol red, a common media ingredient used as a pH indicator and which imparts its red colour to media, was found to possess oestrogen-like qualities (Berthois *et al*., 1986; Rajendran *et al*., 1987). This was determined to produce undesired background effects in certain breast cancer studies. This provided greater incentive for the marketing of phenol-red free media by many companies, and the avoidance of the use of phenol red by those engaged in those types of experiments.

Passage Number

A major consideration in the use of tissue cultured cells in cancer research is passage number. A number of different studies have indicated that certain cultured cancer cells will show a drift in certain behaviours as passage number increases. Welch *et al*. (1984) found that the drug resistance and metastatic capability of certain rat mammary adenocarcinoma cells will change with increasing passage number. Investigators will usually freeze down large numbers of early passage cells or cells at a state known to be stable, and limit their scope of experiments to cells which have undergone minimal passaging from that state.

Monodispersed Cells

The ability to obtain monodispersed culture cells can be problematic. Isolated single cell suspensions or monodispersed cells are the best for certain assays such as tail-vein injection (experimental) metastasis assays, and for certain other techniques such as FACs analysis or sorting. Many tumour cells will grow as sheets and will be released from plates as sheets after removal with trypsin–EDTA or EDTA alone. Passage of suspensions through sterile nylon meshes of various sizes can aid in reducing multicellular aggregates. One method is to trypsinize stock cultures and vigorously to pipette up and down to disaggregate cells as much as possible. This suspension is then passed through a sterile 45-μm nylon mesh and all cells replated at approximately 25% of the starting density. The next day, these are removed from plates with EDTA only, passed through a 45-μm filter and used in assays.

Logarithmic-phase Growth

When rapidly growing cells exist in culture with plentiful nutrients and growing space, their numbers will increase exponentially. Confluency is the degree of coverage of the growing vessel that cells occupy. If cells are covering far less than the available growing area, then exponential growth can usually be assumed. Cells in this state are said to be in logarithmic phase growth (Paul, 1975). When two or more cell lines are to be compared in a given assay; e.g. for metastatic potential, both should be in logarithmic phase growth as this will dictate that the cells are highly viable and that both have approximately the same percentage of cells in each of the cell cycle phases. Many researchers do not perform complicated growth curve assays to ascertain logarithmic phase growth and ensure that a given culture is in this state. Instead, care is taken to only harvest cells for an experiment when the dish or flask on which they are growing is 40–60% confluent. The cells should therefore exhibit an identical size and DNA content range, etc. When dealing with cells growing in suspension, it is best to be familiar with the maximum density (in cells per millilitre) that a particular culture will normally reach, and to harvest these for a procedure when the cell count is no more than 60% of maximum.

Cell Cycle Synchronization

A number of agents are available which will synchronize cells at a particular stage of the cell cycle without inducing toxicity (Spadari *et al*., 1985). Synchronizing cells is one method of eliminating cell cycle size and other cell cycle variations in a population. Tumour cells have been shown to display varied behaviours dependent on cell cycle (Iwasaki *et al*., 1995). This might be considered important when performing experiments such as tail vein injection metastasis assays, as cell size will change with cell cycle along with the propensity of a certain percentage of the cells to divide and in effect increase the injected cell number. Synchronizing cells for procedures is not usually performed but is a method that can be considered to render cells more constant (Merrill, 1998).

PERSPECTIVES

Cell culture is the foundation upon which many cancer research operations rest. Voyaging back to the tissue culture facility to obtain the cells needed for a particular experiment is a routine trip in many laboratories. Learning the basics of the properties of the equipment, the solutions, the cells and procedures involved is perhaps the most valuable background information that a researcher can have, whether involved in the actual performance of the tasks or engaged in a supervisory role. This chapter was written to acquaint those entirely inexperienced with tissue culture with the terms and materials used. The pitfalls associated with the use of routine tissue culture reagents in certain experiments were pointed out in an effort to convince new researchers to monitor continuously all procedures for reagents and practices which will adversely affect their own particular experiments.

- Perspectives

INTRODUCTION

As discussed elsewhere in this book, oncogenes were first discovered by studying oncogenic viruses and by transfection studies of tumour DNA into cell lines. Tumour suppressors were identified based on loss of heterozygosity in human tumour studies. However, the understanding of the mechanism of action of oncogenes and tumour suppressors *in vivo* has been made possible by the use of genetically altered organisms, particularly the mouse. The technology for mammalian germ-line genetic manipulation was developed in the mouse, which has become the workhorse model organism for genetic studies. Like much of modern biology, genetic manipulation of the mouse via transgenic or knockout techniques has revolutionized the study of genes that cause cancer. The development of this technology has allowed investigators to examine the biological activity of genes important for the formation of cancer.

The basic experimental design differs for the study of oncogenes and tumour-suppressor genes. For oncogenes, transgenic mice are typically produced that overexpress oncogenes in specific tissues under the guidance of tissue-specific promoters. The expectation is that mice will develop tumours in the tissue where the oncogene is overexpressed. To study tumour suppressors, however, it is necessary to inactivate the gene to study its function. Therefore, knockout mice are produced with inactivation of tumour-suppressor function. If the tumour suppressor is required for embryonic development or viability of the organism, then special conditional knockouts can be produced that allow for gene inactivation in specific tissues at specific developmental times or adulthood.

In this chapter, the methodology for genetic manipulation of the mouse are outlined, then examples of the application of these techniques for the study of oncogenes and tumour suppressors are presented.

PRINCIPLES OF MODEL ESTABLISHMENT AND TECHNICAL CONSIDERATIONS: PRODUCTION OF GENETICALLY ALTERED MICE

The ability to manipulate the mouse genetically was made possible by those who developed techniques for the culture of mouse embryos and embryonic stem cells. Scientists developed preimplantation embryo culture conditions in the 1950s and 1960s, and included Wesley Whitten at the Australian National University and the Jackson Laboratory and John Biggers and Ralph Brinster at the University of Pennsylvania. In addition, uterine and oviduct transfer techniques were developed at the same time by Anne McLaren at Cambridge University. These techniques made possible the study and development of embryos outside of the mammalian uterus. This led to the development of teratocarcinoma cell lines that could be injected into these early embryos and contribute to a variety of somatic tissues, and then to embryonic stem cells that could contribute to somatic tissues and the germ line. Embryonic stem cells were derived from blastocysts independently by Gail Martin at UCSF and Martin Evans at Cambridge University, and soon were demonstrated to contribute to the germ line after injection into blastocysts.

These embryological techniques opened the door for the targeted genetic manipulation of the mouse genome.

Genetically altered mice can be produced in one of two ways: direct pronuclear injection of cloned DNA into the male pronucleus of a fertilized mouse egg, or targeted introduction of transgenes by homologous recombination using embryonic stem (ES) cells. Cloned genes were injected into fertilized eggs in the early 1980s by Ralph Brinster of the University of Pennsylvania, Tom Wagner at Ohio University, Erwin Wagner and Beatrice Mintz of the University of Pennsylvania, Jon Gordon and Frank Ruddle at Yale Univeristy and Frank Costantini and Elizabeth Lacy from Columbia University, and were found to pass stabily through the germ line.

A number of investigators studied the requirements for homologous recombination in cultured cells during the 1980s, including Mario Capecchi at the University of Utah, Oliver Smithies at the University of Wisconsin and then University of North Carolina and Raju Kucherlapati at Princeton. These principles were applied successfully to the modification of ES cells and then mice were made with germline transmission of modified alleles by the groups of Capecchi and Smithies, as well as groups from the laboratories of Elizabeth Robertson of Columbia University, Rudolph Jaenisch of Heidelberg University and MIT and Allan Bradley at Baylor University.

Detailed protocols and brief descriptions of the history of the development of transgenic manipulation and gene targeting techniques are available in several excellent laboratory manuals (see Further Reading). These techniques have allowed for the stable transfer of normal, altered or chimaeric genes into the mouse germ line, thus providing powerful tools with which to study mechanisms underlying development, function, tumorigenesis and gene expression within a physiological context.

Production of Transgenic Mice by Pronuclear Injection

Transgenic mice are produced by microinjection of DNA directly into pronuclei of fertilized mouse eggs, and results in the random integration of foreign DNA into the mouse genome. To express a particular protein in a specific tissue, the injected DNA is built by standard molecular biological cloning techniques in the form of an expressed eukaryotic gene (**Figure 1**). Constructs for injection consist of a promoter and polyadenylation site to provide signals for initiating and terminating transcription, respectively, and it has been found with extensive experience that an intron in the construct leads to much higher levels of expression of the transgene. These artificial genes used for injection are termed ‘transgenes,’ and mice made from the insertion of transgenes are referred to as ‘transgenic mice.’ The gene of interest must be expressed in the appropriate cell type within the mouse, and at an appropriate time in development to have a desired effect. Therefore, the choice of an appropriate promoter is critical to insure appropriate patterns of expression of the transgene. It often takes several modifications of endogenous promoters to identify sequences that will give appropriate levels of tissue specific transcription of transgenes in animals. Fortunately, such modified promoters have been identified that reproducibly give restricted expression patterns in transgenic mice, and can be used to express oncogenic sequences.

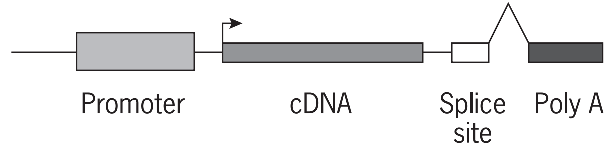

Figure 1 Structure of a transgene or transgenic construct. The transgene consists of a promoter, the cDNA to be expressed, a splice site and a polyA addition site.

After fertilization, the male and female pronuclei do not fuse immediately. The male pronucleus is large and, using micromanipulators to stabilize the egg, 100–200 copies of the purified DNA can be injected into the male pronucleus (**Figure 2**). Most of the injected eggs do not integrate the injected transgene. However, some fraction of injected eggs will integrate the injected DNA into a random chromosomal locus. The transgenic DNA usually integrates at the one cell stage and therefore foreign DNA will be present in every cell of the ‘transgenic’ animal. The manipulated embryo is implanted into the oviduct of a pseudopregnant female where the embryo will continue to develop until delivered at term. Offspring are analysed by molecular techniques such Southern blotting or polymerase chain reaction (PCR), and transgenic animals that have integrated the gene into their DNA are referred to as founders. These founders usually transmit the transgene as a heritable trait and hence a transgenic line is established. Under ideal conditions, the efficiency for generating transgenic founder mice containing 5–50 kb fragments is between 10 and 30%. In most cases, the transgene integrates at a single site randomly in the genome as 1–50 copies arranged in a head-to-tail orientation (tandem repeats). The site of integration can have profound effects on the expression of the transgene, so different founder lines may display vastly different levels of expression. In addition, enhancer elements at the site of integration can sometimes direct transgene expression to unexpected tissues in unpredictable spatial and temporal patterns of expression. Founders must therefore be screened for expression of the transgene RNA or protein, and the best founder line(s) for a particular experiment can be selected from the available founder lines. Once an appropriately expressing founder line has been identified, the expression pattern from integrated transgenes generally remains stable over many generations.

Recently, it has been possible to produce transgenic mice by pronuclear injection of large DNA fragments

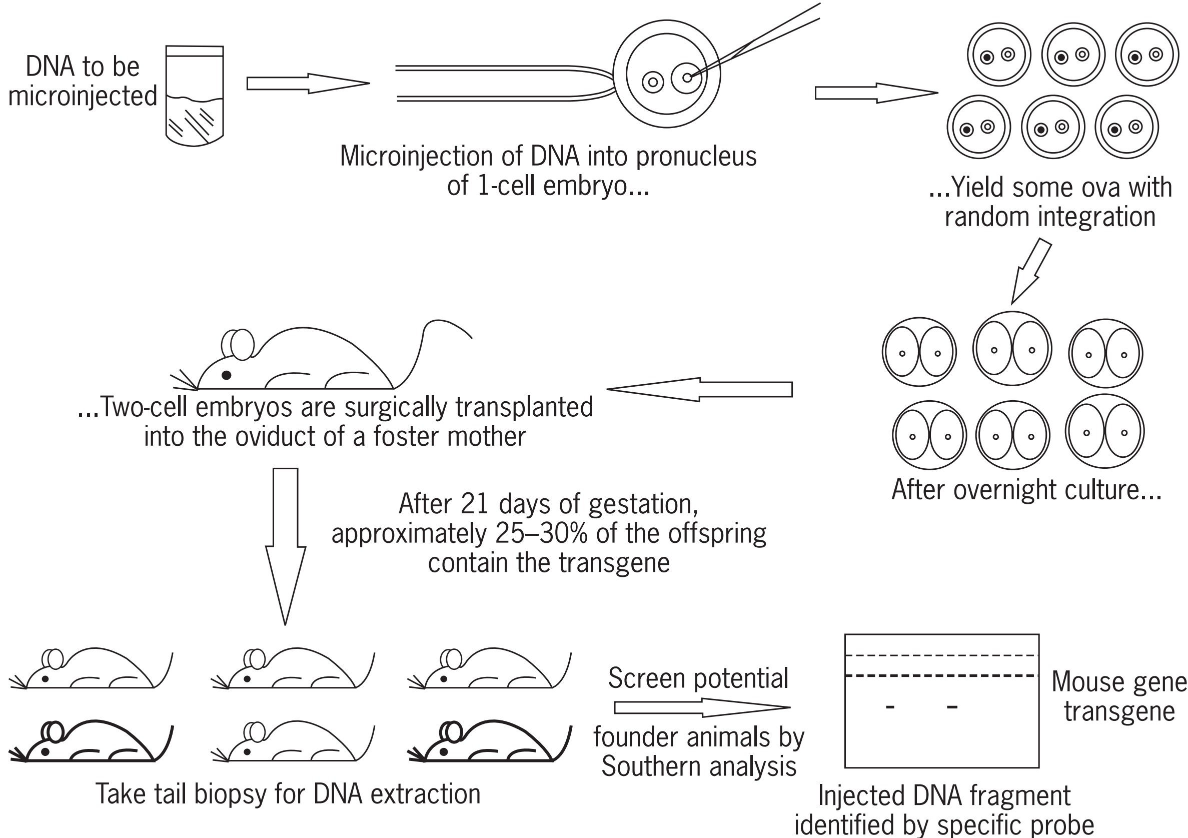

Figure 2 Generation of transgenic mice.

derived from yeast artificial chromosomes (YACs) and bacterial artificial chromosomes (BACs). Even large genes will be included on most YACs or BACs with important regulatory regions. Expression from these large DNA fragments appears to be more uniform and predictable in transgenic mice than expression from traditional transgenic constructs. This is probably the consequence of at least two factors: it is more likely that all regulatory sequences important for reproducible expression are contained in these large DNA fragments; and this added DNA sequence insulates the transgene from influences from the integration site. YACs can accommodate larger inserts of DNA (several hundred kilobases) compared with BACs (100–150 kb). However, YACs are more unstable during manipulation and transgenesis than BACs, and several excellent mouse BAC genomic libraries are available. Therefore, BACs have become the vector of choice for producing transgenic mice from large DNA fragments.

Gene Targeting via Homologous Recombination in ES Cells

In contrast to the random integration of DNA that occurs due to nonhomologous recombination during pronuclear injection of DNA, DNA can also integrate in a site-specific manner by homologous recombination. Foreign DNA introduced into mammalian cells generally integrates into the host genome via nonhomologous recombination, with a frequency of homologous to nonhomologous recombination of 1 in 1000. However, techniques were developed for the growth and transfection of ES cells in culture and selection for those cells that have undergone homologous recombination, while maintaining the ES cells in an undifferentiated (pluripotent) state. This technology has allowed for the extensive manipulation of the mouse genome that is occurring in many laboratories throughout the world. Meticulous culture procedures are required to maintain ES cells in culture so that they retain a normal karyotype and do not differentiate, to insure that the genetically manipulated cells can contribute to the germ line after injection into the host blastocyst.

ES cells are grown in culture and manipulated DNA of interest is transferred by electroporation (**Figure 3**). The manipulated DNA contains a marker that allows for the selection of cells that have stabily incorporated the DNA, whether it is integrated via homologous or nonhomologous recombination. Following electroporation, cells are subcloned so that DNA can be extracted. Genomic DNA from the clones is screened using standard molecular biology procedures to identify clones that

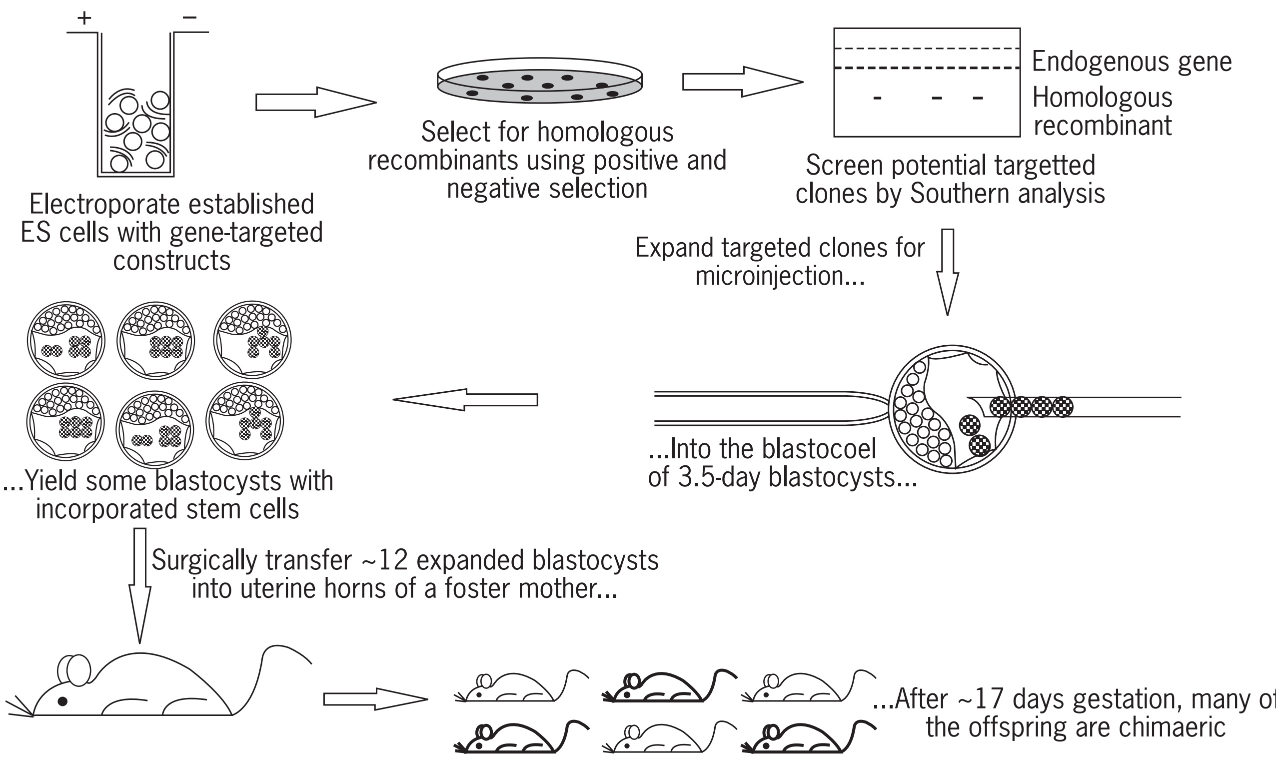

Figure 3 Construction of transgenic mice using embryonic stem cells.

have undergone homologous recombination at one allele. Once ES cell clones have been identified they are injected into blastocysts (host blastocysts) obtained by flushing the uterus of a 3.5-day pregnant female. The injected blastocysts are then transplanted into the uterus of a pseudopregnant female where the embryo continues to develop. Offspring are screened for the presence of the altered allele. Offspring are referred to as chimaeras, as some of the animal is derived from the host blastocyst and some from the injected ES cells that contain the altered allele or transgene. If the manipulated ES cells contribute to the germ line, then the chimaera can be bred and some of its offspring will be heterozygous for the altered allele. This is referred to as germ-line transmission. Germ-line transmission is essential for establishing a knockout line.

Several factors have been defined which facilitate the growth of ES cells, enhance the frequency of homologous recombination and simplify screening procedures. For example, use of isogenic DNA (DNA from the identical strain of mice as the ES cells), use of linearized DNA and the use of two selectable markers improve the ratio of homologous to nonhomologous clones surviving selection to the range of 1 in 15–300. In general, rates of homologous to nonhomologous recombination using optimized systems are 1 in 25 to 1 in 100.

Using homologous recombination in ES cells, it is possible to make a variety of modifications to specific genomic loci. Most commonly, gene targeting has been used to completely inactivate a specific gene (**Figure 4**). A selectable marker (usually neomycin phosphotransferase, or *neo*, expressed from a promoter active in ES cells) can be placed into a convenient restriction enzyme site of an exon, introducing stop codons into all three reading frames of the gene. This will completely inactivate the gene as long a stable truncated protein is not produced, or splicing does not occur around the exon containing the inserted *neo* gene. Alternatively, *neo* can be used to replace exons containing critical protein domains. The goal of these types of disruptions is to create complete loss-of-function or null alleles.

It is possible to make more subtle changes to genes using gene targeting. Various strategies have been used to introduce point mutations at specific residues of several genes. For example, a point mutation can be introduced in an exon of a gene, closely linked to the selectable marker. Clones that have undergone homologous recombination can be screened for the presence of the point mutation by restriction mapping or PCR. Conditional knockouts are designed to inactivate a gene in specific tissues at specific times of development or adulthood. Currently, several laboratories are refining this technology, involving Cre/*loxP*-mediated recombination and tetracycline-mediated induction and repression of gene expression to allow such subtle genetic alterations to be done routinely. Finally, it is possible to create large deletions in the mouse germ line using Cre/*loxP* technology. *LoxP* sites are introduced into the genome to surround a region to be

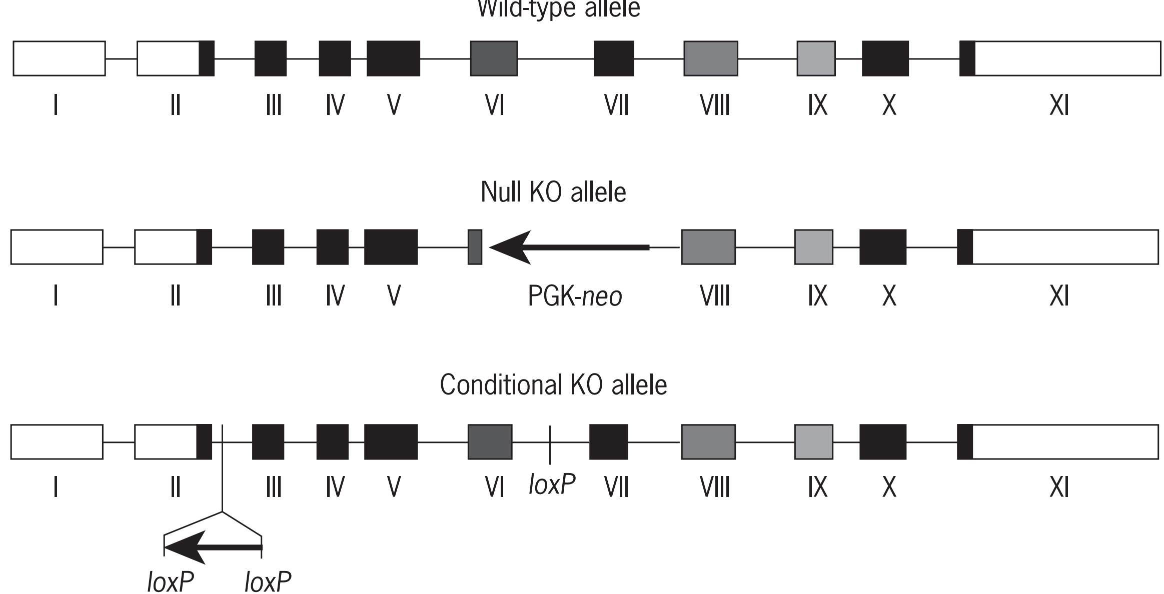

Figure 4 The general form of the most common types of gene targeting constructs. A wild-type gene with 11 exons (boxes, where clear boxes are 5′ and 3′ untranslated sequences and the filled boxes are coding sequences) is shown at the top. For the knockout construct (Null KO allele, middle), part of exon 6 and all of exon 7 are replaced by a gene that can be selected in culture, usually the neomycin transferase gene driven by a broad strong promoter (PGK-*neo*). For the conditional KO allele (bottom), the PCK-*neo* gene (arrow) surrounded by *loxP* recombinase sites are placed in intron 2, and a third *loxP* site is placed in intron 6. The inclusion of the *neo* gene in an intron often results in a hypomorphic allele, so this gene is surrounded by *loxP* sites for removal.

deleted. Cre-mediation deletion of the entire region can be accomplished in cell lines or in animals. Using these approaches, deletions of more than 1 Mb have been made *in vivo*.

The use of specific strains for the derivation of ES cells which have dominant coat colour, in combination with the isolation of blastocysts from strains with a recessive coat colour allow for the simplified screening procedure and identification of offspring in which the ES cells have contributed to the mouse. The most commonly used mouse strain for derivation of ES cells is one of the 129 strains. This strain carries the agouti coat colour locus that is dominant over the recessively inherited black coat colour locus of the C57BL/6J mouse strain from which the host blastocysts are obtained. Offspring in which the 129 ES cells have contributed to the embryo will have agouti and black fur due to the difference in origin of the cells, agouti from the ES cells or black from the cells of the host blastocyst. This is referred to as coat colour chimaerism. If ES cells have also contributed to the germ line, then mating of the chimaera to a female with a recessive coat colour results in offspring with the coat colour of the ES cell-derived strain. ES cell-derived offspring can then be screened for the presence of the mutated allele. Once animals heterozygous for the recombined allele have been identified, they can be interbred to generate animals homozygous for the mutated allele. In this way, null mutations or ‘knockouts’ of a specific gene can be obtained.

GENERAL APPLICATIONS: USE OF TRANSGENIC AND KNOCKOUT MICE TO STUDY THE FUNCTION OF CANCER-CAUSING GENES

In this section, examples will be presented that illustrate the value of genetic manipulation in the mouse to study the role of oncogenes and tumour-suppressor genes.

Study of Oncogenes *In Vivo* in Transgenic Mice

Mouse mammary tumour virus (MMTV) is a retrovirus that, like other retroviruses, integrates randomly into DNA. As a consequence of integration, it induces mammary tumours in a high proportion of infected animals. It was discovered that MMTV harbours regulatory sequences in its long terminal repeat (LTR) that allow for high levels of expression in the breast. Random integration of this LTR near the site of an oncogene that can promote breast cancer results in mammary tumorigenesis. The LTR of MMTV has been isolated from the integrated provirus and

characterized in transgenic mice. It has been found to be highly efficient in directing transgene expression to the mammary ductal epithelium.

Several investigators have taken advantage of these properties of the MMTV promoter to make transgenic mice that overexpress oncogenes in the breast. The first of these were performed in the laboratory of Philip Leder at Harvard (Stewart *et al*., 1984). A number of transgenic constructs were produced that fused the normal mouse c-*myc* gene with various lengths of its own promoter to the MMTV promoter (**Figure 5**). c-Myc is a basic helix–loop–helix (bHLH) transcription factor. It heterodimerizes with another bHLH transcription factor Max to activate transcription at E-box sites in promoters. It was one of the first identified oncogenes. In these first studies, two female founders of thirteen transgenic lines developed spontaneous mammary adenocarcinomas during an early pregnancy. The tumours and the breast tissue of these founder animals expressed RNA transcripts of the fusion gene. In addition, all female progeny of these two founder lines that inherited the MMTV/c-*myc* transgene also developed mammary adenocarcinomas during their second or third pregnancies. These mice were the first to describe the utility of the MMTV promoter in directing expression in the breast of transgenic mice, and were the first genetically manipulated mice to be susceptible to cancer. These mice were also the first mice to be patented and have been termed the Oncomouse.

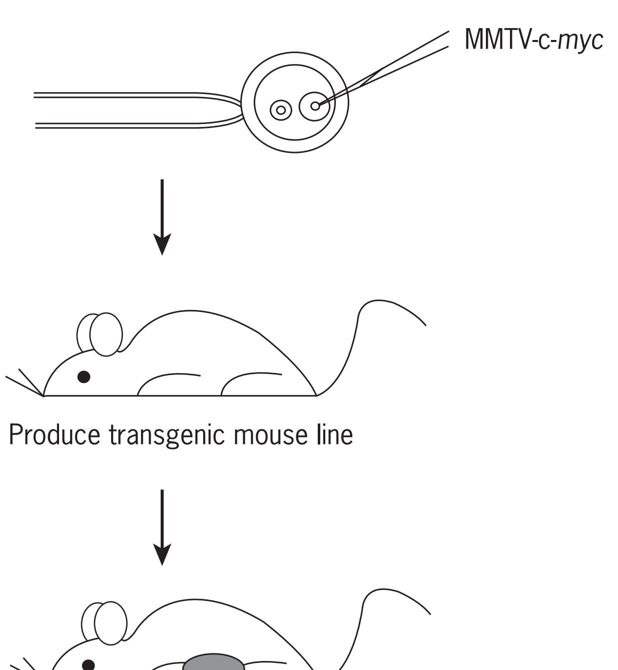

Figure 5 The production of MMTV-c-myc transgenic mice that get breast cancer.

Inactivation of Tumour Suppressors by Gene Targeting

In response to cellular DNA damage, cell cycle checkpoints are activated to arrest progression so that DNA can be repaired, and, if damage is extensive, the cell undergoes apoptosis. p53 plays a central, crucial role in regulating the distinct pathways that control these responses after DNA damage by diverse agents such as ultraviolet light, ionizing radiation (IR) and chemical carcinogens. p53 is maintained at a low level within the normal, undamaged cell. When a DNA damage signal is transmitted to p53 via upstream molecules that sense and respond to particular types of DNA damage, p53 is induced and regulates distinct downstream cell cycle checkpoint and apoptotic pathways. The importance of p53 in DNA damage responses is highlighted by the fact that mutation of p53 is the most common genetic abnormality in human cancer. Humans with Li–Fraumeni syndrome carry heterozygous p53 mutations and are predisposed to a wide variety of tumours.

p53 is a transcription factor that confers its effects by DNA binding and transcriptional regulation (Ko and Prives, 1990; Levine, 1997). p53 activates transcription of several genes by binding as a tetramer to p53-specific promoter elements, recruiting general transcription factors and activators to promoters of these genes. At least six genes have been demonstrated to be direct transcriptional targets of p53: *p21/WAF1/Cip1*, *mdm-2*, *GADD45*, *cyclin G*, *Bax* and *IGF-BP3*. Several of these genes have potential roles in cell cycle control and apoptosis, particularly *p21/WAF1/Cip1* (*p21*) and *Bax*. p53-dependent G1 arrest is mediated at least in part by transcriptional activation of p21, since p21 binds to cyclin/CDK complexes, and at high concentration p21 inhibits their activity. Bax forms a heterodimer with Bcl-2 and other family members, and these two proteins have opposing effects on apoptosis: Bax enhances apoptosis, whereas Bcl-2 promotes cell survival.

p53 activity can be increased by induction of protein levels or by activation of an inactive form of p53. DNA damage-induced increases in levels of p53 protein occur post-transcriptionally from decreased turnover or increased translation of p53. p53 can also be converted from inactive to active forms *in vitro* by a variety of agents, including antibodies to specific regions of p53, redox conditions, single stranded DNA and phosphorylation, suggesting that p53 activation may occur *in vivo*. Altered phosphorylation is a particularly attractive mechanism for rapid regulation of p53 activity. There are several phosphorylation sites at the N- and C-terminal regions of p53, and p53 can be multiply phosphorylated. These regions of the protein may be required for growth inhibition, suggesting a potential role for phosphorylated forms of p53 in cell cycle responses.

Because of the central role of p53 in choreographing the response to DNA damage, animals deficient for p53

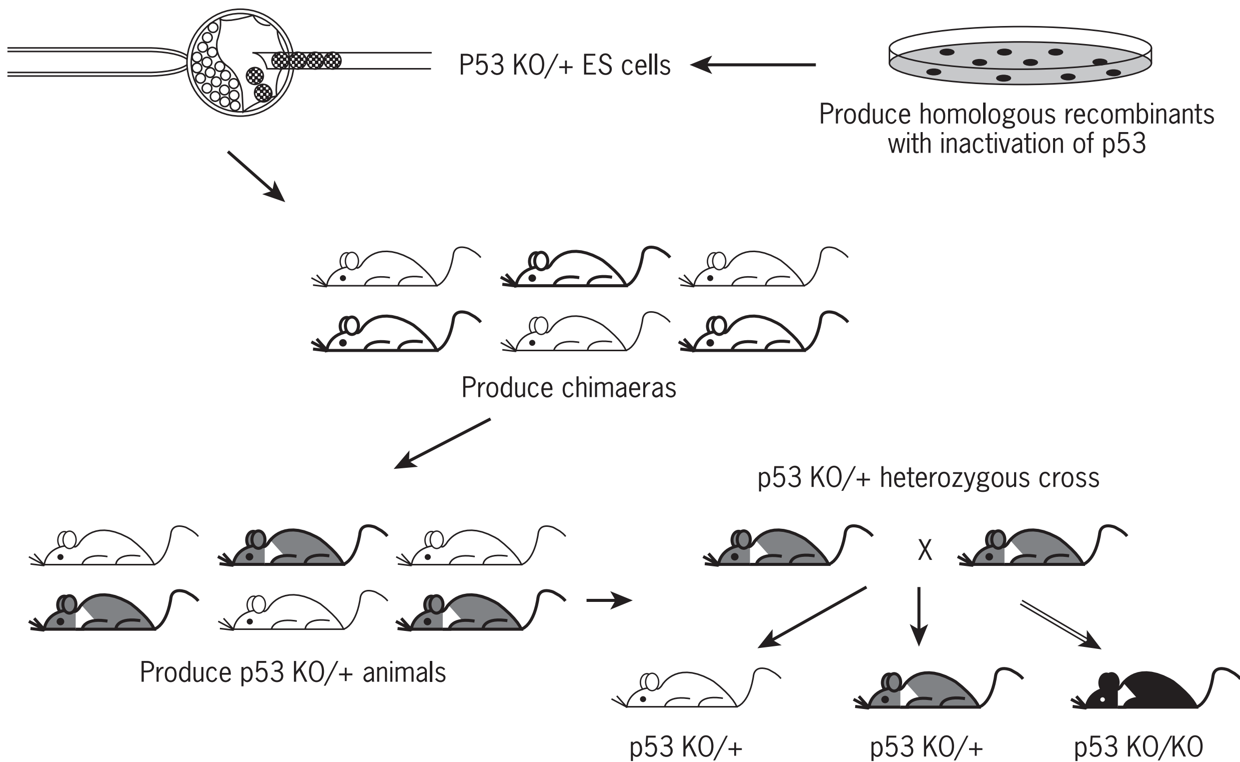

Figure 6 The production of p53-deficient mice by gene targeting.

were produced in two different laboratories (Donehower *et al*., 1992; Jacks *et al*., 1994). These animals were produced by gene targeting in the mouse (**Figure 6**). In both laboratories, it was found that p53 homozygous null mice were viable and developed normally, but displayed the spontaneous development of a variety of cancers by 4–6 months of age. Heterozygous animals also have an increased cancer risk, although with a longer latency to tumour formation. The distribution of tumour types in p53 heterozygous animals differs from that in homozygous mutants. In most cases, tumorigenesis in heterozygous animals is accompanied by loss of the wild-type *p53* allele. (See also chapter on *Regulation of the Cell Cycle*.)

Conditional Gene Knockouts for Tissue-specific Gene Inactivation

Breast cancer is the most common female cancer and the second leading cause of mortality in women. Approximately one in nine females are affected during their lifetime. About 5% of these women display an inherited form of breast cancer caused by loss of function mutations in the *BRCA1* gene. In fact, 90% of women with familial breast and ovarian cancers and about 50% of women with familial breast cancer alone display heterozygous germ-line mutations in *BRCA1*. Consequently, as for p53, many groups attempted to make a mouse model for this important human disease. However, it was found that homozygous *BRCA1*-null mice died during early embryonic development, and heterozygous mice did not develop tumours.

To overcome the early lethality, the *Brca1* gene was inactivated specifically in mammary epithelial cells of female mice using the Cre–*loxP* recombination system (**Figure 7**) (Xu *et al*., 1999). Mice were generated that carry a *Brca1* null allele, a *Brca1* conditional allele where exon 11 was flanked with *loxP* recombinase sites, and a *Cre* transgene under the control of the MMTV-LTR or the whey acidic protein (*WAP*) gene promoter, another mammary epithelial promoter. Cre-mediated excision of *Brca1* exon 11 occurred in the majority of mammary epithelial cells and was accompanied by a sharp reduction of *Brca1* transcripts. The reduction of BRCA1 impaired ductal outgrowth during pregnancy, and was frequently accompanied by apoptosis. Specifically, the ducts did not fully penetrate the fat pad. These results demonstrate that BRCA1 controls ductal elongation and branching morphogenesis during mammary gland development.

Most importantly, though, mammary tumour formation occurred after a long (10–12 months) latency. These tumours displayed genomic instability that was characterized by aneuploidy, chromosomal rearrangements and alterations of p53 transcription. Mating of these mice with the p53 null mice demonstrated that a loss of p53 accelerated the formation of mammary tumours. This example demonstrates the versatility of options available to study

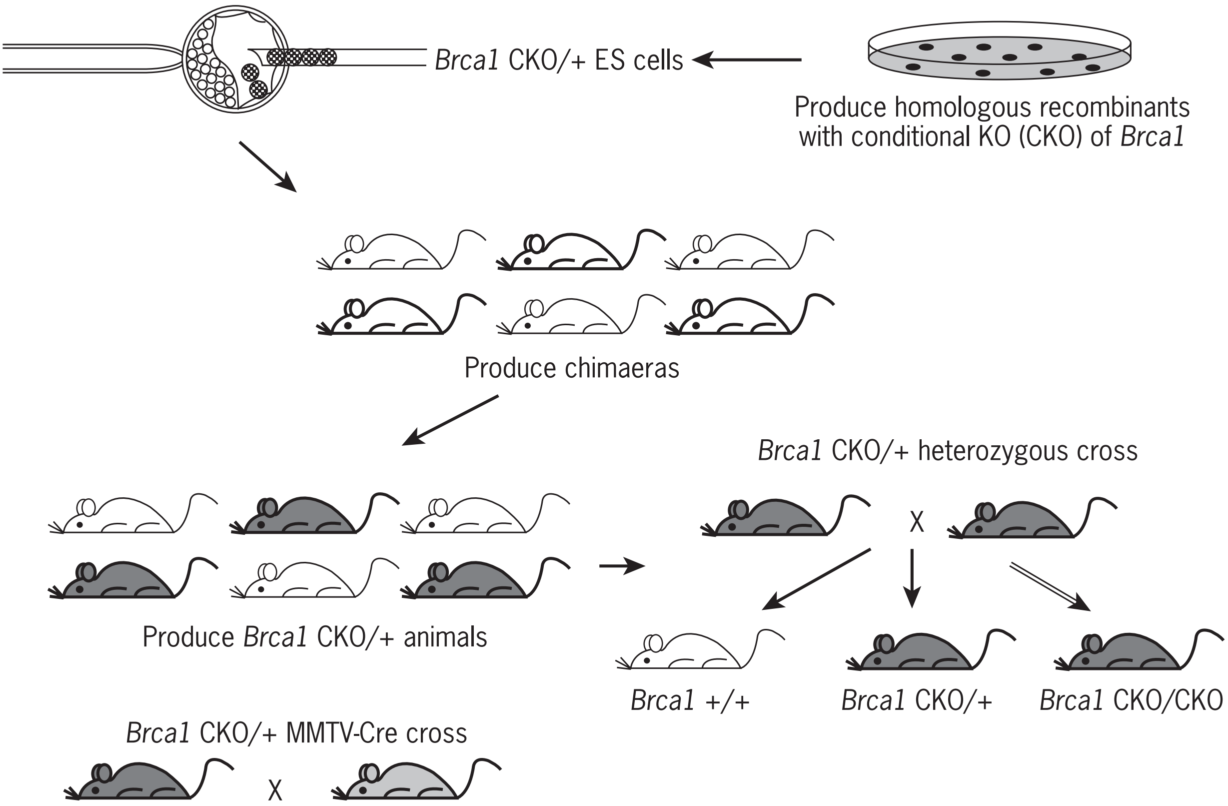

Figure 7 The production of *Brca1* conditional KO mice by gene targeting.

the role of cancer-causing genes *in vivo* in the mouse, even when the gene is essential for normal development.

Construction of Mice Bearing Deletions of Chromosome 11

Although single gene mutations often predispose to the development of cancer, tumorigenesis is ultimately caused by genomic instability. Among the changes that are often observed in tumours are regions of chromosomal deletion and duplication. These changes arise only in the tumour (i.e. they are not germ-line mutations). In addition, similar regions are often deleted or duplicated in the same type of cancer, suggesting that these regions contain genes important for certain types of cancer. The identification of the causative gene in these regions is often difficult.

Over the past few years, Allan Bradley's laboratory has been developing the ability to make deletions and/or duplications across an entire chromosome using ES cell technology (**Figure 8**), and approach that they have termed 'chromosome engineering' (Ramirez-Solis *et al*., 1995). Their first study focused on a small portion of chromosome 11. They constructed deficiencies, duplications and inversions in ES cells with sizes ranging from 1 Mb to 22 centimorgans (cM). Two deficiencies and three duplications were made into mice. Mice with a 1-Mb duplication developed corneal hyperplasia and thymic tumours, whereas two different 3–4-cM deficiencies were embryonically lethal in heterozygous mice. A duplication

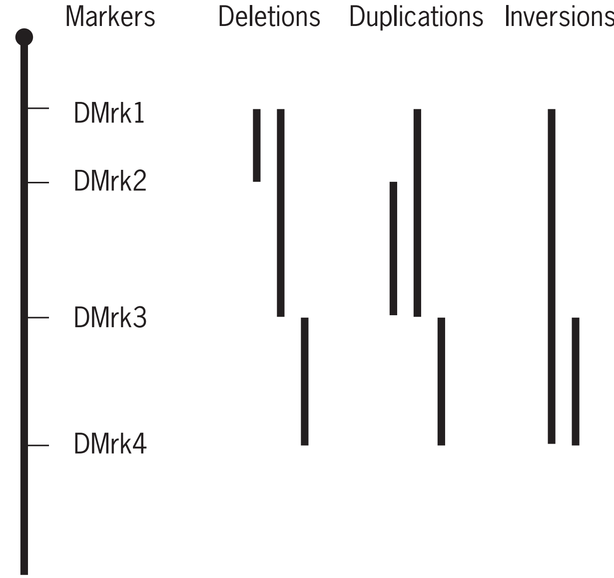

Figure 8 Deletions produced in mice from chromosome engineering. (Adapted from Liu *et al.*, 1998.) *DMrk1*, *DMrk2*, *DMrk3* and *DMrk4* refer to hypothetical marker sites.

corresponding to one of these two deficiencies was able to rescue its lethality, demonstrating that haploinsufficiency was in fact the cause of the lethality. Thus, they were able to produce mice that had defined deletions and duplications, and one of the deletions resulted in cancer.

INTERPRETATION OF EXPERIMENTAL RESULTS

Transgenic mice produced to express a dominant oncogene in a particular tissue are examined at regular intervals (usually weekly) for the presence of tumours in that tissue. Using the example of MMTV-driven oncogenes, breast tumours can be palpated along the lateral body wall of mice. Mice have five pairs of mammary glands, and tumours can arise in any of the glands. There are some unique properties to the MMTV promoter. Pregnancy stimulates expression from this promoter, so in practice, female mice bearing the MMTV-oncogene transgene are continuously mated to generate the highest possible levels of transgene expression. MMTV is often also expressed in the salivary glands and Harderian glands. Harderian glands are specialized tear glands located in the orbit. These tissues can also be the site of tumours in MMTV-oncogene transgenic mice.

Litter mate or age-matched controls are used to compare latency to tumour detection. Wild-type mice display spontaneous tumours only in rare cases and at relatively old age. Therefore, reproducible tumorigenesis in the target tissue is strong evidence for an oncogenic effect of the transgene.

For tumour suppressors in which the gene is inactivated in all tissues, any tissue could be the site of a tumour. The commonly used inbred mouse strains are somewhat susceptible to lymphomas, so lymphomagenesis is a likely outcome of broad inactivation of tumour-suppressor genes. As an example of this, p53 mutant mice mutant display lymphomas at a high frequency. As described above, litter mate or age-matched controls are used to compare latency to tumour detection, and reproducible tumorigenesis in any tissue is strong evidence for tumour-suppressor effect.

Latency to tumorigenesis or to tumour-free survival in a population of animals is normally represented as a Kaplan–Meier plot. Tumorigenesis is represented in a population by determining the age at which all animals in that population succomb to tumours (**Figure 9**). The proportion of animals surviving at each age is plotted over the entire life span of animals in a population. As mentioned above, wild-type animals rarely display spontaneous tumours, so the surviving fraction is usually 100% at all ages. In contrast, a population of tumour-prone animals will display a progressive decline in the numbers of animals. The age at which 50% of animals survive is used as a simple comparative measure between two populations.

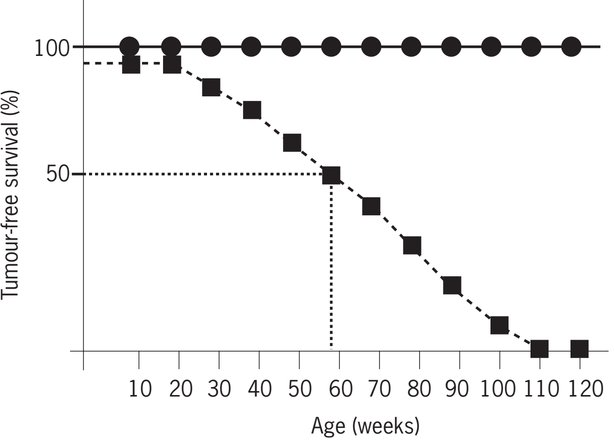

Figure 9 Kaplan–Meier survival analysis of wild-type (circles) and mutant cancer-prone (squares) mice. Note that 50% of the mutant mice have died by 58 weeks.

Genetic interactions can be determined in mice by mating two or more tumour-prone mice, and performing genetic epistasis analysis on the double mutants. If there is a genetic interaction between two different mutants, this provides strong evidence that the two mutant proteins cooperate in tumorigenesis. For example, suppose a putative oncogene 'A' overexpressed in the breast gives no detectable tumours, and that a different oncogene 'B' overexpressed in the breast gives tumours in 50% of animals by 1 year of age. Suppose now that double 'A + B' mutant mice with both transgenes overexpressed in the breast display aggressive breast tumours in 50% of animals by 2 months of age. These data suggest that these two oncogenes interact to promote tumours in the breast.

The hallmark of cancer is genomic instability, and it can be measured using several approaches (Ried *et al*., 1997). The major cytogenetic approaches are multicolour FISH techniques such as spectral karyotyping (SKY) (Schröck *et al*., 1996) and comparative genomic hybridization (CGH). SKY is a method which allows the simultaneous, unambiguous identification of each chromosome using individual chromosome painting probes, and is primarily used to determine whether translocations are present in a tumour sample (**Figure 10; see colour plate section**). SKY allows for the rapid identification of any chromosome, and is performed using flow sorted individual chromosome libraries. Using SKY and mouse chromosomal painting probes, all mouse chromosomes can be analysed and identified simultaneously in metaphase spreads and each displayed using a different colour. Metaphase chromosomes are prepared from a tumour using standard procedures. The mouse chromosome specific painting probes are generated from flow sorted mouse chromosomes differentiated by size. DNA labelling of each chromosome is performed in the presence of different combinations of five fluorochromes, such that

after excitation, each chromosomal probe will emit a slightly different wavelength of light. *In situ* hybridization is performed by combining the labelled DNA pools with an excess of a *Cot-1* fraction of mouse DNA to reduce background from repeat sequences. Multicolour hybridization is visualized using a combination of Fourier transform spectroscopy, CCD imaging and optical microscopy. The spectrum of the emitted light is recorded by the CCD camera and measured by the spectrophotometer at each pixel of the image to assign a specific spectrum to each chromosome. The measurement of specific emission spectra then allows the simultaneous display of all mouse chromosomes, each with a different colour, as shown in **Figure 10; see colour plate section**. Note how easy it is to determine the presence of multiple translocations in a metaphase spread. The location of translocation breakpoints can be used to identify genes deregulated as a result of the genomic rearrangement. Often the location will suggest candidate genes that can be tested using conventional FISH probes. Alternatively, the breakpoint can be cloned by conventional molecular biological techniques.

CGH is used primarily to identify regions of chromosomal gains and losses in a tumour (**Figure 11; see colour plate section**). DNA is prepared from a tumour and a nontumour control tissue or cell line. It is important that this control DNA is uniformly diploid, since it will be used as a standard to compare gene dosage in tumours. The control DNA is labelled with one fluorochrome (green, for example) and the tumour DNA is labelled with another fluorochrome (red, for instance). These two probes are mixed in equimolar amounts, and used as a hybridization probe against a normal metaphase chromosome spread. If a chromosomal region is diploid in the tumour sample, there will be equal hybridization of the control and tumour DNA, and the chromosomal region will appear yellow. In contrast, if there are regions of amplification or deletion in the tumour, then the chromosomal region will appear red for amplification and green for deleted regions. These CGH metaphase spreads can be captured and analysed by commercially available software dedicated to CGH analysis, and can even estimate relative levels of amplification and loss of chromosomal regions. The location of these genomic rearrangements can point to candidate genes in that region of the chromosome for further analysis.

Microsatellite instability is an additional type of genomic instability seen in mismatch repair proteins of the MLH and MSH families. Microsatellites are small repeat sequences present in the genome that can change sizes in the absence of fully functional mismatch repair. The length of these microsatellites can be determined by sensitive PCR assays, and this assay can be used to provide evidence for the involvement of mismatch repair pathways in tumorigenesis of a particular mutant.

It is clearly of great interest to understand the genes and ultimately the genetic pathways that are disrupted during the genesis of a particular tumour. It has recently become possible to analyse global gene expression by the use of a variety of PCR-based techniques to assay broadly for changes in gene expression. Subtracted libraries are used to clone mRNAs that show differences between the reference and test samples. Serial analysis of gene expression (SAGE) and differential display methods employ PCR techniques to measure differences between two different populations of mRNA, and to clone these differences. Differential display techniques use oligonucleotides synthesized with all possible sequence combinations to assess broadly gene expression between two populations of mRNA. Each of these methods depends upon large differences between reference and test samples. Recently, it has become possible to sample the expression pattern of thousands of genes simultaneously using high-density cDNA arrays (Duggan *et al*., 1999). The advantage of this method is that each spot of a microarray represents a known gene. As all genes of a genome are discovered, it is possible to develop arrays containing every gene in a genome to assess quantitatively mRNA expression of every gene simultaneously.

There are several available options to carry out reproducible, high-throughput analysis of the expression of thousands of genes simultaneously using microarrays. It is possible to purchase premade filters or arrays that contain hundreds to thousands of cDNAs. These filters are hybridized against radioactive probes made from a single source, so two filters must be purchased for any comparative study, and they must be read on a phosphorimager. Premade filters have little flexibility, in terms of adding genes as the human and mouse genome sequencing efforts progress, but have the advantage of being simple to use in any laboratory that performs Southern or Northern blot hybridization analysis. In addition, it is thought that these filters will be useful for detecting only high- and medium-abundance mRNAs. Another option is to use high-density microarrays of cDNAs or of oligonucleotides that represent parts of different cDNAs made by companies such as Incyte or Affymetrix. At the moment, these commercially available arrays are expensive, and the supply of chips is limiting.

Microarray technology has been developed in academic laboratories and industry as a cost-effective and reliable means to analyse comparatively genome-wide patterns of mRNA expression (**Figure 12; see colour plate section**). Ultimately, the goal is to develop arrays containing every gene in a genome to assess quantitatively mRNA expression of every gene simultaneously. At this time, every gene is known only for three eukaryotic organisms: *Saccharomyces cerevisiae*, *Caenorhabditis elegans* and *Drosophila melanogaster*, where the genomes have been completely sequenced. A working draft of the human genome has now been published (February 15, 2001, *Nature*, **409**; February 16, 2001; *Science*, **291**), and a working draft of the mouse genome is predicted for 2005. For mammalian organisms at present, UniGene sets for the human (15 000, cDNAs, or approximately 15% of the

human genome) and mouse (8000 cDNAs, or approximately 8% of the murine genome) are commercially available. cDNA-based microarrays are made by robotically printing cDNA inserts on to a glass slide and subsequently hybridizing these slides to two differentially labelled fluorescent probes. The probes are pools of cDNAs generated after isolating mRNA from cells or tissues in two or more different states, so that one can compare expression patterns of all genes under different conditions. The resulting fluorescent intensities are assayed with a fluorescent reader, and the ratio of expression in the two states is obtained following image processing. The crucial elements to this technology are an arrayer, a representative cDNA set, a microarray reader, image analysis software and database management protocols. With these elements, it is possible to compare global RNA expression patterns in two or more different RNA pools and to define differences in expression between pools. Several academic and commercial groups have developed robotic arrayers to place thousands of cDNA clones on defined spots of an array, and these arrayers are often matched with chip readers to capture the data after hybridization. In addition, many groups are working to develop the bioinformatics capabilities needed to handle this very large volume of data.

BIOLOGICAL LIMITATIONS

In many ways, the mouse is the perfect experimental system for the creation of models of human genetic diseases such as cancer. The genome size and number of genes are similar between human and mouse, as are patterns of development. It is relatively cheap to house mice, in comparison with other mammals. Mice have relatively short gestation periods, a brief time of maturation to sexual maturity and large litter sizes. Most importantly, it is the best mammalian species for genetic manipulation, and the only one where it is currently possible to perform germline knockouts in embryonic stem cells.

Although the mouse is good as an experimental system, it is not perfect for modelling human diseases. Often a knockout or transgenic mouse has a phenotype that is different from the human genetic disease. There are many explanations for why this might occur, and a few examples are provided here.

1. There may be redundant pathways in the mouse not present in the human. There are many examples of this in the literature. Mice have redundant pathways not present in the human for Tay–Sachs disease, Lowe's syndrome and galactokinase deficiency, to name a few examples.
2. The pattern of overexpression of the transgene is not similar to that of the human disease gene. The inherent variability of expression of transgene expression in mice often leads to unpredictable and variable phenotypes. Regulatory elements may not be present in the transgene, or the site of integration may modify the pattern of expression.
3. The developmental pathway that is disrupted in the human disease is either not present or is different in the mouse. In general, the mouse is related closely enough to humans that this should not pose a major problem. However, there must be genes in the human that are involved in unique processes such as complex brain folding and development which may not have a similarly important role in the mouse. If so, it may not be possible to use the mouse to model certain genetic diseases.
4. The life span of the mouse is too short to develop cancer. An advantage to using the mouse as a model is that it develops rapidly. However, if a certain type of cancer requires years to develop, a mouse may not live long enough to develop tumours.
5. The human mutation is not faithfully reproduced in the mouse. Transgenic constructs are usually made with promoters that express cDNAs in a desired spatial and temporal pattern. Knockout constructs are usually made by insertion of a *neo* gene into the gene that is being targeted for positive selection, with or without the deletion of coding sequences. These strategies, although extremely valuable, may not faithfully reproduce the mutation that is seen in a human disease.
6. Inherent tumour spectrum of inbred mouse strains. Many inbred mouse strains used for transgenic experiments seem particularly susceptible to certain types of tumours. For example, lymphomas are commonly seen in mice with inactivation of tumour suppressors such as *p53* and *ATM*. Fortunately, many inbred strains are available that can be used to alter the tumour spectrum displayed in a particular transgenic mouse.
7. Developmental role for the cancer-causing gene. Although a somatic mutation in a particular gene can lead to cancer, the complete inactivation of the same gene in the germ line could result in severe developmental defects. As described above, it is possible to inactivate genes in somatic tissues using conditional knockouts of such genes in conjunction with mice that express recombinase in the appropriate spatial and temporal pattern. This type of approach was illustrated above for *Brca1*.

Notwithstanding these limitations, the mouse remains an excellent mammalian genetic organism to model human cancer, and will likely be the model of choice for the next decade and longer.

PERSPECTIVES

The development of transgenic and gene targeting techniques for genetic modification of the mouse has resulted

in tremendous insights into the genetic processes that cause cancer. The continued use of these techniques to analyse *in vivo* the consequences of these genetic changes will allow for even greater insights into the genetic causes of cancer. With the imminent completion of the human and mouse genomic sequences, we will soon have at our disposal a catalogue of all of the genes in these mammalian organisms. The importance of any of these genes to tumorigenesis can be tested directly in the mouse using the techiques described in this chapter. Although much has been learned, much remains to be unravelled using these approaches.

BIOLOGICAL BACKGROUND: MOUSE MODELLING OF CANCER: A NEEDED TOOL?

'Mouse modelling' is intrinsically and conceptually an inappropriate definition in that it implies that the ultimate goal of these experiments is to reproduce in the mouse a human disease. On the contrary, the data accumulated in the past two decades have shown that these experiments go beyond pure mimicry of the disease itself, and have indeed enabled us to gain tremendous insight and dissect the molecular mechanisms underlying oncogenesis and the pathogenesis of any cancer.

Numerous laboratories have used the transgenic approach as well as gene targeting in order to create mouse models for the study of cancer pathogenesis. The analysis of these mutants has led to a better understanding of the normal function of genes involved in tumorigenesis, the relationship between the histopathological progression of cancer and acquisition of specific genetics lesions as well as many other aspects of disease progression such as the biology of metastasis, which have to be studied in the context of the whole animal.

Transgenic mice harbouring activated forms of proto-oncogenes or dominant negative forms of tumour-suppressor genes have been generated in order to test the causal relationship between their expression and tumour development as reviewed in the chapter *Transgenic Technology in the Study of Oncogenes and Tumour Suppressor Genes*. (See also the chapter on *Human Tumours in Animal Hosts*.) Mouse strains where putative tumour-suppressor genes have been inactivated (or 'knocked out') have been useful to assess the consequences of the lack of their function in tumorigenesis (reviewed in this chapter). Animal models have also determined the importance of specific gene mutations in tumorigenesis. These studies have provided an in-depth insight into cancer-related molecular pathways and the relationship between normal developmental processes and tumorigenesis. Interbreeding of transgenic and knockout mutants has allowed the introduction of multiple cancer-associated mutations in a single animal and, in turn, the discovery of cooperating mutations/pathways. Mouse models, unlike *in vitro* studies, allow one to integrate the analysis at the organismal and cellular levels with the overall physiological response of the animal to the disease (e.g. immune response).

Understanding genetic pathways still remains a prerequisite for the development of molecular and pharmacological therapies in order to treat and prevent cancer effectively. Thus, these models will represent an invaluable instrument not only to study the pathogenesis of human cancer, but also to exploit novel therapeutic approaches.

PRINCIPLES OF MODEL ESTABLISHMENT

The Knockout Approach in the Mouse

The possibility to manipulate and to culture pluripotent mouse embryonic stem (ES) cells has allowed for the generation of mice with a specific alteration in a chosen target gene. ES cells are in fact capable of contributing to the formation of all organs including the germ line when introduced into the developing blastocysts (3.5 dpc embryo). To engineer knockout mice, the first step is therefore to generate a targeting vector, which is transfected into ES cells (**Figure 1**). This vector contains sequences that allow the introduction of a specific disrupting mutation into a defined locus by homologous recombination (**Figure 1**). The vector is next transfected into embryonic stem cells. Recombination between the endogenous locus and the vector in the regions of homology occurs spontaneously since ES cells are competent for recombination. However, recombination occurs at very low frequency, thus rendering necessary a selection step to identify the cells

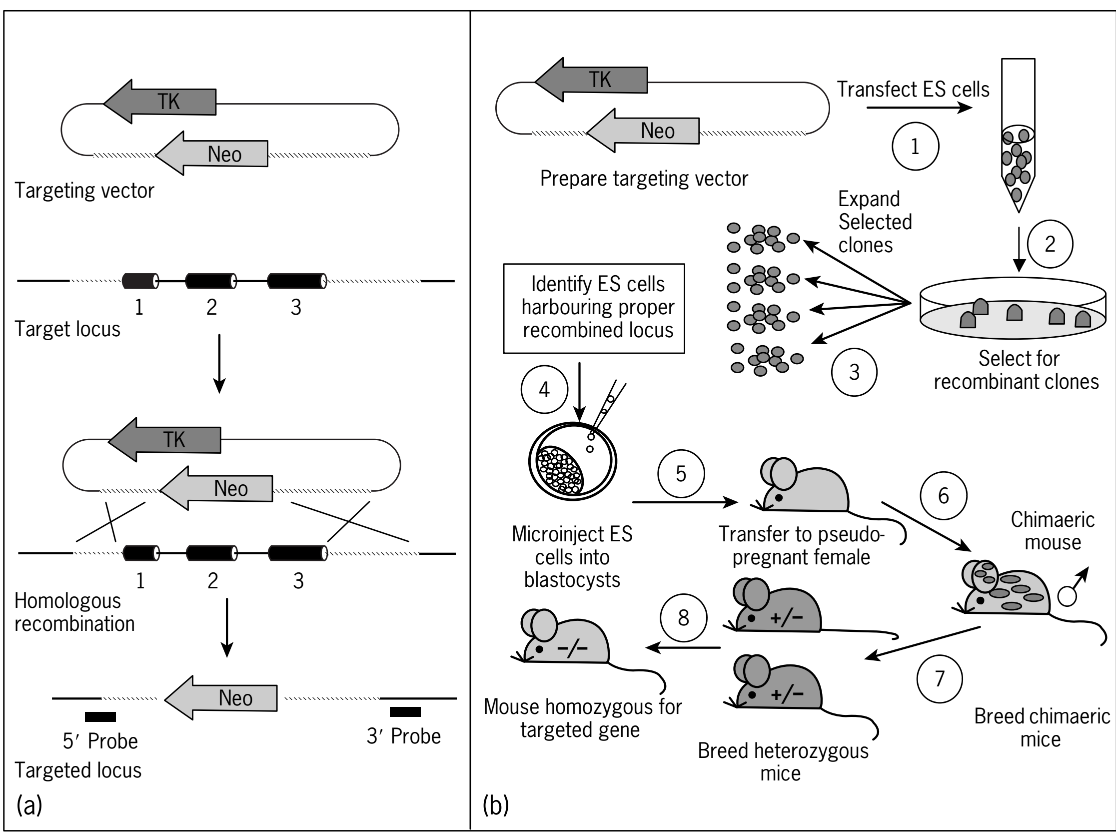

Figure 1 Schematic representation of the strategy for the generation of knockout mice. (a) targeting strategy. The targeting vector contains two regions homologous to the desired chromosomal integration site (▨). Homologous recombination between sequences of the targeting vector and the target locus will result in the disruption of the target gene by the replacement of the region containing exons 1, 2 and 3 (as an example) with the positive selectable marker: the *neo* (neomycin phosphotransferase) resistance gene cassette. The HSV*tk* (herpes simplex thymidine kinase) gene, which is used as a negative selectable marker and renders the cells sensitive to Gancyclovir, is lost in the case when proper recombination has occurred. Thus, recombined clones become resistant to both G418 and Gancyclovir. Southern blot analysis on individual clones with appropriate probes external to the targeting vector will identify the recombined locus in view of the fact that the presence of the *Neo* cassette will change the configuration of the targeted locus. The hatched lines represent the regions of homology to the target locus; the thin line represents the bacterial plasmid. The black cylinders identify the exons of the target gene. The two large crosses represent the crossover points. (b) Generation of knockout mice. (1) The replacement vector is linearized outside the region of homology and transfected into ES cells. (2) Transfected ES cells are then plated on feeder layer cells and subjected to positive selection (G418 in the case of the *neo* gene) and in some cases to negative selection (Gancyclovir in the case of HSV*tk* gene). This process gives rise to ES cells colonies after few days of selection (7–10 days). (3) The different ES clones are picked and expanded in order to have enough cells to prepare DNA. Genotyping is subsequently performed either by Southern blot or PCR in order to identify recombined clones. (4) Recombined clones are then independently microinjected in the blastocoelic cavity of blastocysts. (5) Injected blastocysts are transferred into pseudopregnant females. (6) Pups are born with various degrees of chimaerism. The chimaerism is scored by simple colour coat inspection. The ES cells are typically derived from 129*sv* mouse strain with agouti coat. The recipient blastocysts are generally derived from C57B/6 strain with black coat. Thus, a high degree of chimaerism will be shown by a highly agouti coat in chimaeric mice. (7) The chimaeric mice are crossed with wild-type mice to obtain heterozygous mutants in case the mutation has been transmitted to the germ line. (8) Finally, heterozygous mutants are intercrossed to generate null homozygous mice.

where the recombination took place. ES cells are therefore subjected to both positive and negative selection for markers, which are contained in the targeting vector (**Figure 1**).

Mutant ES cells that harbour a mutation on one allele (heterozygous or hemizygous for the mutation) are next microinjected into mouse blastocysts to generate mice constituted in part by cells of the recipient blastocyst

and the mutant ES cells. These organisms are therefore referred to as chimaeric mice (**Figure 1**). When ES cells contribute to the germ line of a chimaera it is possible to identify mice derived entirely from the mutant ES cells and therefore heterozygous/hemizygous for the mutation among its offspring. Subsequent interbreeding of heterozygotes yields animals homozygous for the desired mutation, which can be studied for the phenotypic manifestations of gene inactivation (e.g. tumorigenesis if the gene inactivated is a putative tumour-suppressor gene). This approach can be utilized not only to disrupt genes, but also to introduce specific mutations in the coding of a gene (e.g. an activating or dominant negative mutation in an oncogene or a tumour-suppressor gene, respectively). Gene targeting in mouse ES cells is, without a doubt, the most elegant and selective tool for the manipulation of the vertebrate genome ever devised in order to study *in vivo* the function of a gene and how it relates to human cancer pathogenesis. However, this approach also has limitations described in the following paragraphs that rendered necessary further implementations of this powerful technique.

The Cre–*loxP* System for *In Vivo* Tissue-specific Gene Targeting

As mentioned before, the conventional 'knockout' approach has been extremely useful in studying the function of numerous genes involved in cancer pathogenesis; however, in many instances the mutant mice die prenatally because the missing gene exerts a critical role in embryogenesis. In order to circumvent this limitation, a conditional targetting strategy utilizing the Cre–*loxP* system has been developed (**Figure 2**). The Cre–*loxP* system represents an ideal instrument for the manipulation of chromosomal organisation and the control of gene expression *in vivo*, in a tissue-specific manner, and at a specific time in development. Cre, the recombinase of bacteriophage P1, is able to mediate the specific excision of DNA flanked by *loxP* recognition sites from the genome of mammalian cells in culture and transgenic mice. The experimental procedure to generate mouse models by using this system consists of three distinct phases: (1) generate a mutant mouse, where the gene of interest is flanked by *loxP* sites; (2) generate transgenic animals in which the *Cre* gene is expressed in a tissue-specific manner; (3) intercross the mutant mice generated in step 1 with the ones generated in step 2. As a result, Cre will excise the intervening sequence, removing the coding region of the gene of interest and resulting in inactivation of the gene only in the tissue or cells in which the *Cre* gene is expressed. The consequences of the tissue specific gene disruption can now be analysed, thus circumventing embryonic lethality. A similar system termed Flp–frt has been also widely utilized. In this case, Flp is the recombinase and FLP recognition targets (frt) are the equivalent of the *loxP* sites.

The 'Knock-in' Approach

The 'Knock-in' approach refers to the generation of mice in which one particular gene (or sequence) is replaced by another gene or aberrant gene by homologous recombination (**Figure 3**). ES cells containing the targeted gene are generated following the same procedure as in the knockout approach. These cells are subsequently utilized to generate mice expressing the 'knocked-in' gene. This strategy is generally utilized as an alternative approach to the generation of transgenic mice which, although time consuming, offers several advantages. Compared with the transgenic approach, the main advantage is the possibility of expressing the gene of interest under the control of an endogenous promoter, thus providing expression levels similar to that observed in normal physiological situations (e.g. a cancer-associated fusion gene can be targeted into the locus of the parental gene, thus closely mimicking what happens at the somatic level in a cancerous cell upon a chromosomal translocation). An additional advantage of this methodology is that the copy number of the 'knocked-in' gene is a known parameter to start with, and can be increased simply by modifying the targeting vector. Finally, this approach can also be used to knock in a reporter gene such as GFP (green fluorescent protein) or Lac-Z, under the control of regulatory elements of the gene of interest, in order to define more precisely its expression pattern during embryogenesis and in adulthood (e.g. the reporter gene can be placed in frame with the first coding amino acids of the target protein).

GENERAL APPLICATIONS AND INTERPRETATION OF EXPERIMENTAL RESULTS

We will provide here representative examples of how knockout technology has been utilized to prove the critical tumour-suppressive role of genes implicated in human cancer pathogenesis. We will also assess the usefulness of some of these knockout mutants as models for the corresponding human cancer syndrome.

p53-deficient Mice (Li–Fraumeni Syndrome)

Mutations in the *p53* tumour-suppressor gene occur in about 40% of all human tumours and represent one of the most frequent genetic alterations observed in human cancer. Most *p53* alterations are missense mutations resulting in the expression of a functionally altered protein. Discovered

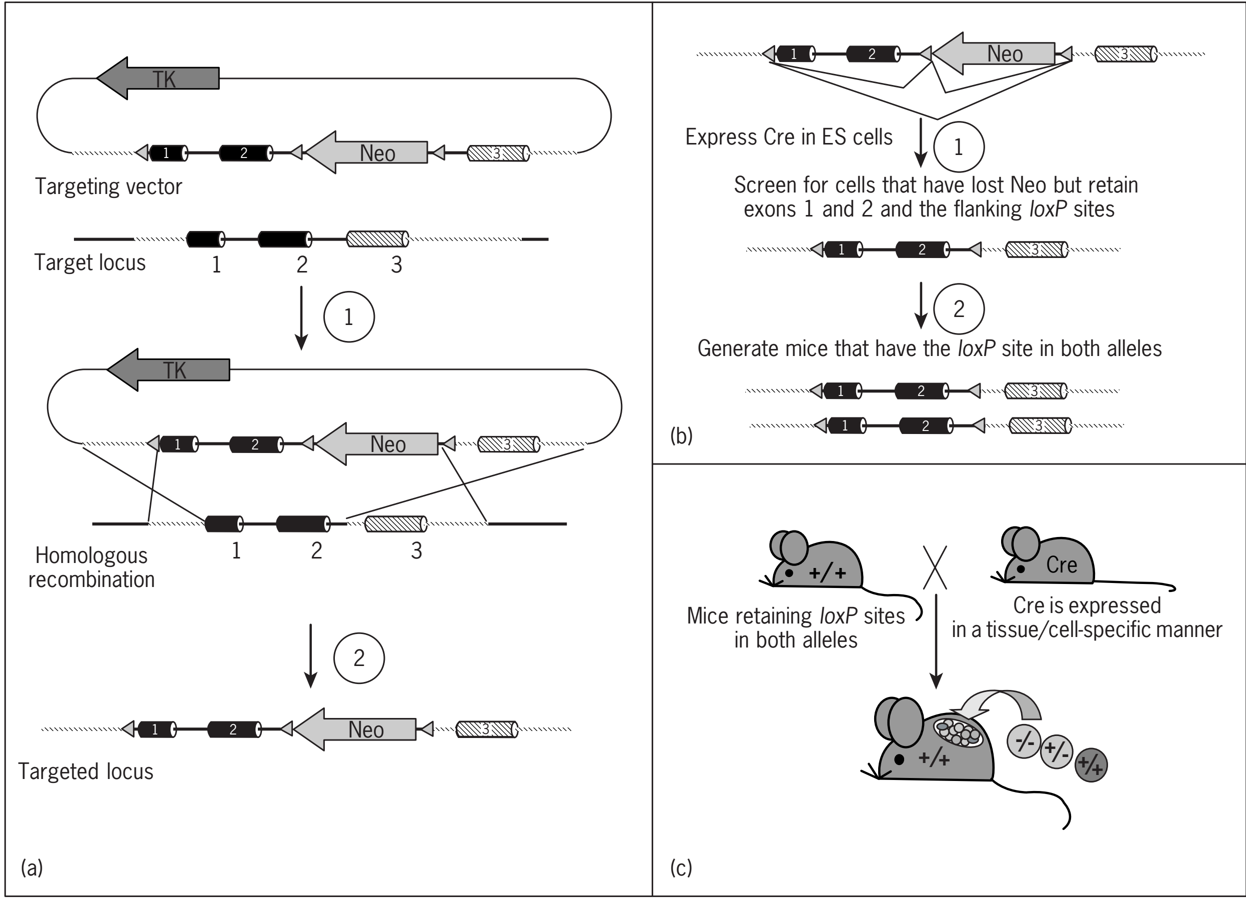

Figure 2 Schematic representation of the strategy for *in vivo* tissue specific Cre–*loxP* mediated recombination. (a) Targeting strategy. Following the same strategy as described in **Figure 1**, *loxP* sites and *neo* cassette will be inserted within intronic regions of a gene. (b) Cre-mediated recombination *in vitro*. In a first step, Cre recombinase is expressed in ES cells (this can be achieved by retroviral expression or by transient transfection). Cre will mediate the specific excision of DNA sequence flanked by *loxP* sites. *LoxP* sites are approximately 20 base pairs in length and do not interfere with the proper transcription of the locus. Consequently, this step results in the generation of ES cells with three distinct genotypes: (i) allele lacking *neo*, exons 1 and 2; (ii) allele lacking exons 1 and 2; (iii) allele only lacking *neo*. The ES cells lacking *neo* (iii) are expanded, and chimaeric mice are generated as described in **Figure 1**. Chimaeras and heterozygous mutants are intercrossed in order to generate mice homozygous for exon 1 and 2 flanked by two *loxP* sites. (c) Generation of tissue specific knockout mice. Transgenic mice expressing Cre in a tissue-specific manner are intercrossed with homozygous mice from step (b) In the resulting double mutants, Cre will excise exons 1 and 2, leading to the inactivation of the gene of interest only in tissues and cells where Cre is expressed. The hatched lines and hatched cylinders represent the vector homology to the target locus. Black cylinders indicate exons; the thin black line represents the bacterial plasmid. The triangle represents the *loxP* sites. The neo (neomycin phosphotransferase) is the positive selectable marker. The *TK* (herpes simplex thymidine kinase gene) is the negative selectable marker. The large crosses represent the crossover points.

in 1979 as a cellular protein complexed with a tumour virus protein, *p53* was initially considered an oncogene, because mutant p53 had an oncogenic activity in transformation assays. However, subsequent reports have shown that the *p53* gene encodes for a tumour-suppressor protein. Wild-type p53 has been referred to as the ‘guardian’ of the genome, as p53 responds to DNA damage or cell cycle checkpoint failure, either by arresting cells in the G1 phase of the cell cycle for damage repair or through the initiation of an apoptotic pathway to eliminate the damaged cell entirely. Whether arrest or apoptosis is induced, the result is that the cell with DNA damage is prevented from replicating damaged DNA templates, thus avoiding potential oncogenic lesions. The role of p53 in cell cycle arrest is mainly due to direct regulation of gene transcription. p53 can positively regulate the transcription of genes such as $p21^{\mathrm{WAF1/CIP1}}$, a G1 cyclin-dependent kinase inhibitor, *mdm*-2, *GADD*45, *IGF-BP3* and *Bax*. p53 is also involved in the negative regulation of certain genes that are implicated in positive growth regulation such as PCNA

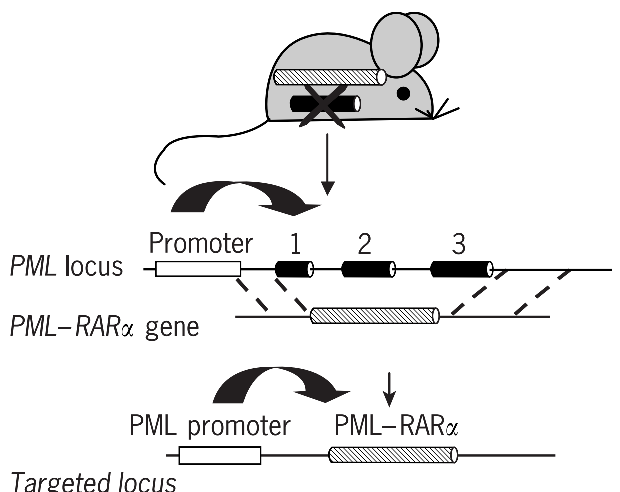

Figure 3 Schematic and representative example of a 'knock-in' experiment. In this case, a gene such as the PML gene of APL can be replaced by an oncogenic aberrant fusion gene such as *PML–RARα*. As a result, the expression of *PML–RARα* will be under the control of the promoter/regulatory regions of the PML gene as in human APL blasts. The targeting vector can be designed in a way that the first few exons of the *PML* gene are precisely replaced by the coding region of the *PML–RARα*.

and Bcl-2. p53 is critical for the maintenance of genomic stability. Several assays have shown that cells missing p53 display frequent genetic aberrations of various types: aberrant ploidy, gene amplification, increased recombination and centrosomal dysregulation. Mutation of p53 may result in the loss of wild-type function and also in the generation of dominant negative and gain of function mutants. p53 heterozygous mutations have been found in Li–Fraumeni patients which are susceptible to develop tumour of various histological origins. (See also chapter on *Regulation of the Cell Cycle*.)

Owing to its importance for cell cycle control and cancer prevention, the generation of p53 knockout mice was essential. Several groups have developed p53 null mice. These mice have a normal development, but, as expected, 75% of the p53 null mice develop tumours of various histotypes by 6 months of age and all die by 10 months of age. p53 null mice developed mainly thymic T cell lymphomas and soft tissue sarcomas and testicular teratomas and osteosarcomas. $p53^{+/-}$ mice are also prone to develop cancer. Tumours are observed starting from the ninth month of age and by 24 months more than 95% of the animals die. $p53^{+/-}$ mice are more prone to develop osteosarcomas and soft tissue sarcomas than null mice, which more commonly develop lymphomas.

The $p53^{+/-}$ mouse shares similarities with Li–Fraumeni patients. The tumour types found in mice are also observed in Li–Fraumeni patients. However, the overlap is not complete since, for instance, brain and breast tumours observed in Li–Fraumeni patients are not observed in the mouse model.

Of interest, Southern blot and sequencing analysis of the wild-type allele in tumours arising from $p53^{+/-}$ mice shows that it is structurally intact in more than 50% of tumours. Furthermore, the analysis of p53 function in these tumours shows that the p53 protein retains normal transcriptional activity and apoptosis induction. The inactivation of both copies of a tumour-suppressor gene is considered the prerequisite for tumour formation as postulated in the 'two-hit' model of Knudson. In the case of p53, however, the reduction of gene dosage to heterozygosity seems to be sufficient for tumorigenesis.

It is also worth noting that onset of tumorigenesis may vary depending on the mice strain. For instance, the $p53^{-/-}$ and $p53^{+/-}$ mice generated in the 129/*sv* background develop tumours sooner than mutants in a C57BL/6 background. Moreover their tumour spectrum is different. In the 129/*sv* background the mice develop mainly testicular teratomas and lymphomas, whereas the C57BL/6 mice develop mainly lymphomas. These differences demonstrate the importance of tumour-modifier genes in cancer susceptibility by p53 inactivation and make the mouse a unique tool for gene discovery, also in view of the fact that the mouse genome project will soon be completed.

PTEN-deficient Mice (Cowden Syndrome)

The *PTEN* (phosphatase and tensin homologue deleted from chromosome 10 gene), also known as *MMAC1* (mutated in multiple advanced cancers) or TEP1 (TGFβ-regulated and epithelial cell-enriched phosphatase) has been recently identified as a tumour-suppressor gene. Somatic mutation or deletions of this gene have been found in a large fraction of tumours, including glioblastomas, endometrial and prostate cancer, placing *PTEN* among the most commonly mutated genes in human cancers. Germline heterozygous *PTEN* mutations are associated with Cowden disease. This syndrome is characterized by developmental defects as well as susceptibility to breast, thyroid and brain tumours. *PTEN* is also mutated in two related familial syndromes, Lhermitte–Duclos disease and Bannayan–Zonana syndrome, which show similar predisposition to tumours but distinct developmental defects.

PTEN is the first example of a tumour-suppressor gene that encodes a phosphatase. PTEN contains a tyrosine phosphatase domain with features resembling those of the dual-specificity phosphatases, which are able to dephosphorylate both tyrosine and serine/threonine residues. Despite its homology with the dual-specificity phosphatses, PTEN is an inefficient protein phosphatase *in vitro*. However, phosphatidylinositol 3,4,5-triphosphate has proved to be the main PTEN substrate. Recent studies suggest that the focal adhesion kinase and Shc may be

regulated by PTEN. However, the tumour-suppressive function of PTEN is dependent solely on its lipid phosphatase activity.

Several groups have generated PTEN-deficient mice. Null embryos displayed an early embryonic lethal phenotype between days 6.5 and 9.5 d.p.c. (possibly depending on the genetic background), owing to aberrant differentiation and patterning of the embryonic germ layers. Analysis of the embryos shows poorly organized ectodermal and mesodermal layers and over growth of the cephalic and caudal region due to aberrant patterning.

The role of PTEN in tumorigenesis was confirmed by the fact that $PTEN^{+/-}$ mice develop a broad range of tumours including thyroid, prostate, small and large intestine, endometrial tumours and phaeochromocytomas. Furthermore, it has recently been shown that, the concomitant inactivation of one *Pten* allele and one or both $p27^{KIP1}$ alleles dramatically accelerates spontaneous neoplastic transformation and incidence of tumours of various histological origins. Cell proliferation, but not cell survival, is markedly increased in $Pten^{+/-}/p27^{-/-}$ mice. Furthermore, $Pten^{+/-}/p27^{-/-}$ mutants develop prostate carcinoma at complete penetrance within 3 months from birth. These cancers recapitulate the natural history and pathological features of human prostate cancer. Thus, PTEN and $p27^{KIP1}$ play a pivotal cooperative role in tumour suppression in epithelial tissues, and combined loss of PTEN and $p27^{KIP1}$ are key events in the pathogenesis of epithelial cancers as suggested by the short latency and complete penetrance of these tumours in *Pten/p27* double-mutant mice.

Rb-deficient Mice (Inherited Childhood Retinoblastoma)

Childhood retinoblastoma has both an inherited and sporadic condition component: about 60% of cases are nonhereditary and 40% are inherited. In familial retinoblastoma, young children can develop multifocal bilateral tumours of the retina. These individuals inherit one defective autosomal allele through the germ line and the wild-type allele is lost due to somatic mutation leading to tumorigenesis. Individuals who inherit an inactivated copy of *Rb* gene have an estimated 90% probability of developing retinoblastomas at an early age. *Rb* is also commonly mutated in sporadic retinoblastomas, lung, breast, prostate and bladder cancer.

Rb is a nuclear phosphoprotein, which shares homology with p107 and p130, two other members of the same family of proteins. The Rb protein is an important regulator of the G1 checkpoint. It binds to members of the E2F family of transcription factors needed for the expression of S phase early genes and prevents S phase entry. Hyperphosphorylation of Rb by G1/S cyclin-dependent kinases release E2Fs from Rb-mediated repression and enables the progression of the cell cycle.

In order to study the role of the *Rb* gene in tumour suppression, several groups have inactivated Rb in the mouse germ-line. Rb null mice die at mid-gestation and show aberrant haematopoiesis and severe defects in the nervous system. However, $Rb^{+/-}$ mice and chimaeric mice derived from Rb null ES cells develop tumours of the pituitary gland. In the tumours arising in the $Rb^{+/-}$ mice the *Rb* wild-type allele is lost. Despite the important role of Rb in G1/S transition, the Rb null mice can progress throughout early stages of development. One could postulate that other members of the Rb family of proteins (p107 and p130) might compensate for the lack of Rb. However, p107 and p130 null mice develop normally without any developmental defect. Double-deficient p107 and p130 mutants show neonatal lethality. The $p107/Rb^{-/-}$ embryos show earlier lethality (11.5 d.p.c.) than $Rb^{-/-}$ embryos, which die at mid-gestation (14.5 d.p.c.). These observations suggest that the Rb family of proteins exert overlapping functions as well as distinct functions. This example illustrates the importance of the *in vivo* analysis in the mouse in dissecting the relative contribution of family members to controlling molecular pathways important for cancer pathogenesis.

In order to overcome the embryonic lethality of the Rb null mice and to study the effect of Rb mutation in specific organs/cells, mice carrying a conditional allele of *Rb* (with *loxP*, or Frt) have been generated. Mice carrying *loxP* or Frt modified *Rb* allele were viable and showed no cancer predisposition. By contrast, pituitary expression of the Cre recombinase in mice carrying a conditional allele of *Rb* resulted in the rapid onset of intermediate lobe tumours of the pituitary gland in 100% of the cases. No other abnormalities were observed in these mice. Although this may not be regarded as a relevant mouse model of human cancer, the Rb conditional model system is nevertheless a straightforward example of the utility of conditional gene inactivation for the *in vivo* analysis of the molecular basis of tumorigenesis.

Along the same line, in order to address the mutational requirement of Rb, p107 and p53 in tumorigenesis, mice where the targeted loss of Rb was directed to the photoreceptor cell compartment of the retina were generated using the conditional Cre–*loxP* system. The targeted loss of *Rb* gene was achieved by expressing the Cre under the control of interphotoreceptor retinoid binding protein (IRBP) promoter. IRBP is expressed in both rod and cone cells of the photoreceptor layer as well as in the pineal gland. Mice with conditional loss of Rb were crossed with p107 and p53 null mice to obtain compound mutant mice with all the possible gene combinations. The resulting mice developed two types of tumours: anterior lobe of the pituitary gland and pineal gland tumours. All the tumours underwent Cre-mediated loss of *Rb*. The pineal gland tumours were expected, since Cre expression was directed to the pineal gland. However, the tumours of pituitary glands were unforeseen and are very likely due to the

ectopic expression of the *Cre* transgene. The onset of tumours in both cases was accelerated in the $p53^{+/-}$ mice and the tumours showed loss of the wild-type allele. Pineal gland tumours also developed in $Rb^{+/-}$, $p53^{-/-}$ mice with loss of the wild-type *Rb* allele.

Recently a mouse model for medulloblastomas has been generated using a similar approach: both Rb and p53 have been knocked out through a Cre–*loxP*-mediated approach in the cerebellar external granular layer cells. The resulting mice developed highly aggressive embryonal tumours of the cerebellum with typical features of medulloblastomas. This demonstrates the importance of the loss of Rb function in medulloblastomas and supports the hypothesis that medulloblastomas arise from cells located in the cerebellar external granular layer.

All together, these models underscore the crucial importance of conditional knockout mutants to study the mechanisms of tumorigenesis and in particular the function of tumour-suppressor genes which are required for early developmental stages.

PML-deficient Mice (Acute Promyelocytic Leukaemia)

PML (promyelocytic leukaemia gene) originally termed *myl*, was cloned by virtue of its involvement in t(15;17)(q22;q11.2-q12) associated with acute promyelocytic leukaemia (APL), where *PML* fuses to the retinoic acid receptor alpha gene (*RARα*). PML is the most frequent partner of *RARα* in APL. It is important to note that unlike other tumour-suppressor genes, *PML* was not originally found mutated in cancer. Instead, it is the evidence accumulated *in vitro* and *in vivo* in mouse models that has uncovered the tumour-suppressive role of PML, in turn prompting further studies of this gene in tumours other than APL.

PML belongs to a family of proteins characterized by the presence of a RING-B-box-coiled-coil (RBCC) motif. The PML protein is typically found concentrated in discrete nuclear structures along with other proteins variably named PML nuclear bodies (NB) or PODs (PML oncogenic domains). In APL, PML, together with the other nuclear body components, is delocalized from the NB into aberrant nuclear structures as results of its heterodimerization with the translocation fusion gene product PML–RARα. This observation led to the hypothesis that PML function might be impaired in APL leading to leukaemogenesis. (See also chapter on *Haematological Malignancies in Cancer Research*.)

In order to address this issue, PML knockout ($PML^{-/-}$) mice have been generated. Like p53 null mice, PML null mice were developmentally normal. They succumbed, however, to spontaneous infections that prevented a long-term follow-up for tumour incidence. However, when challenged with tumour-promoting activity such as 12-*O*-tetradecanoylphorbol-13-acetate (TPA) and with carcinogens such as dimethylbenzanthracene (DMBA), $PML^{-/-}$ mice developed skin papillomas and carcinomas as well as B and T lymphomas and histiocytomas at a much higher frequency than in wild-type controls. Therefore, PML can suppress tumorigenesis *in vivo*. In addition, cells of $PML^{-/-}$ mice are protected from multiple caspase-dependent apoptotic signals such as Fas, tumour necrosis factor (TNF), ceramide, interferon (INF) and ionizing radiations, demonstrating an essential role for PML in multiple apoptotic pathways. Furthermore, as observed in cells from Bloom syndrome patients, an increased rate of sister chromatid exchange is observed in PML null cells implicating PML and the PML–NB in the maintenance of genomic stability. In this respect it is important to note that PML and BLM were found to co-localize in the NB. All together, these data indicate that PML might exert its tumour-suppressive activity at multiple levels, by controlling cell growth, cell survival and genomic stability. Based on these findings it may be logical to propose that PML–RARα oncoprotein antagonizes the normal function of PML. In APL, this may be facilitated by the reduction to heterozygosity of the normal *PML* allele. Indeed, the progressive reduction of the dose of *PML* resulted in a dramatic and dose-dependent increase in the incidence of leukaemia, and in an acceleration of leukaemia onset in *PML–RARα* transgenic mice. Thus, *in vivo*, PML is haploinsufficient in antagonizing the leukaemogenic potential of PML–RARα. This also suggests that PML's reduction to heterozygosity as a consequence of its involvement in the t(15;17) translocation may be a critical event in APL pathogenesis. In conclusion, mouse modelling has allowed the identification of a new tumour-suppressor gene, prompting a comprehensive analysis of the role of PML in tumorigenesis.

BIOLOGICAL LIMITATIONS AND TECHNICAL CONSIDERATIONS

As mentioned, in several cases, the mutation of a certain gene in mice does not necessarily give rise to the same tumour observed in humans. A number of explanations have been proposed. The difference might result, for instance, from subtle differences in growth control pathways in mouse and human cells. The susceptibility to loss of the remaining wild-type allele may not be the same in human and murine cells. The shorter life span in mice may affect the tumour susceptibility in certain tissues. Moreover, the high incidence of lymphomas and sarcomas in various mouse models generated may simply reflect the fact that the C57BL/6 strain into which the mutated allele are usually crossed is highly susceptible to these tumour types. Thus, the tumour-suppressor inactivation might exacerbate a pre-existing predisposition. In fact, crossing

the tumour-suppressor mutation into inbred strains of different backgrounds has revealed strain-specific differences in tumour development and spectra. The availability of markers spanning the mouse genome will allow the identification of new tumour-modifier genes and cooperating oncogenes or tumour-suppressor genes. Nevertheless, these differences have to be taken into account when comparing different studies and differences between human and mouse phenotypes. (See also chapter on *Human Tumours in Animal Hosts*.)

Combining multiple cancer-associated mutations or multiple inactivated genes in a single animal has proven to be a very useful tool to study cooperative effects and define pathways involved in tumour pathogenesis; however, the number of mutations that can be introduced in a single animal are limited by Mendelian laws: the introduction of homozygous mutation in more than three genes at the same time requires an enormous amount of interbreeding, rendering the experiment time consuming and expensive. A possible way to overcome this problem would be to introduce several mutations by targeting multiple genes in a single ES cell clone. This approach, however, is complicated by the limited number of selectable markers that can be used at once to enrich for the targeted ES cells. Moreover, ES cells cannot be subjected to multiple rounds of manipulations and passages in culture without losing their totipotency and acquiring karyotypic abnormalities. Along a different line, it has to be remembered that the generation of knockout mice is a very costly operation. The high cost of the generation of mouse models has to be added to the elevated cost of animal maintenance and husbandry. Finally, the phenotypic characterization of the knockout mice and their pathological analysis needs to be performed in an appropriate qualified setting.

Although there are limitations to the large-scale and effective application of these techniques for the study of cancer pathogenesis and other human disease, still further applications of this methodology have been underutilized and will generate in the future exciting findings. As an example, the Cre–*loxP* system can be used to introduce chromosomal rearrangements such as deletions, duplications and inversions into the mouse genome. This is of importance in view of the fact that in many tumours these rearrangements accompany more discrete mutations in tumour-suppressor or oncogenes. Recently, rearrangements encompassing up to three-quarters of chromosome 11 have been introduced in ES cells by this approach. The Cre–*loxP* system can also be used to recreate reciprocal chromosomal translocations in ES cells or *in vivo*, thus providing mouse models of human cancer associated with these genetic lesions. Finally, gene targeting can also be utilized to introduce point mutations and isoform specific deletions that will be critical, in the future, to refine our understanding of gene function and its relationship with the genesis of cancer.

PERSPECTIVES

The development of a second generation of gene-targeting technologies such as conditional or inducible systems has made it possible to introduce in the mouse germ line more subtle gene alterations that can provide functional information beyond that provided by the generation of null alleles. The comparison between the effects of tumour-suppressor losses in different mouse strains will allow the discovery of novel tumour modifiers. The identification of modifier genes may indeed be one of the most definitive ways to determine the critical biochemical pathways responsible for cancer pathogenesis. Standard biochemical studies tell us how genes and gene pathways can intermingle, and have proven and pointed out the intricacy of these cellular pathways. The mouse genetics can be effective in simplifying and thus shedding light on this complexity. There has been an explosive growth of accessible genetic databases and available collections of genomic and expressed gene reagents and rapidly evolving tools for detecting genomic alterations and gene expression patterns. As an example, gene expression profiling by microarrays and protein arrays will allow the determination of the genes or pathways affected in a particular tissue of a knockout mouse. Spectral karyotyping (SKY), multiple fluorescence *in situ* hybridization (M-FISH), multicolor chromosome banding and other labelling techniques and strategies are recent technical developments in the field of molecular cytogenetics. The use of these techniques in mouse models will allow screening for specific chromosomal aberrations. The presence of recurrent abnormalities associated with a specific tumour type will allow the identification of additional genetic events in tumour progression and metastasis. All these novel tools, if applied on a comparative basis on multiple mouse models, will allow the definition of pathways specifically or universally affected as a consequence of oncogenic activities and loss of tumour-suppressor gene functions.

- Biological and Technical Limitations
- Conclusions and Future Prospects

ANIMAL MODELS IN CANCER RESEARCH

Animal models have been used in cancer research for many years. Often these provide the only way to model effectively the complex interactions between host and tumour. For example, while many new technologies are being developed, it remains virtually impossible to predict accurately the pharmacokinetic and toxicological properties of experimental antineoplastic agents from only *in vitro* studies. Assessing the activity of new drugs, or of the full tumorigenic or metastatic properties of cells, also remains beyond the capability of *in vitro* technologies. Thus, for the moment, it remains necessary to use animal models for many studies in cancer research. Nonetheless, it is to be hoped that, at some point in the future, *in vivo* models will be superseded by new technologies that will no longer require the use of live animals.

While the research community currently retains the privilege of using live animals, the longevity of this privilege is uncertain. Animal rights organisations continue to campaign for the elimination of *in vivo* studies. In recent years, many governments have enacted legislation to control more carefully the use of animals in research. Most of these changes have been beneficial and have significantly improved the conditions under which animals are maintained and studied. Further legislation and limitations will almost certainly follow in the coming years. It is imperative that investigators are aware of the legislation to which they are subject. In some cases, such legislation may be less than ideal, such that ensuring the minimum level of regulatory compliance may not be optimal. Ultimately, if the research community is to maintain an adequate ability to use *in vivo* models, at least until viable and validated alternatives become available, its members must be seen to use animals rationally and responsibly.

The use of live animals has clear ethical and scientific implications. Many research institutions are required to establish an oversight body to regulate the use of animals by its members. Investigators must justify the use of animals, their choice of species, strain and number of animals, and to document their search for alternate *in vitro* systems. Where surgical or other invasive techniques are required, individuals must demonstrate that they are adequately trained/experienced in the procedures, and provide for appropriate anaesthesia and analgesia. Some investigators using animals are required to obtain a specific licence from their government or other oversight body.

The precise definition of what constitutes an 'appropriate use of animals' varies considerably among investigators and across international boundaries. Many of the differences are cultural. However, for scientists some issues should remain constant. These include a high level of awareness, and an unrelenting commitment to the health and welfare of animals under their care. Such issues are not only ethically valid, but are demanded by the nature of science. An appropriate environment, and the provision of high-quality animal care, are central to the performance of reliable and reproducible science. Quality of diet, environmental hygiene, density of animal housing, health monitoring of animals and various other concerns, which are well beyond the scope of this article, are some examples (Schiffer, 1997). Specific requirements vary among species. There are many excellent sources for specific information on animal care and welfare (see Further Reading and Websites).

Ultimately, animal models represent the most complex tool available for research scientists. They can provide information and knowledge well beyond that produced by some of our most complex machinery. As such, at the very least, the animals in our care deserve a greater degree of consideration than the most expensive and complex piece of equipment designed and built by humans.

Biology of Graft Models

The grafting of tissues into another host may be across species (xenograft) or to another animal of the same species (allograft). Immunocompromised rodents will maintain both allografts and xenografts. While tumour cells are more frequently transplanted, some normal tissue xenografts also can be successfully initiated.

Generally, the biology of xenografts is comparable to that seen *in vitro* or in the original host. Continual passage of some xenografts can produce cells better acclimated to their new host, and take rates may increase and/or latency decrease. Most xenografted cell lines exhibit comparable genetic stability *in vivo* as they do *in vitro* in the absence of any specific selective pressure. The removal of endocrine stimuli (Clarke *et al*., 1989), immunological effectors or the imposition of other selective pressures, e.g. drug treatments, can produce phenotypic, and probably epigenetic, changes in some xenografts. This has proven to be an effective way to generate variant cell lines with desired phenotypes, so they can be compared with wild-type cells to identify the genes and proteins conferring the variant phenotype.

Given the diversity and complexity of human tumour xenografts, it is not possible to discuss adequately all of the issues related to their development and use in cancer research. This chapter will focus on several general topics related to experimental design, including choice of model, number of animals required and assays for tumorigenicity, metastasis and the screening of experimental antineoplastic agents. The major immunodeficient rodent models are described, since these are the hosts for the xenografts.

PRINCIPLES OF ESTABLISHMENT: ISSUES RELATING TO EXPERIMENTAL DESIGN

Xenografts can be initiated from suspensions of cells grown *in vitro* or from effusions in patients, or from tissue pieces obtained directly from patients or other animals. The size of the tumour piece, or the number of cells inoculated, varies with the characteristics of the graft cells/tissues. Xenografts from many solid tumours can be initiated or maintained by placing pieces as small as 1 mm^3 into the appropriate site in the recipient animal. As a general guide, 1×10^6–5×10^6 cells provide a reasonable inoculum if the cells are being transferred from cells proliferating *in vitro*. Investigators should determine the optimal inoculum for their chosen model either from the literature or by experimentation.

It is also important to know the biological characteristics of the model being used. For example, what is the anticipated tumour doubling time (T_D), are the growth properties adequately reproducible, is the tumour sufficiently invasive or metastatic, or might extension of the primary tumour cause neurological problems such that the animals can no longer obtain food and water? Rapidly proliferating or highly metastatic tumours could create health problems before the desired experimental endpoints are reached. For many established models, the critical biological characteristics are well known and should be widely reported. Where these are not known, a small pilot study in a few animals can help reduce total animal use and save considerable resources (see the next sub-section).

Generating an appropriate experimental design is among the most important aspects of working with xenografts and other animal models. As with all experiments, careful consideration of controls and experimental groups are essential. However, other issues also are important, including statistical power of the study design, choice of model, selection of recipient and site of inoculation. These issues are briefly discussed in the following sections.

Animal Numbers and Statistical Power

One of the more common errors in designing animal studies is the tendency of some investigators to leave issues of data analysis until the experiment is completed and the data have been collected. Unfortunately, only then is it realized that the study was underpowered, or that the statistical analysis of the data is not straightforward. Considerable resources and animals can be spared by consultation with a biostatistician prior to starting an *in vivo* study. Clearly, this has substantial ethical, scientific and economic advantages.

The number of animals required for hypothesis testing will reflect the characteristics of the model, and particularly the magnitude of the expected response. Essentially, the ability of a study design to detect accurately differences among experimental/control groups is its statistical power. Studies are usually considered to be adequately powered when they have an 80% chance or better of detecting a true difference with a $p < 0.05$. An underpowered study may produce an inconclusive result, and perhaps require additional studies that ultimately use more animals than a single but appropriately powered experiment. Alternatively, an overpowered study may use more animals than necessary to test the hypothesis, while identifying statistically significant differences of uncertain or questionable biological relevance.

Some treatments or procedures result in the death of animals before the desired endpoints are reached. Thus, power can be lost during the performance of the study. This also needs to be considered during the initial experimental design. The censoring of data occurring from loss of animals also has implications for the statistical approaches used to analyze the data (Hanfelt, 1997).

In xenograft studies, it may be tempting to try to increase power by inoculating more sites per animal. Although this can increase power, the issue is complicated. There is a potential for multiple tumours in one animal to behave more like each other than like tumours in other animals of the same experimental group. Thus, a doubling of the number of sites may not produce a doubling in statistical power. Readers are directed to an excellent review of this, and other issues of statistical analysis and experimental design relevant to animal model studies, by Hanfelt (1997).

Choice of Model

Several aspects of experimental design impact upon the choice of model. Perhaps the most important is the ability of the model to facilitate testing of the investigator's hypothesis. Animal models represent specific phenotypic/genetic characteristics that occur in a potentially comparable human condition. No matter how well an experiment may be designed, if the model does not adequately reflect the critical aspects of the human disease, any resulting data may have little relevance and the hypothesis may remain untested. Thus, the utility/applicability of a model depends on how well it reflects the most appropriate characteristics of the original disease/disease process.

Perhaps one of the first questions cancer researchers should ask during the experimental design phase is whether their choice of model(s) will clearly allow them to address their hypothesis in a way that has some relevance for the human disease. One possible example of when this tenet was inadequately followed was the use, for many years, of the murine P388 and L1210 lymphocytic leukaemias to screen new antineoplastic agents. Many drugs active in this *in vivo* screen showed limited activity against solid cancers in humans. Following considerable criticism and debate, the National Cancer Institute (Bethesda, MD, USA) decided to instigate a broader initial screen using a panel of cell lines with comprising representatives of each of the major cancers. Many of these cell lines also are useful as xenografts, allowing agents active *in vitro* to be subsequently evaluated *in vivo* in the same models. To the extent that the selected cell lines for each cancer adequately reflect key aspects of that cancer's biology, this approach should allow for the identification of potent agents with even limited applicability. Thus, one potential advantage is that agents with specific patterns of activity, perhaps active against some but not all cancers, may be identified.

The P388 and L1210 models, while they remain useful and widely used, provide another example of issues relating to model selection. Many cytotoxic agents are designed to be, or are expected to be, more active against proliferating rather than resting cells. Drugs active against a leukaemia with a short tumour T_D, high growth fraction and relatively short cell cycle time are expected to appear less potent in solid tumour models with a long T_D, small growth fraction and long cell cycle time. Thus, screening against the leukaemias could identify false positives in the context of solid tumours. Where specific pharmacological or kinetic requirements of drug action are known, clearly these should be effectively reflected in the biologies of the models selected for *in vivo* evaluation.

It is not always necessary, and it may be the exception rather than the rule, that a single model reflects all the characteristics of the original disease. For example, the divergent characteristics of breast tumours provide important clues to their biology and how they should be treated. Some breast tumours express receptors for the steroid hormones oestradiol and progesterone. These tumours respond well to antioestrogens and other endocrine therapies. In marked contrast, tumours that do not express these receptors rarely respond to endocrine manipulations. While tumours that respond to antioestrogens can still metastasize in patients, most antioestrogen-responsive human breast cancer xenografts are poorly metastatic or non-metastatic. These models are not invalid because of their poor metastatic potential. Rather, it limits the aspects of the human disease that they represent and, consequently, the hypotheses they can be used to test.

When selecting experimental *in vivo* models, it is often apparent that no single model may adequately reflect all aspects of the human disease required for testing an investigator's hypothesis. Thus, several models may be required. The choice to use several models requires careful evaluation, since there is a need to reduce the number of animals used in research. Cost also may be an issue. However, an inadequately tested hypothesis in a small study could lead to a need for more animals than a carefully designed, larger single study. Clearly, a realistic appreciation of each model's advantages and limitations, require careful consideration.

Immune-deficient Rodent Models as Xenograft Recipients

Although there are more than 30 loci at which mutations produce an immunocompromised phenotype, relatively few are widely used in cancer research. The most familiar is the nude mouse, homozygous for the *nu* mutation on mouse chromosome 11. Originally identified in Glasgow, Scotland, in 1962, the predominating immunodeficiency was described shortly thereafter. The first report of the ability of these mice to sustain human tumour xenografts was published by Rygaard and Povlsen in 1969. Another widely used single mutation immunodeficient model is the severe combined immunodeficiency (SCID) mutation. Several combined mutation models also are popular, and recent years have seen the emergence of additional immunodeficient models. A brief description of

the major characteristics of selected models follows. Several have been reviewed in detail elsewhere (Shultz, 1989; Clarke, 1996).

The different immunobiologies of these other rodent models provide viable alternatives to the nude mouse. However, it remains controversial whether there are substantial differences in their respective abilities to maintain xenografts (Fodstad, 1991). Some investigators find SCID or *bg/nu/xid* mice to have a reproducibly higher overall take rate than *nu/nu* mice, but many find these models essentially equivalent. Graft take rates may vary by cancer type. Several mouse models reject leukaemic cell line xenografts, but the further immunosuppression produced by gamma-irradiation can be beneficial in helping to alleviate rejection (Ghetie *et al*., 1996). However, the effects can be highly strain/mutation deficient. Irradiation of SCID mice can overcome the defective V(D)J recombination (Livak *et al*., 1996). While this can increase B-cell lymphoma tumour take, metastasis and response to immunotoxins, the response of xenografts to chemotherapy is reduced (Ghetie *et al*., 1996). Thus, the respective immunobiologies may have significant implications for the choice of model and strain. A general representation of the major immunedeficiencies of several common models is shown in **Figure 1** (adapted from Clarke, 1996).

Besides maintaining neoplastic cells, immunocompromised rodents also can allow the study of normal tissues, the effects of therapies on normal cell function or the events associated with virally or chemically induced carcinogenesis. For example, several models can be 'reconstituted' with human cells. Reconstitution of SCID mice with normal peripheral blood lymphocytes from Epstein–Barr-positive human donors develop fatal B cell lymphomas. Human skin grafts in SCID mice can model the vascular leak syndrome seen in some human immunotoxin trials.

Nude (nu/nu) Mice

More than 70 congenic strains of nude mice have been generated, and strain-dependent differences in their respective immunologies and abilities to support xenografts have been described (Maruo *et al*., 1982; Clarke, 1996). The mice are often called athymic nude mice, although a rudimentary thymus is present in some individuals. B cell maturation is defective but normal virgin B cells are present. T-lymphocyte levels are very low

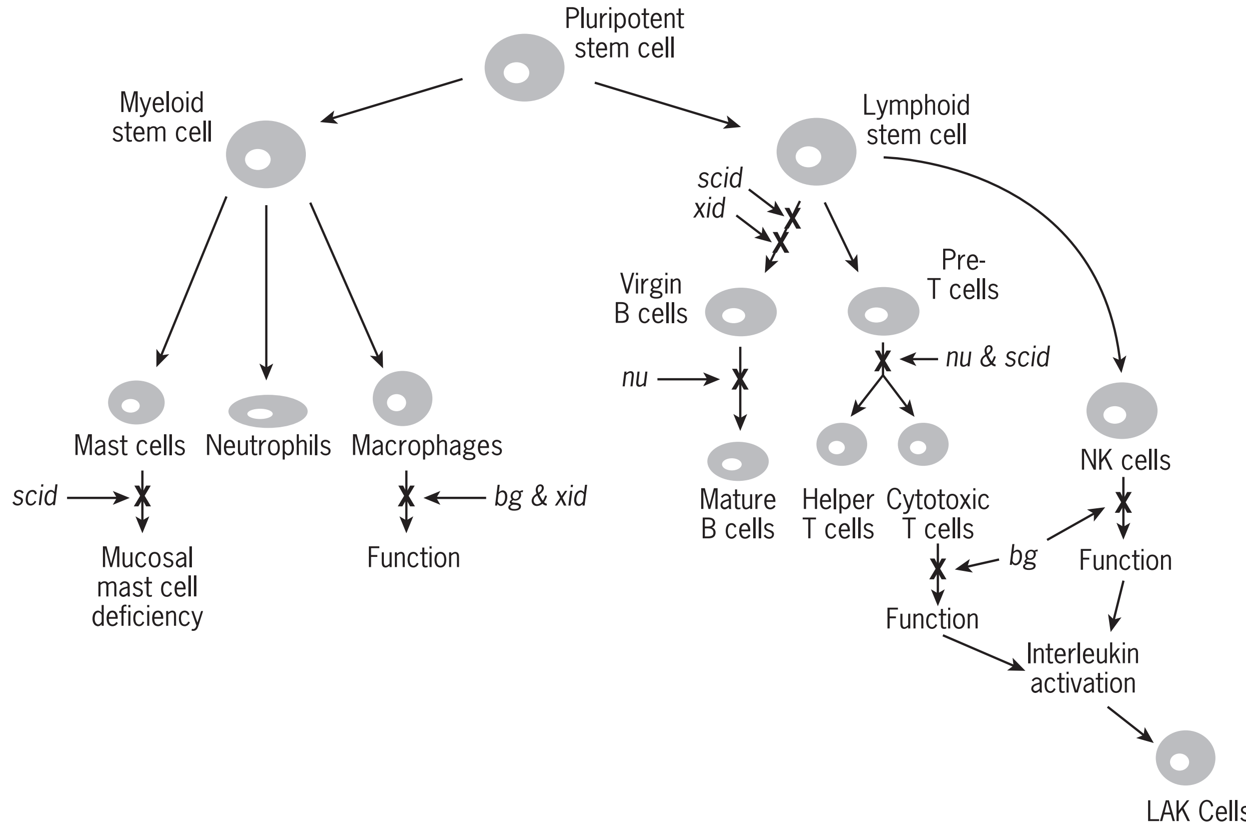

Figure 1 Immunobiologies of several rodent models. (Adapted from Clarke, 1996.) This is a general representation. The degree to which each cell type is affected varies by mutation and often by individual animal. The location of the defects is not intended to be precise, rather it should provide a simple means to assess the likely changes in different models.

or undetectable in most strains, as are responses to T cell-dependent antigens. Substantial immune function can be restored by reconstitution with T cells. Nonetheless, serum IgM levels are similar to, or higher than, those in *nu/+* mice. Occasionally, circulating IgG and IgA are detected in individual animals.

While humoral immunity is compromised, nude mice retain several key mediators of cell-mediated immunity. T cell-independent antigen responses are often normal, and the levels of natural killer (NK) cell activity are greater than that in normal and *nu/+* mice. There is no apparent defect in tumoricidal macrophages, and nude mice can produce lymphokine activated killer (LAK) cell numbers comparable to +/+ mice. Thus, nude mice are relatively robust and easier to maintain than some of the more severely immunocompromised rodent models.

The high NK cell activity in nude mice may contribute to the poor take rate of some primary human xenografts. This can be increased by embedding the transplant tissues in an artificial basement membrane (Fridman *et al*., 1991), which probably protects the tumours from lysis by cell mediated effector cells, and provides a structural/dimensional environment containing attachment molecules and mitogens (Clarke, 1996).

While mice are the most common species in which the nude mutation is used, a comparable mutation also exists in rats. The rat nude mutation (*rnu*) produces athymic nude rats, which appear to have an immunobiology broadly comparable to that of nude mice (Hougen and Klausen, 1984). Nude rats also will support tumour xenografts, but are more expensive to maintain. However, the size of the rat may make these a useful alternative, particularly where orthotopic transplantation or other surgical studies are difficult or impractical in mice.

Combined Beige (bg)/nu Mutations

To eliminate the higher NK cell activity seen in nude mice, double congenic *bg/nu* mice have been generated (Karre *et al*., 1980). The *bg* mutation, located on mouse chromosome 13, produces a reduced synthesis of pigment granules in melanocytes which results in a light coat colour. Analogous to the multisystem autosomal recessive disease Chédiak–Higashi syndrome in humans, the main immune-deficiency in *bg/bg* mice is a block in NK function. Other immunodeficiencies produced include an impaired production of cytotoxic T cells and defects in macrophages and granulocytes.

The *bg* mutation significantly reduces NK activity when introduced along with the nude mutation. However, residual NK activity is detectable in *bg/nu* mice, which is clearly higher than that seen in *bg/bg* mice. A further contribution of the *bg* mutation is a clotting disorder, seen in both *bg/bg* and *bg/nu* mice. This can be problematic when the experimental design requires surgery, e.g. for orthotopic implantation (Clarke, 1996).

Combined bg/nu/xid Mutations

A further reduction in immune competence was obtained by adding the X-linked immunodeficiency (*xid*) to that of the *nu/bg* genotype (Andriole *et al*., 1985). The major contribution of the *xid* mutation to the phenotype is an impaired development of B cells. B cell colonies are not detected in *in vitro* assays, probably because of an inability of otherwise normal immature B cells to respond to early activation signals. Immunoglobulin levels, particularly IgM and IgG_3, are low. Mice bearing the *bg/nu/xid* mutations have characteristics of each of the individual mutations. Thus, they are essentially athymic, have intermediate NK cell activities, low numbers of LAK cells, and have defects in both B and T cell maturation. While more immunodeficient than the single or double congenic strains, the clotting disorder conferred by the *bg* mutation also is apparent (Clarke, 1996).

Severe Combined Immune Deficiency (SCID) Mutation

The *scid* locus on mouse chromosome 16 is equivalent to the human locus at chromosome 8q11. The *scid* mutation disrupts the process of rearrangement of genes encoding antigen-specific receptors on B and T cells (Bosma and Carroll, 1991). This reflects an inability to effectively join the cleaved variable region segments catalysed by the immunoglobulin V(D)J recombinase. Affected mice have small lymphoid organs and defective differentiation/maturation of lymphocytes. While the myeloid lineage cells are normal, pre-B and B cells cannot be detected and remaining T cells are defective. IgG 2a, 2b and 3a, IgM and IgA are rarely detected. However, individual mice may produce detectable levels of two or more IgG isotypes and/or IgM. There are no major defects in macrophages, NK cells and LAK cells but a lack of specific lymphokines required for their development from progenitors can produce a deficiency in mucosal mast cells.

Some earlier SCID models were described as ‘leaky.’ These mice often produce detectable numbers of functional B and T cells. In many SCID mouse strains, individuals become ‘leaky’ with age, i.e. by 10–14 months of age. As with most immunocompromised rodent models, there can be some variability in tumour take rates among SCID mice of different backgrounds and from different vendors.

Other Immunodeficient Models

In recent years, other gene mutations have been shown to affect immunity in rodents. Their use as xenograft hosts, relative to the more established models, remains to be firmly established. However, it seems likely that additional models will continue to emerge. For example, null mutations in the *RAG-1* and *RAG-2* genes in humans produce a severe immunodeficiency characterized by lack of mature

B and T cells (Omenn syndrome). The deficiency is a result of a loss of V(D)J recombination activity, and comparable mutations in these genes in mice produce immunocompromised animals. These mice do not become leaky with age. Mice bearing the non-obese diabetes mutation (NOD) also exhibit an unusual T cell ontogeny. When both the NOD and *scid* mutations are present, the mice develop thymic lymphomas. While the mice have a relatively short life span, when a strain that does not exhibit reintegrations with the Emv30 retrovirus is used, the frequency of large lymphomas is reduced. More recently, NOD/LtSz-Rag1^{null} mice have been generated. These mice have an increased life span, reflecting the later onset of lymphomas, have no mature B or T cells, and exhibit low levels of NK cell activity. These mice will support grafts of human haematopoietic stem cells and lymphoid cells. Engrafted T cells can be infected with the HIV virus (Shultz *et al*., 2000).

Sites of Inoculation and Assays for Tumorigenesis and Metastasis

Important experimental endpoints include determining factors that influence the tumorigenic or metastatic potential of cells. These also are important characteristics of new cell line models. The metastatic cascade is a complex process, requiring cells to invade, migrate, intravasate, survive in the circulation, extravasate and, finally, to colonize distant sites successfully. While some aspects can be modelled *in vitro,* e.g. invasiveness and motility, several different assays have been used to measure metastasis *in vivo*. Direct inoculation of tumour cells into the circulation is among the more common approaches. The route of systemic inoculation can affect the likely pattern of metastasis. Intracardiac injection increases the probability of obtaining bone metastases (Thompson *et al*., 1999). This can be important for studying cancers such as breast cancer, where bone metastasis is a common feature of the human disease.

Systemic inoculation does not fully replicate the entire metastatic process, e.g. the initial steps of local invasion, migration and intravasation are not required. These approaches are often referred to as representing experimental metastasis. More rigorous estimates of metastatic potential, at least for solid tumour models, require the demonstration of an ability to metastasize from a solid tumour.

The site of inoculation becomes an important issue in assessing metastatic or tumorigenic potential. Despite the widespread use of subcutaneous inoculations, there is substantial and compelling evidence that the biology of grafts at orthotopic sites (site of the original tumour) can be more biologically relevant (Morikawa *et al*., 1988).

Perhaps the most widely used model for studying metastasis has been the B16 mouse melanoma cell line, which forms pigmented metastases in several tissues. Most non-melanoma models do not produce such easily detectable metastases. However, cells can be tagged with expressed genes producing marker proteins, e.g. enhanced green fluorescent protein, β-galactosidase. Tumours tagged with these genes should be readily detected, but for the models to be useful, their phenotypes also should not be markedly affected by high levels of marker gene expression.

For some assays there are practical restrictions on the site of inoculation. Ease and accuracy of solid tumour measurement are critical and can restrict inoculation sites. An immune-privileged site may be required. The sub-renal capsule has been used successfully. Nonetheless, where possible, orthotopic transplantation is preferred for most studies. Tumour take also can be increased by embedding cells/tissues in an artificial basement membrane (Matrigel; Collaborative Research, Bedford, MA, USA) (Fridman *et al*., 1991).

An individual cell line may be tumorigenic or metastatic in one immune-deficient model and not in another. This might occur most frequently when assessing metastatic potential but variability among cell lines for tumorigenicity endpoints also may occur. Where *in vivo* growth is assessed as part of the characterization of a new cell line, more than one model should be used. This is more important when a cell line appears non-tumorigenic or is not metastatic. Thus, the designation of a cell line as non-tumorigenic or non-metastatic should indicate in which model(s) these endpoints were assessed.

GENERAL APPLICATIONS

Xenograft models have been widely used in many cancer research-based studies. As indicated above, such studies can allow for evaluations on endpoints of tumorigenesis and metastasis, e.g. in the characterization of new experimental models. One of the most common uses of human tumour xenografts is for the evaluation of the antineoplastic activity of novel therapeutic strategies. This can include irradiation regimens, cytotoxic, endocrine or gene therapies, or nutritional studies. For drug-based therapies, xenograft models can be used to determine pharmacokinetics, toxicology and activity. In principle, investigators perform in animals the equivalent of a clinical trial in humans. The aims include the prediction of safe and appropriate starting doses, and the identification of potential toxicities, for subsequent human trials. When successfully designed and implicated, these animal studies should significantly reduce human suffering without excessive and unnecessary burden to the animals. The following sections will briefly describe some of the more important issues relating mostly to drug-based studies.

Screening of Experimental Agents *In Vivo*: Dose Selection and Toxicology

The determination of safety and antineoplastic activity in animal models is effectively a prerequisite for the preclinical evaluation of experimental agents. Determination of the starting dose or dose range is an important consideration. Since the presence of tumours can often alter toxicity, it is not uncommon for rodent toxicological studies to be performed in tumour-bearing mice, although this is not essential. This can be useful where subsequent studies are to be performed at the estimated maximum tolerated dose (MTD).

The issues of toxicology and establishing a starting dose for *in vivo* studies are closely related. Many such studies are based on estimations of activity at or below a drug's MTD. To estimate the MTD, one simple approach is to do a pilot dose range finding study. A broad range of doses is evaluated using only one or two animals per dose. This limits the number of animals exposed to toxic/lethal doses. A more definitive subsequent study can then be done based on the data from the pilot analysis, and a MTD estimated, if necessary (UKCCCR, 1998; Clarke, 1997a). In such toxicological studies, change in animal body weights is often used as an indicator of toxicity. While a loss of body weight is frequently used as the endpoint, a more sensitive measure is the detection of a reduction in the rate of weight gain in young animals. A loss of 10% body weight should be an adequate estimate of toxicity in most studies using adult animals.

Some drugs will produce a severe but transient toxicity. Drug-related deaths that occur within several hours of administration should not be used to establish the MTD. These toxicities often reflect sensitivity to the peak plasma concentration resulting from the bolus. The vehicle for drug delivery also may be an important contributor to toxicity. The volume in which the drug is delivered will vary with route of administration, but should be the smallest volume practicable for reproducibility of administration. More detailed discussions of toxicologic studies can be found elsewhere (LoRusso *et al*., 1990; Clarke, 1997a; UKCCCR, 1998).

Screening of Experimental Agents *In Vivo*: Endpoints for Assessing Activity

Determining the *in vivo* activity of experimental agents is done using a variety of endpoints. These are generally either excision assays, where the tumours are treated *in vivo* and the response measured either *ex vivo* following transplantation into a new untreated host; or in *in situ* assays, where the tumours are both treated and their response measured *in vivo* in the same host (Clarke, 1997a). Excision assays remove the contribution of reproductively dead cells to tumour volume, but the tumour microenvironment is lost if activity is assessed *in vitro*. *In situ* assays also can be complicated where the kinetics of regrowth are variable or unpredictable. Nonetheless, these are generally preferred to excision assays.

The *in situ* techniques should be performed on proliferating tumours. Growth delay is commonly assessed, and is defined as the time difference between the tumours in treated and control groups to reach a predetermined size (Clarke, 1997a). Since tumours are of the same size, the data are not confounded by the gompertzian or exponential–quadratic kinetics involved (Hanfelt, 1997). For growth delay assays, a predetermined endpoint size is required. This should be sufficient to produce tumours that are easily measured, but not so large that they include areas of substantial hypoxia or necrosis. Generally, the best endpoint size is close to the size at treatment, e.g. twice the treatment volume, which reduces any effects of treatment on growth rate. Data can be analysed as specific growth delay, total cell kill, cell kill/dose or net cell kill (Clarke, 1997a).

Tumour growth delay estimates often compare treated (T)/control (C) or $T-C$ values, with a T/C of $\leq 42\%$ usually taken as indicating activity. Whether these are based on mean or median values, longitudinal analyses may be a more effective use of the data. Other approaches for statistically exploring growth delay data are described elsewhere (Clarke, 1997a; Hanfelt, 1997)

Overall survival also has been widely used as an endpoint for antineoplastic activity. When the lethal tumour burden of the model is well established, e.g. as with the P388 and L1210 growing as ascites, survival estimates are reliable. However, many solid tumours exhibit a poor or unpredictable metastatic potential. Tumour burden as a percentage of total body weight can readily exceed that observed in humans. When drugs are administered intravenously and the P388/L1210 models are growing as ascites, a percentage increased life span (%ILS) of $>40\%$ is often used as an estimate of adequate activity. %ILS is estimated as

$$\%ILS = 100(T - C)/C$$

Where there is heterogeneity in survival data, this may be better estimated as previously described:

$$\%ILS = 100(HR - 1)$$

where HR is the hazard ratio obtained by Cox proportion hazards regression analyses (Clarke, 1997a).

While survival may appear the best defined endpoint, and is the definitive endpoint in many human trials, few institutions now allow death to be used routinely as an endpoint without considerable justification. This is not surprising, given the discomfort and suffering often associated with the survival endpoint. It is difficult to justify for solid tumours, since most can be used in growth delay or excision assays.

Where possible, survival as an endpoint could be restricted to ascites models. It also may be possible to substitute morbidity for death. This requires knowledge of the time from the onset of morbidity to death, and evidence that this period be consistent. To allow others to use the same endpoints and models, the criteria used to define morbidity, and the verification of its applicability as a surrogate for death, should be reported (Clarke, 1997a).

When the endpoints are 'cure' or the proportion of 'long-term survivors,' the time point at which 'cure' or 'survival' is attributed must be defined. Even a rapidly proliferating tumour with $T_D = 48$ h could require up to 16 weeks post-treatment to establish 'cure.' The proportion of long-term survivors is also often reported. A reasonable definition of this endpoint is the proportion of animals that survive to three times the mean or median survival of the appropriate control groups.

Studies on Diet and Cancer

It is now evident that diet and nutrition may play an important role in the development, progression and management of many cancers. Interest in dietary supplements, nutrients and micronutrients continues to increase, as does the need adequately to identify and determine their importance and place in cancer prevention and therapy. Many such studies require the feeding of complex but controlled diets to rodents, in a manner that allows for appropriate hypothesis testing (Clarke, 1997b).

Unfortunately, the regular rodent chow diets are not controlled in terms of a reproducible source for nutrients and micronutrients. Thus, when performing nutritional studies, or studies on the effects of specific nutritional components, it is necessary to use an appropriately formulated, semipurified diet. While there are many choices available, those formulated by the American Institute of Nutrition's *Ad Hoc* Committees on Standards for Nutritional Studies in Rodents have become widely accepted. The modified AIN-76A diet has been updated and reformulated to reflect better the varying needs of the animals at different stages of growth. The resulting AIN-93G, designed for growth, pregnancy and lactation, and AIN-93M, designed for the maintenance of adult rats (Reeves *et al.*, 1993), also are more appropriate for long-term carcinogenesis studies.

Many laboratory chows also contain high isoflavone concentrations, and could contribute to some of the variations in tumorigenesis reported among laboratories (Thigpen *et al.*, 1999). Perhaps the most widely studied of these isoflavones is genistein, which is reported to have antineoplastic activity in several cell line and xenograft models, including mammary, liver, prostate and colon cancer models. It also can act as an antioxidant and is an inhibitor of protein tyrosine kinases, angiogenesis and topoisomerase activity. Effects on serum cholesterol and bone mineral density in rodents also have been reported (Thigpen *et al.*, 1999). These activities could confound data interpretation in endocrine, antineoplastic activity and other studies. Where this is a major concern, or may be suspected of contributing to outcome, investigators may need to consider using a semipurified diet, such as the appropriate AIN-93 modification.

BIOLOGICAL AND TECHNICAL LIMITATIONS

There are several limitations to the use of xenograft models. Some ethical considerations have already been alluded to above. Clearly, there should be restrictions on the use of live animals, particularly where this use may involve prolonged discomfort, pain and/or death. A detailed discussion of the major issues is beyond the scope of this chapter, but some should be self-evident. For example, the use of animal models must be carefully considered and justified, no viable alternatives should be available, the minimum number of animals required for adequate hypothesis testing should be used and every precaution should be taken to eliminate/minimize pain or discomfort. All animals should receive the highest quality of humane care by appropriately trained individuals.

While the *in vivo* environment may be more physiologically relevant than growth *in vitro*, it cannot eliminate many of the problems associated with the use of human cell lines. For example, some cell lines are genetically or phenotypically unstable. The adaptation for growth *in vitro,* or many years of culture on plastic, may produce changes that do not occur in tumours arising in patients.

For grafts to be successful, the hosts must be severely immunocompromised. The immunobiology of the recipient hosts may be very different from the original human host. Consequently, some immune effects may be missed and the consequences of others exaggerated by the immunity present in the animal model.

While metastasis is a critical component of the biology of cancer in humans, relatively few xenografts accurately reproduce the frequency and distribution of metastases. Whether this is a problem with the animal hosts or the cells/tissue grafted is not always clear.

There are other obvious potential problems associated with the use of non-human species to attempt to predict the safety and activity of an experimental agent or regimen in humans. For example, the pharmacokinetics of a drug in rodents may be very different to that in humans. Generally, it is necessary to adjust for interspecies differences, particularly in their metabolic rates. One approach is simply to correct for body weight, administering the same amount of drug on a milligrams of drug per kilogram body weight basis. However, this is often considered inadequate, with estimates based on body surface area (milligrams of drug

per square metre) providing more comparable data. The approximate correction values for milligrams per kilogram, based on surface area, have been estimated as (Freireich *et al*., 1966)

mouse $\rightarrow$ rat (rat dose = mouse dose in mg kg^{-1} $\times$ 0.5)

rat $\rightarrow$ human (human dose = rat dose in mg kg^{-1} $\times$ 0.14)

Starting doses for human trials are often selected based on one-tenth MTD in rodents as the approximate starting dose for a Phase I trial in humans. Using a dose that produces comparable pharmacokinetics can increase the predictability of the mouse xenograft-to-human tumour model. However, in a recent study of 25 drugs, a starting dose of one-tenth the MTD in mice was shown to be safe in humans. Rodent toxicological studies can accurately predicted the dose-limiting toxicity. Toxicological studies in mice also produced better estimates than those in rats (Newell *et al*., 1999). Thus, carefully designed studies in mice can produce data that have direct relevance for the design of Phase I clinical trials.

Other limitations or concerns may relate to endocrinological investigations. Hormonal supplementation of rodents has been widely used to study the regulation of tumorigenesis, e.g. in breast and prostate cancers. Several endocrine agents are known to influence the cell-mediated immunity effector cells present in many immune-compromised rodent models. Oestrogens produce a biphasic effect on NK cell activity, and tamoxifen can induce NK cell activity. Oestrogens also may alter B cell function, increase IgM secretion and inhibit T-suppressor function and T-helper maturation. Medroxyprogesterone acetate alters the T4+/T8+ ratio, whereas lynoestrenol stimulates active T rosetting and phagocytosis by monocytes. Thus, the effects of endocrine treatments on immune function may require special attention in some study designs, and could provide a limitation in data analysis and interpretation.

CONCLUSIONS AND FUTURE PROSPECTS

Despite their limitations, graft models of human cancers have provided considerable information. Data from these studies have significantly reduced the risks to humans in Phase 1 clinical trials and provided invaluable information in the design and testing of new cancer therapies. For the moment, there are no viable alternatives for many of these types of studies. Consequently, investigators must strive to refine, reduce and replace the use of animal models. At some point in the future, this should lead to a time when there will no longer be either a need, or a place, for the use of live animals in cancer research.

BIOLOGICAL BASICS

Breast cancer is the most frequent spontaneous malignancy diagnosed in women in the Western world and it is also observed in rodent experimental models. In the United States alone 186 000 new cases were diagnosed in 1999; its incidence has been increasing for several decades. Early diagnosis has improved the rates of cure and prolonged survival, but stage-specific survival rates have increased only slightly since the mid-1970s, and breast cancer remains second only to lung cancer as a cause of death (Wingo *et al*., 1998).

From all experimental systems available for the study of mammary cancer, rodent models have been particularly useful, because these species develop spontaneous mammary tumours. In several strains of female rats they are the most common hormone-dependent spontaneous neoplasms developed (Welsh, 1987).

The susceptibility of the rodent mammary gland to develop neoplasms has made this organ a unique target for testing the carcinogenic potential of specific chemicals. Several carcinogens which induce mammary tumours in both mice and rats have been extensively studied in both species (Welsh, 1987). Tumours induced by administration of chemical carcinogens constitute useful tools for dissecting the multistep process of carcinogenesis, which involves initiation, promotion and progression, and serve as a baseline for testing the carcinogenic potential of chemicals in risk assessment. Chemically induced mammary tumours are, in general, hormone-dependent adenocarcinomas. Their incidence, number of tumours per animal and even tumour type, are influenced by the age of the host at the time of carcinogen exposure, reproductive history, endocrinological milieu and diet, among other factors. These factors, in turn, influence the development and degree of mammary gland differentiation (Russo, I. H., *et al*., 1989), which are subject to a multiplicity of endocrine stimulatory and inhibitory influences from embryogenesis onward (Daniel and Silberstein, 1987). If these influences are not exerted in proper temporal, sequential and quantitative relationships, normal development, differentiation and function are adversely affected. Mammary gland development, in turn, cannot be separated from its ageing, a process that markedly influences the incidence of spontaneous tumours in all strains of rats, as well as in mice infected with the mouse mammary tumour virus (MMTV).

The ideal animal tumour model should mimic the human disease. This means that the investigator should be able to ascertain the influence of host factors on the initiation of tumorigenesis, mimic the susceptibility of tumour response based on age and reproductive history and determine the response of the tumours induced to chemotherapy. The utilization of experimental models of mammary carcinogenesis in risk assessment requires that the influence of ovarian, pituitary and placental hormones, among others and also overall reproductive events, and age at menarche and menopause, are taken into consideration, since they are important modifiers of the susceptibility of the organ to neoplastic development. Several species, such as rodents, dogs, cats and monkeys, have been evaluated for these purposes; however, none of them fulfil all the criteria specified above. Rodents, however, are the most widely used models, and therefore this chapter will concentrate in discussing the rodent model.

PRINCIPLES OF ESTABLISHMENT

The mammary gland, a specialized accessory gland of the skin that characterizes the mammalian species, is

a frequent source of tumours or neoplasms. The terms tumour and neoplasm are applied indistinctly to either benign or malignant lesions, since tumour (from the Latin *tumere*, to swell), means any pathological enlargement or new growth, also called neoplasm (from the Greek *neos*, new, +*plasma*, formation); however, none of them defines the true nature of a given growth. Benign tumours are those that do not invade adjacent tissues, do not metastasize to distant sites and can be cured by local excision. Malignant tumours, or cancer, are neoplasms characterized by their ability to invade, metastasize and ultimately cause the death of the host. They are called 'carcinomas' when they are derived from epithelial cells and 'sarcomas' if they are mesenchymal in origin.

Spontaneous mammary tumours are frequently observed in long-term rodent studies (Rao *et al*., 1987). In mice the development of 'spontaneous' mammary tumours is linked to the infection of female mice with either an exogenous MMTV or a less virulent endogenous provirus. A third strain of MMTV transmitted through the milk and through the germ line has also been identified in the European mouse strain GR. The exogenous MMTV is an RNA virus first recognized to be transmitted through the milk of A and C3H strain mothers, the Bittner factor. DBA and RIII are also inbred strains of mice that harbour the highly oncogenic MMTV transmitted through the milk. Foster-nursed neonate mice (i.e. C3Hf or DBAf) become free of the milk-transmitted MMTV, although they retain the genetically transmitted MMTV, which induces mammary tumours late in life. In high-incidence strains of mice, tumours develop as a multistep process initiated in pre-neoplastic lesions, the hyperplastic alveolar nodules, which evolve from pregnancy-dependent to pregnancy-independent adenocarcinomas. Nulliparous mice develop a low incidence of mammary tumours. Out of a total of 1361 female B6Cf$_1$/CrlBR mice, only five adenomas (0.4%), four fibroadenomas (0.3%), 10 adenocarcinomas (0.9%) and seven carcinomas (0.6%) developed by the end of a 24-month follow-up. Some mammary tumours that develop in females of susceptible strains, such as C3H, A, DBA, CBA and certain sub-strains of Balb/c, are strongly hormone dependent in terms of their initiation. Multiple pregnancies enhance tumour development, and final tumorigenic response is greater in multiparous than in nulliparous animals. In RIII, BR6, DD, and GR mice mammary tumours develop during the first pregnancy, but they regress during lactation. In some strains of mice the growth of mammary tumours is stimulated by chronic administration of oestrogens, certain steroidal contraceptives, progesterone, PRL and epidermal growth factor (EGF), whereas hormone deprivation, induced by hypophysectomy, ovariectomy, ovariectomy–adrenalectomy, and siladenectomy, suppress mammary carcinogenesis (Welsh, 1987).

In the rat, the majority of spontaneously developed tumours, with the exception of leukaemia, are neoplasms of endocrine organs or of organs under endocrine control. Spontaneous mammary tumours develop in females of various strains of rats, such as August, Albany–Hooded, Copenhagen, Fisher, Lewis, Osborne–Mendel, Sprague–Dawley, Wistar and Wistar/Furth (Welsh, 1987). Spontaneous mammary tumours are third in incidence among spontaneous tumours found in the Fisher 344 rat used in the National Cancer Institute (NCI)/National Toxicology Program (NTP) carcinogenicity bioassays (Rao *et al*., 1987). They are predominantly benign tumours, i.e. fibroadenomas (**Figure 1**), fibromas and more rarely adenomas. Malignant tumours such as adenocarcinomas are rare, although they are the most frequent tumours induced by chemical carcinogens (**Figure 2**). The development of spontaneous tumours varies as a function of strain, age and endocrine influences. Mammary gland tumours develop in older females; they are more frequent in multiparous than in nulliparous rats. As in mice, hormone withdrawal inhibits tumour development, and hormone supplementation, such as chronic administration of oestrogens, increases the incidence of adenocarcinomas, whereas chronic administration of prolactin or of growth hormone stimulates benign tumour growth (Welsh, 1987).

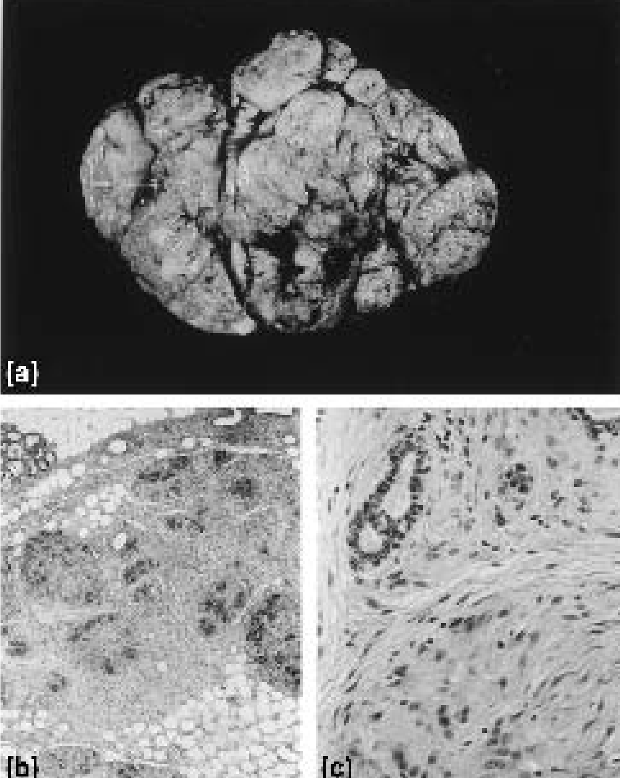

Figure 1 Spontaneous fibroadenoma in a female rat: (a) gross appearance of the dissected tumour; (b) and (c), histological sections of the same tumour reveal the predominance of stromal cells with few ductules interspersed among collagenous fibres. (b) and (c) haematoxylin and eosin stain, ×4 and ×25, respectively.

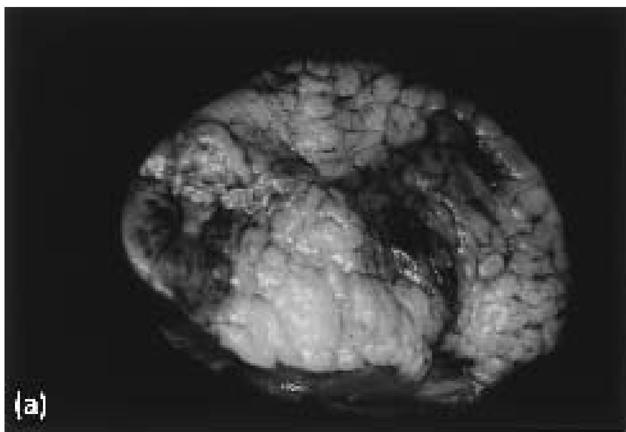

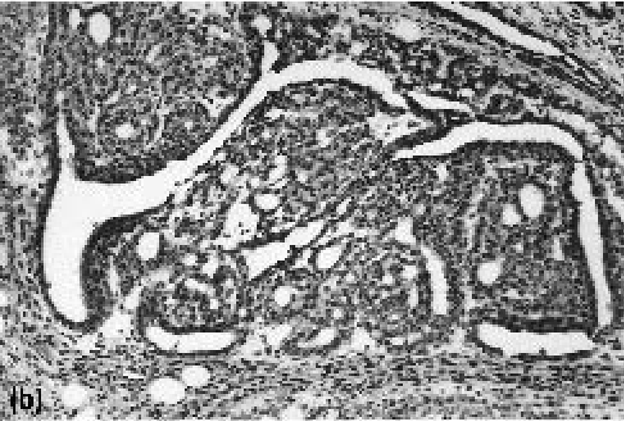

Figure 2 Adenocarcinoma induced by DMBA in virgin rats. (a) Gross appearance; (b) histological section of a papillary adenocarcinoma stained with haematoxylin and eosin, ×25.

The long latency period for spontaneous tumour development, up to 2 years in susceptible strains to develop a 50–70% tumour incidence, limits the usefulness of this model for experimental studies. (See also chapters *Transgenic Technology in the Study of Oncogenes and Tumour Suppressor Genes*; *Gene Knockouts in Cancer Research*.)

GENERAL APPLICATIONS

Chemically Induced Mammary Tumorigenesis

The potential of chemicals to induce cancer was recognized almost two centuries ago as an occupational disease, when a high incidence of skin cancer was linked to exposure to coal tar. Although it has not been proved that human breast cancer is caused by a given chemical or physical genotoxic agent, the human population is exposed to a large number of environmental chemicals, such as polycyclic aromatic hydrocarbons, nitrosoureas and aromatic amines, that have been demonstrated to be carcinogenic in experimental animal models and to induce mutagenesis and neoplastic transformation of human breast epithelial cells *in vitro* (Russo, J. *et al*., 1993). Although a specific aetiological agent or the conditions that might explain the initiation and progression of breast cancer in humans have not been identified, experimental animal models have proved to be useful tools for answering specific questions on the biology of mammary cancer relative to their validity to the human disease, and also for assessing the risk of breast cancer posed by toxic chemicals. *In vivo* experimental animal models provide information not available in human populations; they are adequate for hazard identification, dose–response modelling, exposure assessment and risk characterization, the four required steps for quantifying the estimated risk of cancer development associated with toxic chemical exposure. The utilization of experimental models of mammary carcinogenesis in risk assessment requires that the influence of ovarian, pituitary and placental hormones, among others, and also overall reproductive events, are taken into consideration, since they are important modifiers of the susceptibility of the organ to undergo neoplastic transformation.

Chemically induced mammary tumours develop by a multistep process. The initial step is a biochemical lesion caused by the interaction of the carcinogen with cellular DNA. In this interaction the DNA is damaged, and if the damage is not repaired efficiently, the result is a mutation, chromosomal translocation, inactivation of regulatory genes or more subtle changes not well identified as yet. Neoplastic development requires that the lesion becomes fixed, aided by cell proliferation, progressing to a third stage of autonomous growth, resulting in cancer, when the lesion acquires the capacity to invade and metastasize. Several carcinogens that induce mammary tumours in rodents have been identified and extensively studied for more than 50 years in mice and for more than 30 years in rats (Welsh, 1987). Mammary carcinomas have been induced in strains of mice with low spontaneous mammary cancer incidence with 3,4-benzopyrene, 3-methylcholanthrene (MCA), 1,2,5,6-dibenzanthracene, 7,12-dimethylbenz[*a*]anthracene (DMBA) and urethane. Most of the mammary tumours induced in mice by chemical carcinogens are adenoacanthomas and type B adenocarcinomas. They develop after a relatively long period of time, and their induction requires multiple applications. Enhanced tumorigenicity has been obtained with prolonged hormonal stimulation. However, the hormone responsiveness of chemically induced mammary tumours in mice has not been as thoroughly studied as it has been in the rat.

The most frequently utilized rat mammary carcinogens are DMBA and *N*-methyl-*N*-nitrosourea (MNU), although MCA, 2-acetylaminofluorene, 3,4-benzopyrene, ethylnitrosourea, and butylnitrosourea have also been extensively utilized as mammary cancer inducers (Zwieten, 1984; Welsh, 1987). The majority of rat mammary carcinomas induced by either DMBA or MNU are hormone dependent. Maximum tumour incidence is elicited when the carcinogens are administered to young virgin females

with an intact endocrine system. These models of hormone-dependent tumours constitute useful tools for dissecting the multistep process of carcinogenesis, and serve as a baseline for testing the carcinogenic potential of chemicals in risk assessment.

Radiation-induced Mammary Tumorigenesis

Ionizing radiation is probably the most widely acknowledged and studied human carcinogen (Zwieten, 1984). Exposure to radiation, either accidentally or for therapeutic reasons, has long being associated with a greater incidence of neoplasms, namely haematopoietic, gonadal and of the breast. The female breast is one of the tissues with the highest sensitivity to radiation carcinogenesis. Breast cancer developed in irradiated women shows a strong association with young age at the time of exposure, an association not observed in irradiated rodents, but similar to what has been observed in chemically induced mammary carcinogenesis in rats (Russo, J. *et al.*, 1977, 1979). Since controversy exists concerning the shape of the dose–response curve, the effects of fractionated irradiation and the effect of low levels of radiation, animal studies are necessary to address these issues. The rat model has been widely used in this regard, mainly since the demonstration in the early 1950s that a single lethal dose of X-rays to female Holtzman rats (a Sprague–Dawley stock) maintained by temporary parabiosis induced an increased number of benign and malignant mammary tumours within 6 months of exposure. Sublethal doses of different types of radiation, including X-rays and neutrons, have been shown to induce mammary tumour development, often within 1 year, with linear dose–effect relationships for neutrons over the total dose range and for X-rays down to dose levels of 0.2 Gy. Irradiation of animals with fractionated doses of γ-radiation has resulted in linear–quadratic dose–response curves.

Although most studies have utilized whole-body irradiation, localized irradiation also induces mammary tumours in the rat within the irradiated field. This effect occurs also in women, but reportedly not in several other animal species studied, e.g. mice, dogs and guinea pigs. In rats, mammary carcinomas can be induced by whole-body or segmental radiation with either X-rays, γ-rays or neutrons (Zwieten, 1984). Several studies utilizing a variety of fractionated irradiation protocols, i.e. at 12-h intervals for 60 days, semi-weekly for up to 16 weeks and monthly for up to 10 months, have shown in general, no increase in tumour latency, incidence or total number of mammary tumours, and no sparing or enhancing effect on mammary tumour development when compared with animals exposed to single doses of radiation. Some investigators, however, have reported an increased number of mammary carcinomas in animals receiving fractionated doses. Sprague–Dawley and Lewis rats are the most susceptible to radiation-induced tumorigenesis. AxC, Fisher, Long–Evans and Wistar/Furth strains are also susceptible, but to a lesser degree. The mammary tumours developed by irradiated rats are, in general, hormone-dependent adenocarcinomas or fibroadenomas. The hormonal status of the female rat is of paramount importance in determining the outcome of irradiation of the mammary gland. Ovariectomy completely prevents, and oestrogen treatment enhances, radiation-induced mammary tumour formation. The latency period for tumour development is shortened and tumour incidence is increased considerably in oestrogen-treated rats. The number of cribriform-type adenocarcinomas, and the number of tumours per tumour-bearing rat are also increased. Radiation and oestrogens, namely 17β-oestradiol (E_2) or diethylstilboestrol (DES), have been reported to exert either an additive or synergistic effect. The effect of E_2 administration and irradiation on mammary tumorigenesis has been reported to be equal for hormone administration 1 week before or beginning 12 weeks after irradiation, but no additive effect has been observed when hormone administration was begun 24 weeks after irradiation. The amplification of radiation-induced mammary tumorigenesis by oestrogens has been attributed by several investigators to the effects of this hormone on the pituitary, an interpretation supported by the observations that DES treatment of ACI rats and E_2 treatment of rats of three different strains, for example, result in increased incidence of pituitary tumours, accompanied by a marked increases in plasma prolactin (PRL) levels. The development of malignant mammary tumours in these rats appeared to be associated with the extent of increase in plasma PRL. Mammary tumour incidence and number or type of mammary tumours are not modified by irradiation during pregnancy, lactation or postlactational regression in comparison with irradiation in the virginal state, in contrast to what has been reported in chemically induced mammary carcinogenesis (Russo, J. *et al.*, 1979). Furthermore, radiation-induced mammary tumours developed in rats do not exhibit the age dependency observed in women or in chemically induced rat mammary carcinomas (Russo, J. *et al.*, 1977, 1979; Russo, J. and Russo, I. H., 1980a,b). They do not exhibit topographic selectivity in their development, since they arise randomly in thoracic and abdomino-inguinal regions (Russo, J. and Russo, I. H., 1987; Welsh, 1987). Further studies are needed to clarify these differences in tumour incidence between radiation- and chemically induced mammary tumours in rats for validating this model for risk assessment. The reason for the differences in physiological influences on the inductive action of chemicals and irradiation in rat mammary gland is not clear. It has been speculated that radiation-induced changes might occur in a specific stem cell population maintained throughout the reproductive life, whereas chemically induced changes depend upon the number and rate of turnover of other types

of mammary gland cells (Russo, J. and Russo, I. H., 1980a).

Genetic Background and Mammary Carcinogenesis

Genetic differences among individuals may affect their susceptibility to the carcinogenic effect of chemicals. Inheritance may well predispose an individual to develop certain specific types of cancer. These influences have been carefully dissected in rodent experimental animal models (Isaacs, 1986). In carefully designed experiments, it has been demonstrated that the susceptibility of rats to the chemical carcinogens 2-acetylaminofluorene (AAF), DMBA and MNU is genetically determined (Isaacs, 1986). Isaacs demonstrated that Buffalo, Lewis, Wistar/Furth and inbred Sprague–Dawley rats, all strains of Wistar genetic background, are highly susceptible to chemically induced carcinogenesis, whereas the non-Wistar-derived strains Fischer, August, ACI and Copenhagen are of low susceptibility. However, there are exceptions to this rule, since the Wistar-derived inbred WN strain is of low susceptibility, and the non-Wistar-derived Osborne–Mendel strain is highly susceptible. Of the commonly used strains, Sprague–Dawley and Wistar–Furth are the most susceptible and Fischer 344 and ACI rats show intermediate susceptibility. Copenhagen rats are essentially completely resistant even to the direct application of DMBA to the gland, although they do develop fibrosarcomas in response to parenteral DMBA. Extensive analyses comparing DMBA tumorigenesis, mammary gland growth rate, serum hormone levels and DMBA toxicokinetics in female rats of several strains and F_1 hybrids between the strains have not found major differences that correlated with susceptibility to tumorigenesis, since both susceptible and resistant strains develop similar percentages of malignant changes (60% in resistant, 80% in susceptible). However, macroscopically detectable tumours developed in 70% of susceptible and only in 10% of resistant glands. These findings have been confirmed by transplantation experiments between resistant or susceptible strains into F_1 hybrids, and between the two strains, and by direct exposure to DMBA. These observations indicate that genetic factors govern the progression from microscopic to macroscopic tumour, rather than from normal to histologically malignant epithelium, and furthermore, that resistant rats possess a dominant suppressor allele for the gene governing susceptibility. In contrast, tumour induction by DES is demonstrable in the ACI but not in the Sprague–Dawley strain of rats, although a co-carcinogenic effect of DES with DMBA can be shown in the latter. Both malignant and benign tumours are increased by the combined treatment, but there is a relatively greater increase in benign tumours. The response of target organs other than the mammary gland to DES is also different in these two strains of rats, but the mechanisms are not known.

PATHOGENESIS OF RAT MAMMARY TUMOURS

Chemical carcinogen induction of mammary tumours in rodents is one of the most widely studied and useful models of mammary carcinogenesis (Huggins *et al*., 1961; Russo, J. *et al*., 1977; Russo, I. H. and Russo, J., 1978; Russo, J. and Russo, I. H., 1978; Zwieten, 1984; Russo, I. H. *et al*., 1989). For those reasons, this section will focus mainly on that model. The two most widely utilized experimental systems of mammary tumorigenesis are the induction of rat mammary tumours by administration of either the indirectly acting polycyclic hydrocarbon DMBA, given intragastrically (i.g.) to Sprague–Dawley rats (Huggins *et al*., 1961), or the direct acting carcinogen NMU, given intravenously (i.v.) or subcutaneously (s.c.) to Sprague–Dawley or Fischer 344 rats, respectively (Gullino *et al*., 1975). A single i.g. dose of 80–100 mg of DMBA per kg body weight induces tumours with latencies that generally range between 8 and 21 weeks. The final tumour incidence reaches 100% when the carcinogen is administered to intact virgin rats in their peak of maximal susceptibility, that in Sprague–Dawley rats occurs between the ages of 40 and 60 days (Russo, J. *et al*., 1983). NMU, given in a single i.v. dose of 25 or 50 mg/kg body weight, yields tumours with similar latency and incidence (Gullino *et al*., 1975). In a comparative study between the carcinogenic potential of DMBA, administered i.g. at a dose of 20 mg/kg, and NMU, given i.v. at a dose of 50 mg/kg, it was demonstrated that both induce approximately equal tumour incidence and number of tumours per animal, with approximately equal latency, but a somewhat greater percentage of NMU-induced tumours were histologically malignant.

The analysis of the factors that modulate the tumorigenic response of the mammary gland, especially in short-term studies, have revealed that the most sensitive and reliable end points are both tumour latency and tumour histological type. Tumour latency is, in general, inversely related to carcinogen dose, whereas overall tumour incidence and number of malignant tumours per animal are directly related, especially when relatively early end points are used. No such a relationship has been found for benign tumours. The number of tumours per rat or per group and the number or incidence of malignant tumours are additional end points useful in analysis of data. Comparison of data among laboratories requires strict standardization of the experimental conditions, since considerable variations in tumour incidence and latencies between laboratories and between experiments in the same laboratory are frequently seen.

The induction of mammary carcinomas in the rat requires that the carcinogen acts on a specific compartment

of the mammary gland, the terminal end bud (TEB), a club-shaped undifferentiated structure found at the peripheral margins of the developing mammary parenchyma in young virgin rats (**Figure 3a** and **b**). Although TEBs are present in the six pairs of mammary glands, tumour development does not occur as a random event. Tumour incidence in animals treated with the carcinogen between the ages of 20 and 180 days is greater in those glands located in the thoracic region, whereas glands located in the abdominal and inguinal areas develop a smaller number of tumours (**Figure 4**). In addition to differences in tumour incidence as a consequence of the topographic location of the gland, there are differences in tumour type, which seem to vary with the age of the animal at the time of carcinogen treatment. Ductal and papillary adenocarcinomas are more frequent in both thoracic and abdominal glands of younger animals, whereas adenocarcinomas with a tubular pattern are found mostly in abdominal glands and in older animals. The development of the rat mammary gland occurs through a combined process of branching and differentiation of the parenchyma, mainly in those ducts ending in TEBs that progressively divide and differentiate into alveolar buds (ABs) (**Figure 3c**). These structures in turn differentiate into lobules. Although this pattern of development is common to the six pairs of mammary glands, it does not occur simultaneously in all of them, but varies in relation to the topographic location of each specific pair. Individual structures, i.e. TEBs, ABs and lobules, appear similar in morphology in all the glands, but their relative number and

(b) Enlargement of terminal end buds indicated in (a), $\times 10$. (c) Alveolar buds from the area shown in (a), $\times 10$.

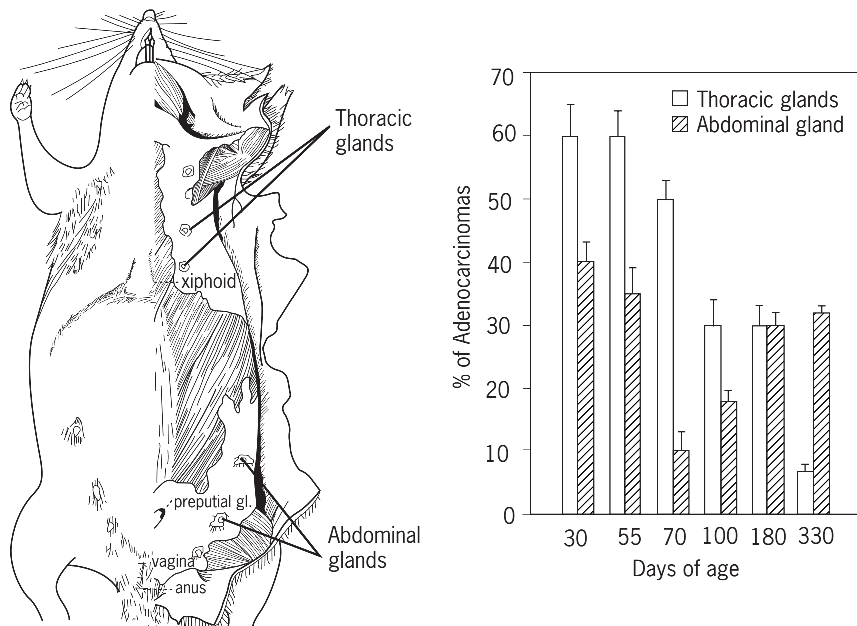

Figure 4 Drawing of a rat showing the distribution of the six pairs of mammary glands. The fourth pair, or abdominal mammary gland, is the most frequently utilized for morphological, cell kinetic and tumorigenic studies because of its large size and ease of access. However, they are less susceptible to be transformed by chemical carcinogens, as indicated in the histogram at the right-hand side, which shows that the higher incidence of adenocarcinomas occurs in thoracic mammary glands in those animals inoculated with the carcinogen at ages younger than 100 days. These results were obtained by inoculating virgin Sprague–Dawley rats intragastrically with a single dose of 8 mg of 7,12-dimethylbenz[a]anthracene (DMBA) (Sigma Chemical, St. Louis, MO, USA) per 100 g body weight. The carcinogen was dissolved in corn oil at a concentration of 16 mg mL^{-1} by heating in a water-bath at 95°C for 30 min.

the general architecture of the organ vary considerably from one pair of glands to another. The most notable ones are the thoracic mammary glands, since each single gland is composed of two different layers separated by connective and muscular tissue; one layer is composed of more numerous ABs and small lobules, whereas the adjacent one is more extensive and contains thin long ducts ending in prominent TEBs. The abdominal glands have a markedly reduced number of TEBs, which are located exclusively in the most distal portion of the gland, whereas the middle and proximal portions show a much more differentiated appearance. The difference in number of TEBs in thoracic versus abdominal mammary glands is significant. With ageing, TEBs decrease progressively and their reduction is proportional in all the glands. This reduction is mostly due to either their regression to TDs or to a greater differentiation to ABs and lobules (**Figure 5**). The higher incidence of ductal carcinomas observed in thoracic glands is attributed to the difference in degree of development of the undifferentiated layer of this gland in comparison with the glands located in other topographic areas (Russo, I. H. *et al*., 1989).

Mammary Gland Differentiation as a Modulator of Carcinogenic Response

Mammary cancer in experimental models is the result of the interaction of a carcinogen with the target organ, the mammary gland. This target, however, is extremely complex, since the mammary gland does not respond to the carcinogen as whole, but only specific structures within the gland are affected by given genotoxic agents. The knowledge of the architecture and cell kinetic characteristics of the mammary gland at the time of carcinogen administration constitutes a necessary initial step for understanding the pathogenesis of the disease. It is also required for distinguishing those changes induced by the carcinogen from changes reflecting normal gland development, especially when evaluating early tumorigenic response in short-term studies (Russo, J. *et al*., 1977; Russo, J. and Russo, I. H., 1978; Russo, I. H. and Russo, J. 1978).

The susceptibility of the mammary gland to DMBA- or NMU-induced carcinogenesis is strongly age dependent; it is maximum when the carcinogens are administered to virgin females between the ages of 40 and 60 days, that is, soon after vaginal opening and during early sexual maturity (**Figure 5**) (Russo, J. *et al*., 1977). Active organogenesis and high rate of proliferation of the glandular epithelium are characteristics of that period, in which there is also high DMBA activation (**Figure 6**) (Russo, I. H. and Russo, J., 1978; Russo, J. and Russo, I. H., 1978, 1980a,b). Its significance, however, is uncertain, since NMU, which is also most effective at that age, does not require activation. The incidence of DMBA-induced tumours reaches 100% when the carcinogen is administered to rats aged 30–55 days, but the highest number of tumours per animal is observed when the carcinogen is given to animals between the ages

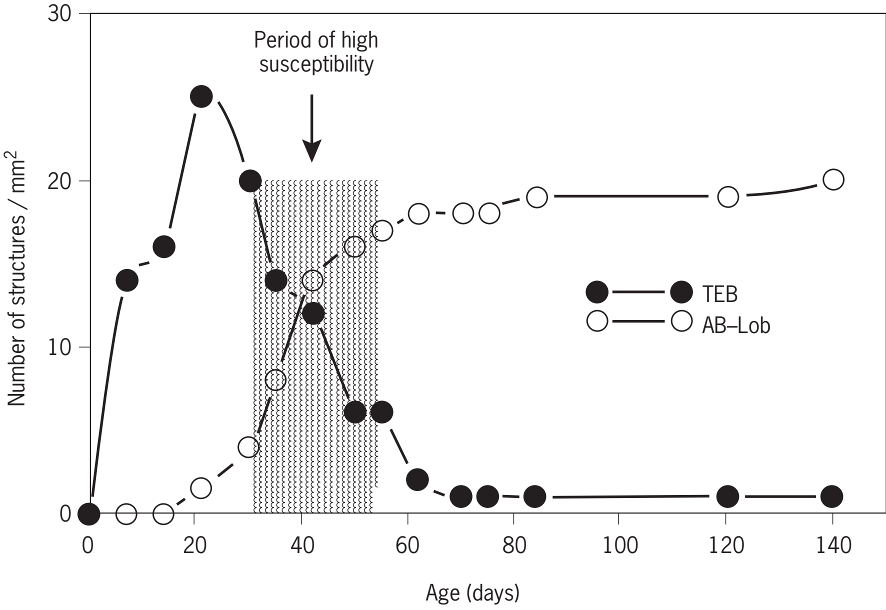

Figure 5 Histogram representing the number of structures per mm^2 (ordinate) of the rat mammary gland in relation to age (abscissa). Hatched area, period of highest susceptibility of the mammary gland to neoplastic transformation by chemical carcinogens. (From Russo, J. and Russo, I. H., 1994, *Cancer Epidemiology Biomarkers and Prevention*, **3**, 353–364.)

AB	4%	28.18 h	G_2 M, S, G_1(17 h)	0.13	1.3 ± 0.8	Cysts Hyperplastic Alveolar Nodules Adenomas Fibroadenomas
Lobule	0.1%	49.63 h	S, G_2 M, G_1(35 h)	0.0049	0.9 ± 0.5	None

Figure 6 Correlation between type of structure, terminal end bud (TEB), alveolar bud (AB) and lobule with the DNA-labelling index (DNA-LI), length of the cell cycle in hours (Tc), cell cycle and growth fraction (GF). Nuclear uptake of [^{3}H]DMBA, detected by autoradiography and expressed as the number of grains per nucleus, is directly proportional to the DNA-LI and GF and inversely proportional to the Tc of each specific structure. The development of carcinomas also correlated with high DNA-LI, Tc and DMBA binding, whereas benign lesions or the absence of neoplasms were seen in an inverse relation. (From Russo, J. and Russo, I. H., 1994, *Cancer Epidemiology Biomarkers and Prevention*, **3**, 353–364.)

of 40 and 46 days, coincident with the period in which the mammary gland exhibits a high density of highly proliferating TEBs (**Figures 3, 5 and 6**). This high susceptibility is attributed to the specific characteristics of the mammary gland prevailing during that period of life. Administration of DMBA to virgin rats induces the largest number of transformed foci when TEBs are decreasing in number owing to their differentiation into ABs (**Figures 3 and 5**). These structures, instead of differentiating into ABs, become progressively larger owing to epithelial proliferation, with multi-layering, secondary lumen formation and early papillary projections to the widened lumen; at this stage, transformed TEBs are called intraductal proliferations (IDPs) (**Figure 7**). Their confluence leads to the formation of microtumours that histologically are classified as adenocarcinomas, first intraductal, which progress to invasive tumours, developing various patterns such as cribriform, comedo or papillary types (**Figures 2 and 7**) (Russo, J. *et al*., 1977).

Even though TEB differentiation into AB is inhibited by carcinogen treatment, not all the TEBs present in the mammary gland at the time of DMBA administration progress to IDPs. Some of them still differentiate into ABs but their number is always smaller than that of control animals. Occasional lobular development is observed, although it is negligible. Some TEBs become smaller with an atrophic appearance being called at this stage terminal ducts (TDs). TDs are also susceptible to neoplastic transformation and are the main target of carcinogens in older animals (Russo, I. H., *et al*., 1989). Those TEBs which were already differentiated into ABs and early lobular structures before DMBA administration do not develop carcinomas. Most of them either remain unmodified or undergo dilatation of the lumen, giving rise to hyperplastic lesions, such as alveolar bud hyperplasia (**Figure 7**). Others exhibit epithelial proliferation, forming tubular adenomas, give rise to cystic dilatations, or fibroadenomas (**Figure 7**). When DMBA is inoculated into old virgin females, ranging in age from 180 to 330

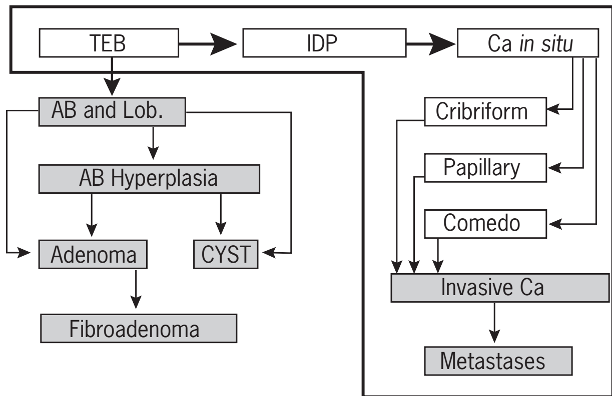

Figure 7 Pathogenesis of chemically induced rat mammary tumours. The undifferentiated terminal end bud (TEB) affected by the carcinogen progresses to intraductal proliferation (IDP), and *in situ* ductal carcinoma (Ca *in situ*) that exhibit various histopathological types. Further tumoural growth and coalescence of neighbouring lesions originate invasive carcinomas (Invasive Ca), which might become metastatic. When the carcinogen affects more differentiated structures, such as alveolar buds (AB) and lobules (Lob.) the lesions developed are more benign in nature and appear later than the ductal carcinomas. Alveolar bud hyperplasia (AB Hyperplasia).

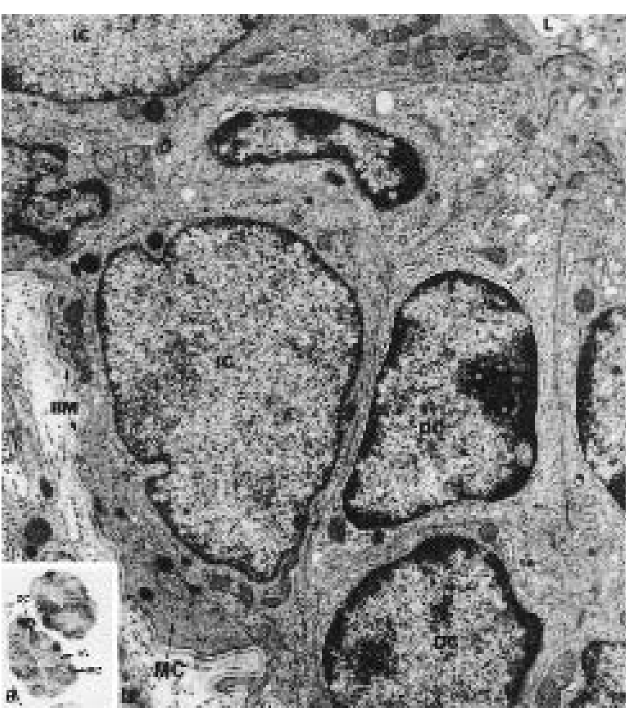

Figure 8 The rat mammary gland ductal system is lined by three types of cells, myoepithelial cells (MC), dark cells (DC) and intermediate cells (IC). (a) A 1-μm section of a rat mammary gland embedded in plastic and stained with toluidine blue, $\times$40. (b) Electron micrograph of the rat mammary gland showing the three cell types. The basement membrane (BM), that separates the epithelial cells from the stroma, is opposite to the lumen (L). Uranyl acetate–lead citrate, $\times$4000.

days, they develop tubular adenomas that exhibit focal areas of malignant transformation, giving rise to well-differentiated adenocarcinomas with a tubular pattern. These lesions develop predominantly in the abdominal glands, in which a higher incidence of tumours is observed in older animals (**Figure 4**). The observation that mammary carcinomas arise from undifferentiated structures of the gland, namely TEBs and TDs, whereas benign lesions such as adenomas, cysts and fibroadenomas (**Figures 1 and 2**) arise from structures that were more differentiated at the time of carcinogen administration, indicates that the carcinogen requires an adequate structural target, and the type of lesion induced is dependent upon the area of the mammary gland that the carcinogen affects (**Figure 7**). Hence the more differentiated the structure at the time of carcinogen administration, the more benign and organized is the lesion that develops.

Cell of Origin of Rat Mammary Carcinomas

In the rat mammary gland parenchyma, three types of cells have been described, dark, intermediate and myoepithelial cells (**Figure 8**). The distribution of cell populations in the mammary gland during carcinogenesis varies in TEBs and TDs (**Figure 9a and b**), starting as early as 24 h post-DMBA administration, but no changes in cell composition occur in more differentiated structures such as ABs and lobules. The changes taking place in TEBs and TDs are limited to the dark-cell type, the proportion of which decreases from 76 to 67% and to the intermediate cell, the proportion of which increases from 11 to 19%. Myoepithelial cells are unaffected. The trend is a progressive shift of cell population distribution, with a continuous decrease in dark cells and a concomitant increase in intermediate cells (**Figure 10**). By 14 days post-DMBA, the latter constitute about 40 and 50% of the proliferative compartment in TEBs and TDs, respectively. At this time the morphological manifestations of tumorigenesis have started to become apparent: increased number of epithelial cell layers, greater irregularity of the luminal border and progressively larger intercellular spaces, which in some cases form secondary lumina, are features indicative of the formation of an intraductal proliferation (IDP).

The basal lamina becomes distorted, thus rendering the identification of myoepithelial cells more difficult, and the surrounding stroma becomes fibrotic and infiltrated by inflammatory cells. Between 21 and 40 days post-DMBA

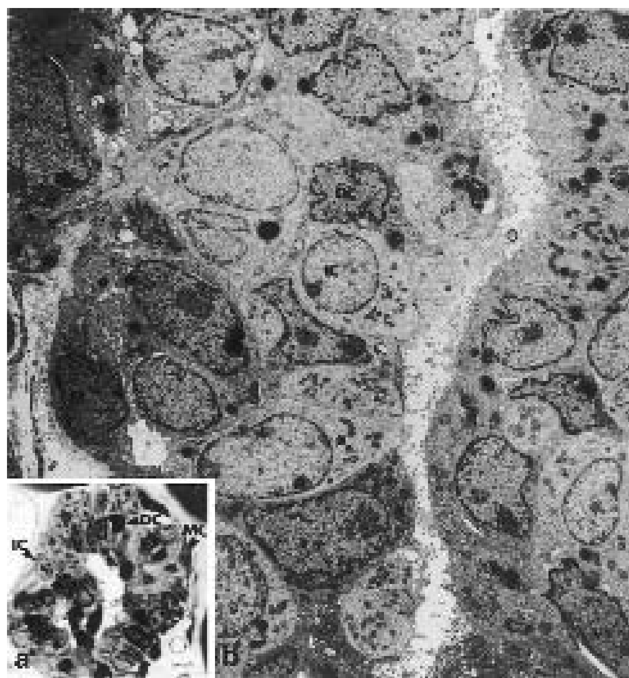

Figure 9 The terminal end bud (TEB) of the rat mammary gland is composed of the three cell types described in **Figure 8**. (a) A 1-μm section of the TEB embedded in plastic and stained with toluidine blue, ×40 (b) Electron micrograph of the TEB showing the three cell types. Uranyl acetate–lead citrate, ×2000. (Part (b) from Russo *et al*., 1983, *American Journal of Pathology*, **113**, 50–66.)

treatment, the descending curve of dark cells crosses over the progressively ascending curve of intermediate cells. By 40 days, the tumours display a cell distribution of >65% intermediate cells and <35% dark cells (**Figure 10**). The proportion of intermediate cells continues to increase with tumour age, and at 70 days they represent >75% of the cells. Dark cells, at this point, have been reduced to <20%, whereas myoepithelial cells remain at approximately 5%. The 100-day-old tumours are dominated by intermediate cells comprising nearly 90% of the total number of cells (Russo, J. *et al*., 1983).

Cell Kinetics and Mammary Carcinogenesis

In every tissue, normal or abnormal, cell composition consists of a balance of three different cell populations: cycling cells, resting cells (cells in G_0), and dying cells (cell loss). In the mammary gland these three cell populations can be identified through the study of the cell cycle and determination of the growth fraction and the rate of cell loss. The growth fraction refers to the fraction of cycling cells, while the rate of cell loss refers to the fraction of cells that die or migrate to other tissues. Both cell cycle time and the growth fraction determine the number of cells produced per unit time, and the rate of cell loss determines the number of cells lost per unit time. The growth of normal cells involves a net increase in cell number resulting from more cells being born than dying. In the differentiated or in the adult tissue, in which growth has ceased, the number of cells produced per unit time is equal to the number of cells that die. (See also chapter *Models for Tumour Growth and Differentiation*.)

The higher susceptibility of the TEB to neoplastic transformation is attributed to the fact that this structure is composed of an actively proliferating epithelium, as determined by the mitotic index (MI), DNA-labelling indices (DNA-LI), length of the cell cycle (Tc), and growth fraction (GF) (**Table 1**, **Figure 6**) (Russo, J. and Russo, I. H., 1980a,b). Both the MI and DNA-LI are very high at the tip of TEBs, decreasing progressively toward the ductal or proximal portion of the gland and even further in ABs and lobules. TEBs are also characterized by having the highest growth fraction, which progressively diminishes in the more differentiated ABs and lobules (**Table 1**, **Figure 6**). By using these cell kinetic parameters we calculated the rate of cell loss in each one of the compartments of the mammary tree. Interestingly, the TEB is the structure not only with the highest proliferative ratio, but also with the lowest percentage of cell loss in comparison with other parenchymal structures. The rate of cell loss is very high in the lobular structures present in the mammary gland

Table 1 Cell kinetics in the mammary gland[a]

	Growth fraction	Rate of cell birth/hr	Rate of cell loss/hr
Y.V. TEB	0.55	472	44.96
Y.V. ducts	0.39	187	60.99
Y.V. lobules	0.13	46	87.00
Parous ducts	0.009	4.05	99.00
Parous lobules	0.004	0.96	98.00

[a]The growth of the mammary gland is the result of a balance between cell birth and cell loss. The growth fraction (GF) represents the total population of cycling cells, and is determined as the rate of ^{3}[H]thymidine incorporation after 5 days of continuous infusion (GF_5). It is maximum in the terminal end bud (TEB) of the young virgin (Y.V.) rat, decreasing progressively in ducts and lobules of the Y.V. animal. Pregnancy results in a more dramatic reduction on GF in both ducts and lobules.

of parous rats. This clearly indicates that the TEB of the young virgin female is the truly proliferating structure of the gland that reaches a steady state only after acquiring full differentiation. The differences in proliferative activity and growth fraction observed between TEBs and the more differentiated structures of the mammary gland are also reflected in variations in the length of Tc (**Figure 6**). Tc in TEBs of young virgin rats has an average length of 11 h, increasing to 20.81 h and 28.18 h in TDs and ABs, respectively. Further mammary gland differentiation as a consequence of ageing and pregnancy results in an even longer Tc, mainly due to a lengthening of the G_1 phase of the cell cycle (**Figure 6**) (Russo, J. and Russo, I. H., 1980a). The length of Tc also varies according to the cell type and to the specific compartment in which each given cell type is located in. The shortest Tc is observed in intermediate cells located in TEBs, whereas it lengthens when the same cell type is located in ABs or lobules. These differences in the length of Tc are due mainly to differences in the length of the G_1 phase of the cell cycle, whereas all the other phases remain constant. Intermediate-type cells located in TEBs have a Tc lasting 13 h. When the same cell type is located in more differentiated structures, such as ABs, it exhibits a lengthened Tc, lasting 34 h. These differences in cell kinetic parameters among the different cell types could explain the higher susceptibility of the intermediate cell of the TEBs to be affected by the carcinogen, which causes further expansion of the proliferative compartment of the intermediate cells and depression in the dark cell population after initiation of the carcinogenic stimulus (Russo, J. *et al*., 1983).

Mammary epithelial cells metabolize DMBA to polar metabolites with the formation of epoxides that cause DNA damage. When dissociated mammary epithelial cells of young virgin and of parous animals, that basically represent the cells of the TEBs and of the lobules, respectively, are grown *in vitro*, they exhibit different rates of formation of polar metabolites. TEB cells produce more polar and less phenolic metabolites than lobular cells, indicating that the former, in addition to their higher proliferative activity, are also producing more epoxides, as is manifested by a higher binding of DMBA to DNA (**Figure 6**). Autoradiographic studies performed *in vivo* confirm the observation that the greatest uptake of [^{3}H]DMBA occurs in the nucleus of epithelial cells of TEBs and the lowest in ABs and lobules, indicating that the highest DMBA–DNA binding is associated with the structure of the gland with the highest replicative properties. The ability of the cells to remove DMBA adducts from the DNA is an indication of their capability to repair the damage. TEB cells remove adducts formed less efficiently than lobular cells. This is attributed to the shorter G_1 phase of Tc and not to a lack of reparative enzymes (Tay and Russo, 1981).

These studies support the conclusion that the differentiation of the mammary gland modifies the following parameters: (1) glandular structure; (2) cell kinetics characteristics of the mammary epithelium, decreasing the growth fraction and lengthening the cell cycle, mainly the G_1 phase; (3) decreasing formation of polar metabolites and increasing phenolic metabolites; and (4) decreasing binding of the carcinogen. All the parameters listed above affect the susceptibility of the mammary gland to carcinogenesis, and should be taken into account when assessing chemicals for cancer risk.

BIOLOGICAL AND TECHNICAL LIMITATIONS

This chapter has described and compared experimental *in vivo* models currently used for assessing the mammary carcinogenic potential of given chemical and physical agents, and addressed the need for identifying those models that provide an answer regarding the mechanisms involved in cancer initiation and progression in the human population. The main problems identified in this study are the complexity and multistep nature of the carcinogenic process, the lack of understanding of the mechanism(s) involved in the initiation and progression of the disease and the lack of identification of a specific aetiological agent or agents of human breast cancer. The usefulness of chemically induced mammary tumours lies in their hormone dependence, the high frequency of adenocarcinomas histologically similar to human breast cancers, the possibility that they offer for dissecting the initiation, promotion and progression steps of carcinogenesis and the baseline information they provide in risk assessment. Chemically induced mammary tumours develop by a multistep process, which initiates as a biochemical lesion caused by the interaction of the carcinogen with cellular DNA. In this interaction the DNA is damaged, and if the damage is not repaired efficiently, the result is a mutation, chromosomal

translocation, inactivation of regulatory genes or more subtle changes not well identified as yet. Neoplastic development requires that the lesion becomes fixed, aided by cell proliferation, progressing to a third stage of autonomous growth, resulting in cancer, when the lesion acquires the capacity to invade and metastasize. Several carcinogens, such as 3,4-benzopyrene, MCA, 1,2,5,6-dibenzanthracene, DMBA and MNU, have been extensively studied in mice and/or rats. DMBA and MNU have been the most frequently used; the majority of the mammary tumours induced in rats by either one of these agents are hormone-dependent adenocarcinomas. The observation that maximum tumour incidence is elicited when the carcinogens are administered to young virgin female rats has led to important discoveries on the role of mammary gland development and differentiation in cancer initiation. Hormonally induced differentiation and the interplay of ovarian, pituitary and placental hormones have been identified as powerful modulators of the tumorigenic response elicited by genotoxic chemicals.

BIOLOGICAL BACKGROUND

The aim of this chapter is to introduce several mathematical models which have been developed to analyse theoretically the growth and development of solid tumours and other associated processes (such as angiogenesis). Strictly, the mathematical models we will present are neither *in vitro* nor animal models; perhaps the terms *in silico* (given that an important part of the modelling work is carried out on a computer) or *in mente* (given that much of the modelling must be carried out in one's mind) are more appropriate (cf. Little *et al*., 1998). Whatever the most appropriate description of this type of activity, it is clear that these are not *in vivo* models. These are theoretical models, which nonetheless can be used to shed light on a complicated phenomenon. It is hoped that the work in this chapter will be of direct relevance to and will link with the work in the following chapters: *Human Tumours in Animal Hosts*; *Mammary Tumour Induction in Animals as a Model for Human Breast Cancer*; *Angiogenesis Models*; *Models for Tumour Cell Adhesion and Invasion*; *Tumour Metastasis Models*; *Models for Tumour Cell–Endothlial Cell Interactions* and *Models for Immunotherapy and Cancer Vaccines*. Before introducing the mathematical models, we will first give a brief biological overview of the key stages of cancer progression on which we intend to focus and model with systems of mathematical equations. Specifically, we focus on the immune response to cancer (at an early avascular stage), angiogenesis, invasion and metastasis.

The development of a primary solid tumour (e.g. a carcinoma) begins with normal individual cells becoming transformed as a result of mutations in certain key genes. These transformed cells differ from normal ones in several ways, one of the most notable being their escape from the body's homeostatic mechanisms, leading to inappropriate proliferation. Individual tumour cells have the potential, over successive divisions, to develop into clusters (or nodules) of tumour cells. Subsequent growth and development require many coordinating factors to occur and these are described below. In the most general terms then, a neoplasm (tumour) may be defined as an abnormal mass of tissue whose growth exceeds that of normal tissue, is uncoordinated with that of the normal tissue and persists in the same excessive manner after cessation of the stimuli which evoked the change (MacSween and Whaley, 1992). A cancer, or malignant tumour, is a tumour that invades surrounding tissues, traverses at least one basement membrane zone, grows in the host tissue at the primary site and has the ability to grow in a distant host tissue, forming secondary cancers or metastases.

In the following section we describe the various stages of growth involved in tumour progression in more detail.

Early Solid Tumour Growth and the Immune Response

Tumours which originate spontaneously in humans or animals usually grow slowly. Many months, years or even dozens of years are required for their clinical manifestation (Uhr *et al*., 1997) and the precise nature of this phenomenon remains unclear. One of the reasons for the slow growth of tumours and, in some cases, for their regression, may be the reaction of the host immune system to the nascent tumour cells. Many authors point out that intensive lymphoid, granulocyte and monocyte infiltration in a tumour, especially pronounced at the early stages, correlates with a favourable prognosis (Lord and Burckhardt, 1984). However, the possible involvement of the immune system in the control of growth and development, including metastases in humans, is still a matter of some debate. Indeed, some researchers do not confirm the prognostic role of lymphoid infiltration in a tumour. Moreover, data have been reported which suggest a stimulating effect of certain cells of the immune system on the growth of tumours (Prehn, 1994). These apparent contradictions may

be associated with, and partly explained by the fact that carcinogenesis is a multi-stage process and that right from its inception there exists a complex tissue architecture within the tumour. Indeed, a tumour is a highly intricate, heterogeneous structure consisting of various cells which secrete a not inconsiderable quantity of biologically active compounds into the local environment (Franks and Teich, 1986).

The early stage of primary tumour formation often occurs in the absence of a vascular network and it is believed that this stage may last up to several years. The tumour nodule grows to an approximate size of 1–3 mm in diameter, containing close to 10^6 cells, and then growth slows and/or ceases. This limitation of growth is attributed by researchers to the competition between tumour cells for metabolites, the competition between tumour cells and cells of the immune system for metabolites and/or a direct cytostatic/cytotoxic effect produced by the tumour cells on each other. In addition, the early (avascular) stage and the subsequent stages of tumour growth are characterized by a chronic inflammatory infiltration of neutrophils, eosinophils, basophils, monocytes/macrophages, T-lymphocytes, B-lymphocytes and natural killer cells (Wilson and Lord, 1987). These cells penetrate the interior of the tumour and accumulate in it owing to attractants secreted from the tumour tissue and the high locomotive ability of activated immune cells (Ratner and Heppner, 1986). During the avascular stage, tumour development can be effectively eliminated by tumour-infiltrating cytotoxic lymphocytes (TICLs) (Loeffler and Ratner, 1989). The TICLs may be cytotoxic lymphocytes, natural killer cells and/or lymphokine-activated killer cells (Lord and Burckhardt, 1984; Wilson and Lord, 1987). The cytostatic/cytotoxic activity of granulocytes and monocytes/macrophages located in the tumour is determined less frequently. In some cases, relatively small tumours are in cell-cycle arrest or there is a balance between cell proliferation and cell death. This steady-state of fully malignant, but regulated, growth could continue for a period of many months or years (Uhr *et al.*, 1997). In many (but not all) cases such a latent form of small numbers of malignant tumours is mediated by cellular immunity (Uhr *et al.*, 1997). Clinically, such latent forms of tumours have been referred to as 'cancer dormancy'.

An important factor, which may influence the outcome of the interactions between tumour cells and TICLs in a solid tumour, is the spatial distribution of the TICLs. A thick shell of lymphoid infiltration is often revealed around the tumour and even near the central hypoxic zone. This would define an internal structure whereby the regions of cell proliferation and cell death alternate, with the TICLs located near the groups of dying tumour cells. In spite of some progress into the investigation of TICLs and their mechanisms of interaction with tumour cells, our understanding of the spatio-temporal dynamics of TICLs in small tumours and in micrometastases *in vivo* is still limited. It is perhaps not surprising, therefore, that this complicated picture has not yet received an adequate explanation. Certainly, other components of the immune system (e.g. cytokines) are involved in modulating the local cellular immune response dynamics. Many cytokines are produced during cell–cell interactions, which can be focused to perform their function over short ranges in space and over short intervals of time. Interestingly, strong local immune reactions are induced by the release of interleukin 1 (IL-1), IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12, IL-13, IL-15, G-CSF, GM-CSF, INF-α, TNF-α, INF-γ, etc. Each of these cytokines recruits and activates some distinct cell population, which could be tumour-infiltrating cells, or the tumour cells themselves. Besides immune reactions, other processes (e.g. cell proliferation, development, migration and apoptosis) are governed through complicated feedback loops. The experimental analysis of such *in vivo* functions requires gene transfer technology and adoptive cell transfer studies, among others. Such studies are, however, hampered by the availability of *in vitro* cloned TICLs and by the frustrating experience that these *in vitro* propagated killer cells perform relatively badly *in vivo*, owing to, for example, the down-regulation of their homing receptors and the up-regulation of many of the cytokines amongst other things.

Angiogenesis, Vascular Growth, Invasion and Metastasis

As we have seen in the previous section, repeated growth and proliferation of the tumour cells during the early phase of growth leads to the development of an avascular tumour consisting of approximately 10^6 cells. A solid tumour in this state cannot grow any further, owing to its dependence on diffusion processes as the only means of receiving nutrients and removing waste products. For any further development to occur the tumour itself must initiate angiogenesis – the recruitment of blood vessels. The tumour cells first secrete a variety of angiogenic factors which in turn induce endothelial cells in any neighbouring blood vessels to degrade their basal lamina and begin to migrate towards the tumour. As it migrates, the endothelium begins to form sprouts which can then form loops and branches through which blood circulates. From these branches more sprouts form and the whole process repeats, forming a capillary network which eventually connects with the tumour, completing angiogenesis and supplying the tumour with the nutrients it needs to grow further. There is now also the possibility of tumour cells finding their way into the circulation and being deposited in distant sites in the body, resulting in metastasis. The complete process of metastasis involves several sequential steps, each of which must be successfully completed by cells of the primary tumour before a secondary tumour

(a metastasis) is formed. A summary of the key stages of the metastatic cascade is as follows:

- cancer cells escape from the primary tumour;
- they locally degrade the surrounding tissue and continue migration;
- they enter the lymphatic or blood circulation system (intravasation);
- they must survive their journey in the circulation system;
- they must escape from the blood circulation (extravasation);
- the cancer cells (from the primary tumour) must then establish a new colony in distant organs;
- the new colony of cells must then begin to grow to form a secondary tumour in the new organ;
- the complete process of growth, angiogenesis, invasion can then begin all over again.

(See also the chapter *Extracellular Matrix: The Networking Solution*.)

It is highly likely that *in vivo*, the two processes of tumour-induced angiogenesis and degradation of the local surrounding tissue (extracellular matrix) by the tumour cells occur simultaneously. Once the capillary network has reached the tumour, vascular growth occurs and at this stage there is a complex interaction between the vascular network, the invading tumour cells and the extracellular matrix. However, for clarity of purpose, we describe each of the processes of angiogenesis and tumour invasion/matrix degradation separately.

Tumour-induced Angiogenesis

Angiogenesis (syn. neovascularization), the formation of blood vessels from a pre-existing vasculature, is a crucial component of many mammalian growth processes. It occurs in early embryogenesis during the formation of the placenta, after implantation of the blastocyst in the uterine wall. It also occurs, in a controlled manner, in adult mammals during tissue repair. By contrast, uncontrolled or excessive blood-vessel formation, is essential for tumorigenesis and is also observed in arthritis, abnormal neovascularization of the eye, duodenal ulcers and following myocardial infarction (Folkman, 1985, 1995; Folkman and Klagsbrun, 1987). These instances may be considered pathological examples of angiogenesis (Muthukkaruppan *et al*., 1982). In each case, however, the well-ordered sequence of events characterizing angiogenesis is the same, beginning with the rearrangement and migration of endothelial cells from a pre-existing vasculature and culminating in the formation of an extensive network, or bed, of new capillaries (Madri and Pratt, 1986). (See also the chapter *Angiogenesis Models*.)

The first event of tumour-induced angiogenesis involves the cancerous cells of a solid tumour secreting a number of chemicals, collectively known as tumour angiogenic factors (TAF) (Folkman and Klagsbrun, 1987), into the surrounding tissue. These factors diffuse through the tissue space creating a chemical gradient between the tumour and any existing vasculature. Upon reaching any neighbouring blood vessels, endothelial cells lining these vessels are first induced to degrade the parent venule basement membranes and then migrate through the disrupted membrane towards the tumour. Several angiogenic factors e.g. vascular endothelial growth factor (VEGF), acidic and basic fibroblast growth factor (aFGF, bFGF), angiogenin and others, have been isolated (Folkman and Klagsbrun, 1987) and endothelial cell receptors for these proteins have been discovered. Indeed, there is now clear experimental evidence that disrupting these receptors has a direct effect on the final structure of the capillary network (Hanahan, 1997).

The initial response of the endothelial cells to these angiogenic factors is a chemotactic one (Paweletz and Knierim, 1989), whereby the endothelial cells respond to the gradients of TAF and migrate towards the source of these secreted cytokines, the tumour. Following this, small, finger-like capillary sprouts are formed by accumulation of endothelial cells which are recruited from the parent vessel. The sprouts grow in length due to the migration and further recruitment of endothelial cells and continue to move toward the tumour directed by the motion of the leading endothelial cell at the sprout-tip. Further sprout extension occurs when some of the endothelial cells of the sprout-wall begin to proliferate. Cell division is largely confined to a region just behind the cluster of mitotically inactive endothelial cells that constitute the sprout-tip. This process of sprout-tip migration and proliferation of sprout-wall cells forms solid strands of endothelial cells amongst the extracellular matrix. The cells continue to make their way through the extracellular matrix which consists, among other things, of interstitial tissue, collagen fibres, fibronectin and laminin (Liotta *et al*., 1983; Paweletz and Knierim, 1989). Interactions between the endothelial cells and the extracellular matrix are very important and directly affect cell migration. In particular, the specific interactions between the endothelial cells and fibronectin, a major component of the extracellular matrix, have been shown to enhance cell adhesion to the matrix.

Cultured endothelial cells are known to synthesize and secrete cellular fibronectin and the expression of this secreted fibronectin by the endothelial cells in cultures (*in vitro*) closely reflects the distribution of pre-existing fibronectin observed in matrices *in vivo* (Hynes, 1990). The fibronectin which is produced and secreted by endothelial cells does not diffuse, but remains bound to the extracellular matrix (Hynes, 1990), its central function being the adhesion of cells to the matrix. It is a major ligand (both cellular fibronectin and plasma fibronectin) between cells and matrix materials in many situations. Endothelial cells use fibronectin for attachment to the matrix via integrins, a family of cell-surface receptors (Hynes, 1990; Alberts *et al*., 1994). It has been verified experimentally that fibronectin stimulates directional

migration of a number of cell types (including endothelial cells) in Boyden chamber assays. These results have demonstrated that fibronectin promotes cell migration up a concentration gradient and the results of McCarthy and Furcht (1984) have further demonstrated that this is a response of the cells to a gradient of adhesiveness of bound fibronectin, termed haptotaxis (Carter, 1967). Therefore, in addition to the chemotactic response of the endothelial cells to the TAF, there is a complementary haptotactic response to the fibronectin present within the extracellular matrix. (See also the chapter *Modelling Tumour–Tissue Interactions*.)

Initially, the sprouts arising from the parent vessel grow essentially parallel to each other. It is observed that once the finger-like capillary sprouts have reached a certain distance from the parent vessel, they tend to incline toward each other (Paweletz and Knierim, 1989), leading to numerous tip-to-tip and tip-to-sprout fusions known as anastomoses. Such anastomoses result in the fusing of the finger-like sprouts into a network of poorly perfused loops or arcades. Following this process of anastomosis, the first signs of circulation can be recognized and from the primary loops, new buds and sprouts emerge repeating the angiogenic sequence of events and providing for the further extension of the new capillary bed. The production of new capillary sprouts from the sprout-tips is often referred to as sprout branching, and as the sprouts approach the tumour, their branching dramatically increases until the tumour is eventually penetrated, resulting in vascularization (Muthukkaruppan *et al*., 1982).

Tumour-induced angiogenesis provides the crucial link between the avascular phase of solid tumour growth and the more harmful vascular phase, wherein the tumour invades the surrounding host tissue and blood system (Chaplain, 1996). However, these apparently insidious features of tumour-induced angiogenesis are now being used to combat cancer growth and the clinical importance of angiogenesis as a prognostic tool is now well recognized. Anti-angiogenesis strategies are also being developed as a potentially powerful, noninvasive weapon against the spread of cancer.

Matrix Degradation and Cancer Invasion

A crucial part of the invasive/metastatic process is the ability of the cancer cells to degrade the surrounding tissue or extracellular matrix (ECM) (Liotta *et al*., 1983; Stetler-Stevenson *et al*., 1993). As mentioned in the previous section, the extracellular matrix is a complex mixture of macromolecules, some of which, like the collagens, are believed to play a structural role and others, such as laminin, fibronectin and vitronectin, are important for cell adhesion, spreading and motility. We note that all of these macromolecules are bound within the tissue, i.e. they are nondiffusible. The ECM can also sequester growth factors and itself be degraded to release fragments which can have growth-promoting activity. Thus, while ECM may have to be physically removed in order to allow a tumour to spread or intra- or extravasate, its degradation may in addition have biological effects on tumour cells.

A number of matrix degradative enzymes (MDEs) such as the plasminogen activator (PA) system and the large family of matrix metalloproteinases (MMPs) have been described (Matrisian, 1992; Mignatti and Rifkin, 1993). While no MDE is completely specific for one element of the ECM, some broad preferences are expressed, for example the gelatinases (two members of the MMP family) preferentially cleave the laminar collagens IV and V and denatured fibrillar collagens I, II and III but can also digest vitronectin and laminin, at least *in vitro*. Both PAs and the MMPs have been repeatedly implicated in all of the above steps of tumour invasion and metastasis (Stetler-Stevenson *et al*., 1996; Chambers and Matrisian, 1997). Regulation of matrix-degradative activity is highly complex. In both these enzyme systems (PAs/MMPs) there exist several endogenous inhibitors (Kleiner and Stetler-Stevenson, 1993), and the enzymes are often secreted as inactive precursors which must themselves be partially degraded to reach full activity. More than one cell type may be involved in the activation of any one enzyme (Kleiner and Stetler-Stevenson, 1993). (See also the chapter *Invasion and Metastasis*.)

Having described in some detail the key processes that we are going to model using mathematical techniques, we now turn our attention to the aspect of the mathematical modelling itself. In the following sections, we introduce and describe several mathematical models for the growth of an avascular solid tumour, the immune response to cancer, tumour-induced angiogenesis and tumour invasion/metastasis.

PRINCIPLES OF MATHEMATICAL MODELLING

It is difficult to control experimentally all of the interacting elements in a tumour. Furthermore, complex biological systems, such as the immune system and a cancer *in vivo*, do not always behave or act as predicted by experimental investigations *in vitro* (Prehn, 1994). Mathematical modelling and computer simulations of these models can be helpful in understanding important features in these complex inter-related systems. In order to understand how one goes about formulating a mathematical model and then using it to shed light on a given complex biological process, it is useful to have in mind the following algorithm:

- identify the key biological processes and the key biological variables (e.g. various tumour cell types, cytokines, matrix macromolecules);
- identify interactions between these variables (e.g. which cells produce which cytokines, etc.);
- translate these interactions into a mathematical model using the appropriate mathematical tools (e.g. ordinary or partial differential equations; cellular automata);

- carry out computer simulations of the model using, where possible, experimentally measured parameter values (e.g. cytokine production rates, cell migration rates);
- Analyse the results of the model which should, if the model is a good one, at least reproduce observed events. A good model will, of course, go further and will provide extra information on (perhaps only qualitative) or explanations of how the biological process functions.

While the first four points of the above algorithm are relatively straightforward, and indeed so is the first statement of the fifth point, it is the final step of producing a model which sheds extra light on a process which is the most challenging. However, once a reliable model has been developed, it is then relatively easy to perform a range of 'mathematical experiments' on the system (e.g. by making changes to the system parameters) and test various hypotheses associated with the system or to examine the risk associated with these changes.

In developing mathematical models of cancer growth, we are interested in particular in the rates of change of variables with time and how the amount (e.g. concentration, density) of the variables change from point to point in space. The changes in the variables that we study depend on their spatial position and on time and mathematically we use tools known as differential equations to describe these changes.

A variable, V, say (e.g. concentration of a cytokine or the number of cancer cells per unit area/volume, i.e. cell density), will therefore be a function of its spatial coordinates (x, y, z) and time t. We denote this mathematically by writing $V(x, y, z, t)$. To construct a differential equation model we make use of the calculus (which enables us to describe the rate of change of variables) and the law of the conservation of mass. Applying these two rules we can formulate a generic 'conceptual' equation describing the rate of change of a substance with respect to time, its migration and its production/decay. Thus we have:

$$\text{rate of change of variable} = \text{spatial migration} + \text{production} - \text{decay/uptake}$$

By solving the above equation mathematically, at any given time one can predict how much of the variable (e.g. number of cells, amount of cytokine) is present in one's system. One may draw an analogy between the above equation describing a biological population (e.g. of cells, amount of a cytokine) and the population of a country – at any given time the number of people in the country can be calculated from the number of immigrants/emigrants (cf. migration/diffusion) and the number of births/deaths (cf. production/decay).

APPLICATIONS OF MATHEMATICAL MODELLING TO TUMOUR GROWTH

In the following sections we present three specific mathematical models which examine the three important processes of the immune response to cancer, tumour-induced angiogenesis and tumour invasion and metastasis. In each case, the mathematical model is an attempt to capture the essential biological processes, while retaining a certain simplicity. Each process has already been described in some detail in the first section and the reader can refer back to this section if necessary to follow the details of the mathematical equations. In addition, full details of each model can be found in certain key references which are cited.

Modelling the Immune Response to Cancer

We consider a simplified process of a small, growing, avascular tumour which produces signals (e.g. secretes cytokines) which attract a population of lymphocytes. These signals are recognized by lymphocytes and the tumour cells (TCs) are then directly attacked by tumour-infiltrating cytotoxic lymphocytes (TICLs) (Ioannides *et al.*, 1993). The humoral immune response, the interactions between cells of the immune system and dynamics of cytokines in the tumour, will be accounted for indirectly, because data related to these processes are often contradictory and many important mechanisms of cytokine dynamics in tumours are unknown. Local interactions between TICLs and tumour cells *in vivo* may be described by the following simplified kinetic scheme (see Kuznetsov *et al.* (1994) and Chaplain *et al.* (1998) for full details):
