$$E + T \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C \quad \begin{array}{l} \xrightarrow{k_2 p} E + T^* \\ \xrightarrow{k_2(1-p)} E^* + T \end{array}$$

where E, T, C, E^* and T^* are the local concentrations of TICLs, TCs, TICL–TC complexes, inactivated TICLs and 'lethally hit' or 'dead' TCs, respectively. The parameters k_1, k_{-1} and k_2 are non-negative kinetic constants defined as follows: k_1 and k_{-1} describe the rate of binding of TICL to TC and detachment of TICL from TC without damaging cells; k_2 is the rate of detachment of TICL from TC, resulting in either irreversibly programming TC for lysis with probability p or inactivating TICLs with probability $(1-p)$. Substantiation of the above scheme has already been discussed at greater length by Kuznetsov *et al.*,

(1994). It can be shown (Chaplain *et al.*, 1998) that it is sufficient to study the interaction of the three populations T, E and C (the other two can then be deduced from these). Using the law of mass action, and under the assumption that the tumour cells and the TICLs can diffuse, but the complexes cannot, the above scheme can be translated into the following system of differential equations:

$$\frac{\partial E}{\partial t} = \overbrace{\frac{\partial^2 E}{\partial x^2}}^{\text{diffusion}} + \overbrace{\sigma + \frac{\rho ET}{\eta + T}}^{\text{recruitment}} - \overbrace{\sigma E}^{\text{death}} - \overbrace{\mu ET + \epsilon C}^{\text{complexing}} \qquad [1]$$

$$\frac{\partial T}{\partial t} = \omega \overbrace{\frac{\partial^2 T}{\partial x^2}}^{\text{diffusion}} + \overbrace{\alpha(1-\beta T)T}^{\text{proliferation}} - \overbrace{\phi ET + \lambda C}^{\text{complexing}} \qquad [2]$$

$$\frac{\partial C}{\partial t} = \mu ET - \chi C \qquad [3]$$

In addition to kinetic interactions, we have also assumed that both the TICLs and the tumour cells can diffuse throughout the tissue and this cell migration is represented by the first two terms in eqns [1] and [2], respectively. The other terms in the model, in addition to those derived from the kinetic interaction scheme, account for (1) a recruitment of TICLs from the host tissue, under the assumption that the host immune response provides a constant supply σ of TICLs; (2) an additional recruitment of TICLs modelling the migratory response of the TICLs to the secretion of cytokines by the complexes (represented by the term $\rho ET/(\eta+T)$; (3) the natural death of the TICLs (represented by the term $-\sigma$); and (4) the proliferation of the tumour cells (represented by the logistic growth function $\alpha(1-\beta T)T$).

All of the parameters in the model equations can be estimated from actual experiments (Kuznetsov *et al.*, 1994; Chaplain *et al.*, 1998). With this information one can analyse eqns [1]–[3] numerically and simulate the interactions between a small avascular tumour and the immune system represented by lymphocyte infiltration. The results are presented in the next section.

Interpretation of Model Results

We simulated eqns [1]–[3] in a one-dimensional spatial domain $0 \leq x \leq 1$ representing a unit of tissue. **Figure 1** shows the initial conditions used in the model simulations. The tumour cells are initially located in a small cluster representing a small avascular tumour in the left-hand region of the domain between $x = 0$ and 0.2. The TICLs are initially located in the right-hand region of the domain between $x = 0.2$ and 1. Between the two cell populations is an initial group of TICL–TC complexes.

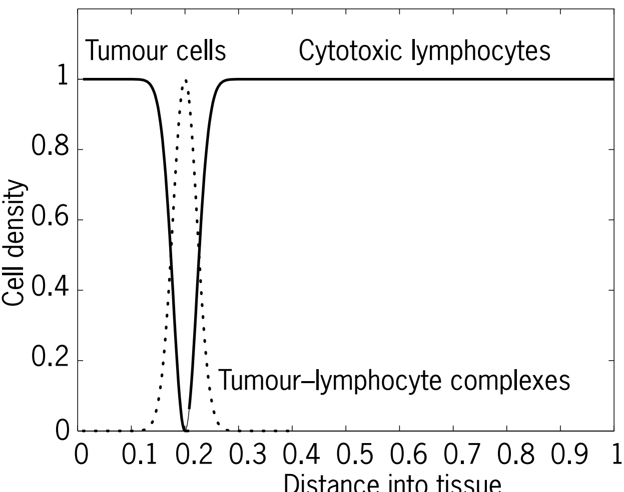

Figure 1 Initial conditions used for the tumour cells, tumour–lymphocyte complexes and the tumour-infiltrating cytotoxic lymphocytes. The tumour cells are initially confined to the left-hand side of the domain between $x = 0$ and 0.2 representing a small tumour; the cytotoxic tumour-infiltrating lymphocytes initially occupy the right-hand region of the domain between $x = 0.2$ and 1. The tumour–lymphocyte complexes are initially distributed between the two and are shown by the dotted curve.

Figures 2, **3** and **4** show the distributions of each variable (TICL, TC and complexes) throughout the domain at increasing times. One can see that as the cells interact and migrate, they produce rich spatio-temporal dynamics resulting in a highly heterogeneous distribution of lymphocytes, tumour cells and complexes throughout tissue. This heterogeneity is certainly observed in actual small solid tumours, infiltrated by lymphocytes (cf. Kuznetsov *et al.*, 1994).

Figures 5 and **6** show the (scaled) total number of lymphocytes and tumour cells within the tissue. From these results, we clearly see that, although these is a very heterogeneous spatial distribution of cells in the tissue, the total number of lymphocytes increases over time to a maximum, while the total number of tumour cells decreases to a minimum. This results in the tumour being kept under control by the immune system (cf. tumour dormancy). However, one can show (results not presented here) that by changing one of the key parameters of the model by a small amount (the parameter P), the tumour escapes the immune system control and completely invades the tissue, increasing its total number of cells as it proceeds. This result has certain implications for maintaining tumour dormancy via immunotherapy treatment (cf. Uhr *et al.*, 1997).

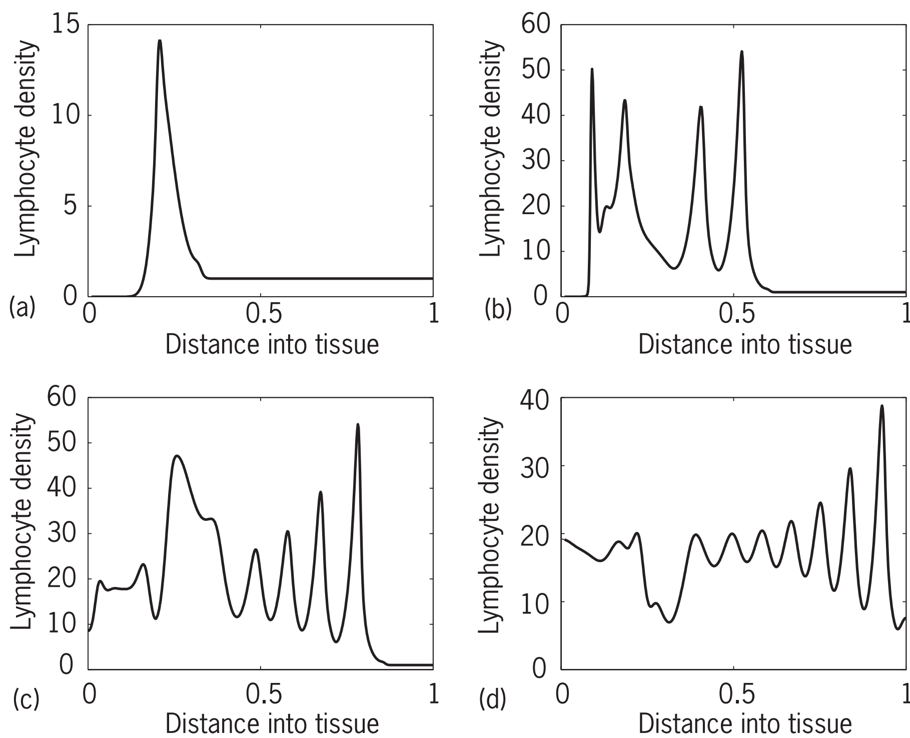

Figure 2 Spatio-temporal evolution of the tumour-infiltrating cytotoxic lymphocytes (TICLs) within the tissue at times corresponding to (a) 100, (b) 400, (c) 700 and (d) 1000 days, respectively. As time evolves, the interactions between the lymphocytes and the tumour cells become more complicated and the lymphocyte distribution within the tissue is highly heterogeneous and almost 'spatially chaotic'.

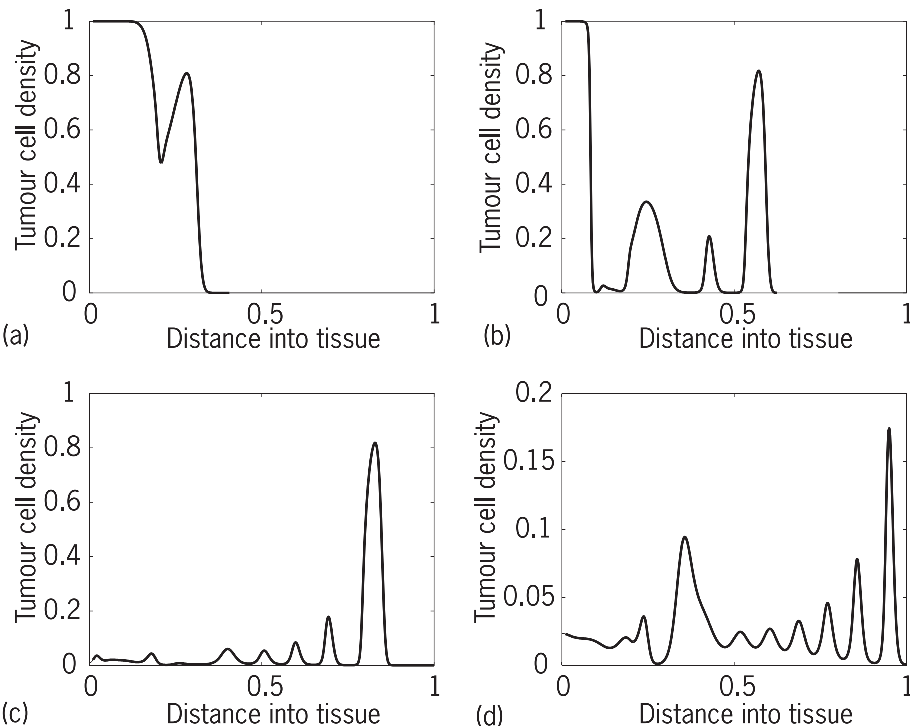

Figure 3 Spatio-temporal evolution of the tumour cells within the tissue at times corresponding to (a) 100, (b) 400, (c) 700 and (d) 1000 days, respectively. The tumour cells initially invade the tissue moving from left to right and are then attacked by the lymphocytes (see **Figure 2**). The complicated spatial interactions between the tumour cell and the lymphocytes result in isolated groups or solitary pulses of tumour cells invading the tissue rather than the whole tumour mass.

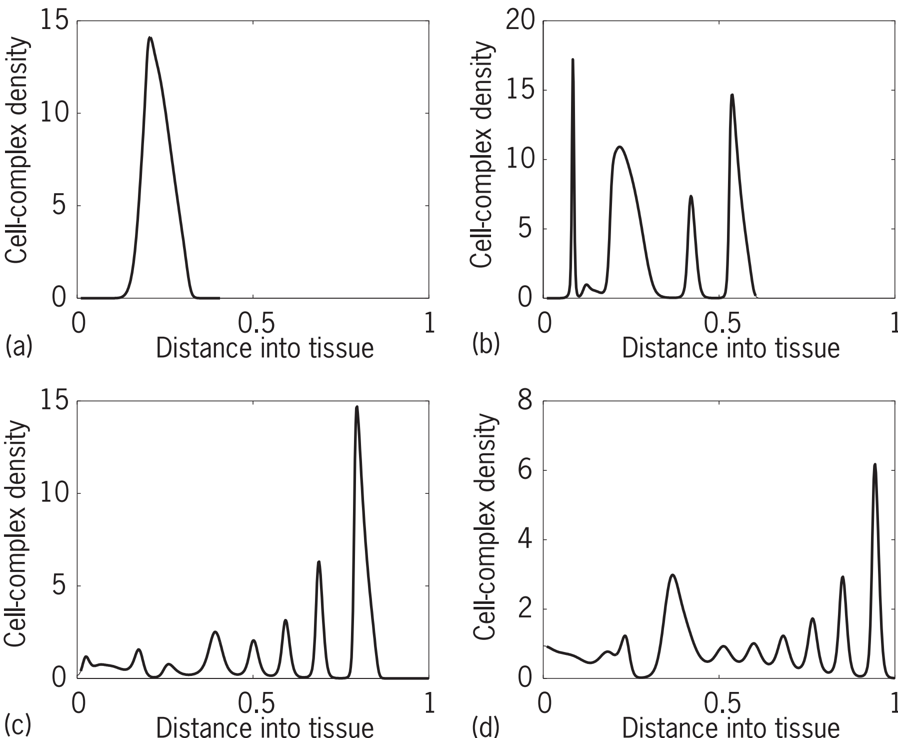

Figure 4 Spatio-temporal evolution of the tumour cell-TICL complexes within the tissue corresponding to the evolution of both TICLs and tumour cells in the previous two figures. The times correspond to (a) 100, (b) 400, (c) 700 and (d) 1000 days, respectively.

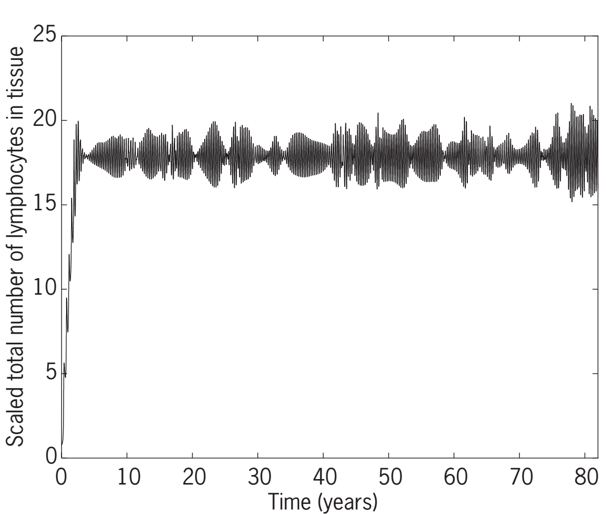

Figure 5 Plot of the total number of lymphocytes within the tissue over a period of 80 years. As can be seen, the lymphocyte number initially increases from a relatively small number to a stable but oscillatory distribution around 18. At this level the immune response is sufficient to suppress the growth of the tumour, as can be seen from the results in **Figure 6**.

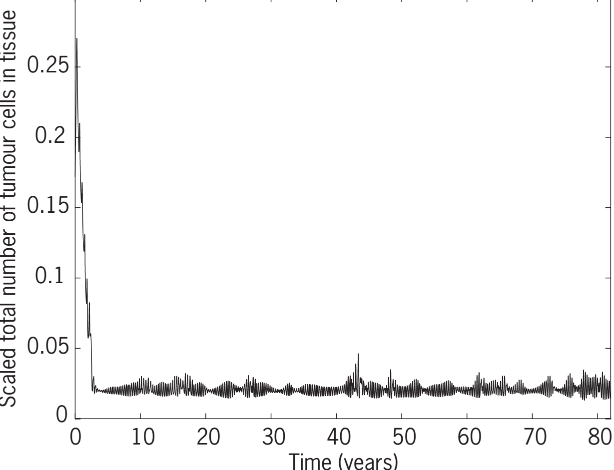

Figure 6 Plot of the total number of tumour cells within the tissue over a period of 80 years. The number of tumour cells initially decreases as the tumour is attacked and is infiltrated by the cytotoxic lymphocytes. Eventually the total number of tumour cells settles down to an oscillatory behaviour around a stationary level of approximately 0.02. Although the tumour is not eradicated completely, this simulation represents the case where the immune response is sufficient to keep the tumour in a harmless, dormant state.

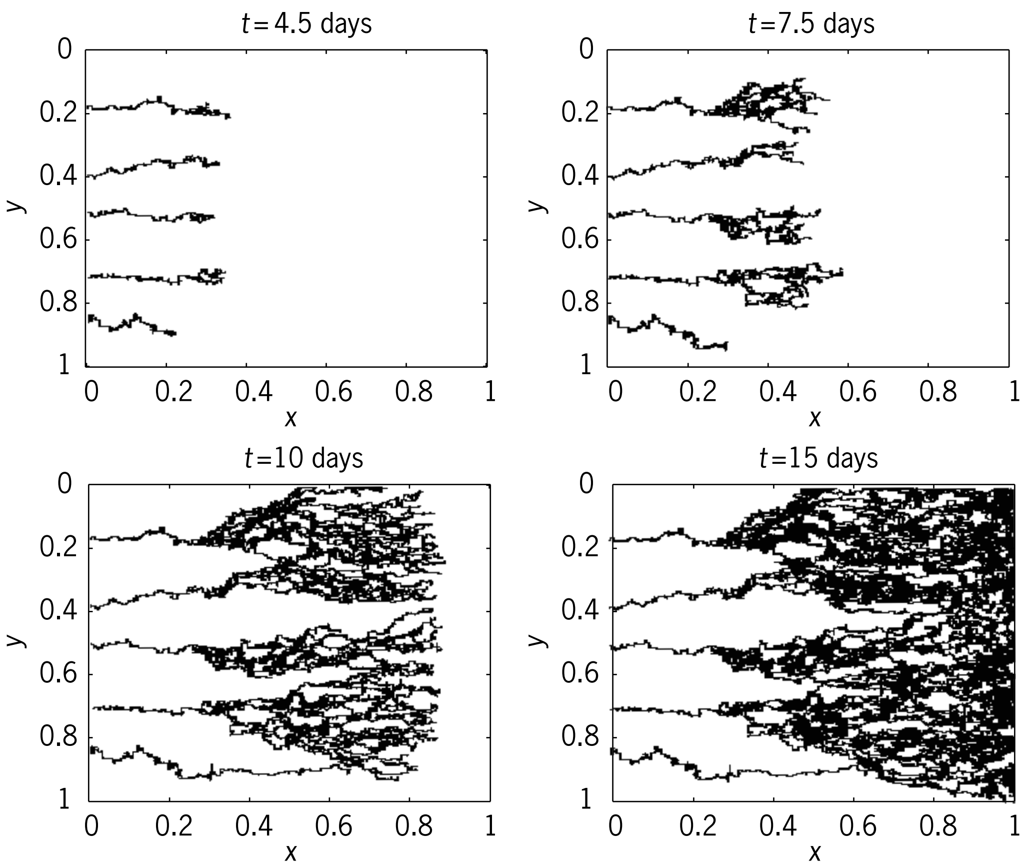

Figure 7 Spatio-temporal evolution of a theoretical capillary network generated from the mathematical model. The figure shows the migration of endothelial cells at sprout-tips in response to a line source of tumour cells. The parent vessel is located along the left-hand boundary while the tumour cells are located along the right-hand boundary. The cells respond chemotactically to TAF gradients and haptotactically to fibronectin gradients as well as proliferating. As the sprouts grow and migrate, a branched, connected network is formed which connects with the tumour between a time of 10 and 15 days and vascularization is achieved.

Modelling Tumour-induced Angiogenesis

The mathematical model in this section describes the interactions between endothelial cells n, angiogenic factors (cytokines) c and an adhesive matrix macromolecule such as fibronectin f. Full details of the model can be found in papers by Chaplain and Anderson (1997, 1999), Anderson and Chaplain (1998) and Schor *et al*. (1999). The basic assumptions of the model are as follows: (1) the endothelial cells migrate randomly, respond to the cytokines via chemotaxis and respond to the matrix macromolecule via haptotaxis; (2) the cytokine is produced by tumour cells and diffuses into the matrix where it is taken up by endothelial cells through binding; (3) fibronectin is present in the matrix, is synthesized by endothelial cells and is bound by the cells via integrins; there is also some degradation due to degradative enzymes. (See also the chapters *Extracellular Matrix: The Networking Solution*; *Angiogenesis Models*.)

The complete system of equations describing the interactions of the endothelial cells, the angiogenic factors and fibronectin is therefore given by

$$\frac{\partial n}{\partial t} = \overbrace{D_n \nabla^2 n}^{\text{random motility}} - \overbrace{\chi \nabla \cdot \left(\frac{n}{k_1 + c} \nabla c \right)}^{\text{chemotaxis}} - \overbrace{\rho \nabla \cdot (n \nabla f)}^{\text{haptotaxis}} \qquad [4]$$

$$\frac{\partial f}{\partial t} = \overbrace{\omega n}^{\text{production}} - \overbrace{\mu n f}^{\text{binding/degradation}} \qquad [5]$$

$$\frac{\partial c}{\partial t} = - \overbrace{\lambda n c}^{\text{uptake}} \qquad [6]$$

The model as presented describes the so-called basic ‘tissue response unit’ (Chaplain and Anderson, 1999; Schor *et al*., 1999), whereby individual cells respond to

their local tissue milieu through interactions with cytokines and matrix macromolecules. Once again, as with the model of the previous section, all parameters in the model are estimated from experimental data found in the literature. One can use the model to simulate the basic interactions between the endothelial cells, the matrix and a generic angiogenic cytokine. The mathematical technique of discrete biased random walks pioneered by Chaplain and Anderson (Chaplain and Anderson, 1997; Anderson and Chaplain, 1998) enables us to follow the paths of individual endothelial cells. This technique also enables us to include explicitly in the model crucial processes such as sprout branching, anastomosis and localized cell proliferation. The theoretical results of our numerical simulations are presented in the next section.

Interpretation of Model Results

The following figures show the theoretical capillary networks generated and predicted by the mathematical model of eqns [4]–[6].

Figure 7 shows the evolution of a theoretical capillary network at various stages in its development between 4 and 15 days. The parent vessel (cf. a limbal vessel) is located along the left-hand edge of the domain, while the tumour cells are located along the right-hand edge. The size of the domain is 2.5×2.5 mm. As can be seen, the capillary sprouts grow, elongate, branch and fuse together as they progress through the tissue towards the tumour cells before they finally connect up in the final figure. **Figure 8** shows the evolution of a theoretical capillary network in response to a small circular tumour implant. All parameter values were the same as those used to generate the results in **Figure 7**. The only difference is the 'shape' of the underlying concentration field of angiogenic factor.

These two figures are a mathematical simulation/representation of actual experiments carried out using the corneal assay technique (Muthukkaruppan *et al.*, 1982).

Figures 9 and **10** show the results of the model in three spatial dimensions in a cube of tissue of size

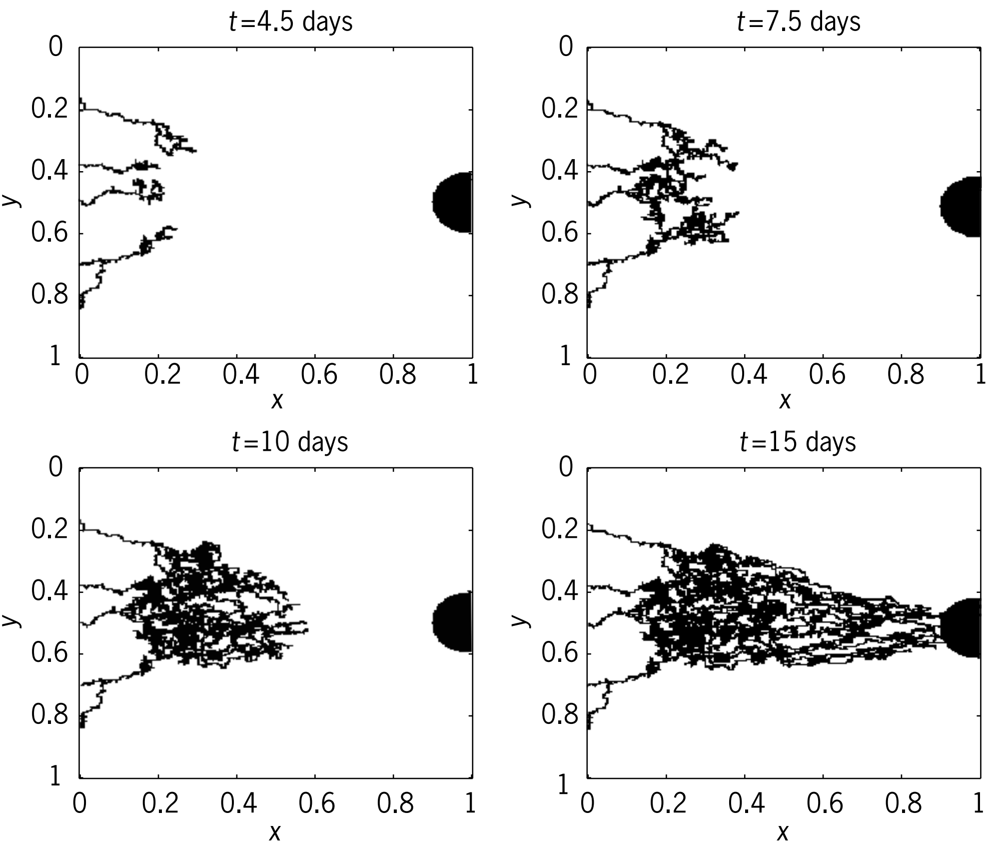

Figure 8 Spatio-temporal evolution of a theoretical capillary network generated from the mathematical model. The figure shows the migration of endothelial cells at sprout-tips in response to a circular source of tumour cells. The parent vessel is once again located along the left-hand boundary while the circular tumour implant is shown in black at the opposite boundary. The cells respond chemotactically to TAF gradients and haptotactically to fibronectin gradients as well as proliferating. As the sprouts grow and migrate, a branched, connected network is formed. Once again the network connects with the tumour around 15 days and vascularization is achieved.

$2.5 \times 2.5 \times 2.5$ mm. In these cases, the capillary networks generated are theoretical representations of the actual *in vivo* situation. In **Figure 9**, the network responds to a flat layer of tumour cells on the bottom face of the cube of tissue. In **Figure 10**, the network is reponding to a central spherical mass of tumour cells, representing a small, spherical tumour.

In all cases, the model generates quantitatively realistic networks in terms of the morphology, structure and growth rate.

Once again, one can change certain key parameters of the model (e.g. chemotactic response, haptotactic response of the endothelial cells) and can perform anti-angiogenic experiments (Orme and Chaplain, 1997). One can also use the model to calculate important variables such as flow rate through the network, vessel length, network area/volume and the fractal dimension of the network. All these variables are important in designing drugs to target tumours (Jain *et al.*, 1997) and, with some refinement, the model could be implemented to optimize anti-angiogenic strategies in terms of drug design or drug scheduling.

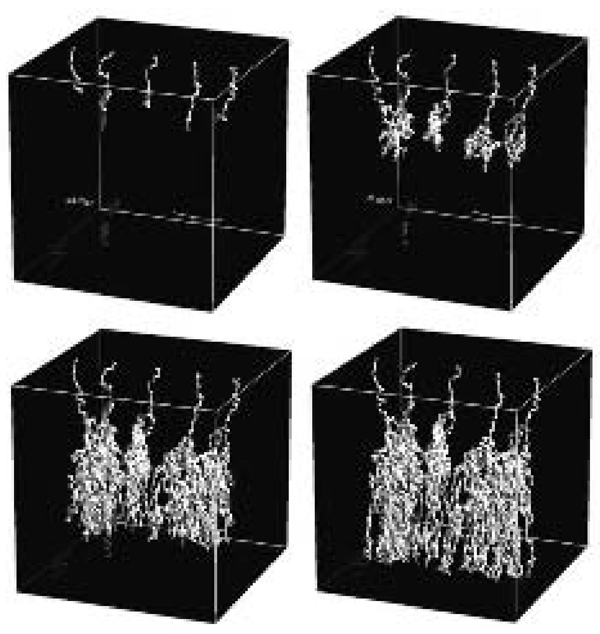

Figure 9 Spatio-temporal evolution of a three dimensional capillary network towards a single layer (plane) of tumour cells positioned on the bottom face of the cube. There is a gradient of TAF within the tissue, with a high concentration on the bottom face and a lower concentration on the top face. The endothelial cells respond chemotactically to this gradient as well as gradients of fibronectin in the tissue. A branching network is formed which eventually connects with the tumour on the bottom face.

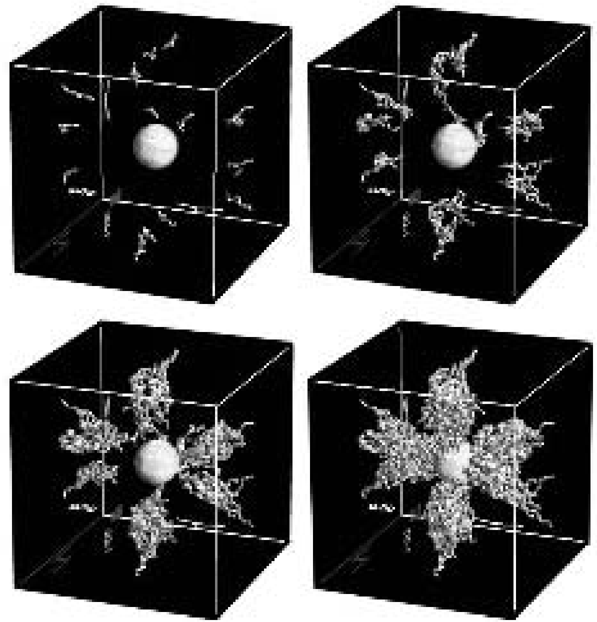

Figure 10 Spatio-temporal evolution of a three-dimensional capillary network towards a central spherical source of tumour cells (cf. avascular tumour or multicell spheroid). There is a gradient of TAF within the tissue, with a high concentration around the central spheroid decaying to lower concentrations in a radially symmetric manner on the boundaries. Once again the endothelial cells respond chemotactically to this gradient as well as gradients of fibronectin in the tissue. A branching network is formed which eventually connects with the avascular tumour in the centre, thus providing the tumour with extra nutrients and opening the way for tumour cells to escape into the bloodstream.

Modelling Tumour Invasion and Metastasis

The mathematical model in this section describes the basic interactions between tumour cells and the extracellular matrix during the process of tissue invasion. Full details of the model can be found in Anderson *et al.* (2000). The key variables in the model are the tumour cells n, matrix degrading enzymes e (MDE), and the matrix (ECM) m. The enzymes are assumed to be produced by the tumour cells, diffuse into the tissue and degrade the matrix; the tumour cells are assumed to migrate randomly and also via haptotaxis in response to gradients of the enzymes; and finally, the matrix is passively degraded by the enzymes. Hence the complete system of equations describing the interactions of the tumour cells, ECM and MDE is as

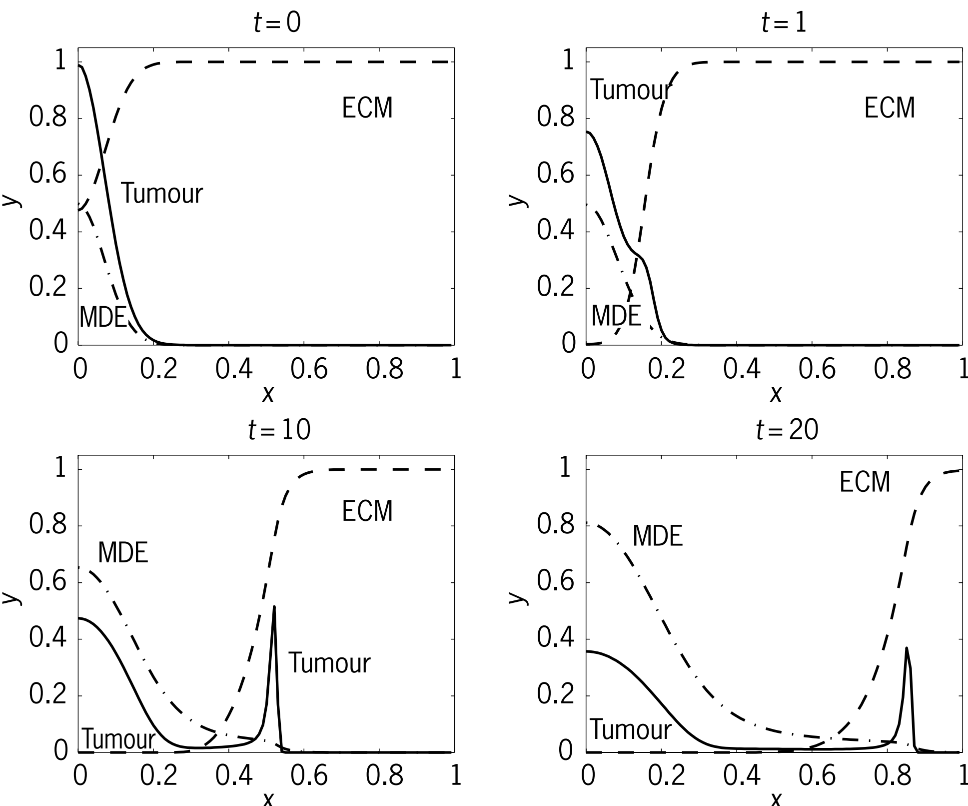

Figure 11 Spatio-temporal evolution of tumour cells invading tissue while secreting matrix-degrading enzymes. As the enzymes degrade the tissue (ECM) the tumour cells invade and form two distinct clusters, those mainly driven by diffusion and those driven by haptotaxis. The cluster of tumour cells at the front may break away completely from the original mass and either go undetected in surgery or connect with the lymph/circulatory systems and then go on to form metastases.

follows:

$$\frac{\partial n}{\partial t} = \overbrace{D_n \nabla^2 n}^{\text{random motility}} - \overbrace{\rho \nabla \cdot (n \nabla m)}^{\text{haptotaxis}} \quad [7]$$

$$\frac{\partial m}{\partial t} = - \overbrace{\delta e m}^{\text{degradation}} \quad [8]$$

$$\frac{\partial e}{\partial t} = \overbrace{D_e \nabla^2 e}^{\text{diffusion}} + \overbrace{\mu n}^{\text{production}} - \overbrace{\lambda e}^{\text{decay}} \quad [9]$$

(See also the chapters *Invasion and Metastasis*; *Modelling Tumour–Tissue Interactions*.)

As in the previous two models, once again we estimate the model parameters from the experimental literature. Using the model, we can therefore simulate the basic interaction between the cancer cells, the matrix and a generic matrix-degrading enzyme, e.g. a matrix metalloproteinase.

Interpretation of Model Results

The following figures show the theoretical invasive spread of cancer cells as predicted by the mathematical model of eqns [7]–[9].

Figure 11 shows the migration of a group of tumour cells as it invades a one-dimensional domain $0 \le x \le 1$ representing the host tissue. As can be seen as time evolves, the matrix is degraded by the enzyme, creating a gradient in matrix concentration. Through haptotaxis (directed migration in response to the gradient of matrix) a portion of the tumour almost 'breaks away' from the main tumour mass and continues to invade as a solitary front while a central mass of tumour is left behind.

Figures 12 and **13** show the results of model simulations in two space dimensions. In these figures we use the model to track the paths of individual invading cancer cells. Initially a small central mass of cancer cells are in the centre of the domain, surrounded by tissue (ECM). In the early stages of the process, all cells remain as a compact central mass but, as time goes on, individual cells break free from the central mass and penetrate more deeply into the tissue. These cells could potentially be missed by a surgeon during any operation to remove the primary tumour and could therefore lead either to recurrence of the primary cancer or escape and lead directly to metastases.

The results of the model show that the invasive capability of a cancer is predicted by the model and that cell–matrix interactions are crucial in this process. Once

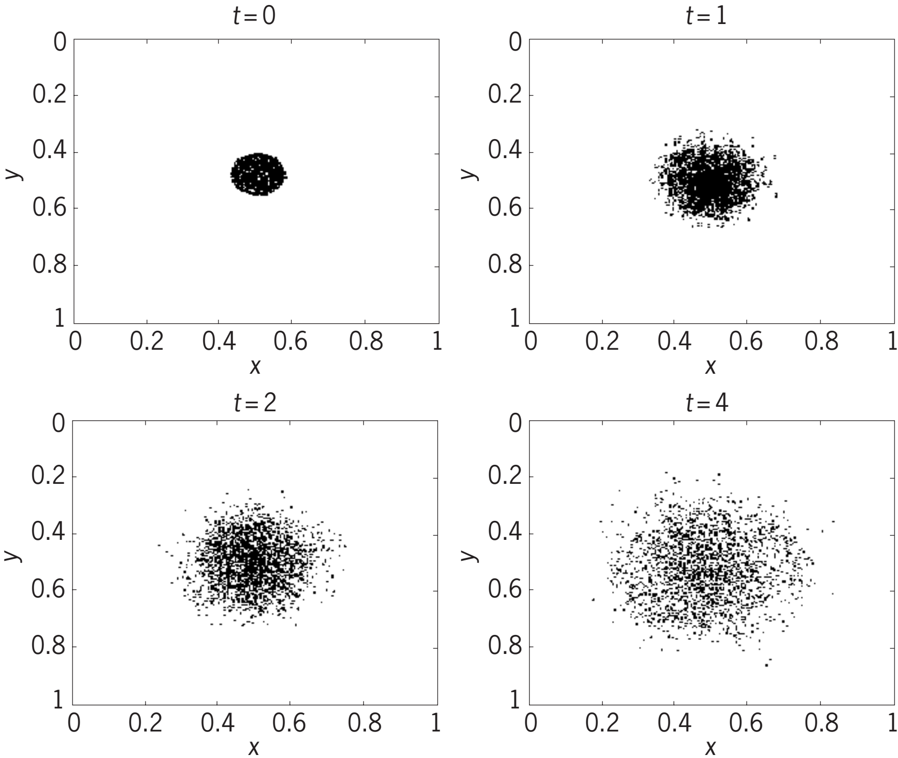

Figure 12 Spatio-temporal evolution of individual tumour cells invading tissue. The figure shows the early stages of invasion with tumour cells migrating from the centre ($x = 0.5$, $y = 0.5$) outwards into the tissue (ECM).

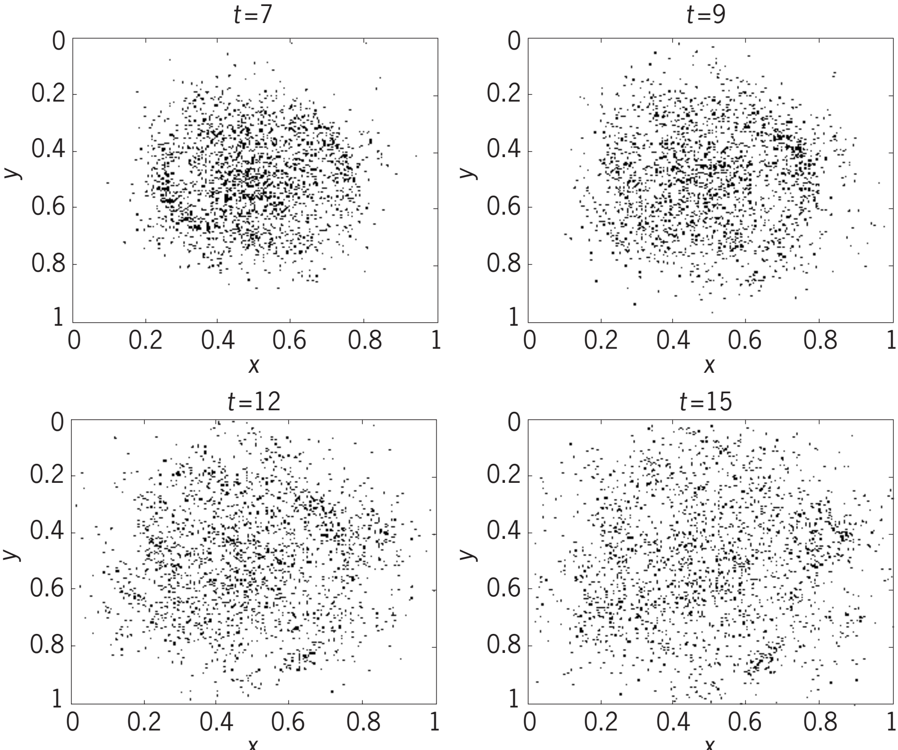

Figure 13 Spatio-temporal evolution of individual tumour cells invading tissue as in **Figure 12** but at later times. As can be seen, a certain number of individual cells break away from the main tumour mass and penetrate the tissue more deeply; some in fact reach the boundaries of the domain. These cells may then either go undetected in surgery or connect with the lymph/circulatory systems and then go on to form metastases.

again, by changing key parameters we can perform theoretical anti-invasive experiments, or predict how far the leading cancer cells penetrate into the tissue. This information could then be used in deciding how much tissue to resect in surgery.

PERSPECTIVES

In this chapter, we have attempted to show how mathematical techniques can be used to model certain key processes and key stages of cancer growth. The first model examined the immune response to cancer and showed that under certain conditions, the host immune response could be sufficient to suppress a small avascular tumour. However, although the tumour remained dormant in the sense that the total number of tumour cells was kept under control, the actual spatial distribution of the cells throughout the tissue was very heterogeneous and complex. Moreover, with a small change in one of the system parameters, the tumour would continue to grow and escape the immune response. More detailed analysis of the model may shed light on how to treat tumours using optimal immunotherapy techniques.

In the second model, the important process of tumour-induced angiogenesis was examined via a mathematical model. Using recently developed mathematical techniques, we were able to study the growth and form of a capillary network by tracking the motion of individual endothelial cells. Using experimental parameter values in our model and incorporating explicitly the processes of sprout branching, anastomosis and localized cell proliferation, we were able to generate quantitatively accurate structures in both two and three spatial dimensions. There is great potential for developing this model further and creating a 'mathematical angiogenesis assay'. This could be used to study and measure important quantities such as flow rates through the network (cf. chemotherapeutic drugs, anti-angiogenic drugs), network growth rate, network area/volume and network connectivity. Knowledge of these variables could then be used to optimize chemotherapy regimes.

In the third model, we examined the process of tumour invasion of the surrounding tissue. Once again, our mathematical model enabled us to focus on the key processes involved in invasion and to make certain predictions. The model enabled us to track individual cancer cells as they secreted matrix-degrading enzymes and migrated through the host tissue. The model naturally captured one of the key features of cancer invasion – that of the break-off of small clumps of cancer cells from the central mass. The model showed that the key process enabling this to happen was haptotaxis and so directed cell migration and therefore cell–matrix interactions are of crucial importance. In developing the model further we will be investigating ways of trying to localize the tumour cells and prevent small clusters from breaking away from the central mass; we will also be investigating how to predict the maximum distance that individual cells may penetrate into the tissue away from the central mass. Such investigations may eventually lead to more accurate surgery being carried out, with a greater survival rate for patients.

All the mathematical models presented are necessarily a simplification of the actual processes they seek to describe. Nevertheless, even in their present form they each shed light on complicated 'nonlinear' processes and make predictions about these processes. As new and more powerful mathematical and computational techniques become available, so the accuracy and predictive power of the models will increase, which in turn will bring them to bear on the clinical decision-making process and eventually benefit patients.

BIOLOGICAL BASICS

From Growth Factors to Gene Expression

In prokaryotes and unicellular eukaryotes, control mechanisms have evolved to allow cell proliferation at maximum sustainable levels, often largely limited by the availability of nutrients. With the development of multicellular eukaryotes, more complex control mechanisms evolved to coordinate cell proliferation spatially and temporally, as needed for optimum function of the organism (Soto and Sonnenschein, 1993). To create functional organs, proliferation of the involved cell types had to be guided and tightly controlled by signals that induced the selective proliferation of specific cells, their alteration by differentiation or their removal by programmed cell death (apoptosis). Key coordinating signals that are exchanged between cells at a distance are transmitted via peptide growth factors (**Figure 1**). These bind to specific cell surface receptors that span the cell membrane of target cells (van der Geer *et al.*, 1994) and can involve endocrine, paracrine, juxtacrine and autocrine mechanisms. Growth factor binding frequently results in dimerization of the target receptor. This aggregated state often leads to the stimulation of an intrinsic tyrosine kinase activity of the receptor that results in autophosphorylation of the intracellular receptor domain on specific tyrosine residues. By this mechanism the growth factor signal is transmitted across the plasma membrane into the interior of the cell. Its specificity depends exclusively on the respective intracellular receptor domain and not on the growth factor (Riedel *et al.*, 1989). The phosphorylated tyrosine residues of the receptor form docking sites for a type of signalling mediator proteins that carry specific binding pockets such as SH2 (Src homology 2) domains. Assembly of these mediators on the receptor sites and their interaction with additional mediators leads to the formation of multicomponent signalling complexes. These include scaffold, anchoring and adapter proteins as well as protein kinase and phosphoprotein phosphatase enzymes. All are important members of signalling cascades that ultimately result in the activation of transcription factors in the cell nucleus by phosphorylation or dephosphorylation (Pawson and Scott, 1997). By these and other mechanisms, growth factors regulate the expression programmes of specific genes that control cell division and proliferation (Schlessinger, 2000).

Control of the Cell Cycle

The cell cycle coordinates the various processes that are involved in cell division including increase in cell mass, protein synthesis, DNA replication, separation and segregation of chromosomes and other mechanisms that lead to the formation of two daughter cells (Fantes and Brooks, 1993). The cycle consists fundamentally of a DNA synthesis phase (S) and a mitotic phase (M) which simply alternate in early embryonic cell division (**Figure 2**). If a doubling of cell mass is involved in subsequent division cycles, two gap phases (G) are introduced in the order $\rightarrow G_1 \rightarrow S \rightarrow G_2 \rightarrow M \rightarrow$ to allow the regulation of and provide the required time for the necessary synthetic cellular activities. In order to differentiate, cells typically leave the cycle in the G_1 phase and enter a G_0 or quiescent state. This state in which growth is halted can also be induced by the withdrawal of growth factors for normal and/or immortalized cells, but not for transformed cells which have lost this control mechanism. Growth factor signalling pathways can normally control progression through the cell cycle by controlling the expression or activity of the two major classes of cell cycle regulators that are deregulated in some cancers. These are represented by cyclins that vary in abundance throughout the cell cycle, and cyclin-dependent kinases which vary in activity (Hunter and Pines, 1994). An important check point or restriction

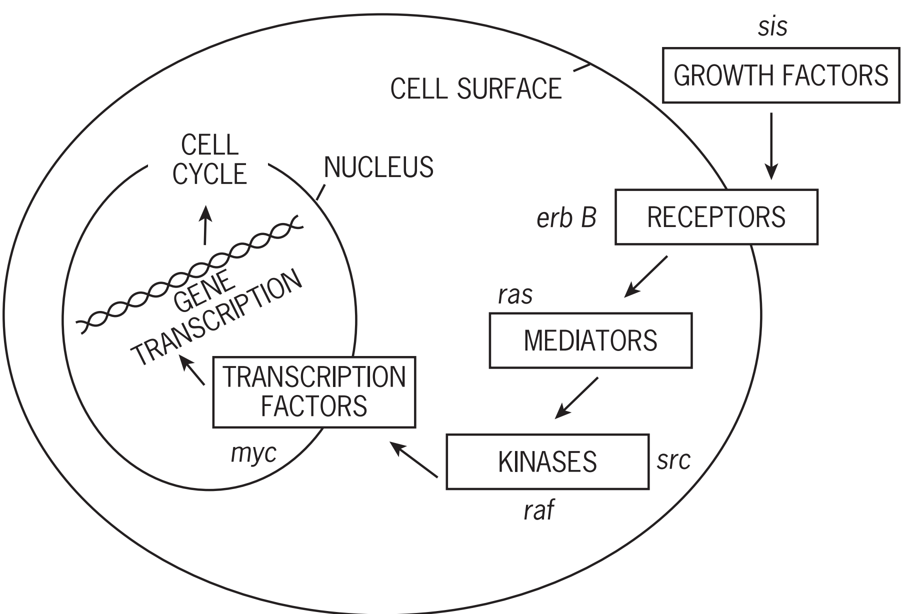

Figure 1 Major classes of signalling mediators in growth control and selected oncogene representatives. Growth factor signals are transmitted into cells via specific membrane-spanning receptors and further by various mediators and kinases to regulate transcription factors that control the expression of specific genes in the cell nucleus, and ultimately the cell cycle. For each class of mediators altered forms are expressed by oncogenes. One or two oncogene examples for each class are shown in lower-case letters (*sis*, *erbB*, *ras*, *src*, *raf*, *myc*) next to the respective mediator (shown boxed in capital letters).

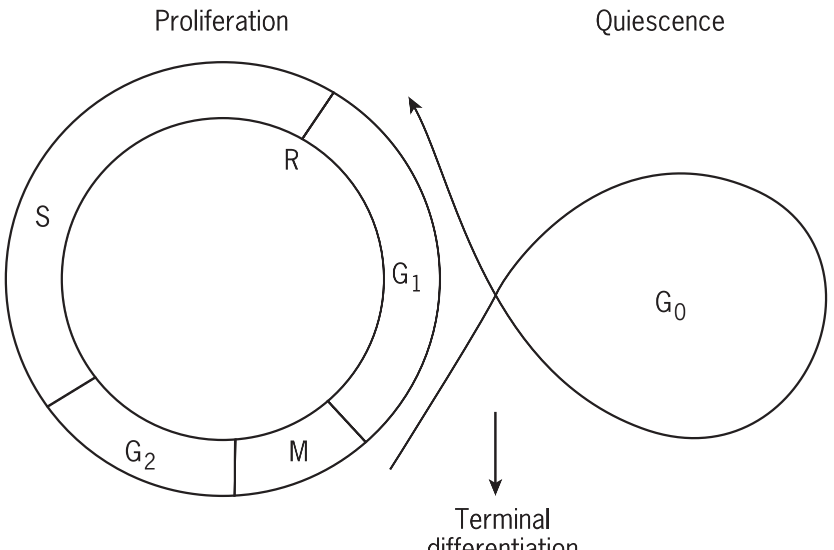

Figure 2 The proliferating and resting phases of the cell cycle. Cells are found in a gap (G) phase when they are not synthesizing DNA (S phase) or completing mitosis (M phase). Normal cells are capable of resting (quiescence) in a non-dividing state, termed G_0. One or more cycles of cell division begin once there is a need to maintain or replace tissue and stop when the required proliferation has been accomplished. Protein and RNA synthesis are active in the first gap phase (G_1). If conditions are permissive for subsequent cell division, cells pass through a restriction point (R) and quickly move into the synthetic phase (S) in which new DNA is synthesized. A second gap phase (G_2) follows when the newly duplicated chromosomes condense. In the mitotic phase (M) the chromosomes divide into two sets and the cell forms two nuclei, and divides into two daughter cells. When normal cells differentiate, typically with a gain in the properties required for organ or tissue functions, they generally lose the capacity to continue cell division. This can be irreversible in terminal differentiation.

point is found early in the G_1 phase which allows growth factor signals to control how the cycle will proceed including the transition from G_1 to S (Grana and Reddy, 1995). (See also chapter on *Overview of Oncogenesis*.)

Oncogenes and Aberrant Growth Regulation

Most human neoplasias result from abnormalities in the expression of genes that participate in the control of cell proliferation and differentiation. Since the underlying functional changes result in cancer, the altered genes are termed cancer-causing genes or oncogenes while their normal counterparts are termed proto-oncogenes. The functional alteration is typically caused either by mutational activation or by a dosage effect, which both result in an increased and/or uncontrolled function of the protein. Oncogenes have been found to encode proteins that are involved in various steps of cell growth control. Many have been originally discovered in retroviruses as nonessential genes. These have been acquired from the host cell chromosome and undergone an activating mutation during their integration into the viral genome (Fine and Haseltine, 1993). Examples of oncogenes are shown in **Figure 1** including altered forms of growth factors such as platelet-derived growth factor (v-sis), growth factor receptors such as epidermal growth factor receptor (v-erbB), nucleotide binding protein signalling mediators such as Ras (v-ras), nonreceptor membrane-bound tyrosine kinases such as Src (v-src), cytoplasmic serine/threonine kinases such as Raf (v-raf) and transcription factors such as Myc (v-myc) (Hanahan and Weinberg, 2000).

Tumour-suppressor Genes and Multi-step Tumorigenesis

Oncogenes typically act in a dominant fashion whereas a second important class of anti-oncogenes or tumour-suppressor genes generally act recessively and require the inactivation of both chromosomal alleles to result in tumorigenesis. This frequently occurs by chromosomal deletion or point mutation (see chapter on *Regulation of Cell Cycle*). The effects of tumour-suppressor genes have been discovered and best described in familial cancers. Examples of tumour-suppressor gene products include DNA repair enzymes such as BRCA1, cell adhesion molecules such as DCC (deleted in colorectal cancer), the p53 protein and the factors and major regulators of the cell cycle such as the retinoblastoma-related Rb protein. Normal cell proliferation is believed to be based on a properly regulated balance between the stimulatory function of proto-oncogenes and the constraining function of tumour-suppressor genes. Tumorigenesis is seen as a multistep process that requires a sequence of distinct alterations before it results in an invasive and metastatic cancer (Hanahan and Weinberg, 2000). A candidate sequence of six alterations in proto-oncogenes and tumour-suppressor genes is shown in **Figure 3**. The alterations involved have been particularly well described for colorectal tumour formation in the progression from normal epithelium via the stages of hyperplasia, early adenoma, late adenoma, early carcinoma and late carcinoma, to the level of metastases (Fearon and Vogelstein, 1993).

Early Tumour Growth is Difficult to Detect in Human Patients

According to the somatic mutation theory of cancer, which is favoured by most cancer researchers, arising from a single cell, a typical human tumour may have to divide about 30 times until it will become clinically detectable inside the body at a weight of about 1 g (Begg, 1993). It will take less than 10 additional divisions to reach a size that is lethal to the host before the mass approaches 1 kg (**Figure 4**). As soon as the tumour is

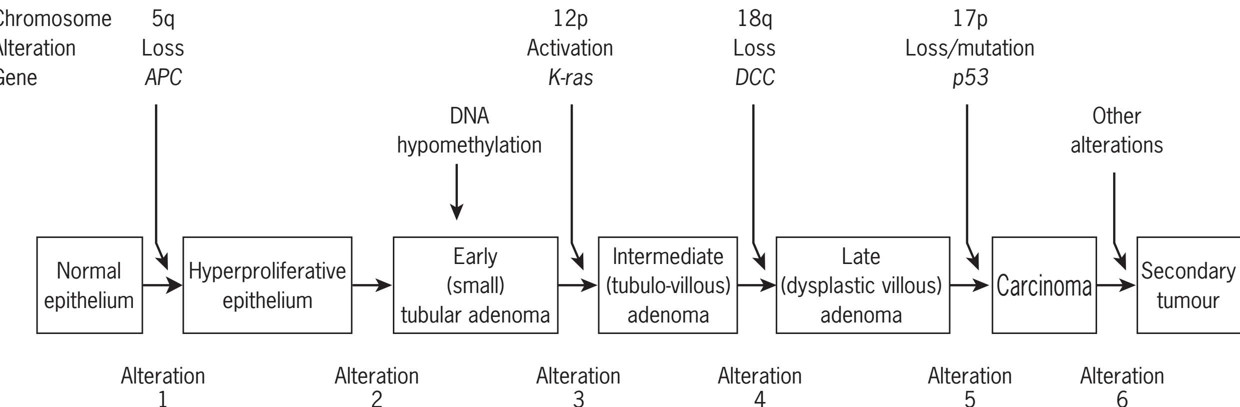

Figure 3 A model for colorectal cancer progression involving a sequence of six genetic alterations to lead from normal epithelium to a metastatic tumour. The gene involved, the type of change and its chromosomal location are indicated.

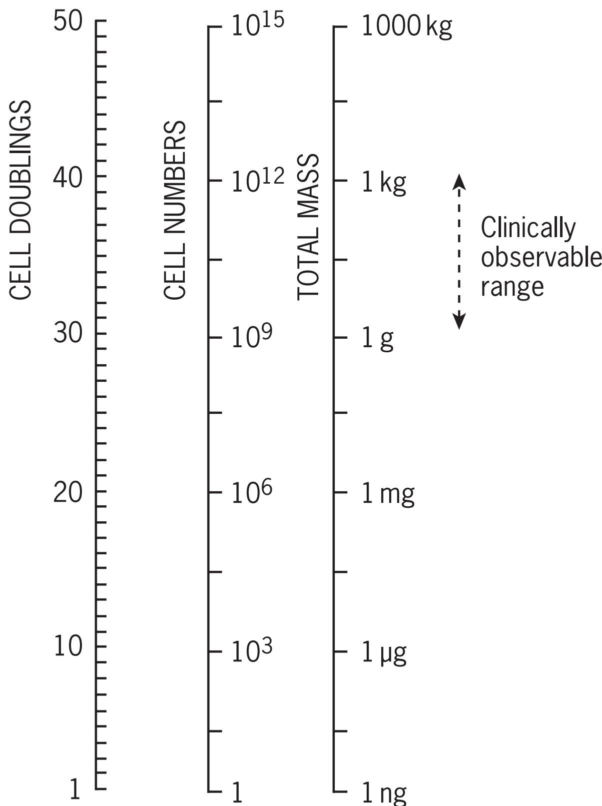

Figure 4 Correlation between the mass of a tumour, its approximate cell numbers and the numbers of required cell doublings (assuming an origin from a single cell and 10^9 cells per gram). Only the final quarter of the growth phase is clinically observable.

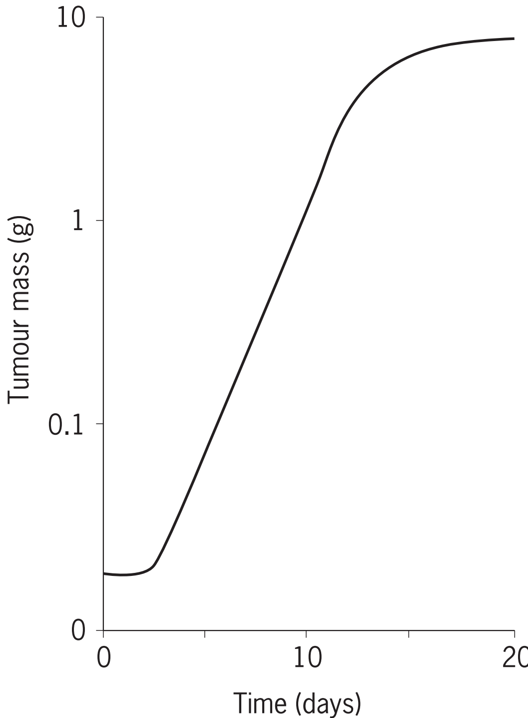

Figure 5 The phases of experimental tumour growth. Following an initial lag phase, early growth proceeds exponentially for several days before it slows and reaches a plateau. This is mainly caused by increased cell loss (such as through necrosis) that essentially balances the continuing proliferation to a static level of viable cells.

detected, therapy has to be initiated immediately. Normally tumour growth in humans can only be studied during less than the last quarter of its growth history and in the presence of inhibitory therapeutic measures. During the final growth stages of large tumours, cell loss rates by necrosis such as due to insufficient blood supply may begin to approach proliferation rates which are not representative of the earlier undetected growth phase (Alison and Sarraf, 1997a). Consequently, much of our limited understanding of tumour growth has been derived from animal models (**Figure 5**) or *in vitro* cell culture models, of which the latter will be the focus of this chapter.

Table 1 Comparison between growth fraction and cell doubling time: a correlation is shown for a number of experimental and human tumours

Tumour	Growth fraction (%)	Doubling time (days)
Experimental tumours		
L1210 (mouse)	86	0.5
B 16 (mouse)	55	1.9
LL (mouse)	38	2.9
DMBA (rat)	10	7.4
Human tumours		
Embryonal carcinoma	90	27
Lymphoma (high grade)	90	29
Squamous cell carcinoma	25	58
Adenocarcinoma	6	83

Parameters of Tumour Growth

In terms of population kinetics, the growth of any tissue including tumours is governed by (1) the rate of individual cell division, (2) the growth fraction of the cell population and (3) the rate of cell loss from the growing population such as through differentiation or cell death (**Table 1**). Healthy organs will be closely controlled with regard to their cell proliferation rate, fraction of proliferating cells and cell loss. In contrast, the cells in a tumour will not necessarily

Table 2 Comparison of growth parameters between human neoplasms and normal tissues: a correlation is shown between the labelling index and the estimated cell doubling time for a number of tissue sources

Cell type	Labelling index (%)	Estimated cell doubling time (days)
Normal bone marrow myeloblasts	32–75	0.7–1.1
Acute myeloid leukaemia	8–25	0.5–8.0
Normal B-cell lymphocytes	0–1	14–21+
High-grade lymphoma	19–29	2–3
Normal intestinal crypts	12–18	1–2
Colon adenocarcinoma	3–35	1.6–5.0
Normal epithelium/pharynx	2–3	—
Squamous cell carcinoma of the nasopharynx	5–16	2–4
Normal epithelium/bronchus	—	9–10
Epidermoid carcinoma of the lung	5–8	8–10
Normal epithelium/cervix	4–8	—
Squamous cell carcinoma of the cervix	13–40	—
Ovarian carcinoma	3–20	5–6
Benign mole of skin	0.3	—
Malignant melanoma of skin	12.8	—

proliferate faster; however, the controls will be greatly relaxed, resulting in continued unrestricted growth. Inflammatory lesions can proliferate up to 20 times faster than tumours but this rapidly ceases owing to intact control mechanisms when healing is complete (**Table 2**). Tumours can often be thought of as wounds that do not heal.

It is generally assumed that tumour cells multiply exponentially during the early phases of tumour growth (Alison, 1995). As the mass increases, the growth rate declines, which results in a sigmoid exponential (Gompertz) growth curve as shown for an experimental animal tumour in **Figure 5**. One important limiting factor is the difficulty of obtaining sufficient blood supply. This frequently results in necrosis in the centre of larger tumours whereas the cell doubling time typically changes little. Under adverse conditions, tumour cells may leave the growth fraction and enter the G_0 or a prolonged G_1 phase of the cell cycle until nutritional conditions become favourable or cell proliferation is stimulated by growth factors.

Measuring Tumour Cell Proliferation

The rate of tumour cell division may not tell us much about the actual rate of increase of tumour size. However, the proliferative index may be a prognostic indicator since high levels of cell proliferation may help identify patients who may benefit particularly from an aggressive antitumour therapy. Cell population kinetics are directed at the state and the rate parameters of proliferating tumour cells. This involves the determination of population size or cell numbers, the rates by which cells transit (fluxes) between different phases of the cell cycle (**Figure 6**) and the time cells spend in a specific phase of the cell cycle (**Figure 2**).

Radioactive Markers for DNA Synthesis

Many simple methods for measuring cell proliferation define only state parameters since they provide information about the proliferative state of cells but not about the rate at which they occur. The mitotic count is often defined as the number of mitoses per 10 high-power microscope fields (HPF) but takes no account of cell size. The typically preferred mitotic index (MI) is the percentage of the cell population that is found in the mitotic phase of the cell cycle. It depends on the time that cells spend in mitosis and also on the fraction of cells in that phase, two parameters that cannot be discriminated. Radioactively labelled [^{3}H]thymidine is specifically incorporated into DNA as opposed to RNA and has been widely used since its first description in 1957. It is typically measured as a pulse labelling index (TLI%), which represents the percentage of cells in the S phase of the cell cycle. It is always larger and presumably more reliable than the MI. The major drawbacks of this method are the cost of the reagent, the required photographic materials, darkroom and technical expertise and the time required for the autoradiographic detection of several weeks. In addition, in human patients the considerable radioactive burden must be added through the ^{3}H radioactive half-life of more than 10 years. This can be reduced by the use of [^{11}C]thymidine with a half-life of only hours to study uptake by positron emission tomography (PET). Bromodeoxyuridine represents a major alternative that is similarly specifically incorporated into DNA during DNA synthesis. It can be detected by specific monoclonal antibodies even in alcohol-based and formalin-fixed, paraffin wax-embedded tissue sections based on standard indirect immunolabelling techniques within days. It is the method of choice for identifying the S phase fraction where the substrate can be administered

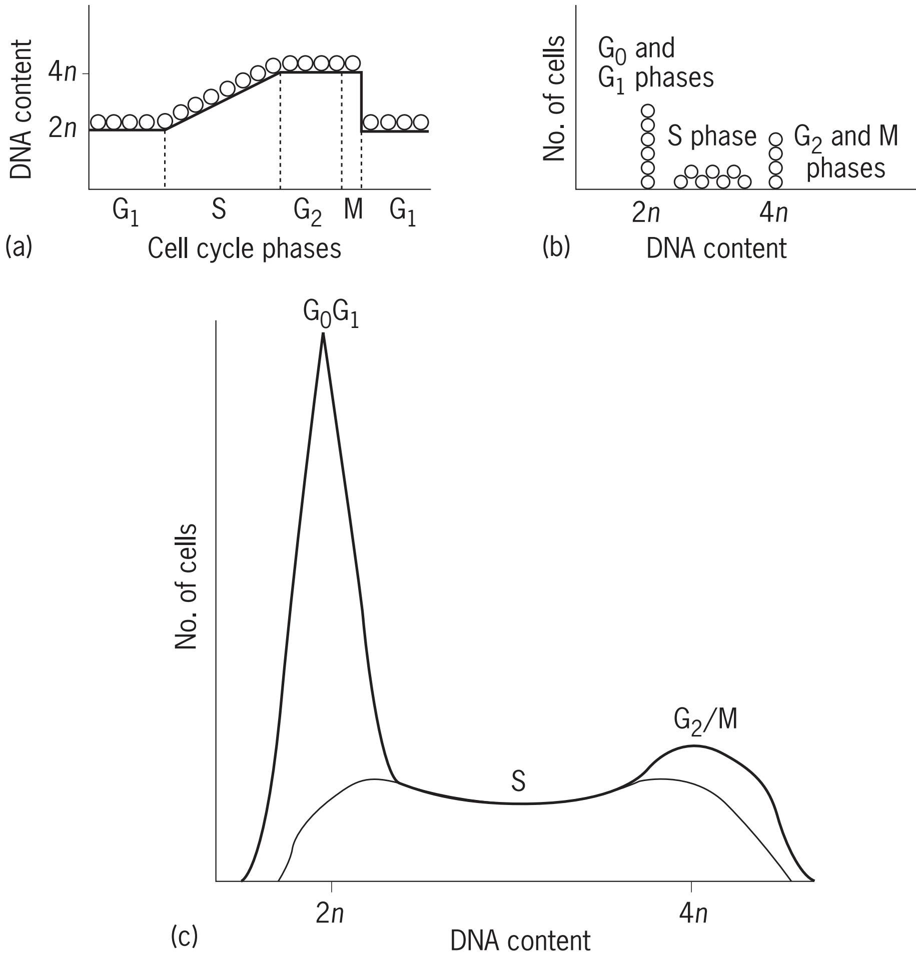

Figure 6 The principle of a DNA histogram as analysed by flow cytometry. (a) Cells double their DNA content as they pass through S phase, so cells in G_2 have twice the DNA content of G_1 cells. (b) Representation of cell segregation by flow cytometry when sorted based on DNA content. (c) DNA histogram obtained by flow cytometry; the exact number of cells in each category is derived by computer analysis. [From Alison and Sarraf, 1997a, in: *Understanding Cancer: from Basic Science to Clinical Practice*, 133–193 (Cambridge University Press, Cambridge).]

to live experimental animals and certain cancer patient groups (Alison and Sarraf, 1997a).

Antibodies for Cell Cycle Markers

Both DNA incorporation methods share as a common disadvantage the requirement for vital tissues and cannot be used on archival material in retrospective experiments (Hall *et al*., 1992). This limitation is overcome by monoclonal antibodies such as MIB1 (Molecular Immunology Borstel). MIB1 is directed against the Ki-67 protein that is expressed in all phases of the cell cycle and represents a preferred diagnostic tool with few disadvantages. An auxiliary factor to DNA polymerase delta provides an alternative: proliferating cell nuclear antigen (PCNA) which can be detected immunohistochemically in routinely processed tissues during and even shortly after the cell cycle owing to the long half-life of the antigen. As a disadvantage it is easily destroyed by prolonged fixation (Alison, 1995).

Metaphase Arrest

All proliferative indices described above reflect changes in the proliferative rate and in the duration of the cell cycle phases that cannot be discriminated. As a remedy, the metaphase arrest technique provides a firm kinetic parameter, the rate of entry into mitosis, over an experimental period as short as 2.5 h. The *Vinca* alkaloids vincristine and vinblastine have found widespread use as arresting agents that disrupt the assembly of the mitotic spindle and result in characteristic, abnormal and easily recognizable mitotic figures. However, for accuracy, this approach requires multiple samples that limit its application to experimental models (Alison, 1995).

Flow Cytometry

A considerable disadvantage of light microscopic evaluation results from having to score several thousand cells, a time-consuming procedure. This is addressed by flow

cytometry that automatically measures the DNA content of large cell numbers in suspension. For this purpose, DNA is stained by a fluorescent DNA-binding dye and individual cells are directed through an exciting laser beam. The resulting fluorescence signal is proportional to the amount of nuclear DNA that reflects the stage of the cell cycle. Data are directly available for computer and statistical analysis of cell populations (**Figure 6**). The labelling index can be estimated by measuring the BrdU–DNA profile in parallel. Patients can be injected with BrdU and its incorporation into cellular DNA can be measured by indirect immunofluorescence with a different fluorescent dye in parallel to the DNA content. Data can be displayed as a two-dimensional histogram of cell populations in different stages of the cell cycle (Alison and Sarraf, 1997a).

Control of Differentiation

In addition to abnormalities in the regulation of cell proliferation most, if not all, tumours show abnormalities in differentiation such as anaplasia. This can help elucidate their aetiology, degree of malignancy, prognosis and sensitivity to therapeutic intervention by differentiation- or maturation-inducing agents. The state of differentiation of a cell refers to its specialization with regard to expression of a specific subset such as 10 000 of its total set of up to 40 000 genes. Differentiation begins shortly after fertilization of the embryo and permits its development into specialized organs and tissues whereas proliferation is the primary mechanism by which cell mass increases early. In a particular cell the subset of expressed genes is controlled by a set of specific transcription factors. They depend upon its embryonic lineage, developmental stage, tissue and cellular environment and the specific physiological role of the cell. Embryonic cells typically have the capability to proliferate vigorously, migrate extensively, produce enzymes that degrade basement membranes and secrete factors that increase the local blood supply. Most of these characteristics are shared with tumour cells and when combined contribute to increased malignancy, but have typically been lost in differentiated adult cells. Consequently, in the adult organism loss of a highly differentiated state or activation of embryonic gene expression programmes has been found to correlate with malignant properties of tumour cells (Mintz and Fleischman, 1981).

Differentiation Versus Proliferation

Stem cells can be multi- or toti-potent and combine the capacity either to differentiate into a variety of cell types or to multiply without change in their gene expression programme by simple proliferation. Differentiation results in the expression of a specific set of genes that is paralleled by a restriction of the cell for further proliferation. Some cells reach the stage of terminal differentiation. This may still allow cells to carry out specialized functions over much of the organism's life span such as in the case of mature muscle or nerve cells. Alternatively, it may result in subsequent cell death such as in the case of keratinocytes in the outer epidermal layer. The capacity for proliferation including malignant proliferation appears to be inversely correlated with the state of differentiation. Accordingly, terminally differentiated cells have never been found to form tumours, in contrast to less differentiated myoblastic or neuronal stem cells. Conversely, when cells are induced to proliferate with a potent mitogen or by transfection of an oncogene, they can no longer undergo terminal differentiation. Tumour-cells are generally characterized by their inability to differentiate terminally under appropriate conditions either *in vivo* or in culture (Rheinwald and Beckett, 1980; Wille *et al*., 1982).

Senescence Versus Immortalization

The finite life span of normal, differentiated cells represents an obstacle for malignant transformation and senescence resembles terminal differentiation in some ways. Escape from senescence by immortalization is therefore seen as a prerequisite step for tumorigenesis. Once human cells senesce it is virtually impossible to induce proliferation by normal stimuli (McCormick and Campisi, 1991). This phenotype is genetically dominant and induces senescence in hybrids between normal and immortal cells or results in a normal phenotype in hybrids between normal and tumour cells. These findings have led to the discovery of tumour-suppressor genes such as those encoding p53 or the retinoblastoma protein Rb. The latter is required for terminal differentiation of myoblasts and for maintenance of the senescent state (Gu *et al*., 1993).

Control of Differentiation at the Cell Surface

Differentiation typically depends on external factors including the extracellular matrix, proximity and type of neighbouring cells and soluble factors. Members of each category bind to specific cell-surface receptors that initiate signal transduction pathways that control gene expression. Tumour cells often lose their ability to sense the extracellular matrix or neighbouring cells. Malignant human breast epithelial cells can often be identified by their ability to grow on extracellular matrix in a gel that inhibits the growth of normal cells *in vitro* (Lin and Bissel, 1993). An important first class of soluble factors includes fibroblast growth factors, transforming growth factors and haematopoietic growth factors such as interleukins (**Table 3**). FGF induces mesoderm differentiation in early embryos, inhibits differentiation of other cells and plays a role in the survival of endothelial cells and in angiogenesis. Like FGF, TGFβ stimulates the differentiation of some cells such as keratinocytes or intestinal epithelial cells but inhibits the differentiation of others such as myoblasts and preadipocytes.

Table 3 Cell culture models for *in vitro* differentiation: for various stem cell types the inducers of differentiation and the resulting marker phenotypes are shown[a]

Stem cell	Differentiation markers[b]	Inducers[b]
Preadipocyte	Adipocyte	Insulin, cort, cell density
Basal keratinocyte	Cornified envelope	RA deficiency, cell density
Myoblast	Myotube	GF deficiency, cell density
Squamous cell carcinoma	Cornified envelope	GF deficiency, cort
Embryonal carcinoma	Endoderm, mesoderm, ectoderm	RA, ara-C, mito, HMBA, co-culture with blastocysts
Neuroblastoma	Neuron, neurotransmitter, action potential	PI, 6TG, ara-C, MTX, dox, bleo, RA, GF deficiency
Melanoma	Dendrite, melanin, tyrosinase	PI, dox, DMSO, TPA, RA, MSH
Colon adenocarcinoma	Mucus, dome formation, CEA, columnar cell	NMF, DMSO, butyrate, low glucose, IFN, HMBA, cell density
Breast adenocarcinoma	Casein, dome formation	RA, PGE, DMSO
Bladder transitional cell carcinoma	Keratin filament, loss of surface antigen	HMBA
Erythroleukaemia	Mature erythroid cell, haemoglobin	Dox, ara-C, 6TG, mito, dact, aza, haemin, DMSO, HMBA, CSF, RA, IFN
Promyelocytic	Granulocyte, macrophage	IFN, CSF, vitD, TPA, DMSO, NMF, dact, HMBA, aza, ara-C, RA
Myelocytic leukaemia	Granulocyte, macrophage	CSF, RA, vitD, ara-C, dact, DMSO, TPA, cort, dox

[a] Data from Cheson *et al.*, 1986, Reiss *et al.*, 1986 and Waxman *et al.*, 1988.
[b] ara-C, cytarabine; aza, 5-azacytidine; bleo, bleomycin; CEA, carcinoembryonic antigen; cort, glucocorticoids; CSF, colony-stimulating factor; dact, dactinomycin; DMSO, dimethyl sulfoxide; dox, doxorubicin; GF, growth factor; HMBA, hexamethylbisacetamide; IFN, alpha- or gamma-interferon; mito, mitomycin C; MSH, melanocyte-stimulating hormone; MTX, methotrexate; NMF, *N,N*-dimethylformamide; PGE, prostaglandin E; PI, phosphodiesterase inhibitor; RA, retinoic acid; TPA, 12-*O*-tetradecanoylphorbol-13-acetate; vitD, 1,25-dihydroxyvitamin D; 6TG, 6-thioguanine.

It promotes a more differentiated phenotype of some human tumour cells and inhibits their proliferation in part by inducing expression of cyclin-dependent kinase inhibitors that result in loss of cyclin-dependent kinase activity which prevents the phosphorylation and thus the inactivation of the Rb protein (Sherr, 1994). The second class of soluble differentiation factors include membrane-permeable regulators such as retinoic acid and its derivatives that regulate morphogenesis in the early embryo via concentration gradients and stimulate or inhibit growth or differentiation dependent on the specific cell type. The sex steroids oestrogen and testosterone are believed to regulate differentiation via similar mechanisms through specific nuclear receptors that control transcription (Dolle *et al*., 1989).

Gene Expression in Differentiation Control

External differentiation factors cooperate with a small number of master regulatory genes including homeotic genes to control the expression of differentiation-specific genes. Homeotic genes carry a conserved sequence motif termed homeobox and play a fundamental role in the definition of major body structures. Mutations in homeotic genes can result in the exchange of body parts such as legs with antennae in insects; in addition, mutations may reactivate parts of an embryonic gene expression programme or suppress aspects of an adult programme. This may result in higher proliferative, invasive or angiogenic potential, features shared by embryonic and tumour cells (Deschamps and Meijlink, 1992). Well-studied master regulatory genes in a restricted lineage are the *myogenin*, *myoD* and *myd* genes which all encode transcription factors that regulate muscle differentiation. Inactivating mutations select mesenchymal stem cells at various stages of commitment to muscle differentiation but cannot terminally differentiate and possess the potential to form tumours. Typically, cells will be controlled by alternative gene expression programmes that regulate either differentiation or the cell cycle, such that they are largely mutually exclusive.

PRINCIPLES OF ESTABLISHMENT

In Vitro Cell Culture Models

Cancer in humans is seen as a slow and complex, multistep process with each step occurring at low frequency at the cellular level (**Figure 3**). The cellular origin of the tumour is often obscured by the heterogeneity and complexity of the tumour tissue and by the loss of differentiation markers (**Table 3**). This makes research on human tumours very difficult, which is further complicated by the inaccessibility of human tumours and the need to interfere therapeutically

as soon as they are detected. The elucidation of the detailed mechanism of human tumour formation and growth requires the tools of molecular and cellular biology and experimental models in which the process of malignant conversion can be predictably induced and reproducibly studied. Cell cultures have become an essential model in experimental oncology. This is based on the principle that normal, including human, cells growing in culture can be altered experimentally into tumorigenic cells that undergo morphological transformation (Hahn *et al*., 1999). These can be injected into animal hosts where they will induce tumour growth in a process termed malignant transformation.

Immortalized Cell Lines

Primary cell cultures are initially established by dissociation of a tissue into single cells such as by mechanical disruption and proteolytic enzyme digestion. In the case of mouse embryo tissue many cells will initially grow but the culture will enter crisis within days. Most cells will die as a result of their limited life span, which is characteristic for all somatic cells. From rodent tissues, but typically not from human tissues, a small number of variants are expected to survive, overgrow the culture and result in immortalized cell lines (**Figure 7**). These are normally fibroblasts that will form a monolayer on the culture plate. Cells can be dissociated by proteolytic treatment and can be subcultured (or passaged) into fresh cultures. In contrast to most primary cultures, immortalized cell lines are able to grow at low cell density and allow the cloning of single cells into homogeneous populations. However, they invariably display abnormal karyotypes, are in many respects already preneoplastic, and may undergo spontaneous transformation since they have already acquired some of the alterations required for the transition to a fully malignant phenotype (Martin, 1996). (See also chapter on *Basic Tissue Culture in Cancer Research*.)

Cell Transformation

Proliferation of cultured cells depends on many nutrients that are routinely supplied by a synthetic medium and on many other components including growth factors that are typically provided by supplementing the medium with serum. In particular, rodent fibroblast cultures have become popular as *in vitro* cancer models since immortalized variants are easily established and can readily undergo neoplastic or malignant transformation by oncogenes such as from tumour viruses or by chemical carcinogens. This is scored most stringently by the cells' ability to form tumours upon injection into experimental animals such as mice. In contrast to normal cells, transformed fibroblasts usually acquire autonomous or unregulated growth properties and lose contact inhibition. They continue to proliferate at high densities and form cell foci, and can proliferate when deprived of growth factors (**Figure 8**). They typically display anchorage independent cell-growth (**Figure 9**) in the absence of adhesion to an extracellular matrix and display a more rounded or spindle-like morphology. These changes result from a disruption of the actin cytoskeleton and its

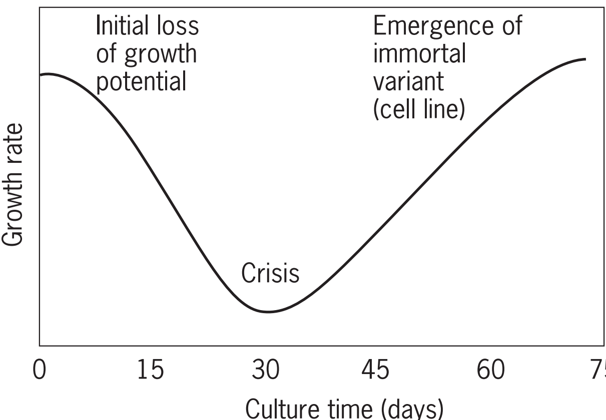

Figure 7 Principle of rodent fibroblast immortalization. In a primary culture of mouse embryo cells initial cell death is paralleled by the emergence of healthy and proliferating cells. As these cells are diluted and continue to divide the culture goes into crisis, and most cells die. Only a small number of cells survive and proliferate until their progeny finally overgrow the culture. These cells constitute an immortalized cell line, which will proliferate as long as it is appropriately diluted and supplied with nutrients.

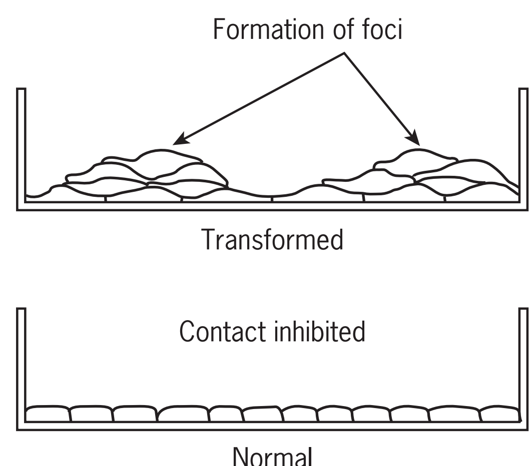

Figure 8 Morphological cell transformation. Normal, immortalized fibroblasts typically grow on a culture dish as a monolayer that is maintained by their response to contact inhibition. Transformed cells have typically lost contact inhibition and grow on top of each other in a less organized pattern. This results in domes of cells termed foci that are frequently visible with the unaided eye after many cell divisions.

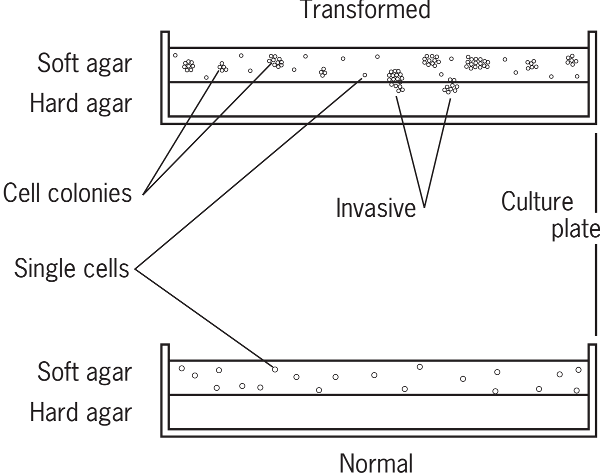

Figure 9 Anchorage-independent cell growth. Normal immortalized fibroblasts do not proliferate in a semisolid medium, such as in soft agar. The loss of anchorage dependence is a key criterion for the transformed phenotype that allows transformed cells to proliferate and form colonies in a semisolid medium. If colony formation proceeds even at increased agar concentration this frequently reflects an invasive phenotype and may correlate with metastatic potential.

connections to and changes in the extracellular matrix. They will often, but not always, correlate with the potential to form tumours *in vivo*. Since transformed cells may be rejected by the immune system, immunologically compromised nude mice are most commonly used for tests of tumorigenicity (Cifone and Fidler, 1980; Li *et al*., 1989).

Malignant Transformation by Tumour Viruses

Tumour viruses are found in many mammalian and avian species and some, in particular papilloma and certain hepatitis viruses are a significant cause of human cancer. Cultured cells can be rapidly and reproducibly transformed by many tumour viruses and the involved viral genomes are relatively simple. This has greatly facilitated the molecular dissection of the resulting cellular changes and of the underlying transforming genes. Two groups of tumour viruses have been particularly important in the development of molecular oncology. Acutely-transforming retroviruses carry transforming genes or oncogenes that have been acquired from normal cellular progenitors, termed proto-oncogenes. The other group is represented by papova viruses including monkey simian virus 40 (SV40) and mouse polyoma virus. Both viruses encode proteins that are involved in DNA replication and malignant transformation. Both virus classes result in the integration of viral DNA into the host chromosome, a critical step for the replication of viral DNA. This permits the consistent expression of viral gene products, in particular those of the viral oncogenes that are responsible for the transformed state of the cell (Topp *et al*., 1980; Klein, 1993).

Some retroviruses, including acute leukaemia viruses, which induce rapid leukaemia *in vivo*, can transform other cell types, in particular haematopoietic cells. When suspended in a gelled medium, normal target cells proliferate to a limited extent before they undergo terminal differentiation, whereas transformed cells grow into larger, less differentiated colonies. Abelson murine leukaemia virus has been shown to transform lymphoid cells, avain erythroblastosis virus to transform erythroid cells and avian myelocytomatosis or myeloblastosis viruses to transform myeloid cells (Beug *et al*., 1994; Rosenberg, 1994). With these approaches the largely opposing effects of cell differentiation and malignant transformation have been characterized. (See also chapter on *Haematological Malignancies in Cancer Research*.)

Many retroviruses transform most of the fibroblast population in a culture at high multiplicities of infection. Transformed cells become anchorage independent and will continue to grow into colonies when suspended in a semisolid medium such as soft agar or methylcellulose, in contrast to normal cells. The reproducible experimental induction of this phenotype by transforming tumour viruses and its correlation with the viral induction of sarcomas in experimental animals represents one of the foundations of experimental tumour virology (Klein, 1993).

DNA Transfection of Cultured Cell Lines

Since oncogenes had been identified as the tumour-causing principle of tumour viruses, experimental approaches were designed to test for the presence of oncogenes in human tumours based on the technique of DNA transfection (Kern, 1996). For this purpose, genomic DNA was isolated from tumour cells and treated with calcium phosphate solution to form a DNA precipitate. Such a precipitate is effectively taken up by cultured mammalian cells into the cytoplasm. Immortalized, normal NIH 3T3 mouse fibroblasts, a model system to study malignant transformation, were transfected and cultured for 2 weeks and their morphology was analysed for the characteristics of malignant transformation (**Figure 10**). Foci of transformed cells were observed, based on the presence of the human EJ bladder carcinoma oncogene which was established as a homologue of the (Harvey) *v-ras* oncogene in human tumour cells by this procedure (Parada *et al*., 1982). In the case of human primary cells, *in vitro* malignant transformation has only recently been accomplished since it requires the deregulation of at least four signalling pathways in some specific nonrandom order. The four steps involve immortalizing cells by overexpression of the enzyme telomerase, activating mitogenic signalling by overexpression of a *v-ras* oncogene, and by interfering with two tumour suppressor genes, cellular *p53* and *Rb*, which is accomplished by

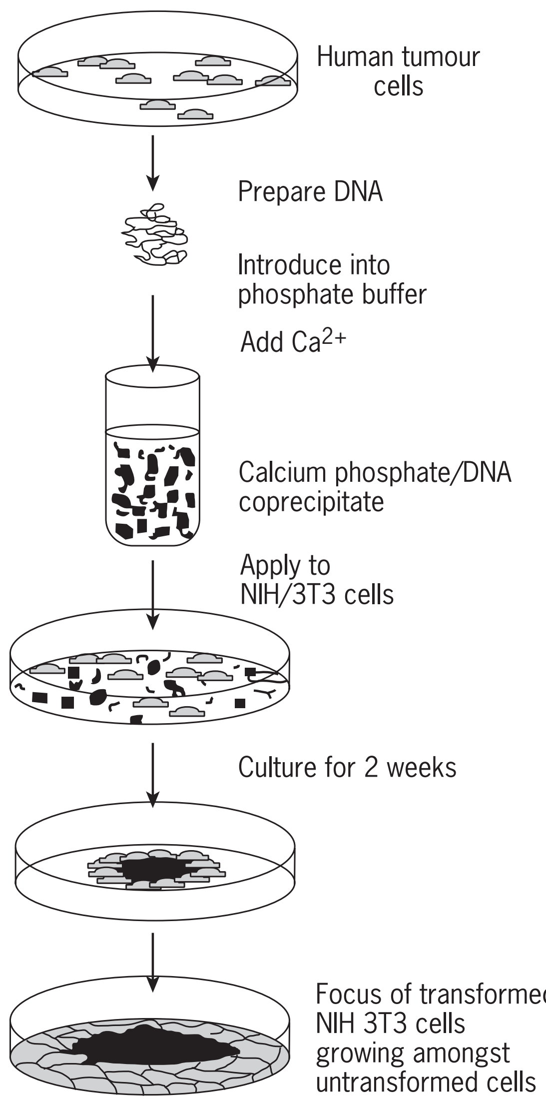

Figure 10 The prototypical transfection experiment to demonstrate a cellular oncogene. [From Alison and Sarraf, 1997b, in: *Understanding Cancer: from Basic Science to Clinical Practice*, 133–193 (Cambridge University Press, Cambridge).]

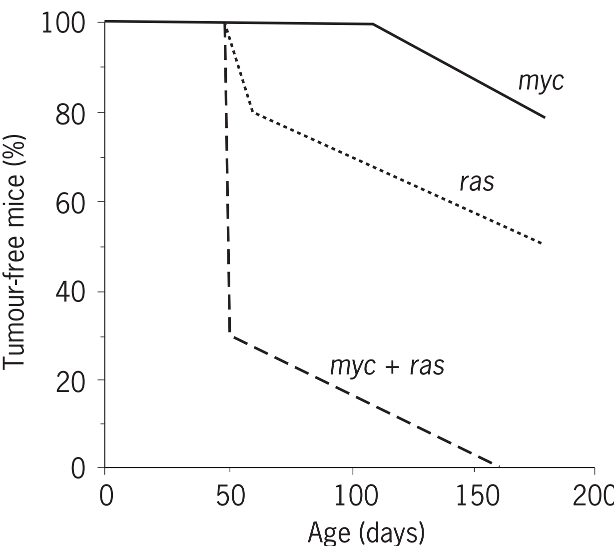

Figure 11 Oncogene cooperation in tumorigenesis. The incidence of tumorigenesis in three types of transgenic mice is shown, one carrying a *myc* oncogene, one carrying a *ras* oncogene and one carrying both oncogenes. Co-expression of *myc* and *ras* results in a dramatic and synergistic acceleration of tumour formation.

overexpression of SV40 T antigen (Hahn *et al*., 1999). For normal mouse fibroblasts, expression of at least two different oncogenes was found to be minimally required to result in cell transformation. Cooperation of different oncogenes has been shown to accelerate and enhance dramatically tumorigenesis in transgenic mice (**Figure 11**).

Alterations in the DNA Sequence of Oncogenes

Molecular cloning and sequence analysis of tumour virus oncogenes and the identification of their cellular proto-oncogene counterparts by nucleic acid hybridization analysis were instrumental techniques in the definition of the specific alterations that convert normal cellular genes into transforming oncogenes (Kern, 1996). Frequently a gene dosage effect was implicated which led to an increased gene expression level in the tumour virus, or to functional gene activation by fusion of the proto-oncogene with a viral gene that resulted in an activated and/or deregulated fusion protein. Similar gain-of-function results were also observed by mutations within the amino acid coding region of the oncogene. These were minimally based on a single nucleotide exchange that resulted in the substitution of one critical amino acid. With this knowledge, it was possible to recreate oncogenes by *in vitro* site-directed mutagenesis of proto-oncogenes that had been isolated from normal cells. These oncogenes were integrated into cDNA expression plasmids that were introduced into normal immortalized rodent fibroblasts to confirm the resulting transformed phenotype as shown in **Figures 8** and **9** (Rodrigues and Park, 1994).

Oncogene-induced Alterations in Cell Morphology

In order to study the molecular details that result in the transforming potential of oncogenes, *in vitro* assays were developed to score oncogene function (Cifone and Fidler, 1980). These assays were based on the observed deregulation of the cell cycle and on alterations in cytoskeletal and adhesion proteins. Typically, oncogene expression results in morphological alterations in rodent fibroblasts that are detectable in the phase contrast microscope, disturb organized growth and often result in a crisscrossed and chaotic growth

pattern rather than in an organized monolayer. Contact inhibition is normally lost and leads to piles of cells or foci that are detectable with the unaided eye. Foci are routinely scored by staining cells with a dye for increased contrast such crystal violet (**Figure 8**). Changes in cytoskeletal organization can be evaluated by indirect immunofluorescence with antibodies or specific dyes directed against major cytoskeletal markers such as actin which frequently display a disorganized pattern in transformed cells. Cell morphology is frequently more rounded and includes new surface projections. Some oncogenes such as v-*abl* of Abelson murine leukaemia virus result in a distinct phenotype of rounded cells that have lost their adherence to the culture plate.

In Vitro Assays for Cell Transformation

Anchorage-independent growth, a classical marker of fibroblast transformation, can be scored by colony formation in semisolid medium such as soft agar, conditions under which normal fibroblasts cannot proliferate (**Figure 9**). Combined with focus formation (**Figure 8**), the observation of anchorage-independent proliferation frequently correlates with the potential of transformed cells to form tumours in nude mice, the ultimate marker for experimental malignant cell transformation. These *in vitro* assays consequently permit the prescreening of numerous samples for their transforming potential and can limit the use of experimental animals to confirm the activity of the samples with the highest *in vitro* scores. The capacity for anchorage-independent growth can be co-evaluated with the invasive potential of transformed cells which is reflected in their ability to grow in agar of increased concentration (**Figure 9**). Cells which proliferate into colonies under these conditions may show invasive and metastatic potential in human and animal hosts (Li *et al*., 1989).

In addition, a minimal dependence of the cell cycle on growth factors is often the result of oncogene action (Aaronson, 1991). Normal fibroblasts typically require a serum supplement to their synthetic growth medium that can be partly replaced by a mixture of several factors including transferrin, insulin and epidermal growth factor. Oncogene expression frequently renders fibroblasts independent of one or more of these factors to undergo several cell divisions whereas normal fibroblasts will not repeatedly divide. Alternatively, oncogene expression may support cell proliferation at reduced serum concentrations where normal fibroblasts will not divide. Cell proliferation is routinely assayed either by cell counts in the phase contrast microscope, in a flow cytometer, or indirectly (MTT assay) by measuring mitochondrial succinate dehydrogenase activity (Denizot and Lang, 1986).

In Vitro Models for Differentiation

The elucidation of the fundametal molecular mechanisms that control cell proliferation, including growth factors and their signalling pathways, the cell cycle and the involved gene expression programmes, has to a large extent been a byproduct of the investigation of oncogene function. Many growth factors are also differentiation factors at specific stages in development and regulate similar signalling cascades in either function which activate distinct gene expression programmes dependent on the specific cell, tissue or developmental context (Cross and Dexter, 1991). With this knowledge, rapid progress was made initially in simple experimental model systems in the unravelling of the molecular mechanisms in differentiation and development. Since the molecular mechanisms and components are frequently shared between proliferation and differentiation programmes, many of experimental approaches described above can be applied interchangeably. In particular, a number of cell culture models were established based on specific stem cells such as preadipocytes or myoblasts which were known to differentiate into adipocytes and myotubes, respectively (**Table 3**). When specific mechanisms of induction were defined, including insulin and cell density or growth factor deficiency and cell density, respectively, experimental models were established to study the control of cell differentiation under defined *in vitro* conditions. These include a significant number of tumour models that permit the molecular dissection of the opposing effects of transformation and differentiation. Future antitumour differentiation therapies will benefit from these experimental strategies.

Simple Genetic Models in Development and Differentiation

Even more importantly, simple experimental models with established genetics were instrumental in the observed rapid progress in this field. They provided a unique advantage by allowing the application of genetic and biochemical experimental strategies in parallel. Even the simplest multicellular organisms undergo differentiation and development but typically malignant transformation is not easily observed. Simple eukaryotic models have not been applicable to study tumorigenesis directly. The most important genetic model systems are the fruit fly *Drosophila melanogaster*, the nematode *Caenorhabditis elegans*, the slime mould *Dictyostelium discoideum* and more recently the mouse *Mus musculus*. In these models, master genes such homeogenes have been identified which control central developmental programmes in most organisms. With the progress of genome mapping and sequencing in mammals including mice and humans, the knowledge gained with the simple genetic models is now rapidly being applied to the understanding of differentiation and development in mammals including humans.

GENERAL APPLICATIONS

Retrovirus Models

Retrovirus models have not only been been instrumental in the dissection of oncogene function but have similarly helped elucidate the pathogenic mechanism involved in other human diseases that they cause. One important example is the human immunodeficiency virus (HIV) and the resulting acquired immunodeficiency syndrome (AIDS). The investigation of the underlying molecular mechanisms and the search for effective therapies has greatly benefitted from the knowledge gained earlier with transforming retroviruses. Since retroviral RNA is integrated into the genome of the host cell as part of the viral life cycle, this mechanism has been exploited to design expression vectors for experimental models as well as for human gene therapy. Such vectors result in the stable and predictable integration of defined protein-coding sequences into the genome. This allows their stable propagation into daughter cells in parallel with genomic DNA replication and cell division. In addition, the expression level of the inserted sequences can be adjusted or externally regulated by the choice of the specific transcriptional promoter. Retrovirus models have greatly contributed to the discovery of fundamental mechanisms in gene expression and transcription. A previously unknown enzymatic function, termed reverse transcriptase, was shown to catalyse the transcription of the retroviral genomic RNA template into a DNA copy to allow integration of the sequence into the DNA genome. This enzyme has been instrumental in the cloning and sequencing of thousands of protein-coding sequences starting with their specific mRNA (Gallo, 1995).

DNA Tumour Virus Models

Other tumour virus models such as polyoma virus and, in particular, simian virus 40 (SV40) have greatly helped elucidate gene structure and function based on their small DNA genome size. They represent one of the smallest self-replicating eukaryotic systems and have resulted in the first completely sequenced viral genome (SV40). In both viruses many regulatory functions are controlled by a transforming early viral protein family termed T or tumour antigen that regulates viral transcription. In contrast, the oncogenes of retroviruses encode cellular growth-regulating proteins that have become activated or deregulated by integration into the retroviral genome. The investigation of retroviruses has helped identify many key mediators of cell proliferation and differentiation, typically one per virus. In contrast, the transforming proteins of DNA tumour viruses had evolved to interact with many key mediators of mitogenic signalling pathways at the same time to maximize the resulting aberrant cell proliferation, and have significantly aided in the identification of the underlying key regulatory mechanism with which they interfere. The early SV40 gene region including the origin of replication has served as a prototype in parallel with retroviruses for the design of mammalian expression vectors which can randomly integrate into the genome of mammalian cells and allow for high levels of cDNA expression when combined with effective selectable markers. Alternatively, vectors based on the early or late SV40 gene regions have been used for effective transient expression of foreign cDNAs (Topp *et al*., 1980).

In Vitro Cell Lines, DNA Transfection and Cell-permeable Peptides

In vitro cell culture models have found numerous applications in every area of modern molecular medicine since they allow the specific and reproducible investigation of molecular processes in the absence of other complicating factors that are found in more complex *in vivo* systems. In combination with the technique of DNA transfection, this approach allows the transient or stable overexpression of essentially any protein or protein fragment (for which a coding cDNA is available) in a large number of immortalized cell lines. This approach can also be used to interfere with the function of a cellular protein in a dominant-negative approach. This involves an antisense expression plasmid that encodes a single-stranded sequence complementary to the cellular message and results in inhibition of the expression of the respective cellular protein (Baserga and Rubin, 1993). Alternatively, protein domains or smaller proteins can be expressed with an attached cell-permeable peptide (such as of the *Drosophila antennapedia* homeodomain or the HIV TAT protein) that will direct effective uptake across the cell membrane into the cytoplasm and nucleus of cultured cells and even spread the protein throughout a whole organism. With this new experimental strategy overexpression of or interference by proteins and their consequences on host regulatory mechanisms can be studied rapidly in a wide variety of cell lines or tissues (Schwarze *et al*., 1999; Riedel *et al*., 2000).

Insulin-like Growth Factor I Receptor as an Anticancer Target

The combination of these experimental models has led to the new concept of transformation competence genes in cancer research. The insulin-like growth factor I (IGF-I) receptor (IGF-IR) has been identified as a candidate mediator which participates in but is not essential for normal cell proliferation whereas normal IGF-IR levels have been found to be essential for malignant cell transformation. This is suggested by the finding that normal immortalized mouse fibroblasts carrying a disruption in the IGF-IR gene generally cannot be transformed by a

number of different oncogenes. Alternatively, malignant transformation in cell culture, in rodents or in human patients can be reversed with a variety of anti-IGF-IR strategies including antisense constructs, specific antibodies or dominant-negative forms. These approaches only result in limited growth inhibition of normal cells but cause massive apoptosis of tumour cells in particular *in vivo* which should result in a favourable therapeutic index. In addition, they elicit an unidentified novel type of host response that eliminates surviving tumour cells and abrogates tumour growth and metastasis. A better understanding of the involved mechanisms will help in the design of rational therapeutic strategies that may also be favourably directed at downstream targets in the IGF-IR signalling pathway (Baserga, 1998).

erbB-2/neu as a Diagnostic Tumour Marker

The improved understanding of the molecular mechanisms that underlie oncogene action *in vitro* has resulted in diagnostics and the development of therapeutic tools that can be applied to human cancer. Important alterations have been identified that can be consistently demonstrated in a significant fraction of human tumours. These include amplification of the *erbB-2* or *neu* gene as an early example and inactivation of the tumour-suppressor gene *p53*. A novel oncogene termed *neu* was identified as a result of chemical carcinogenesis and was later found to represent an altered form of *erbB-2*, a member of the epidermal growth factor receptor gene family. The alteration was limited to a single nucleotide change in the codon for a critical amino acid in the transmembrane domain. Based on these molecular studies, hybridization probes became available that demonstrated increased expression of normal *erbB-2* in 20–60% of various human tumours. These included breast, lung, ovarian, oesophageal, colorectal and prostate cancer, and *erbB-2* amplification in primary tumours was linked to metastatic lesions (Salomon *et al*., 1995).

erbB-2/neu as a Therapeutic Target

The substantially increased expression levels and the location of *erbB-2* at the cell surface as a membrane-spanning protein, identified it as a potential target for a variety of interfering therapeutic strategies and promised a favourable therapeutic index. These strategies predominantly target the extracellular domain of *erbB-2* with specific monoclonal antibodies that alter *erbB-2* activity, present it to the immune system or deliver toxins or enzymes that can activate prodrugs in the transformed cells. Other classes of strategies target the signalling pathway beginning at the receptor level with specific tyrosine kinase inhibitors, downstream signalling mediators, target expression of *erbB-2* via antisense approaches, or focus on potential vaccines that activate an immune response towards the overexpressed *erbB-2* (Esteva-Lorenzo *et al*., 1998). With the rapid progress in the elucidation of the molecular alterations underlying human tumours, in molecular modelling and rational drug design, exciting new diagnostic and therapeutic strategies are being developed at a rapidly increasing pace (Levitzki, 1994).

Differentiation and Cancer Diagnosis

The analysis of tumour cell differentiation can assist in the diagnosis and therapy of human cancers. Tumour cells may release products into body fluids that allow conclusions about their state of differentiation. These are typically quantified with sensitive immunoassays. Serum levels of human chorionic gonadotrophin or α-fetoprotein greatly assist in the diagnosis of male testicular carcinomas and female gestational neoplasms. Similarly the origin of metastatic neoplasms may be identified through the presence of oestrogen receptors and α-lactalbumin in breast cancer, prostate-specific antigen and prostate acid phosphatase in prostate cancers and myoglobin and desmin in sarcomas. Elevation of these markers in serum is often the earliest sign for the relapse of a given neoplasm but specificity is typically poor. Tissue markers for neuroendocrine differentiation help identify carcinoma patients with improved response to chemotherapy (Gorstein and Thor, 1990).

Differentiation as Cancer Therapy

Terminal differentiation has been induced in some tumour cells in culture and in animals (Reiss *et al*., 1986) which often stably suppresses tumour growth. The drugs involved typically exert only minimal toxic effects on normal cells in contrast to most anticancer drugs (Waxman *et al*., 1988). Several differentiation-inducing drugs have been used clinically including oestrogens and androgens to treat specific breast, prostate and gynaecological tumours that express the appropriate nuclear receptor. Retinoic acid, hexamethylenebisacetamide and 5-azacytidine induce differentiation and inhibit the growth of several types of tumours in laboratory models and myelodysplastic syndrome in humans. All-*trans*-retinoic acid has shown promising initial results in the clinical therapy of promyelocytic leukaemia, while retinoids in combination with interferon-alpha have helped in the treatment of patients with squamous cell cancer of the skin or cervix (Chabner, 1993) (see chapter on *Haematological Malignancies in Cancer Research*). Differentiation by mithramycin and hydroxyurea has been linked to remissions in patients diagnosed with the accelerated phase of chronic myelogenous leukaemia. Retinoids have been used against premalignant lesions or the development of cancer of the breast, cervix, colon, skin, lung or oral cavity with encouraging early results. It is difficult to predict the success of treatment to induce terminal differentiation of specific tumour cells and retinoids have the potential

to promote the formation of new tumours in some experimental models. A better understanding of the molecular controls of differentiation should lead to more accurate predictions and to the rational design of more effective and specific anti-tumour therapies (Rowley *et al*., 1993).

BIOLOGICAL AND TECHNICAL LIMITATIONS

Cell Cultures Versus Nude Mice as Models for Tumorigenesis

In vitro experimental models for tumour growth and differentiation allow the reproducible and rapid dissection of specific molecular mechanisms that participate in the process of malignant cell transformation under tightly defined experimental conditions. This represents only the beginning of the chain of successive steps that will be necessary for tumorigenesis to occur in humans. It allows single experimental parameters to be varied and critically evaluated for their contribution to the outcome of the experiment. This is impossible in humans *in vivo* where tumours are found often difficult to access and in a complex tissue environment that introduces unknown factors that contribute to tumour development and growth. Malignant transformation is typically scored *in vitro* by anchorage-independent growth, the formation of cell foci and the underlying changes in cell morphology. This is frequently correlated with the potential of the affected cells to form tumours in immune-compromised nude mice, which represents a generally accepted standard that defines experimental tumorigenesis such as the activity of the underlying oncogenes. Anchorage-independent growth will, however, not necessarily correlate with tumour formation in nude mice and needs to be interpreted with caution. While nude mice represent an advantageous model to score experimental tumour formation in the absence of a host immune response, they certainly do not realistically reflect the tumorigenic potential when compared with wild-type animals. (See also chapter on *Human Tumours in Animal Hosts*.)

Differences Between Human and Rodent Cells

Most importantly, experimental rodents such as mice and rats differ from humans in many ways that are not well understood with regard to their potential to develop cancer. This is reflected in the well-established fact that experimental antitumour therapies will frequently show remarkable efficacy when they are first tested in rodents whereas subsequent human clinical trials may show little or no effects. Consequently, factors or strategies that cause or prevent tumorigenesis *in vitro* or in experimental animals will not necessarily show the same result in humans. Some fundamental differences have been described at the cellular level. Immortalized cell lines, typically fibroblasts, are routinely isolated from rodent but not from human tissues (**Figure 7**). This explains their popularity as *in vitro* model systems but also exposes their limitations. Immortalized rodent fibroblast cells are preneoplastic and malignant transformation will routinely result from the introduction of a single oncogenic alteration. In contrast, primary human fibroblasts or epithelial cells have only recently been transformed since this requires at least four alterations in critical regulatory mechanisms. One important difference from rodent cells is reflected in the absence of telomerase activity in human cells, which results in telomeric erosion with each cell doubling and is thought to cause senescence and limit the cell life span. (See also chapter on *Genomic Instability and DNA Repair*.)

Specific Genetic Alterations Required for the Malignant Transformation of Normal Human Cells

Since normal murine somatic cells express telomerase activity which is also acquired by human tumour cells, this function is seen as a first critical and necessary change to allow human cells to overcome senescence and gain immortality. In addition to the introduction of telomerase, mitogenic signalling pathways were experimentally deregulated and activated by overexpression of a v-*ras* oncogene, and by interfering with two tumour-suppressor genes, cellular *p53* and *Rb*, which were both accomplished by overexpression of SV40 T antigen. The combination of these changes was minimally required to transform normal human primary cells to cause tumorigenesis in nude mice (Hahn *et al*., 1999). Comparable studies in normal human fibroblasts in which SV40 T antigen was replaced by the functionally similar HPV16 E6/E7 transforming proteins did not result in tumorigenesis (Morales *et al*., 1999). This suggests that either SV40 T antigen contributes an unknown fifth alteration in a mitogenic signalling pathway or that successful tumorigenesis depends on the exact order in which the four alterations are introduced into the cell. These recent landmark findings now offer the first *in vitro* experimental model to identify combinations of components and the required order of their introduction to minimally result in the malignant transformation of normal human epithelial and fibroblast cells. In contrast, normal mouse cells can be effectively transformed by the cooperation of only two oncogenes (**Figure 11**).

Somatic Mutation Theory Versus Tissue Organisation Field Theory of Carcinogenesis

Since 1914, the prevalent carcinogenesis model has been the somatic mutation theory. This postulates the initiation

of malignant transformation in a single somatic cell by a sequence of genetic alterations that are propagated to cell progeny and result in tumorigenesis. While this concept is supported by a large body of data including the successful experiment described above to transform normal human cells by a sequence of defined genetic changes in the same cell, it has not been feasible to delineate the formation of invasive tumours from a single mutated cell. Since tumours are complex, often genetically heterogeneous, and closely interact with their surrounding tissue, the somatic mutation theory cannot be easily validated at the level of the tumour. The organisation field theory of carcinogenesis is based on the postulate that proliferation is the default state of all cells (which is not in dispute for unicellular organisms) even in multicellular organisms. This is taken to imply that quiescence is caused by inhibitory factors or lack of serum nutrients rather than by the lack of growth factor stimuli. Carcinogenesis is seen as a phenomenon at the tissue and organ organisational level, not limited to a single cell. *In vitro* models have not been able to contribute much to clarify this dispute given the complexity of tumours *in vivo*. Both conflicting theories can serve as a reminder that tumorigenesis is a multistage process (**Figure 3**), of which only small segments can be studied in *in vitro* models one at a time (**Figure 11**). *In vitro* models can elucidate the mechanism by which steps in tumorigenesis can occur in a test-tube, but they cannot prove the accurate sequence of events that have occurred in a specific tumour (Sonnenschein and Soto, 1999).

- *In Vitro* Models
- Utilizing Angiogenesis Models to Study Signalling Events Related to Angiogenesis
- Conclusion

ANGIOGENESIS

Angiogenesis, the formation of new blood vessels, occurs during cancer progression, wound healing and embryogenesis. Like normal cells, tumour cells obtain their metabolic and nutrient requirements such as oxygen, glucose and amino acids from the blood supply. Without this rich nutrient broth, a tumour is unable to grow beyond 2 mm in size. The secretion of angiogenic factors by tumour and stromal cells may induce neovascularization allowing exponential growth of the neoplasm (Folkman, 1970). In addition to providing the means for massive tumour growth, angiogenesis has been shown to be necessary although not sufficient for successful metastases (Liotta *et al*., 1974). The new blood vessels provide both an outlet and a pathway for invasive tumour cells to enter the bloodstream, circulate and extravasate at a distant site to initiate a secondary tumour (Kohn and Liotta, 1995). Mortality from cancer occurs most commonly as a result of complications from the primary tumour and/or as a result of distant metastases. Experimental methods and models have been developed to study the complex process of angiogenesis in malignancy to identify mechanisms and dissect the process. This has led to the discovery and characterization of antiangiogenic therapies that hold promise to stabilize or reduce many types of cancers.

The induction of neovascularization has been shown to be a discrete event during the early stages of tumour development. This angiogenic switch is the rate-limiting step in tumour progression and is hypothesized to be caused by an imbalance of anti- and proangiogenic signals from either the tumour, stromal, endothelial or host inflammatory cells (Hanahan and Folkman, 1996). Growth factors and cytokines such as vascular endothelial cell growth factor (VEGF), transforming growth factor-β (TGFβ), tumour necrosis factor-α (TNF-α), basic fibroblast growth factor (bFGF), angiogenin and interleukin-8 (IL-8) are examples of proangiogenic molecules (Cockerill *et al*., 1995; Hanahan and Folkman, 1996). Promotion of capillary growth also may be induced by insoluble factors such as the extracellular matrix (ECM) components thrombospondin-1 (TSP-1), laminin, fibronectin and types I, III, IV and V collagen, which promote endothelial cell migration, proliferation or differentiation into vascular tubules (Ingber and Folkman, 1989). Potent endogenous antiangiogenic molecules include TGF-β and also small segments of larger, often inactive, parent polypeptides such as angiostatin from plasminogen, endostatin from type XVIII collagen or fibronectin and prolactin fragments (Hanahan and Folkman, 1996). Fumagillin and cyclosporin A are natural antiangiogenic products, and platelet factor 4 is an endogenous antiangiogenic agent (Cockerill *et al*., 1995). The result of a net imbalance of pro- and antiangiogenic factors results in induction or inhibition of capillary sprouting from pre-existing blood vessels. Activated endothelial cells secrete proteases to degrade the local basement membrane after which the cells may be stimulated by matrix components and growth factors elaborated during proteolysis. Endothelial cells migrate towards the tumour, and a capillary sprout is formed. A lumen develops within the newly formed tubes and with anastomosis, the vessel is complete. Maturation of the new capillary bed requires recruitment of pericytes and deposition of new basement membrane (Ausprunk and Folkman, 1977). (See also chapter on *Angiogenesis*.)

APPLICATIONS OF ANGIOGENESIS MODELS

Observations that a cancerous mass requires neovascularization to grow (Folkman, 1970) and that metastasis cannot occur unless the neoplastic cells have access to the

vasculature (Liotta *et al*., 1974) have led to increased interest in the field of angiogenesis. There is an earnest search under way for antiangiogenic agents in response to the hypothesis that inhibition of angiogenesis may lead to the arrest of the growth and metastasis of malignancy. This concerted effort has led to a better understanding of the steps involved in new vessel formation and identification of factors that influence this process. This progress could not have been made without the extensive use of a variety of models of angiogenesis. **Table 1** presents the various uses of models of angiogenesis. The major advantages and disadvantages of each of the model systems that we discuss in this chapter are presented in **Table 2**.

Both *in vivo* and *in vitro* models have been developed in order to provide an environment to understand the components that are involved in angiogenesis. *In vivo* models may more accurately depict the natural events occurring in angiogenesis, but are harder to scrutinize experimentally. Although *in vitro* angiogenesis models may not be true replicates of *in vivo* vasculogenesis, they are invaluable tools with which to begin dissecting the components involved in this process. These models can be used for the testing of various experimental parameters of interest in order to investigate their selective effects on the angiogenic process.

Another important use of both *in vivo* and *in vitro* angiogenesis models is the testing of potential angiogenic modulators. Candidate pro- and antiangiogenic compounds

Table 1 Applications of angiogenesis models

Allow testing of putative stimulatory and inhibitory angiogenic modulators
Allow testing of experimental parameters to investigate their selective effects on the angiogenic process
Allow identification of genes and gene products involved in angiogenesis
Allow identification of potential new antiangiogenic targets

Table 2 Major advantages and disadvantages of various models for angiogenesis studies

Model	Advantage	Disadvantage
In vivo		
Cranial and dorsal windows	Allows non-invasive, multiple time-point measurement of several microhaemodynamic parameters such as blood vessel permeability and blood flow velocity	Requires surgical techniques and specialized equipment for intravital microscopy
Exteriorized tissue models		
1. Intradermal assay	Relatively easy to prepare compared with using other *in vivo* models	Traumatizes the tissue; difficult to distinguish the newly formed vessels
2. Chick chorioallantoic membrane assay	Allows quantification of the effects of putative angiogenic and antiangiogenic molecules; lack of rejection of test substances due to underdevelopment of the chick immune system	Discerning neovascularization from alterations in blood vessel density or reorganisation may be difficult
Corneal micropocket assay	Reliable qualitative and quantitative analyses can be performed using image analysis programme	Expensive; good surgical technique required
Matrix implants		
1. Cannulated sponge model	Ability to quantify blood flow sequentially over a period of time	Gross inspection of neovascularization is not possible
2. Disc angiogenesis sponge model	Multiple discs can be implanted to increase statistical accuracy	Angiogenic responses are determined only at defined time points
3. Matrigel plug	Reproducible and quantifiable data with image analysis or manual blood vessel counts; allows histo- and immunohistochemistry, *in situ* hybridization	Only one time point per Matrigel plug so requires more animals
Retinal assay	Ideal for studying the mechanisms and process of hypoxia-induced angiogenesis	Only one time point per animal so requires more animals; requires special equipment for maintaining oxygen levels
In vitro		
Tubulogenesis in culture	Ability to dissect out the component parts of the angiogenic process	Results may not hold true in an *in vivo* setting
Co-culture model	Ability to determine effects of nonendothelial cell types on endothelial cell tubulogenesis	Variation of results due to endothelial cell type or source
Immortalized endothelial lines	Avoids the limitations of primary endothelial culture	Immortalized endothelial cells may not behave as true endothelial cells would in a given condition

can be distinguished from compounds having mixed or no therapeutic potential through the screening provided by model systems. Different models may isolate individual steps, allowing some functional mapping of inducers and inhibitors of angiogenesis if several models are used. This provides a mechanism whereby candidate compounds can be identified quickly and tested to better understand their potential for the clinical setting.

Angiogenesis models are also critical to our understanding of the molecular events that are involved in the formation of new vessels. Although the biological steps involved in the formation of new vessels have been determined, relatively little is known about the molecular genetic events underlying angiogenesis. New models or modifications of existing ones will allow researchers to isolate RNA, DNA or protein of endothelial cells in specific stages of the angiogenesis process. These materials can then be used to identify genes or gene products that play a role in angiogenesis and therefore potential new targets for the development of antiangiogenic therapy.

IN VIVO MODELS

In vivo models used to quantify neovascularization can be classified briefly into five categories: (1) angiogenesis windows or chambers created surgically for the observation of neovascularization in live animals; (2) exteriorized tissue models, such as the chick chorioallantoic membrane (CAM) and intradermal assays; (3) vascular induction on normally avascular tissues such as cornea; (4) implanted materials to induce angiogenesis, such as the Matrigel plug; and (5) physiopathological induction of angiogenesis, such as retinopathy of prematurity. In the following section, these frequently used *in vivo* models will be discussed. A review of the major advantage and disadvantage of each of the *in vivo* models is presented in **Table 2**.

Angiogenesis Windows

There are several types of angiogenic windows such as the cranial window, dorsal skin fold chamber, rabbit ear chambers and the hamster cheek pouch window. The cranial window and dorsal skin fold chamber assays will be the focus of the current discussion. A cranial window is accomplished by drilling a hole on the apex of the skull in an anaesthetized animal, allowing access to the subdural space for placement of the proangiogenic materials, such as a tumour xenograft. A protective closure is applied that allows intravital microscopy for real time observation of outcome (Dellian *et al*., 1996). Quantification of angiogenesis in window assays requires the placement of the anaesthetized animal under a stereomicroscope and images taken for analysis. Many quantitation approaches are used after the initial image analysis including point counting and vascular area.

The paracrine antiangiogenic effects of a prostatic tumour xenograft was observed using the angiogenic window assay in an example of the use of this model. In this variation of the assay, a gel enriched with a proangiogenic molecule(s) such as bFGF was embedded between two pieces of nylon mesh, and implanted inside the cranial window (Sckell *et al*., 1998). The nylon mesh facilitated quantification of blood vessel growth as it provided a grid with which to count newly formed vessels. Tumour tissue was then implanted into the flank of severe combined immunodeficient (SCID) mice and the angiogenic response at the cranial window observed. In this study, the authors demonstrated that the initial implanted tumour volume correlated positively with the inhibition of angiogenesis at the cranial window. These data suggest that the tumour cells in the flank of the mice secreted antiangiogenic factors that suppressed angiogenesis at the cranial window. It is advantageous that *in vivo* quantification of angiogenesis and tumour size can occur concurrently, and that these two biological endpoints can be evaluated at a site other than the primary tumour (Sckell *et al*., 1998).

The dorsal skinfold chamber assay is similar to the cranial window except that Teflon S-treated aluminium frames with spacers between the frames are used to create the angiogenic window. The window-containing frame is used to push out a double layer of skin. A circular area of skin is excised from the upper layer of skin to make the window while the lower layer of subcutaneous tissue remains intact. The remaining frame of the chamber is inserted on the upper layer of skin to complete the window. Catheters are surgically implanted into the external jugular vein of the animal to allow blood flow velocity studies in the conscious animal (Endrich *et al*., 1980). A glioma model of neovascularization required the implantation of a rat glioma cell line on the lower layer of skin of the dorsal skinfold. A fluorescent neuronal tracer was used to differentiate tumour cells from the alternatively stained vasculature such that both tumour and blood vessels could be quantified.

Intravital microscopy (**Figure 1**) makes the real-time quantification of angiogenic window assays possible. Fluorescein isothiocyanate (FITC)–dextran stain of the blood vessels provides contrast against surrounding tissue allowing digitized video imaging analysis of blood vessel length and density (Endrich *et al*., 1980). Quantitation of angiogenesis in this assay is non-invasive and may occur at multiple time points during the life of the animal rather than only post mortem. More recently, multiple microhemodynanic parameters have been quantified such as blood flow velocities, perfusion, patency, microvessel length and diameter and vascular permeability. In addition, serial quantification for up to 4 weeks has been shown to be possible (Sckell *et al*., 1998). Both blood vessel growth and the functionality of the neovessels can be investigated through intravital microscopy of the angiogenic windows.

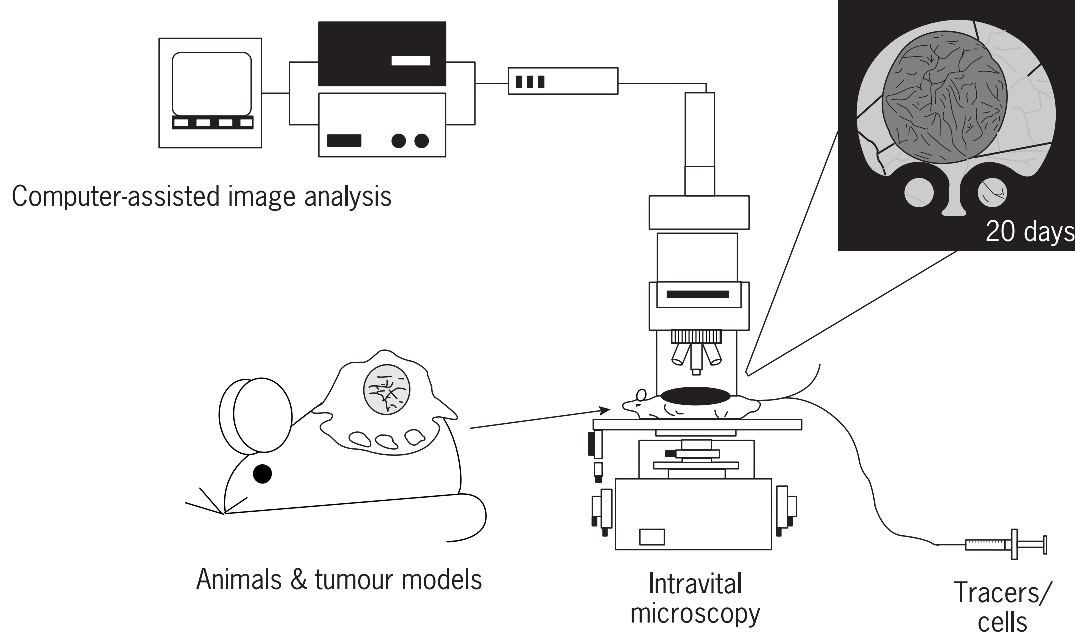

Figure 1 Diagram of the use of angiogenesis windows for intravital microscopy. In this example, an animal with a dorsal fold angiogenic window is anaesthetized and placed under a stereomicroscope connected to video imaging equipment. Insertion of a catheter and administration of stains or tracers allows distinction of the vasculature from other cell types. Using this method, real-time quantification of angiogenesis assays is possible. (Adapted from Jain *et al.*, 1998.)

Hence these assays are particularly powerful *in vivo* angiogenesis models.

Exteriorized Tissue Models

Intradermal Assay

This is a method of innoculating tumour cells intradermally to quantify tumour-induced angiogenesis. Animal skin first has to be separated from its underlying fascia. A triangular skin flap is created in anaesthetized mice by making a skin incision along the midline of the abdomen and extending it to the groin. A defined number of tumour cells or a pellet containing the candidate angiogenic agent is then injected intradermally. At certain time points, the skin flap is everted to measure the angiogenic response, and then replaced. Angiogenesis can be monitored every 2 days for a period of 2 weeks (Runkel *et al.*, 1991). The major concern for this assay is the trauma caused by periodic disruption of the flap. Also, it is difficult to identify all the newly formed blood vessels.

Chick Chorioallantoic Membrane Assay

The chick chorioallantoic membrane (CAM) assay allows the investigation of neovascularization in a developmental setting. This assay lends itself well to the study of pro-angiogenic or inhibitory macromolecules. Three days postfertilization, a window is placed in the shell or the egg contents are removed to a petri dish. Primitive blood vessels developed by day 3 in the extraembryonic membrane are now part of the chorioallantois and can be either stimulated or blocked experimentally. There are three distinct phases of development in the CAM assay. Days 5–7 are characterized by capillary sprouting, days 8–12 by the formation of intercapillary posts that grow to new capillary mesh formations and during days 13 and 14 blood vessels have begun to mature. Final maturation of this *de novo* CAM angiogenesis occurs by about day 17. Test compounds can be applied in methylcellulose discs or filter-paper or dried on a plastic cover-slips and placed on the CAM. Alternatively, inert synthetic polymers allowing sustained release of molecules may be used. Windowed eggs are then sealed or externalized contents moved to an incubator. CAMs are observed for changes in angiogenic development. Tumour cells can be used as angiogenic stimulants for studying the effects on the angiogenic response. An example of angiogenesis inhibition is shown in **Figure 2; see colour plate section**.

A recent advance of the CAM assay has involved the use of a collagen gel on the CAM into which capillaries are induced to grow vertically, thus allowing discrimination of induced capillaries from existing CAM vessels. In one system, a suspension of stimulant or growth factor such as bFGF- and sucralfate-enriched

type I collagen was placed over a mesh that is implanted on day 2 about 2–3 mm away from primary blood vessels in the CAM. A second, smaller layer of mesh is then added to the gel. On days 3–9 the number of squares in the upper grid that contain blood vessels is determined and then expressed as a percentage of the total number of grid squares. Inhibitors of stimulant-induced angiogenesis may be tested by incorporation into the upper layer of mesh, above the collagen gel. Tumour cells in suspension can also be added to the upper mesh to determine the capacity of these tumour cell lines to induce angiogenesis. This preparation is ideal for testing antiangiogenic agents. One advantage of this modification to the CAM assay is that quantitation is rapid. Up to 60 embryos may be quantitated per hour. In addition, the use of image analysis or photography, dyes or histological sectioning is not necessary for quantification (Nguyen *et al*., 1994).

When evaluating neovascularization of the CAM assay, one must be aware of several factors that may effect the angiogenesis. For example, a nonspecific inflammatory response may be induced during preparation of the CAM which results in false positives (Nguyen *et al*., 1994). The incubation environment must be tightly controlled because of environmental factors such as local hypoxia or hypoglycaemia that effect capillary formation (Cockerill *et al*., 1995). Discerning true neovascularization from changes in vascular density or blood vessel rearrangement may be difficult. Interpretation of the results may be dependent on what day(s) of development is used for the assay as a change in pattern of growth may be misinterpreted as an experimental result when it may be physiological. Lastly, some carrier molecules have been reported to induce their own angiogenic response. Despite these apparent disadvantages, the CAM assay is a frequently used *in vivo* angiogenesis model because of its several advantages such as the ability to quantify angiogenesis, the lack of rejection of implanted discs, sponges or cells because of the underdevelopment of the chick immune system and the ability to use the test materials for immunohistochemistry, electron and light microscopy.

Models of Induction on Normally Avascular Tissues

The classical assay of this category is the rabbit corneal micropocket assay, introduced in 1974 (Gimbrone *et al*., 1974). Because the cornea is an avascular tissue, it provides a natural site for continuously monitoring new blood vessel formation. Mouse and rat corneas were later also used for angiogenesis studies. The corneal bioassay requires implantation of tumour cells or angiogenic factors in the cornea. A surgical pocket is made into which the angiogenic factor, tissue to be tested or control is placed. Most commonly, an inert material pocket is implanted. The two most often used polymers are poly (2-hydroxylethyl methacrylate) (Hydron) and ethylene–vinyl acetate copolymer (Elvax). The polymer pellet will release its agent slowly without causing inflammation. Angiogenesis is allowed to proceed for 5–7 days after implantation, during which time animals can be studied by lamp examination or killed for histological examination (**Figure 3; see colour plate section**). A positive response is recorded if ingrowth of capillary loops or sprouts is detected. The vessel length and number can be determined when the vessel development is in its early stages. However, it becomes more difficult to quantify as the vessels grow more three-dimensionally with time. Some researchers have used the methods of perfusing the cornea with colloidal carbon and computer-assisted imaging to quantify vascular length.

This model has been used to test the hypothesis that tumours are angiogenesis dependent. Gimbrone and co-workers demonstrated that when tumour spheroids were free floating in the anterior chamber of the eye, they remained dormant (Gimbrone *et al*., 1974). When tumour spheroids contacted the iris, they became vascularized and grew as a three-dimensional tumour mass. These authors further demonstrated that the tumour-induced angiogenesis required the production of angiogenic factors using the rabbit corneal model.

Because the cornea is avascular, any vessels that penetrate into the corneal stroma can be easily identified as induced vessels. The advantage of using the cornea as a model is that both qualitative and quantitative analysis can be performed and the results are reliable, reproducible and interpretable. Using this model, one can also compare the effects of different angiogenic factors in the same animal. The two major disadvantages of using animal corneal models are that they are expensive and good surgical technique is required. Although it is cheaper to use rats or mice than rabbits, the surgery is more difficult. Because the rat or mouse cornea is thinner than that of the rabbit, it is more difficult to study three-dimensional growth of vessels in the former.

Matrix Implants

Matrix implants consisting of biocompatible polymers have become a popular method to study angiogenesis. These implants are porous and initially do not contain blood vessels. The materials used to make these implants include polyesters, polyurethane, poly(vinyl) alcohols (Ivalon), gelatin (Gelfoam), Matrigel and collagen. After the matrix implants have been placed subcutaneously into the animals for a period of time, neovascularization can be accessed by vascular filtration into the implant (histologically), by vascular density (morphologically) or by haemoglobin or DNA contents (biochemically). The most commonly used implant models are the cannulated sponge, the disc angiogenesis system (DAS) and the Matrigel plug.

Cannulated Sponge Model

Andrade and colleagues were the first to use the cannulated sponge implants (Andrade *et al*., 1987). The sponge model resembles the corneal model in the ability to introduce modulators of angiogenesis. The cannulated sponge model uses a ^{133}Xe clearance technique to quantify blood flow through the implanted sponges over time. The loss of ^{133}Xe from the sponge occurs as a result of neovascularization and outflow of ^{133}Xe from the source. This model has been used to demonstrate that inflammatory polypeptides, such as substance P and bradykinin, could induce neovascularization. Their neovascular response was inhibited by antagonists targeted to the particular receptor subtypes. When tumour cells were put into the sponge implants, nitric oxide (NO) synthesis increased. The increase in NO synthesis is related to neovascularization in the sponge and is important in maintaining tumour blood flow. There are several advantages of using the cannulated sponge model. It can be used to measure blood flow repetitively and sequentially over time (2–3 weeks), because the injected ^{133}Xe is quickly cleared out of the implant within 2 h. Cytokines, growth factors and inflammatory agents can be retrieved from the sponges, thus facilitating the elucidation of the roles of these agents in angiogenesis. The differences of granulation neovasculature and tumour neovasculature may be studied in detail, because either cytokines or tumour cells can be incorporated into the sponges. The model allows the testing of compounds administered locally into the sponges or systemically. The major disadvantage of using this model system is that, unlike the corneal micropocket assay, gross inspection of sponge neovacularization is not possible. Supporting histological evidence of neovascularization in the sponge is required.

Disc Angiogenesis System

The DAS was first developed by Fajardo and co-workers after their initial observation of vascular growth in subcutaneous implanted sponges (Fajardo *et al*., 1988). The implanted sponge is covered with cell-impermeable filters (45 μm) leaving only the sandwiched sponge available for cell penetration. Test agents are incorporated into the sponge in a slow release polymer through a hole in the sponge. A 7–21-day incubation is used for a 13-mm implanted disc. Cell proliferation can be determined by [^{3}H]thymidine incorporation into the disc using intraperitoneal injection prior to killing the animal. The disc system has been modified to allow the introduction of viable cells. Tumour cells or inflammatory cells can be put into the central hole of the disc at various times after implantation. Cytokine stimulation of vascularization was demonstrated in this model system. Epidermal growth factor (EGF), bFGF and prostaglandin E1 were shown to stimulate endothelial cell proliferation and increase microvessel formation. The major advantage of the DAS is that multiple discs can be used for different time and dose points, which allows reproducible measurements of vascular growth and increases statistical accuracy. The disc system also allows the independent measurement of proliferation and migration of endothelial cells and fibroblasts. The DAS is relatively inexpensive and angiogenesis can be easily quantified using histological, autoradiographic and morphometric methods of analysis. Its disadvantage is that the kinetic process of angiogenesis is difficult to determine using this model system. The DAS is more restricted to evaluate responses at a defined time point.

Matrigel Plug Assay

Matrigel is a crude basement membrane extract containing multiple extracellular matrix proteins and growth factors such as laminin, type IV collagen, fibronectin, entactin, TGFβ, bFGF, EGF and platelet-derived growth factor (PDGF). Liquid Matrigel is injected into the animal at a subcutaneous location or into the mammary fat pad, where it solidifies at physiological temperature. Putative angio-stimulatory or angio-inhibitory molecules may be added to the Matrigel, or tumour cells can be injected concomitantly with the Matrigel mixture. It has been shown that Matrigel alone is unable to induce vascularization although the presence of inflammatory cells may be detected in the Matrigel. Matrigel injected with acidic fibroblast growth factor (aFGF) or basic fibroblast growth factor (bFGF) results in an intense stimulated vascularization, optimized by the addition of heparin. Heparin binds the FGFs to present a more favourable conformation to the FGF receptor (Passaniti *et al*., 1992). The progression of neovascularization of the Matrigel plug initiates with endothelial cells invasion into the Matrigel by 24 h. The first evidence of neovascularization occurs by 48 h with capillary-sized vessels detectible by 72 h. Blood vessels continue to grow until day 3–4, after which there is a plateau, and vessels are maintained until the eighth day (Passaniti *et al*., 1992). Excision of the Matrigel plug from the animal allows for histological analyses, immunohistochemical staining and quantitation of results. The presence of endothelial cells can be confirmed by indirect immunofluorescence or immunostaining for von Willebrand factor, CD31 or other angiogenesis markers. Trichrome–Masson stain will stain haemoglobin, confirming blood flow into the newly formed vessels. Quantification of the vascular tubes that have invaded into the Matrigel plug can be accomplished with digitized image analysis of immuno- or Trichrome–Masson-stained tissue. Advantages of this method include the efficiency and reproducibility of the assay and the ability to quantify the blood vessel growth. Implantation and excision of Matrigel is simple, and both angio-stimulatory and angio-inhibitory agents may be tested (Passaniti *et al*., 1992). This model is also an important tool to investigate the vascularization

induced by weakly tumorigenic cell lines. It has been found that concomitant injection of tumour cells and Matrigel augments angiogenesis and may also increase metastatic potential.

Physiopathological Induction of Angiogenesis

Vascularization of the superficial and deep layers of the retina is tightly controlled by oxygen tension and cytokine levels in the local microenvironment. When neuronal metabolism increases in these areas, local hypoxia results stimulating astrocytes on the inner surface of the retina or Müller cells in the deep layer of the retina to secrete vascular endothelial growth factor (VEGF). Capillaries that originate from the optic disc are then induced to grow and eventually branch out to cover the inner surface of the retina to form the superficial layer. The deep layer of retinal vessels is formed from expansion of nearby superficial layer blood vessels. Improved oxygen tension due to new blood vessel flow secondarily downregulates VEGF production and halts new blood vessel formation (Stone *et al.*, 1995). Retinopathy of prematurity (ROP) occurs in premature infants who have required high concentrations of oxygen due to premature lungs. This hyperoxia often leads to blindness. In the first stage of ocular injury, excessive oxygen in the environment causes endothelial cell apoptosis in the retina. This loss of retinal vasculature results in retinal ischaemia when the high administered oxygen concentration is later reduced. The lowered oxygen tension creates a relative hypoxia, even though the administered oxygen may still be supraphysiological. This hypoxia induces the formation of new blood vessels which are frequently abnormal and leaky, causing retinal detachment and, ultimately, blindness (Alon *et al.*, 1995). Consistent with the importance of VEGF in physiological retinal vascularization, it has recently been demonstrated that VEGF expression is downregulated during hyperoxia and increases during relative hypoxia that occurs during return to normal ambient oxygen tension. VEGF increases where new blood vessels begin to form and attenuates when the capillaries are complete. Studies are ongoing to determine the involvement of other growth factors.

Several animal models of ROP including mouse, rat and rabbit have been established to understand better oxygen regulation of angiogenesis. In animal models of hypoxia-induced angiogenesis, postnatal day-5 animals are exposed to hyperbaric oxygen for several days and then removed to room air, stimulating a relative hypoxia. The blood vessel patterns and integrity and growth factor production in the retina are studied (Alon *et al.*, 1995). (See chapter on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*.) Retinal vascularization has also been studied using transgenic mice expressing growth factors or hormone antagonist genes or using implantation of bFGF-impregnated microspheres in rabbit eyes. Recently, it was determined that excessive CO_2 also can stimulate neovascularization of the retina, but the mechanism of this stimulation is unknown. Human retina specimens of ROP or diabetic retinopathy patients have also been studied. These models are important to oncology because the physiology may parallel that of tumour-induced neovascularization. Both oxygen and recently VEGF have been shown to play a role in retinal and tumour-induced neovascularization. In addition, blood vessels in the retina that are produced under the conditions of normal oxygen concentrations preceded by excessive oxygen are often leaky and abnormal like tumour-induced vessels. Limitations of this model are similar to other *in vivo* angiogenic assays such as the fact that only one time point can be used for each set of retinas.

IN VITRO MODELS

In vitro models of angiogenesis offer several advantages over *in vivo* models including the ability to control experimental conditions such as the presence or absence of angiogenic inducers, the ease of observing angiogenic events, the possibility of dissecting out component parts and the lower cost. Disadvantages of the *in vitro* model systems include the variety and overlap of the reagents used such as endothelial cell type and passage number, extracellular matrix, growth media and supplements and the possibility that the results obtained in an *in vitro* setting may not hold true *in vivo* (see chapter on *Basic Tissue Culture in Cancer Research*). Thus, data gathered using *in vitro* models will need to be confirmed in an *in vivo* setting. Differences in the type and source of primary endothelial cell lines may play the major role in the variability of *in vitro* models. Factors that affect endothelial cell behaviour in a given set of culture conditions include species of origin, organ of origin, age of the organism, macrovascular versus microvascular endothelial cells and arterial versus venous endothelial cells, among others. A standardization of *in vitro* models is recommended. The following is a brief review of some of the classical and more common *in vitro* models in use today. A review of the major advantages and disadvantages of each of the *in vitro* models is presented in **Table 2**.

Tubulogenesis in Culture

The spontaneous tubulogenesis model was the first model of angiogenesis to use primary culture endothelial cells to form vasculature structures *in vitro* (Folkman *et al.*, 1979). Folkman and colleagues observed that human umbilical vein endothelial cells (HUVECs) remain as a confluent monolayer on plastic in culture. If so maintained for a prolonged period of time (10–14 days) with associated

depletion of media nutrients, capillary-like structures form spontaneously. During this process, the majority of the endothelial cells die as the nutrient-rich medium is depleted. However, a small subpopulation of endothelial cells differentiate and form quiescent tubules loosely attached to the culture flask (Cockerill *et al.*, 1995). The pertinent stimulating factor(s) in that setting has not been identified. This initial *in vitro* tubulogenesis model may be cumbersome for use in the dissection of vasculogenesis but the recognition of its inherent value led to the development of the newer easier models.

The placement of endothelial cells on a biologically relevant substrate invites tubule-promoting interactions. Several models have been developed which do this. Kubota and co-workers first demonstrated the endothelial cell-differentiating effect of Matrigel (see Baatout, 1997, for a review) after observing that endothelial cells plated on the matrix formed tubule-like structures after 16–24 h in culture (Kubota *et al.*, 1988). **Figure 4** shows a typical progression of events during human umbilical vein endothelial cell differentiation on Matrigel. Within 1 h, endothelial cells have migrated toward each other and begun to align into a reticular network. Cellular morphology changes after 2 h, after which the cells have started to flatten and elongate. The cells have formed a network of structures on the surface of the substratum after 11–16 h. Kubota and colleagues demonstrated these structures contain lumens as visualized by electron microscopy (Kubota *et al.*, 1988). The lumens are each formed by one to two endothelial cells and contain various amounts of cytoplasm, suggesting that the process of tube formation is a result of rapid cellular remodelling. The differentiated endothelial cells still retain endothelial cell markers such as Weibel–Palade bodies and secrete von Willebrand factor, take up dioctadecyltetraethylindocarbocyanine perchlorate acetylated low-density lipoprotein (di-I-LDL), and release prostacyclin (PGI_2) upon stimulation with bradykinin. The cytoskeleton can be seen to have reorganized into bundles of actin filaments oriented along the axis of the tubes. The addition of transcriptional inhibitors prevents tube formation on Matrigel, indicating that gene transcription is required for tubulogenesis. The addition of cycloheximide was found to inhibit tube formation, indicating that protein synthesis also is important in this process. It has been shown also that pertussus toxin blocks differentiation of endothelial cells on Matrigel, suggesting that the process requires receptor-linked heterotrimeric G protein signalling. Activation of protein kinase C (PKC) may also be required in this model.

Since the majority of the capillary-like structures form on top of the gel, quantitation of the structures may be relatively easy, especially with the advent of imaging technology with computer-assisted analysis. Because of the relative lack of invasion of the cells into the substratum, the Matrigel model of angiogenesis may depict events that occur at later stages of angiogenesis *in vivo* and as such represents a differentiation model rather than a proliferation or invasion model. A further benefit of this model is that the majority of the cells plated on Matrigel are stimulated to differentiate so the cellular response is much more uniform than with other *in vitro* models. A disadvantage of this model is that Matrigel can be subject to variability between batches that yields differences in endothelial cell assay results.

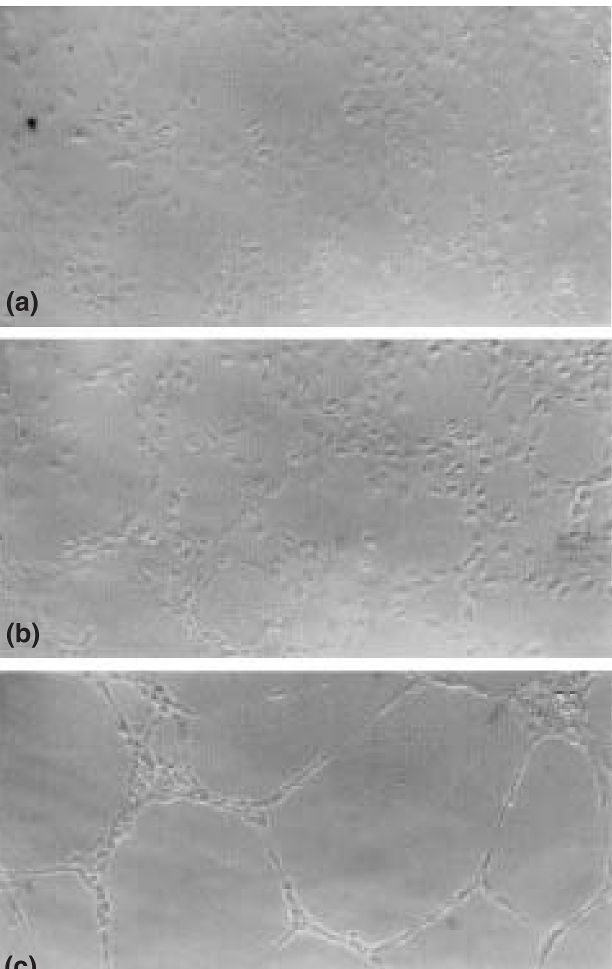

Figure 4 The formation of HUVEC tubules on Matrigel is time dependent. HUVEC cells plated on Matrigel have begun to align after 1 h of culture (a). By 2 h, the HUVECs have begun to flatten and elongate (b). A strong network of tubules is present by 12 h (c).

Tube formation also can occur when endothelial cells are plated on type I collagen gels. The process is completed within 24 h and requires both transcription and translation (Montesano and Orci, 1985). Endothelial cells are seeded on to a thick gel of type I collagen requiring the presence of phorbol myristate acetate (PMA). This induces the cells to invade into the matrix, mimicking the early events seen during angiogenesis *in vivo*. Some cells remain as a monolayer on the surface of the gel and others form

capillary-like structures throughout the gel making quantitation of these structures more difficult. Endothelial cells plated on type I collagen in the absence of PMA proliferate and form a confluent monolayer, but do not differentiate. The requirement for PMA induction of tubulogenesis implies that PKC is involved in this process. Recent evidence suggests that MAP kinase and phosphoinositide 3′-kinase, two parallel signalling pathways, are also involved in tubulogenesis in this model.

A similar model uses a fibrin substrate, a matrix also associated with the extracellular matrix compartment. Endothelial cells are seeded on to a thick fibrin gel in the presence of PMA and fibrinolytic inhibitors, since the presence of PMA alone induces the cells to lyse the fibrin matrix (Montesano *et al*., 1987). Under these conditions, endothelial cells invade the fibrin matrix and form tubules within 3–4 days, again beneath a confluent monolayer. A similar role for PKC is suggested in the process as endothelial cells cultured on fibrin in the absence of PMA fail to invade the gel and proliferate on the surface, eventually to form the confluent monolayer. Not all cells are induced to invade and differentiate and the quantification of those that do is difficult owing to invasion of the gel and its depth.

Nicosia and Ottinetti (1990) showed that 1-mm circumferential sections of rat aorta embedded into a matrix such as collagen, fibrin or Matrigel yields radial outgrowth of microvessel-like structures. This process can be monitored by phase microscopy or by an image analysis-based approach. Vessel outgrowth increases for approximately 10 days and then attenuates. This model contains all three parts of the angiogenic process–invasion, proliferation and differentiation. However, since the aortic ring is most often embedded in a matrix, this model is best suited to investigate the effects of agents on invasion. Some drawbacks of this model include variability of microvessel formation depending on the section of aorta from which the ring was cut and differences in microvessel formation in areas of the ring itself. It is not clear which cells outgrow to form the tubules, the vasa vasorum microvascular endothelial cells or the aortic endothelium.

Co-culture Models

In vitro models have been developed to determine the influence of the local cellular microenvironment on tubule formation since angiogenesis *in vivo* cannot occur in isolation of other cells. Astroglial cells have been shown to induce tubule formation of brain capillary endothelial cells (Laterra *et al*., 1990), thus providing a way to study the development of neural microvessels. Endothelial cells are introduced 24 h after the seeding of C6 astroglial cells on to fibronectin-coated wells. Formation of capillary-like structures occurs within 24 h of co-culture and requires both transcription and translation. This induction of angiogenesis required direct cell–cell contact as no differentiation occurred when the two cell types were separated into adjacent chambers where they were not allowed to touch, but were bathed in the same growth medium. Other co-culture cells have been used successfully in this paradigm to induce endothelial cells to form capillary-like structures without the requirement for direct cell–cell contact including oesophageal tumour cells, keratinocytes and fibroblasts. The oesophageal tumour cell and keratinocyte studies identified TGF-α as an important angiogenic stimulator acting through a paracrine pathway.

Immortalized Endothelial Lines

Some investigators use immortalized endothelial cell lines for *in vitro* work to circumvent the limitations of primary endothelial cell culture. These limitations include a defined life span, strict culture requirements and the presence of functional and structural endothelial cell heterogeneity between and within species and organ sources. Differences in endothelial cells within species occur according to the vessel subtype and organ location. Clonal cell lines offer the advantage of uniformity and reproducibility of cultures, suitability for large-scale experiments and the ability to use recombinant DNA techniques including stable transfections. A major disadvantage of using immortalized endothelial cells is the fact that they may lose characteristics associated with primary culture endothelial cells and therefore may not behave as true endothelial cells would in a given condition.

The EA hy926 cell line is a hybrid line formed from a HUVEC primary culture fused with the A549/8 human lung carcinoma cell line (Edgell *et al*., 1983). This clonal cell line expresses a wide range of differentiated endothelial cell properties including expression of von Willebrand factor protein, Weibel–Palade bodies, prostacyclin production, tissue plasminogen activator and plasminogen activator inhibitor type 1 secretion and uptake of di-I-LDL. Bauer and colleagues in 1992 used the EA hy926 line in the *in vitro* Matrigel model demonstrating that cells underwent differentiation and formed tube-like structures over the course of 16 h in culture. They showed that the tube-like structures contained lumens.

The ECV304 cell line was established by the spontaneous transformation of a HUVEC subline (Takashaki *et al*., 1990). It is characterized by a high proliferative potential without specific growth factor requirements but still retains anchorage dependence with contact inhibition. The original ECV304 cells express endothelial-specific Weibel–Palade bodies and also antigens recognized by human anti-endothelium antibodies including PHM5 and HAM56. The cells do not express several endothelial-specific proteins including von Willebrand factor, CD-31 and CD-34, nor do they efficiently uptake di-I-LDL. When seeded on Matrigel, ECV304 cells undergo differentiation and organize rapidly into an extensive network of tube-like structures within the

course of 1 h. These structures were shown by electron microscopy to contain patent lumens. In mid-1999, an alert was broadcast by the American Type Culture Collection (Rockville, MD, USA) indicating that cells available from at least one ECV304 source were actually the T24/EJ human transitional cell bladder cancer line and that ECV304 should be considered a variant of this line derived by cross-contamination. Users of ECV304 should validate their clone before proceeding.

The HMEC-1 cell line is an immortalized human dermal microvasculature endothelial cell (HMEC) derivative that was established by transfection with a plasmid containing the simian virus 40 large T antigen (Ades *et al*., 1992). The cells are able to proliferate in the absence of serum and still retain anchorage dependence with contact inhibition. HMEC-1 cells retain endothelial cell characteristics including von Willebrand factor expression, uptake of di-I-LDL, CD-31 expression and expression of CD-36, a microvasculature-specific marker. HMEC-1 cells differentiate on Matrigel and form a well-developed network of tube-like structures after 18 h.

UTILIZING ANGIOGENESIS MODELS TO STUDY SIGNALLING EVENTS RELATED TO ANGIOGENESIS

Angiogenesis is not regulated solely by peptide growth factors. Extracellular matrix components such as collagen and adhesion molecules also regulate angiogenesis (Bischoff, 1995). It is therefore logical to use models of angiogenesis to incorporate these different and important signals. The main focus of this section is to show an example how these models were used to study signalling pathways that are related to VEGF-induced angiogenesis.

VEGF is a 46-kDa homodimeric protein that was found to bind to endothelial cells. It stimulates endothelial proliferation and migration and regulates vascular permeability. Hypoxia is known to induce VEGF production and hence it is regarded as an important physical regulator of the endothelium. VEGF binds with high affinity to two receptor tyrosine kinases, the Flt-1 (fms-like tyrosine kinase) and Flk-1/KDR (kinase insert domain-containing receptor). Both Flt-1 and KDR contain intracellular kinase domains and seven immunoglobulin-like domains in their extracellular N-terminal regions. Both receptors are expressed predominantly but not exclusively on endothelial cells.

Friedlander and co-workers used the CAM model to demonstrate that PKC is downstream of the VEGF signalling pathway (Friedlander *et al*., 1995). The PKC inhibitor calphostin C blocked angiogenesis induced by VEGF, PMA and TGFα in the CAM system. Using both the corneal micropocket assay and CAM models, they further demonstrated that *in vivo* angiogenesis initiated by growth factors is influenced also by different types of integrins (Friedlander *et al*., 1995). VEGF-induced rabbit corneal angiogenesis is inhibited by an antibody against $\alpha_v\beta_5$ but not against $\alpha_v\beta_3$ integrins. In contrast, bFGF-induced angiogenesis is inhibited by an antibody against $\alpha_v\beta_3$ in rabbit cornea. These data indicate that these two agonists stimulate *in vivo* angiogenesis in the same model system but through independent and parallel signalling pathways. Their results also argue that adhesion-mediated signals are important in growth of new blood vessels. (See also chapters on *Models for Tumour Cell Adhesion and Invasion*; *Models for Tumour Cell–Endothelial Cell Interactions*.)

Ziche and colleagues reported that the signal transduction pathway for VEGF-induced angiogenesis in the rabbit cornea model differed from that for bFGF-induced angiogenesis through studies of the nitric oxide (NO) system (Ziche *et al*., 1997). They administered an NO synthase inhibitor, N^{ω}-nitro-L-arginine methyl ester (L-NAME), through an implant sewn on the rabbit cornea, and found that inhibition of NO synthesis blocked VEGF-induced but not bFGF-induced corneal angiogenesis. Their studies support the evidence that VEGF and bFGF induce angiogenesis through different signalling pathways.

Hypoxia is known to induce angiogenesis as described above. Ozaki and co-workers used the ischaemic retina model to demonstrate that a hypoxic environment stimulates the production of hypoxia inducible factor-1α (HIF-1α) (Ozaki *et al*., 1999). HIF-1α is a transcription factor that plays an important role in regulation of hypoxia-responsive genes, such as VEGF. They found that the increased expression of HIF-1α in ischaemic retina is temporally and spatially correlated with the expression of VEGF, implying that the synthesis of HIF-1α is upstream of VEGF signalling pathway. The retina model has also been used to demonstrate that VEGF acts as a survival factor for newly formed retinal vessels. Alon *et al*. (1995) reported that hyperoxia induced regression of retinal capillaries by promoting apoptosis of endothelial cells and by downregulating basal production of VEGF. When eyes were injected with VEGF in the setting of experimental hyperoxia, VEGF prevented apoptotic death of endothelial cells and rescued the retinal vasculature. In summary, using angiogenesis models, researchers have begun to map out the pathway of VEGF signalling in endothelial cells. Without the flexibility that angiogenesis models afford, it is probable that little progress would have been made in understanding the process of angiogenesis.

CONCLUSION

The importance of angiogenesis cannot be underestimated because of the unequivocal requirement of tumours to induce neovascularization for cancer progression. The use of *in vitro* and *in vivo* angiogenesis models has helped researchers to understand this process better and has given

rise to the identification of new agents now in clinical trials as antiangiogenic therapies. These models hold promise for the discovery of new antiangiogenic compounds, to understand the molecular mechanisms by which angiogenesis occurs, to identify genes involved in these processes and, ultimately, to decrease the morbidity or mortality of cancer.

- Biological Basics
- Principles of Model Establishment
- General Applications
- Interpretation of Experimental Results
- Biological and Technical Limitations
- Perspectives

BIOLOGICAL BASICS

The prevention of death in most cancer patients is dependent upon understanding the mechanisms of cancer cell spread from the primary tumour to distant organ sites. Although the pathogenesis of metastasis is the subject of numerous studies in basic and clinical research, the complex mechanisms that make a tumour cell metastatic are not well understood. The development of metastases is a non-random process, where the implantation, invasion, survival and growth of a single cell or small numbers of cells can lead to morbidity and death (Nicolson, 1995).

The sequential model for the development of metastases involves tumour growth, neovascularization and invasion at the primary sites, followed by penetration into lymphatics and blood vessels or into body cavities. Malignant cells that loose cellular contacts with surrounding cells or extracellular matrix (ECM) can undergo phenotypic change to greater motility. Subsequently, malignant cells can be released from the primary tumour and be distributed throughout the body via the blood or lymphatic circulation. To survive the circulating tumour cells must adhere to the vessel walls of distant host organs, and eventually penetrate the wall to avoid blood shear forces and host defence mechanisms. Finally, the metastasizing cells have to survive and grow (Nicolson, 1988a,b) (**Figure 1** and see the chapters *Models for Tumour Cell–Endothelial Cell Interactions* and *Invasion and Metastasis*).

The localization of tumour metastases in distant organs is not determined solely by anatomical considerations and blood flow. During haematogenous metastasis tumour cells often show selective colonization of various organs independent of the percentage of microcirculation through the organ or whether the organ is first to be encountered by the blood-borne tumour cell (Nicolson, 1989). This multistep process is thought to be determined by the unique properties of the tumour cells and the host organs (Doerr *et al*., 1989; Fenyves *et al*., 1993). Adhesion of metastatic cells to and migration through the microvascular vessel walls of host organs are very important steps in colonization of distant organs (Nicolson, 1988a,b), and during these steps specific interactions between the tumour cells and endothelial cells, the ECM or surrounding cells are required. During adhesion cells can form temporary attachments to certain structures, e.g. during chemotactic cell movement, or they can establish more long-term adhesive interactions, resulting in the formation of structures such as desmosomes, adherens junctions, gap and tight junctions. Various tumour cell surface molecules mediate these interactions, either by direct interactions, such as integrins or other adhesion molecules, or as receptors for soluble peptides or hormones that modify cellular signalling and indirectly regulate cell adhesion. Usually the same molecules are also found on normal cells where they function in the maintenance of tissue structure and normal cellular regeneration. Maintenance of the proper expression of adhesion molecules is important in tissues (e.g. epithelial layers) for normal tissue morphology and function. Adhesive cell properties play an important role in determining the organisation of tissues, and they allow directed cell migrations found during embryonic development, inflammation, immune response and wound repair. Additionally, they participate in regulation of gene expression, cell growth and differentiation and programmed cell death (Virtanen *et al*., 1990).

Adhesion molecules can also be transmembrane proteins that can anchor cytoskeletal proteins on the cytoplasmic side of the cell membrane, such as actin and actin-binding

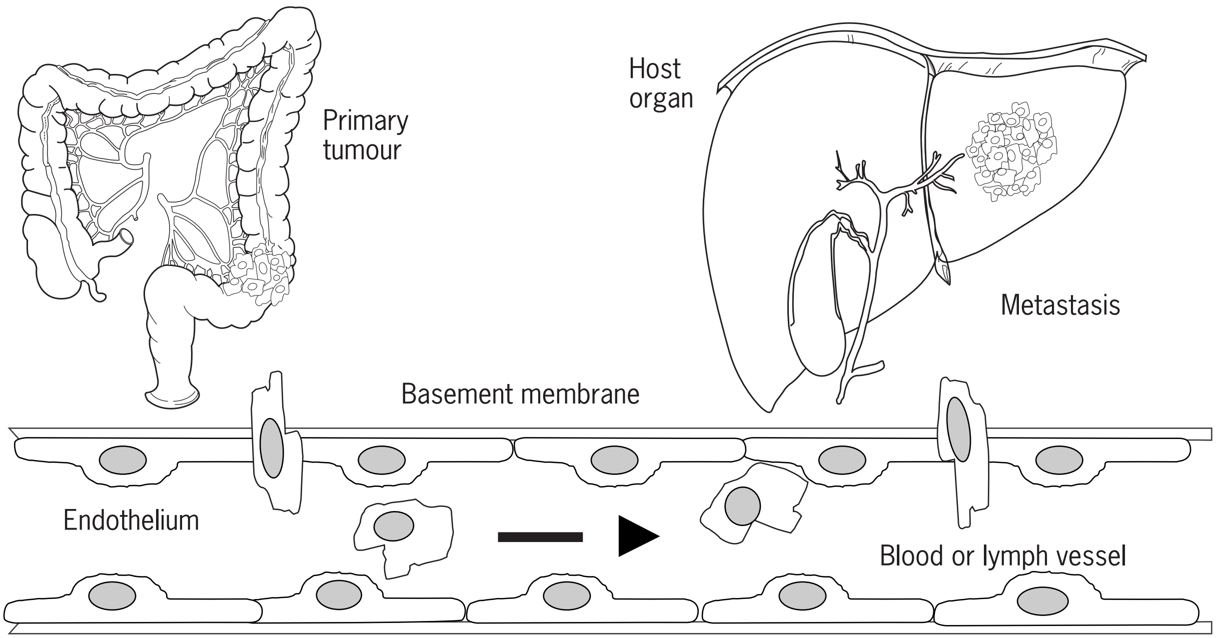

Figure 1 Sequence of events in the development of a distant cancer metastasis.

proteins, while also anchoring extracellular structures on the outer surface of the cell membrane. In addition to physical linkages between the extracellular environment (surrounding cells and ECM) and the cytoskeleton, adhesive complexes participate in important signal transduction systems as modulators or receptors. Their functions in cell signalling are probably at least as important as their cytoskeletal and cell attachment properties. An important feature of the intracellular protein complexes induced by the binding of adhesion molecules is the subsequent induction of various signal transduction molecules that can trigger further downstream signals into the cell. These signalling pathways can generate or influence gene expression, secretion of enzymes or cytokines and conformational changes of the cytoskeleton, among others. Understanding these regulatory functions appears to be of importance in determining how a transformed cell becomes invasive and metastatic. (See also chapters *Wnt Signal Transduction* and *Extracellular Matrix: the Networking Solution*.)

During neoplastic transformation, epithelial and other cells can undergo changes in differentiation status and can change their surface structures by differential expression of molecules at the cell surface or post-translational modifications, such as glycosylation. In addition, distinct organ basement membrane compositions have been found in many malignant tumours (Nicolson, 1995). Moreover, tumours, such as colon carcinomas, produce their own ECM components that can change peritumoral stroma organisation (Burtin *et al*., 1983), including the release of unusual ECM components. For example, oncofetal fibronectin can be produced by tumours and has been correlated with poor prognosis (Inufusa *et al*., 1995). Alternatively, some tumour cells fail to deposit ECM or express certain adhesion components, and subsequently their adhesive interactions are reduced compared to normal cells. Such structural alterations can involve various adhesive systems, resulting in modified or reduced cellular interactions with components in the cellular environment. For example, the loss of cell–cell and cell–ECM interactions promotes motility of tumour cells from the primary site. On the other hand, the establishment of new adhesive interactions is necessary for cell attachment to the endothelium and basement membrane in distant host organs during haematogenous metastasis formation.

Homotypic adhesion between tumour cells at the primary site, their heterotypic interactions with leucocytes and platelets during transport in the circulation and cellular binding with the endothelium and ECM in distant organs involve different cellular adhesion systems, including a broad spectrum of cell surface molecules representing different adhesion families (Nicolson, 1991). These tumour cell molecules can be classified into several main groups: (1) integrins, (2) selectins, (3) immunoglobulin-like, (4) cadherin molecules, and others, such as proteoglycans and glycoconjugates (lectin receptors) that are involved in adhesion processes. Microvascular endothelial cells (EC) and their underlying ECM are the main target structures of these adhesion molecules, and there appears to be some organ specificity in the adhesive interactions that occur (Rice *et al*., 1988; Belloni *et al*., 1992).

The detachment of tumour cells from the primary site is characterized by the loss of cell–cell adhesion, and in epithelial cells the dysfunction of the cadherin–catenin systems appears to play an essential role in this process. In poorly differentiated carcinomas, loss of epithelial cell

contacts is frequently observed, allowing the cells to break away from the primary tumour (Shiozaki *et al*., 1996). Cadherins are the major components of Ca^{2+}-dependent epithelial cell adhesion systems and are present in all epithelial cells, where they bind cells together through homophilic interactions. Members of the various subgroups of cadherins are expressed only in certain tissues; however, cells normally express several cadherin types. Catenins are the intracellular associate molecules of cadherins that provide the links to cytoskeletal components and signal transduction. Dysfunction of cadherin-mediated adhesion can be caused by loss or changes in function of any component of the complex. (See also chapters *Signalling by TGF beta* and *Wnt Signal Transduction*.)

Penetration from the primary tumour mass into the lymphatics or blood circulation requires the secretion and/or activation of degradative enzymes, some classes of which appear to be metalloproteases (MMP), cathepsins, plasminogen-activators and endoglycosidases, such as heparanase (Monsky and Chen, 1993). Under normal physiological conditions the balance between protein synthesis and degradation is well regulated by various activators and inhibitors. These control mechanisms ensure the controlled destruction and replacement of ECM at points where it is required for cell migration, immune response or wound repair (Shapiro, 1998). Degradative enzymes are usually secreted from most cell types into their extracellular environment as inactive proenzyme forms. There they can be bound to specific inhibitors, or they can be proteolytically activated by other proteases. The regulation of ECM or basement membrane degradation is organized into various cross-linked cascades to guarantee restricted activity at specific sites. Tumour cells themselves can produce various degradative enzymes, or they can induce or modify enzyme secretion by EC or stromal cells, such as fibroblasts, mast cells, and macrophages, through release of paracrine factors (Lengyel *et al*., 1995; Polette *et al*., 1997). In many tumours the expression of degradative enzymes and/or expression of their inhibitors were demonstrated to cause an imbalance of degradative activity, especially at the invasion front of malignant tumours (Liotta and Stetler-Stevenson, 1991; Conese and Blasi, 1995). This increased degradation induced by tumour cells results in higher motility and invasiveness and permits remodelling of the cellular environment within and around invasive tumours. (See also chapter *Modelling Tumour–Tissue Interactions*.)

Once tumour cells have reached the circulation or body cavities, they can be transported to near and distant organs where they must bind to host structures to establish distant metastases. The binding of circulating cells to EC and subsequently ECM occurs in discrete steps: initial cell contact, followed by adhesion stabilization and subsequent signal transduction, and finally degradation and cell migration (Nicolson, 1989; Pauli *et al*., 1990; Dorudi and Hart, 1993). Following the primary contact of malignant cells, microvascular EC are stimulated to retract with the subsequent exposure of basement membrane or subendothelial ECM (see the chapter *Models for Tumour Cell–Endothelial Cell Interactions*). Thus many tumour cells reach a relatively rigid ECM structure in blood vessel walls (Nicolson, 1995). In general, the subendothelial ECM has been found to be a better substrate for cell adhesion of tumour cells than the EC surface (Kramer *et al*., 1980; Nicolson *et al*., 1981). Additionally, the adhesive behaviour of tumour cells can be altered by the organ-specific composition of the subendothelial ECM. Moreover, in some metastatic systems differential adhesion of tumour cells to specific organ subendothelial ECM has been seen (Lichtner *et al*., 1989).

Various studies have demonstrated a correlation between the organ preference of metastasis and the *in vitro* adhesion rates of malignant cells to specific organ-derived EC (Tressler *et al*., 1989) or subendothelial ECM (Lichtner *et al*., 1989). For example, contacts between carcinoma cells and the microvascular endothelium seem to be related to the expression of selectins, sialyl-Lewis^x (sLe^x) and other carbohydrate structures, intercellular adhesion molecules (ICAM) and possibly annexins (Menger and Vollmer, 1996). However, integrin-mediated interactions with the subendothelial ECM could be among the most important determinants for organ-specific metastasis. Reflecting on this cell-specific behaviour, distinct adhesive properties of tumour cells with different metastatic potential to EC/ECM were found. In support of this in different cell systems it was demonstrated that adhesion of highly metastatic cell lines to organ EC or ECM occurred at higher rates than seen with comparable poorly metastatic cells (Tressler *et al*., 1989; Haier *et al*., 1999c).

Integrins mediate adhesion to various ECM components. Binding to their receptors and clustering of integrins at the cell surface appear to be the trigger that initiates signals that can induce interactions with cytoskeleton components. Integrins important in this process are the β_1- and β_3-integrins, which are linked to cytoskeletal proteins, such as actin, α-actinin and talin. These components are further connected to various other cytoskeleton proteins such as vinculin and zyxin. This signalling process is also linked to phosphorylation and dephosphorylation events, mainly on tyrosine residues, and this, in turn, may activate the intracellular signalling cascades (Akiyama *et al*., 1994). Different complexes may be involved in downstream signal transduction after the establishment of adhesive interactions, such as focal adhesion kinase (FAK)–paxillin or Grb2–SOS complexes (**Figure 2**). (See also chapter *Extracellular Matrix: the Networking Solution*.)

During the interactions between tumour cells and EC/ECM components, adhesion molecules function both for the primary contact, definitive adhesion stabilization and cell migration. Tumour cells adhere at the points of EC/ECM contacts by sequestering or clustering receptors at zones of adhesive interactions (e.g. focal adhesions). At this time adhesion has not yet been stabilized, and increasing the shear force under flow conditions breaks the adhesive

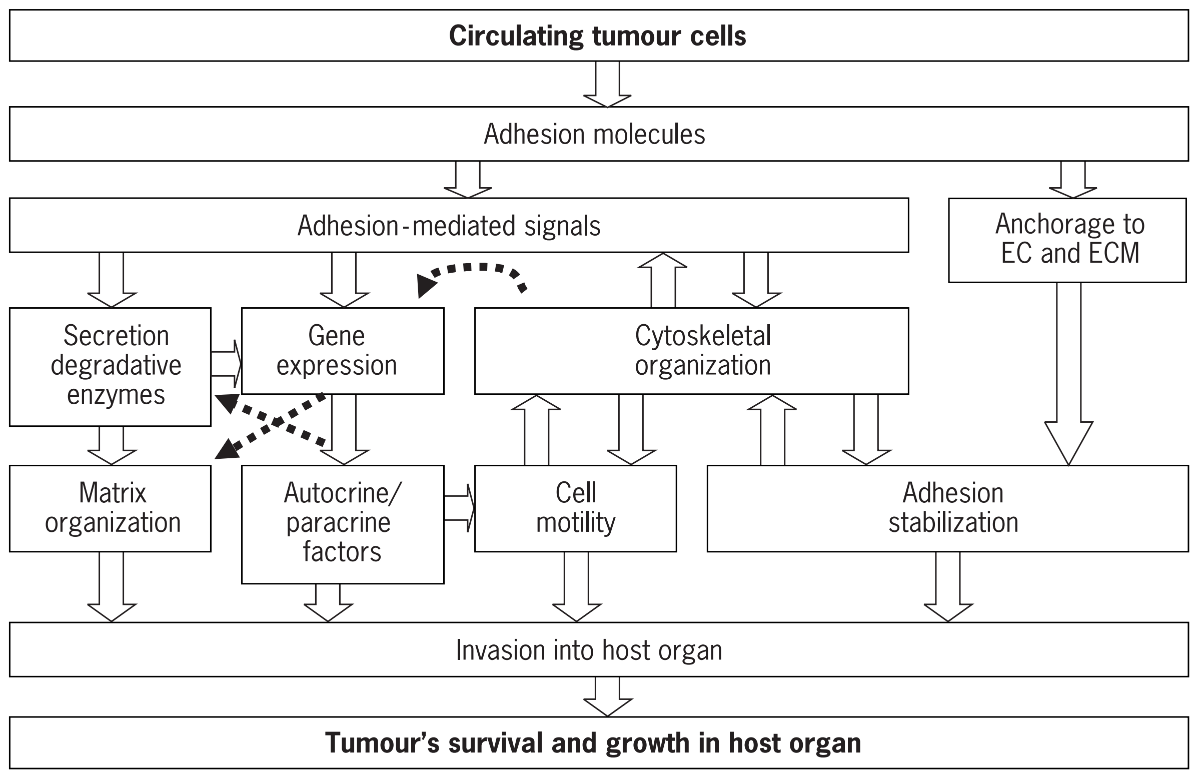

Figure 2 Role of adhesion molecules in metastasis formation at distant organ sites.

contacts and releases the tumour cells from the EC/ECM. However, if adhesion can be stabilized, tumour cells can resist such hydrodynamic shear forces (Nicolson, 1988a). The stabilization process appears to require receptor clustering and possible signalling before actual receptor cross-linking or changes in receptor affinity occur mediated by membrane-associated enzymes or signalling cascades. Following these initial adhesive interactions, the cells have to actively change their shape by spreading or flattening to increase contact areas and initiate cell migration through the vessel wall (Menter *et al.*, 1992, 1995). These processes might be accompanied and regulated by various transmembrane signal transduction events (Haier *et al.*, 1999a,b).

In contrast to static cell adhesion, biophysical factors influence adhesion processes under flow conditions (**Figure 3**). First, under dynamic conditions flow velocity determines the available time for adhesion. Since initial areas of cell contacts to the vessel wall are very small because of the more or less spherical shape of flowing tumour cells, the initial cell contacts may occur via cell protrusions or filopodia. Possible alterations in cell shape and the morphology of participating cells are important in determining the total area of cell–cell contact. Second, cell flattening enables adherent cells to avoid high shear forces within the centre of the parabolic curve of fluid flow. These factors and the character of the flow (laminar under physiological conditions of microcirculation) are responsible for the strength of shear forces acting against adhesion. Flow rate and viscosity are the main factors determining strength of cell shear stress. In addition to these biophysical factors on moving cells shear stress alone induces functional reactions of EC (Lawrence *et al.*, 1987) and possibly other cells. These cells release interleukins IL-1 and IL-6 depending on flow rates and/or changes in the phosphorylation status of proteins related to adhesion complexes.

During adhesion under flow conditions, tumour cells have two different patterns of reaction (Giavazzi *et al.*, 1993). Colon, ovary and breast cancer cells showed modest transient interactions with resting human umbilical cord vein endothelial cells (HUVEC) comparable to the behaviour of leucocytes, such as rolling on IL-1- or tumour necrosis factor-activated HUVEC. In contrast, melanoma and osteosarcoma cell lines bound to EC and demonstrated no rolling. Furthermore, differences in adhesive properties for different ECM components were noted. Initial tumour cell–ECM interactions under flow conditions appear to depend mainly on biophysical or mechanical factors, whereas specific interactions are required for further adhesion stabilization. For example, receptor cross-linking by transglutaminase was found to be an important determinant of adhesion stabilization in several cell systems (Menter *et al.*, 1992). Moreover, various parameters that describe cell adhesion stabilization under flow conditions correlated with the metastatic potential using various ECM components (Smith *et al.*, 1996).

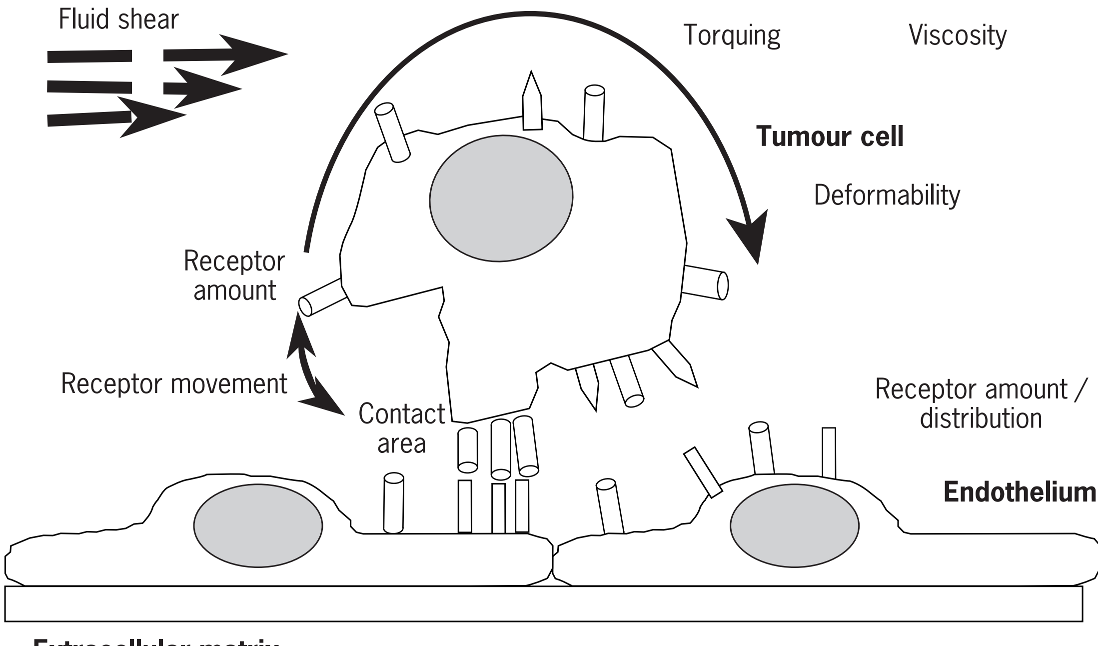

Figure 3 Factors influencing tumour cell adhesion under dynamic conditions of fluid flow. The numbers of receptors in a certain contact area determines the maximum possible number of adhesive interactions. Receptor movement and cellular deformability can affect adhesion stabilization. Fluid shear forces occur as parabolic phenomenon in the microcirculation, and flow velocity, fluid viscosity and resulting cell torque are counteracting forces that prevent cell adhesion.

Parallel to morphological alterations, tumour and host cells undergo functional responses to specific adhesive interactions. For example, they can release hydrolases and proteases, destroying the integrity of the vascular basement membrane (Marchetti *et al*., 1993). As described above, the composition of subendothelial basement membranes is organ-specific, where the main components are type IV collagen, laminin, FN and vitronectin. These matrix proteins are targeted for degradation mainly by different MMPs that have relative substrate specificity. The tumour cells or EC of the host organ can secrete MMPs, and these degradative enzymes are then activated by other membrane-bound proteases, or by inactivation of their inhibitors. Together with the induction of directed cell motility, the porous subendothelial membrane then allows tumour cells to penetrate the basement membrane by active locomotion, thereby leaving the circulation and invading the host organ.

Cancer cell spreading and motility are stimulated by specific chemical stimuli. Cellular motility consists of directed morphological alterations (such as ruffling and pseudopodia formation), establishment of new adhesive interactions at the moving cell front and controlled detachment at the rear of the cell. Complex cellular processes are required for the response to soluble motility factors (chemotaxis) or insoluble motility factors (haptotaxis) (Nicolson, 1989). Alternatively, tumour cells may produce their own autocrine motility factors (Menter *et al*., 1995). Cells that have the capacity to migrate actively towards a soluble chemoattractant must detect the direction of a chemical gradient through recognition of receptor occupancy and respond by orienting toward the gradient and initiating cytoskeletal activation and directed movement. The ability of tumour cells to respond to organ-specific or organ-associated chemoattractants may be an important determinant in the selective migration of malignant cells into specific tissues (Nicolson, 1988a).

A likely source of organ-associated tumour cell motility factors is organ microvascular EC. The EC-produced motility factors might interact with other soluble tissue factors to promote organ-specific tumour cell invasion (see the chapter *Models for Tumour Cell–Endothelial Cell Interactions*). Chemotactic factors are also present in ECM, and they can stimulate directed migration of malignant cells (Cerra and Nathanson, 1989). Indeed, tumour cell chemotaxis appears to be specifically influenced by the composition of the subendothelial basement membrane in the target organ (Aznavoorian *et al*., 1990).

Tumour cells can also synthesize and release their own motility and growth factors. The autocrine motility factor is an important example of such factors made by metastatic cells. This factor is secreted by a wide variety of tumour cells, and it stimulates chemotaxis in various cell systems (Liotta *et al*., 1986; Atnip *et al*., 1987; Siletti *et al*., 1991;

Watanabe *et al*., 1991). One of the interesting tumour cell properties associated with organ-specific metastasis is that tumour cells may respond to local concentrations of growth factors produced by or present in the target organs. In support of this it was shown for various tumour systems that tumour cells could preferentially grow in medium conditioned by the target organs for metastatic colonization. Although the production and secretion of autocrine growth factors was not found to be dependent on the metastatic potential, the general results indicate loss of paracrine growth requirements with tumour progression (Rodeck and Herlyn, 1991), and this often appears to be accompanied by the secretion of autocrine motility and growth factors. Both tendencies together can reduce the dependence of tumour cells from their host environment.

The establishment of suitable tumour cell models remains a challenging task. *In vitro* and *in vivo* models each have their advantages, limitations and specific conditions. For example, results using cells from different cell origins cannot be simply transferred to other cells, and findings obtained with one model must be confirmed for other systems.

PRINCIPLES OF MODEL ESTABLISHMENT

Cell Detachment

Adhesion molecules can be subdivided into two groups with regard to their requirements for calcium (Birchmeier *et al*., 1993). This characteristic allows a simple distinction between major groups of adhesion molecules by removal of calcium from the medium. If the involved adhesion system is calcium dependent, cells detach rapidly after trypsin treatment or they fail to undergo adhesion to a normally good substrate. After removal of calcium (e.g. by EDTA) cultured cells usually dissociate within a few minutes, round up, and gaps between the cells can be found. However, treatment with chelating agents and mechanical forces alone are not sufficient in many cell systems to obtain complete loss of cell–cell interactions. The remaining tight junctions must be destroyed by trypsin treatment. These simple procedures only provide rough information about adhesion systems and do not yield quantitative results or analysis of complex interactions.

A more specific but less sensitive way to evaluate the involvement of specific molecules, such as cadherins, is inhibition of their function by blocking antibodies against their extracellular domains. In antibody-treated cell monolayers morphological changes can be observed, and intercellular gaps become visible after a few hours. In three-dimensional cultures the morphological changes appears as the formation of spherical cell shape and loss of compact cell mass. Various microscopic techniques can be applied for the investigation of the functional consequences of cadherin receptor interference. Frequently, fluorescence or confocal microscopy is used for visualization of cytoskeletal behaviour or molecular changes in cadherin–catenin complexes along with cell morphological changes.

Molecular cloning of truncated or modified cadherins has been developed for specific studies on the role of extra- or intracellular domains of these molecules in adhesion events. cDNA constructs in dominant negative cells with truncated cadherin extracellular domains but an intact intracellular domain or the inverse have been used (**Figure 4**). These two types of molecules are functionally incomplete but compete with normal cadherin function. In these cells the remaining intercellular contacts or cytoskeletal anchorage are severed. However, technical difficulties, and the fact that cells normally express multiple forms of cadherins, limit the application of this method to cells that only express one type of cadherins. In contrast to this technique, mutations of specific protein motifs have been successfully used to modify the functional properties of cadherin–catenin complexes and their related signal transduction pathways with high specificity (**Figure 4**).

Cell Adhesion

Cell Adhesion Assays

The general purpose of cell adhesion assays is to obtain quantitative information on tumour cell–cell and cell–substrate interactions. Their basic principle is to measure reattachment of single cells that have been removed from tissue culture and resuspended as a single cell solution. These *in vitro* assays use labelled tumour cells (fluorescence, radioisotope, or staining) that are allowed to adhere to cell monolayers or substrate-coated plastic surfaces in microtitre or other plates. After a defined period of time, unattached cells are removed by washing, and the remaining cells are enumerated and compared to the total number of cells added to the cell suspension (**Figure 5**). This procedure can be used to evaluate adhesion to certain substrates, such as ECM components, and to identify mediating receptor molecules on the tumour cell surface by inhibition of adhesion with specific antibodies or mimicking synthetic peptides which specifically block the adhesive functions of target molecules (Tressler *et al*., 1989; Haier *et al*., 1999a,b).

Cell attachment to specific substrates is a dynamic process that results in functional cell responses and changes in cell morphology. Within a certain time period, a percentage of attached cells can be seen without specific adhesive interactions, whereas other cells reach stable adhesion states or even begin to spread. However, adhesion–time curves show sigmoid patterns where a plateau value can be reached (see **Figure 10**). Therefore, the adhesion assays have to consider this time-dependent behaviour. Statistical analysis of a large number of cells is necessary to allow the characterization of adhesive properties. Microtitre plate assays do not measure the simple

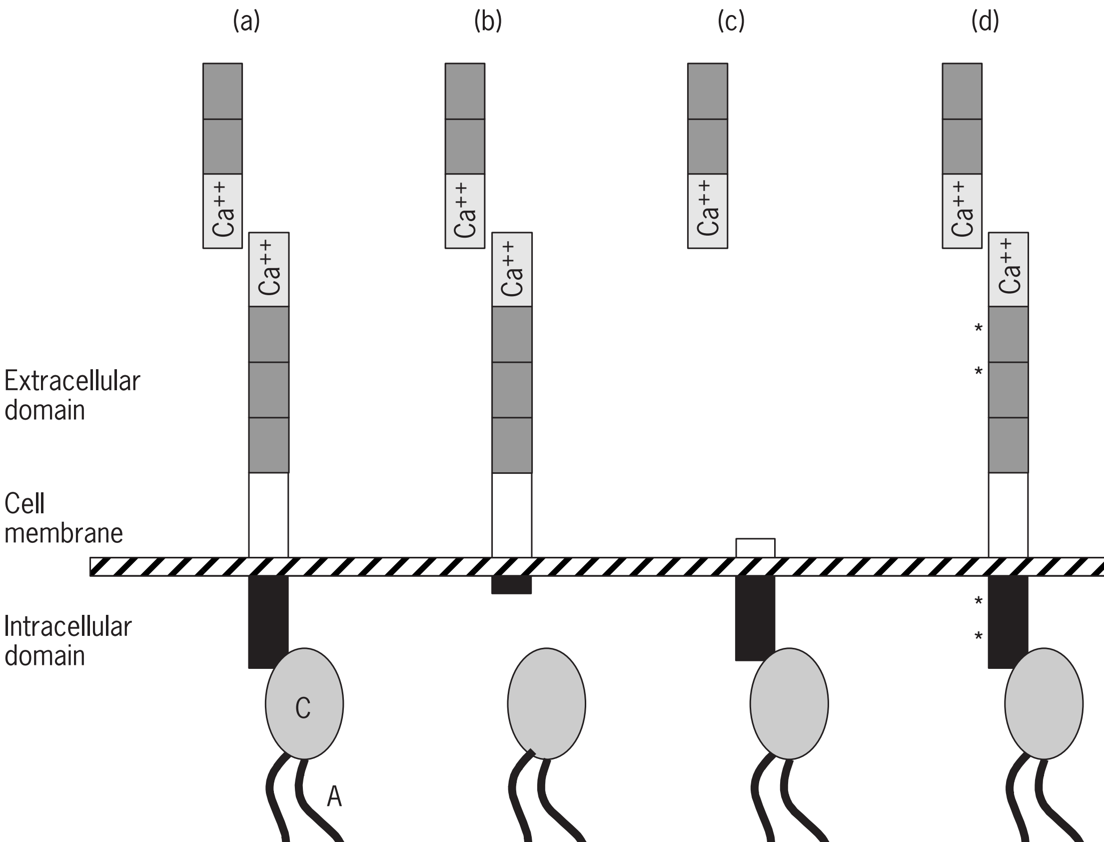

Figure 4 Truncation of cadherin domains for functional investigation of the role of various domains of the molecule. (a) Intact molecule with normal homotypic receptor interaction and cytoskeletal anchorage; (b) truncated intracellular domain with loss of cytoskeletal interactions; (c) truncated extracellular domain with altered adhesive interactions. (d) mutations (*) in different domains resulting in loss of domain functions. C, catenins; A, actin.

interactions between adhesion molecules and their ligands, but a more complex cell response to adhesion receptor binding. They are unable to discriminate between primary cell contact, adhesion stabilization and cell spreading. One of their general limitations is that the washing procedures for removal of unattached cells is essential but difficult to apply reproducibly, and weak specific interactions between adhesion molecules and their substrates may not resist these forces. Additional technical and biological limitations are discussed below.

For further analysis of involved cellular structures and signalling pathways, the tumour cells can be pharmacologically pretreated with specific activators or inhibitors. This technique can be employed, for example, for the investigation of participating cytoskeletal proteins, whose native structures or ability to aggregate are modified. Other frequently used types of pretreatment can evaluate the role of various kinases or phosphatases in the regulation of adhesive properties. Finally, genetically manipulated cells can be used where specific signalling molecules are specifically altered (e.g. modification of binding sites or exchange of amino acids for prevention of phosphorylation). In principle, cell adhesion of untreated and treated cells must be compared, and the relative differences in the number of adherent cells can reflect involvement of target structures or functions in cell adhesion or its regulation.

General cell adhesion techniques have been modified in numerous studies for the investigation of regulation or function of adhesion molecules. Instead of microtitre plates, coated microbeads have been introduced, for example, to study the involvement of cytoskeletal proteins. The use of agarose beads allows the application of confocal, laser scanning or other microscopic techniques to visualize intracellular processes. Using these methods, a hierarchical involvement of actin-binding proteins was found in areas of focal contacts after receptor binding of integrins (Miyamoto *et al*., 1995). Another technique that is frequently employed for studies on receptor clustering is binding and artificial ligation of monoclonal antibodies or the use of chemically cross-linked antibodies with high specificity to the targetted adhesion molecules (**Figure 6**).

Flow or Dynamic Cell Adhesion

Static cell adhesion assays are widely used for characterization of the adhesive properties of various normal and

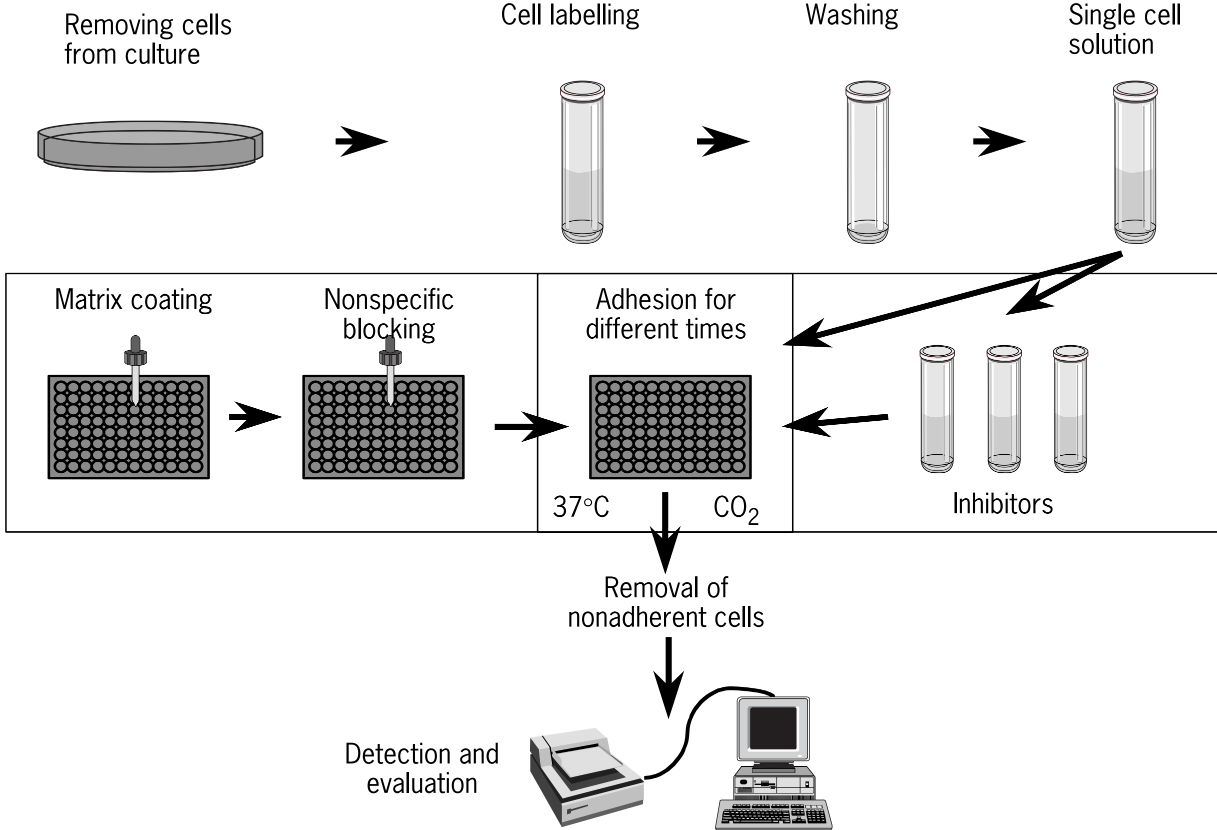

Figure 5 Principle of cell adhesion assay in microtitre plates.

tumour cell lines. Unfortunately, these assays do not consider hydrodynamic forces, such as wall shear stress or the parabolic form of laminar flow that occurs within the microvasculature. In addition, these assays measure cell adhesion as one event, instead of complex initial cell–surface interactions, adhesion stabilization and cell spreading. Hydrodynamic adhesion assays are capable of mimicking haemodynamic conditions in the microcirculation. Using specific parallel plate laminar flow chambers the two phases of adhesive interactions between circulating cells and vascular surfaces (EC or ECM) can be studied separately in haemodynamic adhesion assays (Yun *et al*., 1997; Patton *et al*., 1993). For example, Lawrence *et al*. introduced a parallel plate flow chamber to study adhesion of neutrophils flowing over activated EC (Lawrence *et al*., 1987, 1990) (**Figure 7**). They showed that this system allows controlled studies of the flow effects on cell suspensions. The conditions of hydrodynamic adhesion in these reports revealed that both biophysical and biochemical interactions were involved in cell adhesion.

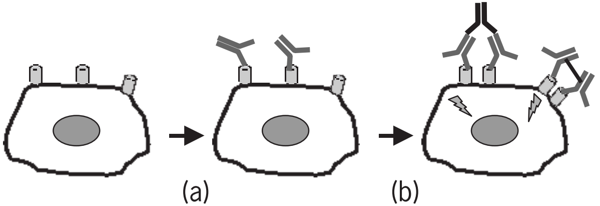

Figure 6 Artificial clustering of adhesion molecules using antibody ligation. (a) Tumour cells are treated with primary antibodies against a specific adhesion molecule which leads to receptor occupancy. (b) Receptor ligation is caused by anti-antibody antibodies that induce receptor-mediated signalling, or chemically cross-linked antibodies are used.

To study initial tumour cell arrest and adhesion stabilization under flow conditions, different parameters can be defined using various flow rates. These parameters can measure (1) the initial arrest of tumour cells to EC/ECM and (2) adhesion stabilization. A major advantage of this system is the reproducible control of flow and shear forces. Each of these steps can be investigated with regard to cell structural and regulatory requirements.

Using this system, we found that adhesive interactions of HT-29 colon carcinoma cells with ECM-coated surfaces under laminar flow conditions occurred in discrete steps: (1) cell rolling, (2) cell sticking or initial adhesion and (3) stabilization of cell adhesion. Under shear flow rolling of tumour cells on ECM surfaces appeared to be mediated mainly by physical/mechanical and nonspecific surface–cell membrane interactions. Differences in shear forces between the centre and margins of the flow curve appear to be responsible for the reduction of tumour cell velocity by

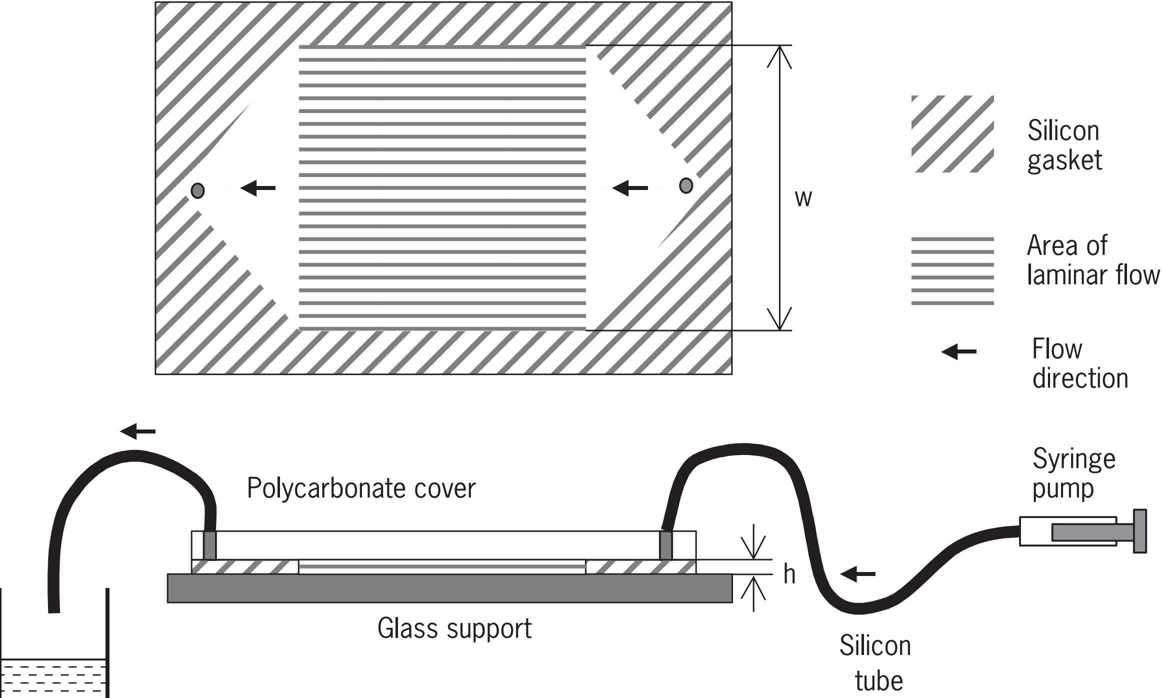

Figure 7 Principle of laminar flow parallel plate chamber. A polycarbonate shear deck supports surface-coated glass-slide to obtain a small height-to-width ratio that is required for maintenance of laminar flow. In this system, wall shear stress can be mathematically calculated as for Newtonian fluid flow. Evaluation is performed under an upright microscope (1:63.5 magnification).

rolling on the ECM surface (**Figure 8**). Once tumour cells move below a critical threshold of flow-related shear forces, specific interactions between tumour cell surface molecules and ECM molecules can be initiated. During various steps of dynamic adhesion the importance of nonspecific interactions decreases compared to static adhesion, and specific integrin-mediated binding occurs as a prerequisite for adhesion stabilization.

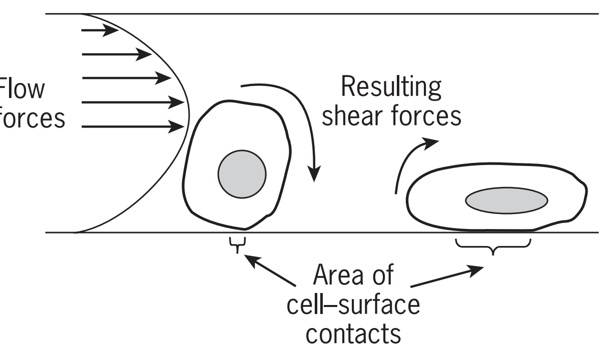

Figure 8 Influence of various parameters on cell-surface interactions. Flow velocity occurs parabolic in a laminar plate flow chamber with maximum flow in the centre of the fluid flow. Resulting shear forces are determined by the differences of fluid flow on the centrifugal and centripetal side of the tumour cell. Flattening of cells results in an increased area of cell–surface contacts and reduction of effective shear forces acting on the cell.

Spreading

Cell spreading is usually the first morphological change seen in cells after adhesion to certain substrates. It is characterized by flattening of cells that are more spherical in single cell suspensions. Spreading of cells requires specific interactions between surface molecules and substrate to initiate cytoskeletal alterations, which leads to enlargement of contact area and loss of round shape. In contrast to initial cell adhesion, active cellular functions are necessary for these shifts in cell morphology, whereas initial cell adhesion includes, in part, nonspecific surface–substrate interactions (see above).

Assays for determination of cell spreading are similar to the cell adhesion assays described above. However, after certain times unattached cells are not removed, and the cells have to be fixed for microscopic analysis. Using an inverted phase-contrast microscope, the relative percentage of bound cells that show the criteria of cell spreading can be evaluated. Specific morphological criteria for spreading are loss of sharp cell borders, development of pseudopodia, alteration in diameters and nucleus–cytoplasm relations. Often these parameters are analysed by digital image software that allows exact measurement

and comparison with average values in the given cell population.

Migration and Motility

The ability of movement is one of the essential features of tumour cell invasiveness. Most eukaryotic cells (including tumour cells) can actively migrate along a concentration gradient of chemoattractants. Three separate functions are required for this response to the cellular environment. First, cells have to recognize the gradient; second, they must establish and break adhesive interactions to their underlying extracellular substrate; and finally, cytoskeletal response is necessary for the movement and resistance to traction forces.

The basic principle of these experiments is very simple. Cells are allowed to adhere to certain substrates, and their movement along a chemical gradient is observed by direct visualization (e.g. time-lapse video-microscopy) or by counting of cells that passed a defined distance after a certain period of time (e.g. filter assays). Cell migration is detected using radioactive, fluorescent or enzymatic cell markers, or cytochemistry. The classical motility assay was described by Boyden and measured migration of cells through a porous membrane. A modified form of Boyden chamber assays is useful for invasion analysis (see below). The assays can identify new chemoattractants and investigate cellular processes required for cell motility. Selection of suitable conditions for the assays is important because cell motility can be found at very different rates and time dependence in response to chemotactic signals.

Various factors influence the experimental design of motility assays. (1) A stable gradient has to be maintained over the observed time period. This requires technical modifications if the cells to be investigated move slowly, which is a characteristic of many types of tumour cells (compared with fast-moving neutrophils). Tumour cells typically move only $0.2–2\,\mu m\,min^{-1}$, possibly because of slow detachment rates from ECM-coated surfaces. (2) Depending on the type of investigation, such as intracellular signalling or identification of chemotactic substances, the assay conditions have to be adapted to the experiment. For example, chemotactic gradients can be applied gradually or suddenly or they can be step or continuous. (3) Chemotactic cell responses are highly concentration dependent, and increasing concentrations of chemoattractants normally results in increased cell motility. However, very high concentrations of chemotactic substances may actually inhibit cellular movement and there is often a concentration curve where maximal response occurs.

Chemotaxis assays are designed to determine if a biological compound can induce directed motility of target cells. For verification of chemotactic responses, a gradient of the factor must stimulate directed locomotion rather than enhance chemokinetic cell movement or movement in random directions (see also Biological and Technical Limitations). Since differences in the motility and growth responsiveness of malignant cells to soluble factors derived from mouse liver, brain and lung microvessel EC have been found, conditioned media can be used to examine the effects of secreted factors on various tumour cell systems. Chemotactic responses of various tumour cells to these factors have been characterized using filter assays. Identified chemoattractants for these cells include, for example, autocrine and paracrine motility factors and growth factors, such as fibroblast growth factor, epidermal growth factor, insulin, platelet-derived growth factor and hepatocyte growth factor/scatter factor.

Invasion

In vitro evaluation of tumour cell invasiveness includes the determination of three combined factors that lead to movement of cells through a ECM layer: (1) cell adhesion, (2) destruction of ECM integrity and (3) chemotactic motility. Models for tumour cell invasion should simulate the extracellular environment or microvessel walls in host organs. Tumour cells that are invasive or metastatic can be studied with regard to the mechanisms that are responsible for these characteristic features of malignant cells. The major barriers for tumour cell invasion into underlying stroma are basement membranes in the primary organ or in blood vessels at secondary organ sites. These basement membranes consist of thin complex layers of various ECM components that can be imitated in invasion experiments.

The main difference between invasion assays and measurement of motility is that invasion assays are performed using thin gel layers of ECM components (as single components, such as collagen gels, or in combination, such as Matrigel) overlaying the invasion filters, whereas motility assays just use coated filters. To invade through an ECM gel layer, tumour cells have to release degradative enzymes. Commonly, in these modified Boyden chamber assays two chambers are separated by a microporous filter (usually polycarbonate). The pore size is variable ($1–8\,\mu m$) depending on the diameter and deformability of the cells to be used. For invasion experiments, a thin layer of ECM gel is put on the upper side of the filter, and cells are added to the upper chamber. Invasion is measured as the numbers of cells that reach the lower surface of the filter during a certain incubation period (**Figure 9**). For further analysis, migrated cells can be carefully removed from the lower surface, for example to isolate highly invasive subpopulations of tumour cells.

Other *in vitro* experimental designs use other types of gel preparations and observe cell migration within a gel using microscopic observation. However, the filter assay described yields better results, especially with Matrigel (or single ECM component preparations), and these artificial conditions are useful for comparisons with *in vivo* characteristics of tumour cell–ECM systems. A different approach to study tumour cell invasion is the use of

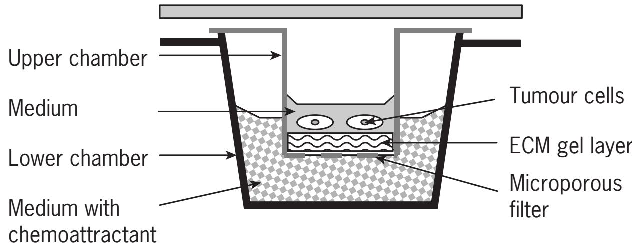

Figure 9 Principle of Boyden chamber assays for cell motility and invasion. Two chambers are separated by a microporous filter membrane. A chemotactic concentration gradient acts as stimulus for directed cell motility or invasion. For motility assays, the upper side of the microporous filter is coated with ECM substrates or EC, whereas invasion assays thin ECM gel layers are placed and completely cover the microporous filter.

xenograft models. In these *in vivo* experiments, mostly suspensions of established tumour cell lines are injected into the animals. Frequently a subcutaneous location is chosen, but intraperitoneal or orthotopic injections can be also used.

Release of Degradative Enzymes

During tissue invasion, malignant cells have to penetrate intertissue barriers, such as subepithelial and subendothelial basement membranes. As mentioned above, the molecular compositions of these basement membranes are organ specific. Moreover, the patterns of degradative enzyme expression by malignant cells may be important in determining organ-specific formation of metastases. Malignant cells can be induced to synthesize, release and activate various types of these enzymes by specific adhesive interactions with EC or components of the basement membranes. There are a variety of degradative enzymes, inhibitors and activators released by tumour cells.

Models for the investigation of degradative enzyme release and/or regulation have been developed based on adhesion assays, where the adhesive interactions between tumour cells and ECM substrates are well known. Two types of modifications can be used for specific questions regarding enzyme synthesis and release. For example, to examine the secretion of degradative enzymes by tumour cells after adhesive contacts the degradative activity in the adhesion medium can be measured during an adhesion assay. Enzyme activity can be detected by zymogram electrophoresis, and active proteolytic enzymes can be identified in the gels. This procedure allows characterization by molecular weight, enzymatic activity and substrate specificity. Alternatively, the enzyme activity can be directly measured using radiolabelled or fluorogenic substrates. It is also possible to determine enzyme amounts immunologically using microtitre assays, or to detect secreted protein amounts of enzymes using Western immunoblotting techniques.

Increase in enzymatic activity in adhesion medium can be the result of activation of proenzyme forms, reduced inhibition or increased secretion, and secretion because of post-translational signalling and/or activated transcription. There are, probably, overlapping signalling pathways involved in regulation of degradative enzyme secretion. Signalling pathways that are involved in the induction of degradative enzyme secretion and activation can be studied using various pharmacological interventions or genetically engineered tumour cells. A distinction between translational processing of downstream signals and cytosolic signalling after adhesive contacts can be examined in a second type of experiments. Using basic types of adhesion assays, the synthesis of mRNA coding for specific degradative enzymes can be measured by hybridization techniques, reverse transcriptase polymerase chain reaction (RT-PCR) or Northern blotting.

GENERAL APPLICATIONS

Models for tumour cell adhesion and invasion have been established for investigation of two essential cellular processes during the development of distant metastases. Historically, they were used to identify participating molecules, which are mainly located on the tumour cell surface. After characterization of various classes of adhesion molecules, research focused more on their functional properties. It became evident that adhesion molecules are not simply anchors for extracellular contact, but also important participants in cellular signalling. This led to further methods, and animal models were frequently replaced by molecular biology approaches to modify specific properties. Since valuable alternatives are available for many hypotheses, the use of animal models for cell adhesion/invasion is under restriction for many reasons.

The current spectrum of investigations with regard to cell adhesion, migration and organ invasion includes most fields of cancer research. However, understanding the basic function of adhesive cell systems is not restricted to malignant cells and has only scratched the surface. Differences between normal cell functions, such as cell–cell interactions during wound healing or leucocyte trafficking, and specific properties of invasive and metastatic tumour cells are still under investigation. Knowledge of these specificities of cancer cells may result in new therapeutic strategies, such as inhibition of cell signalling pathways for cancer treatment. For example, the advantages in understanding the role of metalloproteinases for the formation of secondary tumour locations have already reached clinical importance. Animal models and also phase I and phase II studies have shown that treatment with inhibitors of MMPs might be a valuable new alternative.

INTERPRETATION OF EXPERIMENTAL RESULTS

Many cellular functions change during cell adhesion, migration and invasion, and often these properties are dependent on each other. Although theoretical models describe the processes for a single cell in numerous steps, these are difficult to separate, and they occur in parallel if larger numbers of cells are used. For example, spreading and migration include successful adhesive interactions between cells and substrate. Therefore, assays for cell spreading, migration or invasion are strongly influenced by adhesive properties of the cells. In addition, time is a very critical point for investigation of these cell properties. Certain steps of adhesive interactions are found only in limited periods and models have to consider this time course. Optimal results can be obtained if initial events or plateau values, at least temporarily, are determined. Alternatively, the best approach might be to examine properties when cellular functions are in their linear phase. However, extension of assays beyond plateau values may interfere with secondary cell reactions, such as release of degradative enzymes in adhesion assays. Although assays for cell adhesion, spreading, migration or detachment focus on different points of cell behaviour, these techniques may overlap each other. There are variable advantages and problems for each method and results should be confirmed by different techniques.

Although *in vivo* experiments investigate cell behaviour in a more natural environment, specific problems have to be considered using these experimental designs. In addition to the described problems of invasion assays, the injected cells have to survive in the organ environment, and they have to maintain their invasiveness and tumorigenicity. After subcutaneous injection, these facts are extremely relevant in many tumour cell systems. A second argument against the use of *in vivo* studies is the existence of suitable, reproducible and reliable *in vitro* alternatives. Therefore, the exploitation of *in vivo* invasion assays should be restrictive.

As described above, activation and inhibition of degradative enzymes play essential roles during tumour cell invasion. For interpretation of results with regard to these enzymes, a clear distinction has to be made between detection of enzymatic activity and protein amount, because most degradative enzymes are synthesized and secreted as inactive molecules and are involved in complex regulations of their activity.

Over the last decade, improved computer technology has allowed sophisticated data analysis. However, this tends to describe minor differences without biological relevance. For example, image analysis for the evaluation of cell spreading may give quantitative results, but can also overestimate slight morphological changes. Optimal analysis, but not maximal amounts of data, should be obtained to investigate a certain hypothesis.

BIOLOGICAL AND TECHNICAL LIMITATIONS

Metastatic tumour cells usually show phenotypic instability, which leads to gradual shifts in their behaviour and diversification of cells to form heterogeneous subpopulations that differ in their metastatic properties (Nicolson, 1988b). However, most of the common techniques that are currently available for the characterization of carcinomas and the evaluation of their potential metastatic behaviour are based on statistical analyses and the use of average values. This difference between clonal growth and the possibility for single cells to establish distant metastasis on the one hand and the requirement of most procedures for the use of large numbers of cells for the quantitative examination of cell adhesion and invasion on the other renders it more difficult to answer the question of how a tumour cell becomes metastatic.

The use of cultured tumour cells inherits many advantages and disadvantages (see the chapter *Basic Tissue Culture in Cancer Research*). A significant problem is the stability of cell behaviour in culture systems. For example, evaluation of adhesive properties and their comparison between cell lines with different metastatic behaviour may be influenced by culture conditions, such as duration of passage. In **Figure 10** it is shown that, for example, the quantification of cell adhesion to ECM components depends on the age of culture. Other possible factors are

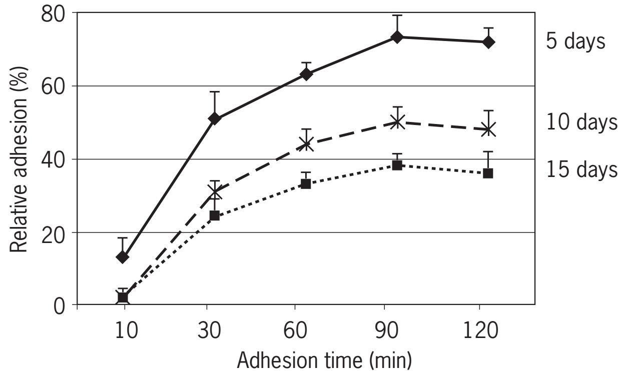

Figure 10 Influence of culture age on adhesive properties. HT-29P colon carcinoma cells were kept in culture for different times (5–15 days after passage) before use in a microtitre plate adhesion assay. With increasing age of culture (cells were leaving the logarithmic phase of growth), they lost their adhesive properties. The adhesion-time curve reached a plateau value where the number of adherent cells was at a maximum; after that time relative adhesion decreased because of release of degradative enzymes and subsequent destruction of the adhesive molecules or substrate (adhesive substrate: collagen I).

number of passages, selected growth and adhesion media, number of cells used for assays and type of cell preparation, among others. Therefore, all experimental data have to be considered with the background of this information. Additionally, once cell behaviour will be compared for cells with different metastatic properties, all conditions in the experimental design have to be analogous.

The choice of experimental designs must also respect technical aspects and possible bias of the method used. For example, in many assays washing steps are extremely critical and can cause false-negative results or a high nonspecific background. Adhesion assays require the removal of nonadherent cells for quantification of adhesive properties. This removal is often done by aspiration and/or washing with saline solutions where shear forces interfere with adhesive interactions. If fluid flow is too high, weak adhesion can be disrupted, but less washing strength increases nonspecific 'background adhesion.'

A further problem is that specific and nonspecific cellular events have to be distinguished. For example, to determine if chemotaxis towards a stimulating gradient is the motogenic factor for cell movement, it must be ruled out that enhanced migration is caused quantitatively by increased random migration. The effects on random migration can be estimated in a series of different concentrations of the supposed chemoattractant. Migration in a gradient of increasing concentrations that exceeds rates of random migration is evidence for chemotactic activity. Some experimental designs do not differentiate between enhanced migration and chemotaxis, and these results should be reported as 'stimulated (or enhanced) cell migration.'

All chemoattractants act by activation of receptors and signalling pathways, which might interfere with target functions, such as signalling mediated by adhesion molecules. Choosing an appropriate attractant is important in many migration or invasion assays. Conditioned medium obtained from cell cultures or various growth factors, such as EGF, bFGF and HGF, are widely used. Tissue extracts have also been found to act as chemoattractants with some cell types. Cells generally respond by migrating toward growth factors for which they have receptors.

Finally, some general remarks are necessary, but will not be discussed in detail. All adhesive or invasive interactions depend strongly on substrate concentrations, pH, cation contents and chosen medium. Antibodies or pharmacological substances may also require certain conditions for optimal action. When pharmacological stimulation or inhibition of cellular processes are investigated, these substances have to reach their target structures under living conditions (cell permeable). In addition, because of the assay's sensitivity, if possible stimulators or inhibitors are being assessed, several different concentrations of the test substance should be examined. Cell labelling has to avoid any interference with cell viability and adhesive/invasive properties. To exclude false-positive or false-negative results it is important to include controls in each assay. These controls have to determine nonspecific 'background' events (e.g. adhesion to nonspecific bovine serum albumin), and estimate effects of additives, such as reconstitution reagents (e.g. dimethyl sulfoxide). Negative results have to be confirmed by positive control experiments. Most assays should be performed in multiple parallel repeats for statistical analysis of test data.

PERSPECTIVES

The development of further models and methods for the examination of adhesive interactions will focus on consideration of *in vitro* conditions, which allow better simulation of *in vivo* characteristics. Real-time visualization of cellular processes, such as cytoskeletal activity or signal transmission, will gain functional understanding. Finally, analysis of complex interactions between different signalling cascades will also take part in investigation of metastatic behaviour.

BIOLOGICAL BACKGROUND

Metastasis is a process in which tumour cells establish new growths at sites in the body distinct from the primary tumour. The spread of the tumour cells can occur either via lymphatic drainage of the primary site leading to local lymph node metastases or via the blood vasculature leading to metastases in distant organs. Further spread of tumour cells from these sites may also occur, particularly spread from the lymphatic system into the blood vasculature. These processes involve a number of specific stages, which include escape of the tumour cell from the primary site, survival in the circulation, arrest in the capillaries at a new location, migration from the capillary into the interstitial space and establishment of a new growth at this new location. These stages represent potential barriers which a tumour cell must be able to surmount if it is to be successful in forming a metastasis. The ability of tumour cells to complete the various stages of this process can be studied using *in vitro* assays, as discussed in earlier chapters (see *Models for Tumour Growth and Differentiation*; *Models for Tumour Cell Adhesion and Invasion*; *Invasion and Metastasis*), but *in vitro* assays do not allow an assessment of whether an individual cell is able to complete all the stages successfully. Such an assessment requires the use of an *in vivo* metastasis model to integrate all the various stages of the process. There is currently no substitute for such *in vivo* models.

The various stages of the metastatic process are illustrated in **Figure 1**. The initial stages involve detachment of cells from the primary tumour and their invasion into the lymphatic or systemic circulation. Since there are few (if any) functional lymphatics in tumours, cells near or at the invasive edge of the tumour are likely to be those which escape into the lymphatic system. Tumour blood vessels are often poorly formed owing to the rapid angiogenesis which may occur during tumour growth and this may provide for easier access of tumour cells into the systemic circulation. Reduced expression of homotypic cell adhesion molecules such as the cadherins may enhance the detachment of cells from the tumour mass. Concurrently, increased expression of proteolytic enzymes, such as matrix metalloproteinases, cathepsins or plasminogen activators, or decreased expression of their inhibitors, may assist invasion of the cells into the circulatory system. Once in the circulation the cells are most likely to be arrested in the first capillary bed that they encounter owing to size constraints and/or to an increased possibility of interacting with adhesion molecules expressed on the surface of the endothelial cells (or exposed basement membrane) at lower flow rates. Depending on the location of the tumour the first capillary bed will be in either the liver (for intestinal tumours growing in organs whose blood drains into the portal system) or the lung (for tumours in organs in other parts of the body). Some of the arrested cells may successfully transit through this initial ‘first-pass’ organ and move on to other sites, but studies with labelled cells have suggested that the proportion of the cells which do so is low and depends on the cell type. In both cases the cells must be able to survive both the physical stress of the bloodstream and also the various components of the immune system. Natural killer cells and classic T cell immunity have been implicated in reducing metastasis formation and this may be a particularly important factor if the tumour cells have any degree of immunogenicity. Following arrest, the cells may establish tight adherence to the vessel wall, extravasate into the interstitial space and possibly migrate within this space before starting to proliferate. The proteolytic enzymes discussed above in relation to intravasation are also likely to be involved in this extravasation stage. Some tumour cells can apparently bypass this stage by initiating growth whilst still in the blood vessel. Initiation of proliferation requires that the cells can either respond to locally available growth factors

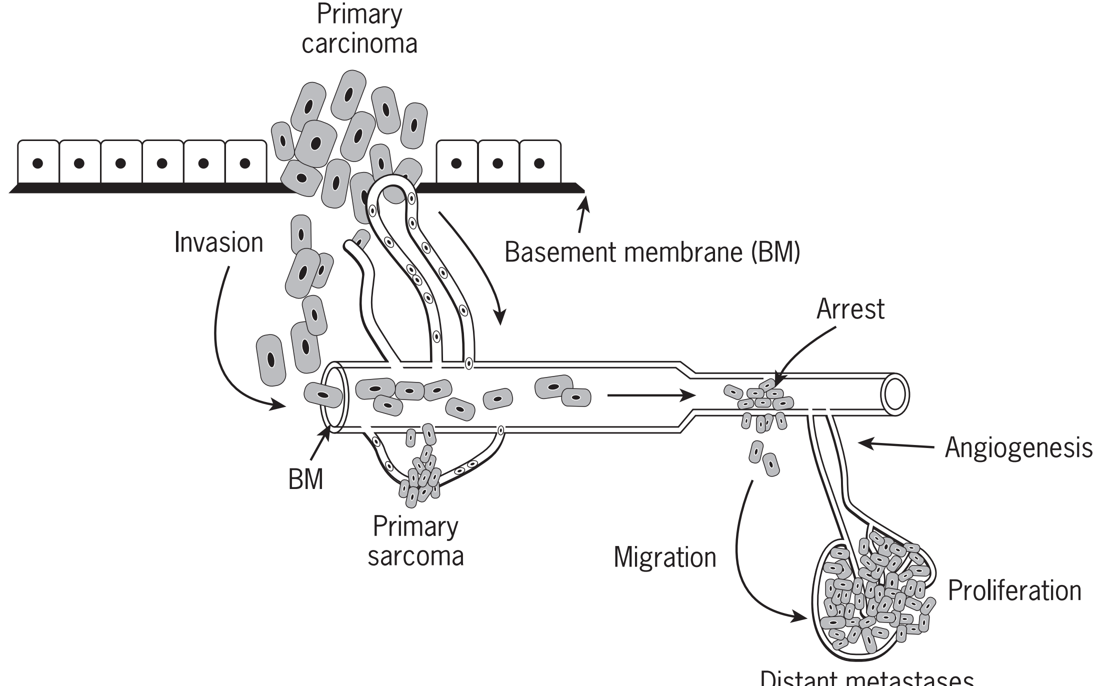

Figure 1 The major steps of the metastatic process. [From Tannock and Hill (eds.), 1998, *The Basic Science of Oncology*, 3rd edn (McGraw-Hill, New York).]

or can make sufficient growth factor themselves to achieve autocrine stimulation of growth. Meanwhile, they must also be able to avoid or ignore any negative growth signals. Finally, if progressive growth to a size greater than about 1 mm diameter is to occur the tumour cells must be able to initiate angiogenesis to stimulate the formation of new blood vessels. Proteolytic enzymes may also be involved in the growth stimulation stage, since some growth factors are sequestered in the interstitial matrix (e.g. VEGF) or are bound to binding proteins in the circulation (e.g. IGF). These factors can be released by proteolytic enzyme activity. (See also chapters on *Angiogenesis Models*; *Models for Tumour Cell Adhesion and Invasion*; *Models for Tumour Cell–Endothelial Cell Interactions*.)

Since these stages are sequential, only a few cells may be successful in completing all of them. Thus an important aspect of metastasis is that it is a very inefficient process. Following intravenous injection of cells even the most malignant cell populations rarely form metastases with an efficiency greater than about 1% and it is often several orders of magnitude lower. Similarly, if radiolabelled tumour cells are injected into the circulation and radioactivity in the host is monitored as a function of time, the remaining activity is usually below 1% within 2–3 days of injection of the cells. If the number of cells escaping into the circulation from a primary tumour is estimated by taking blood samples from efferent veins, it is found that spontaneous metastatic efficiency is also very low, although in this case the viability of the escaping tumour cells is difficult to assess. Whether the low efficiency of metastasis formation represents a situation in which there is a cumulation of low probabilities of surmounting a number of stages or whether it represents a very low probability that a tumour cell can surmount a specific stage of the metastatic process (a rate-limiting step) is currently unclear and certainly these are not mutually exclusive possibilities.

It has been argued that metastatic inefficiency is purely a result of the random chance that any individual tumour cell will surmount all the various stages of the process. This is consistent with the first possibility above and with the findings that cells derived from metastases do not necessarily have a metastatic efficiency much different from those derived from the primary tumour. However, as discussed below, there is increasing evidence that specific phenotypic characteristics can affect the metastatic potential of tumour cells and a number of 'metastasis-related' genes have been isolated in studies of clonal populations of cells, which have different metastatic potential but are derived from the same parental cell population. This evidence favours the 'rate-limiting step' model and the prevailing view is that arrest and extravasation are the primary rate-limiting steps. However, two recent studies have questioned this dogma. Chambers *et al*. (1999), who used intravital videomicroscopy (IVVM) (see **Figure 2**) to track the early stages of metastasis formation by B16 cells in mouse liver or chick embryo chorioallantoic membrane (CAM), found that a major barrier to successful metastasis formation in the system studied occurs at the final 'initiation of new growth' stage of the

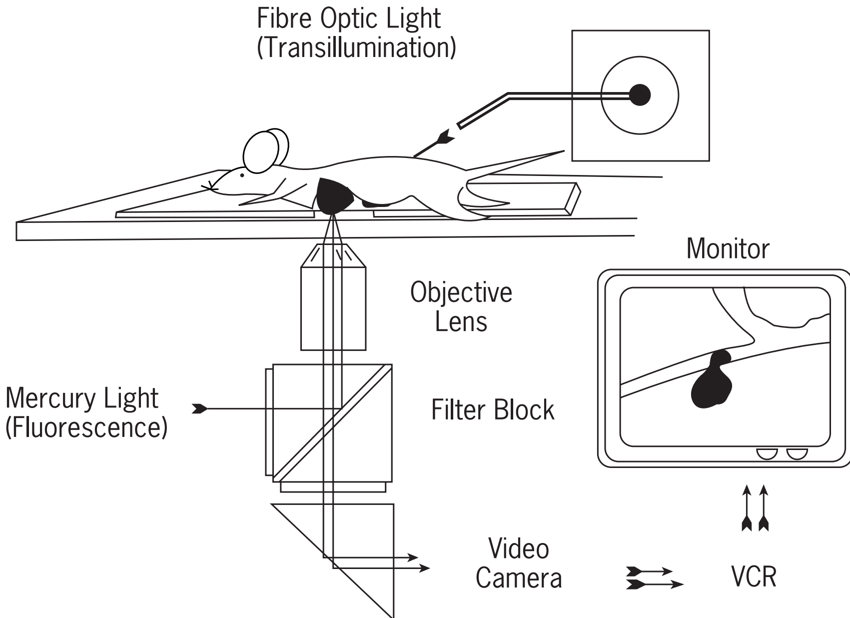

Figure 2 Schematic diagram of the intravital videomicroscopy system for examination of metastases *in vivo*. [From Tannock and Hill (eds.), 1998, *The Basic Science of Oncology*, 3rd edn (McGraw-Hill, New York).]

process. Similar findings, obtained using a careful cell counting technique, have recently been reported by the same group for tumour cells forming metastases in the lung (Cameron *et al*., 2000). In contrast, Al-Mehdi *et al*. (2000) using green fluorescent protein (GFP)-labelled HT-1080 tumour cells observed that arrest in the lung occurred in precapillary arterioles as a result of adhesion to the vessel wall and that initial growth of metastases occurred in the vessel without extravasation.

One of the most compelling pieces of evidence that specific phenotypes are associated with metastasis formation is the clinical observation that certain types of tumours have a propensity to metastasize to specific organs. Thus many tumour types will metastasize to lung or liver but prostate and breast carcinomas have a propensity to metastasize to bone whilst small cell lung carcinomas often metastasize to brain or bone marrow and melanomas to brain or bowel. These clinical observations have been supported by a number of experimental studies which have demonstrated that it is possible to select cells which will preferentially metastasize to specific organs. The now classical example of such studies is the selection of the B16–F10 population of B16 melanoma cells which have increased ability to form lung metastases (Fidler, 1973). These cells were selected by injecting B16 melanoma cells intravenously into syngeneic C57Bl mice, growing cells in culture that were isolated from the lung metastases which formed and then injecting the cells back into animals to form new lung metastases. This cycle was completed 10 times to produce the F10 population. Selection of populations of cells with increased propensity to form metastases in many different organs has been reported using similar techniques. It has been demonstrated that such cells will 'home' to the relevant organ even when it is ectopically transplanted in the animal.

It has also been shown that if multiple (clonal) populations of cells are grown from individual tumour cells there is substantial heterogeneity in the metastatic potential of the cells from the different clones. This finding was initially interpreted as indicating the presence of preexisting metastatic variants within a cell population but the finding that the metastatic properties of these clonal populations tends to be unstable has cast doubt on this interpretation. Tumour cell populations are genetically unstable and the cells rapidly become heterogeneous in their phenotypic properties during the growth of the 'clone.' Nevertheless, 'clonal heterogeneity' of metastasis formation is still consistent with the concept that specific phenotypes are associated with metastasis formation, even though these phenotypes may be only transiently expressed. Since most of the stages of the metastatic process are likely to occur over a short time period of a few hours to a few days, prolonged expression of many of the relevant phenotypes may not be necessary for successful metastasis formation.

These experimental results have provided support for a hypothesis about metastasis formation that was postulated more than 100 years ago (Paget, 1889). The so-called 'soil and seed' hypothesis was based on the idea that tumour cell–host cell interactions can occur and that these are more or less favourable for metastasis development. Thus the preference of specific tumours for metastasis to

specific organs can be explained by the concept that specific organs provide a more suitable growth environment for cells of a particular tumour type. Meanwhile, the propensity of many tumours to form lung or liver metastases can be explained by the fact that cells released into the circulation will tend to be arrested in the first-pass organ, thus producing a high cell burden in these organs.

PRINCIPLES OF MODEL ESTABLISHMENT

Although there are many variations in the applications of *in vivo* metastasis models, there are essentially two types of model (usually in rodents). In a spontaneous metastasis model, a primary tumour is initiated in some location in the body and the formation of metastases is monitored at one or more different locations (**Figure 3**). In an experimental metastasis model tumour cells, obtained from culture or by preparing a cell suspension from a tumour, are introduced directly into the circulation (e.g. by intravenous, intraportal or intra-arterial injection) and development of metastases is monitored at various times later (see chapter on *Human Tumours in Animal Hosts*). For most rodent models intravenous or intraportal injection results in metastases which are usually observed in the lung or liver, respectively, depending on the site of injection, unless specific selection has been undertaken for tumour cells which will form metastases in other organs. Following intra-arterial injection metastases in a wide range of organs may be observed. The experimental metastasis model is believed to provide an intermediate level of complexity, since it bypasses the initial events associated with escape of the tumour cells into the circulation. However, this concept of reduced complexity depends on the assumption that cells which escape from a primary tumour and go on to form metastasis have the same phenotypic characteristics as cells injected from a prepared cell suspension.

A very important factor in the choice of a metastasis model is that it should be appropriate for the question being asked. Issues which need to be considered include whether a syngeneic rodent tumour model or a xenografted human tumour model will be used. A rodent model is easier to handle and there are many highly metastatic rodent tumour models available. Such models are often rapidly growing and the primary tumour may become very large before spontaneous metastases are detectable macroscopically. One solution to this problem is to excise the primary tumour by surgery or ablate it with radiation to allow additional time for metastases to develop. Such a strategy can also be used to provide information about the kinetics of the seeding of spontaneous metastases from a primary tumour. It always needs to be established that such rodent models simulate the relevant clinical scenario. One situation where this may not be the case is in the use of chemically or virally induced tumours. Such tumours are usually immunogenic to a detectable degree. Such immunogenicity may not prevent the growth of a primary tumour from a large cell inoculum but may prevent the growth of small metastases. A rodent model to assess propensity for lymph node metastasis can be set up by transplanting tumour cells into the hind footpad, from where cells can metastasize to the popliteal lymph node.

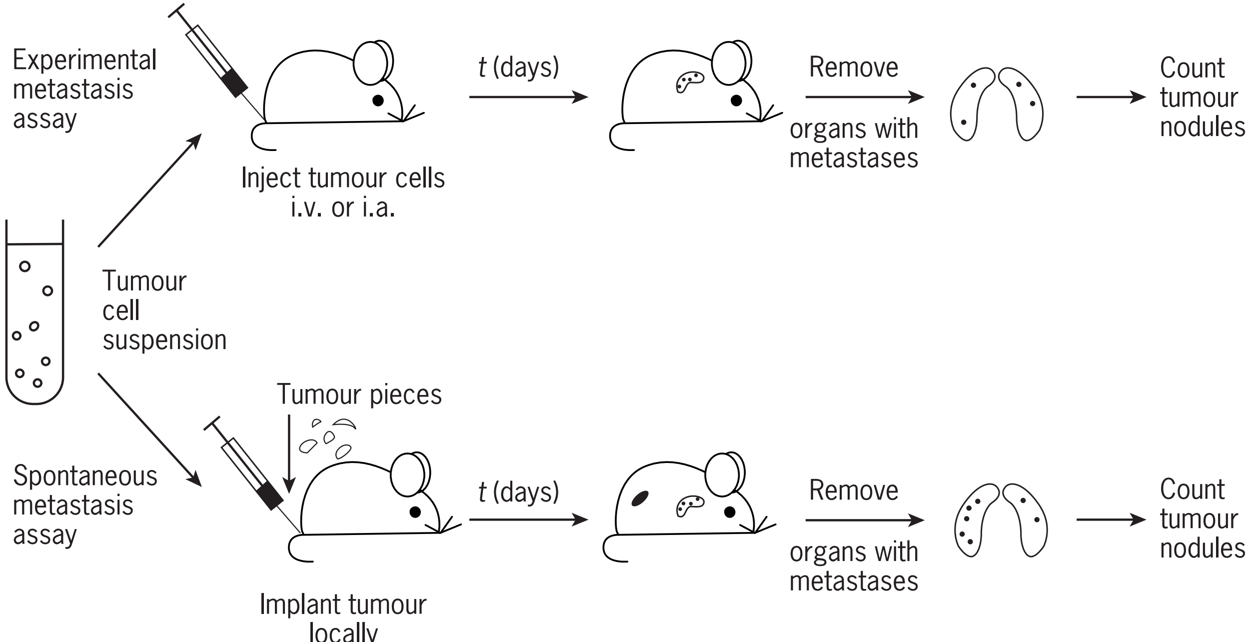

Figure 3 Representation of the experimental and spontaneous metastasis assays in mice. [From Tannock and Hill (eds.), 1998, *The Basic Science of Oncology*, 3rd edn (McGraw-Hill, New York).]

A refinement of rodent tumour model systems is the use of transgenic or knockout mice as hosts for the growth of the primary tumour or as recipient mice in experimental metastasis assays (see chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*). One example of this was the use of mice that were knocked out for the gene for Fas ligand (C3H/gld mice) in studies examining the importance of the expression of Fas on the surface of the tumour cells for metastasis formation. (See chapter on *Apoptosis*.) A difference in the number of experimental metastases which formed in normal C3H mice following injection of cells from two different sublines of a murine melanoma, which expressed different levels of Fas on their surface, was abolished when the cells were injected into C3H/gld mice (Owen-Schaub *et al*., 1998). A second example was the use of a transgenic model carrying the polyoma middle T antigen (PMTA) driven by the mouse mammary tumour virus promotor. These mice develop a high incidence of metastatic mammary tumours at an early age but this is reduced if the gene for Mgat5, a glucosaminyl transferase enzyme involved in a specific type of glycosylation of proteins, is knocked out in the mice (Granovsky *et al*., 2000). In another experiment with these PMTA transgenic mice, crossbreeding with a wide range of other inbred strains of mice demonstrated the importance of the genetic background of the mice on the latent period before tumour growth and on the extent of metastases that develop in the mice (Lifsted *et al*., 1998).

For xenografts various immune-deprived hosts are available, particularly nude or SCID mice (see chapter on *Human Tumours in Animal Hosts*). There have been reports that xenografted human tumours have a greater likelihood of metastasizing if grown in SCID mice (Xie *et al*., 1992). There is also strong evidence that the site of tumour implantation affects the formation of spontaneous metastases and that more metastases are likely if the tumour is transplanted into an orthotopic rather than ectopic site (i.e. if the tumour is growing in the organ of origin of the tumour) (Radinsky and Fidler, 1992). The sites of metastasis formation are also more likely to conform to the pattern observed in clinical practice for that tumour type. One refinement of this model is to use it in conjunction with tumour cells labelled with green fluorescent protein (GFP), which provides for the possibility of direct visualization of the growth of the tumour and its metastasis *in situ* using the GFP marker (Hoffman, 1999). A second refinement of this model is the transplantation of human tissue (e.g. fetal bone) into SCID mice (Shtivelman and Namikawa, 1995; Nemeth *et al*., 1999). These so-called SCID-hu models can then be used as recipients for growth of human xenografts and have been reported to show similar organ preference for metastasis formation to that seen in clinical practice. Such metastases appear to occur preferentially in the transplanted human tissue as opposed to the same murine tissue. These models are believed to recapitulate both the ‘soil’ and ‘seed’ aspects of Paget’s original hypothesis. A recent report has described the development of lymph node metastases following orthotopic transplantation of a human stomach Ca into SCID mice (Fujihara *et al*., 1998).

A nonrodent model that has been widely used for studies of the malignancy of tumour cells is the chick chorioallantoic membrane (CAM) model (**Figure 4**). The CAM functions to provide oxygen to the growing chick and can be exposed by carefully removing a portion of the egg shell. Since the developing chick has no functional immune system during its early growth, the CAM provides a site where human or other tumours can be transplanted and grown. Alternatively, tumour cells can be injected directly into the CAM veins. In both cases the internal organs of the chick can be examined at some time later for evidence of metastatic growth. This system is easy to handle and is amenable to direct microscopic observation but there is a time window of only about 7–10 days for tumour growth before the chick immune system starts to develop.

One advantage of an experimental metastasis model, over a spontaneous metastasis model, is the possibility of quantitating the efficiency of metastasis formation per cell. Such quantitation can be done at the end of the experiment by counting the number of metastatic nodules formed and relating it to the number of cells injected or it can also be done at earlier stages of the process using labelled cells. Tracking of radiolabelled cells immediately after intravenous injection has indicated trapping of essentially all the cells in the lung during their first pass through the capillary bed and has further suggested that there is rapid

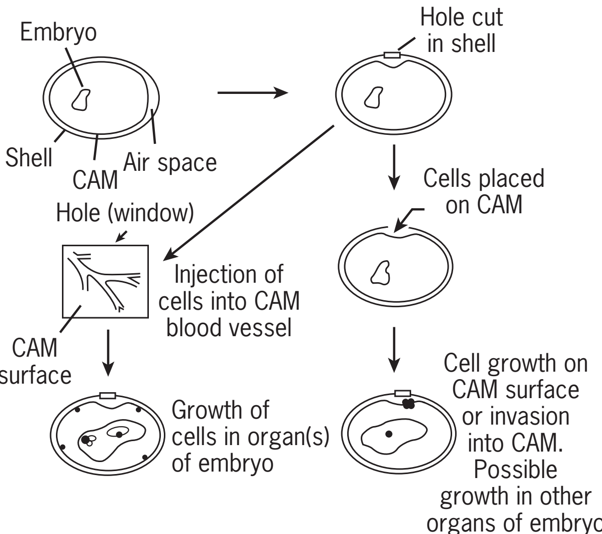

Figure 4 Assay for metastatic properties of tumour cells using the chick chorioallantoic membrane (CAM). [From Tannock and Hill (eds.), 1998, *The Basic Science of Oncology*, 3rd edn (McGraw-Hill, New York).]

death and loss of the majority of cells over the next 24–48 h. Experiments using the IVVM technique and/or with cells labelled with fluorescent markers have indicated a much slower loss of the cells, suggesting that the radiolabel may have played a role in the death of the injected cells. The availability of easily observable genetic markers, such as GFP, *lac Z* or luciferase, will allow further study of this issue and will potentially allow such observations to be extended to spontaneous metastasis models (Hoffman, 1999; Kruger *et al*., 1999; Rubio *et al*., 2001).

An alternative approach in such studies is to remove the lungs (or other organ) at various times after injection, to prepare a cell suspension and to reinject the cells to test for metastatic ability of the trapped cells. In one such study, Young and Hill (1986) found that tumour cells recovered within a few days of injection had increased metastatic ability relative to the initially injected cell population but that cells recovered at 3 weeks after injection, when there were macroscopic metastatic nodules, did not. They interpreted these findings as an indication of the presence of a transient metastatic phenotype which was expressed by cells remaining in the lung at short times after injection but which decayed over the course of the early microscopic growth of the metastases. The role of transient phenotypes in metastasis formation remains to be clearly delineated. It is possible that such phenotypes represent transient differences in the expression of relevant genes in individual cells and that the process of selection of cells for the formation of metastasis in specific organs represents the stabilization of such differences within the cell population. Since the initial establishment of a metastasis is likely to be a process which takes only a short time (minutes to hours) from cell escape from the primary tumour to lodgement and extravasation at a new location, it may not be necessary that phenotypes involved in the early stages of the metastatic process are stably expressed. Conversely, phenotypes associated with the growth of the metastasis at a new site may need to be more stable and, once the micrometastatic growth is established and angiogenesis initiated, such properties may be similar to those expressed by cells in the primary tumour.

INTERPRETATION OF EXPERIMENTAL RESULTS

As noted above, an attractive feature of an experimental metastasis model is that it is possible to quantitate the efficiency of metastasis formation per cell, since a known number of cells are injected (e.g. intravenously) and the number of metastatic nodules formed can be counted. However, there are a number of important issues which need to be considered if quantitative comparisons of different cell populations are to be made (Hill *et al*., 1986). One issue is whether the number of nodules formed is linearly related to the number of cells injected. For highly metastatic cell populations this is only true over a certain range of cell numbers injected ($\lesssim 2 \times 10^5$ tumour cells per mouse) and number of metastatic nodules formed (<100 per mouse lung). When high cell numbers are injected, nonspecific factors may increase nodule formation whilst large numbers of nodules per lung prevent accurate counting of all the nodules, leading to an underestimate of the true number. A second concern is that there is usually substantial heterogeneity in the number of metastases observed from one animal to another. This is particularly noticeable with spontaneous models but is also an issue for experimental metastasis models. Analysis of data from an experimental metastasis model demonstrated that the range in the numbers of metastases observed in different mice, injected with the same number of tumour cells from the same cell suspension, was much greater than that expected from statistical considerations. Furthermore, when two different cell types were injected into the same mice at the same time, the heterogeneity that was observed in the number of metastases arising from the two different cell populations was not correlated between the individual mice. The reason for this heterogeneity is not well understood but it implies that there are significant uncontrolled variables. Whether these are related to the animals or to the cells or both remains to be determined. The practical result of the heterogeneity is that it is necessary to do comparison studies with groups containing a minimum of 5–10 mice and to analyse the results using nonparametric statistical tests. It is also important to run controls at every stage of a series of experiments because there can be significant week to week variations in the efficiency of metastasis formation.

One of the most constant features of metastasis studies has been the heterogeneity of cellular properties which have been associated with metastasis formation (see chapter on *Advantages and Limitations of Models for Cancer and Malignant Cell Progression*). This was well illustrated some years ago by Maslow (1989), who reviewed the literature for studies of factors affecting metastasis of B16 melanoma cells, the tumour line used in the early studies of Fidler. He listed over 50 cellular properties that had been shown to affect metastasis formation by these cells using either spontaneous or experimental assays. These properties spanned the whole range of the metastatic process. He also noted that experimental and spontaneous metastasis assays do not always give the same results. An example is the B16 F10 cell line, which is 10-fold more metastatic than the B16 F1 population when tested in an experimental assay, but these cell lines show no difference in spontaneous metastasis formation. While such results emphasize the complexity of the metastatic process and the need for careful and controlled experimentation, one overall message from a wide range of observations is that different cell types manifest different properties associated with metastasis formation.

BIOLOGICAL LIMITATIONS

Biological limitations of *in vivo* metastasis models include those that limit the question that can be asked and those which affect the extent to which a model is similar to the clinical situation. *In vivo* models are limited by the fact that it is difficult to observe the progress of individual cells through the various steps of the metastatic process. In standard spontaneous or experimental metastasis studies what occurs between the time the cells are injected and metastases are observed can usually only be surmised, based on measured properties of the cell populations that are injected. Thus, if cells with decreased expression of adhesion molecules or increased expression of metalloproteinase activity form more metastases, then it is argued that arrest and/or invasion are important factors in controlling metastasis formation by such cell populations. Whether the cells which actually formed the metastases (a very small fraction of the total number of cells injected) were expressing these specific properties is not known. Furthermore, as shown by the IVVM studies, whether the association of expression of such properties with a specific stage of the metastatic process is necessarily correct is also not known (Chambers and Matrisian, 1997). This 'black box' aspect of the *in vivo* assays has been alleviated to some extent by the use of the IVVM technology and/or the use of labelled cells which allow observation of the tumour cells *in vivo* (Al-Mehdi *et al*., 2000), but the issue of whether the properties of the cell population as a whole reflects the properties of the small fraction of cells which form metastasis remains largely unknown. Addressing this question requires the examination of the properties of individual cells at various stages during the metastatic process. To date the IVVM approach has only been applied with the use of experimental metastasis models and this combination has provided important numerical information about cell seeding and early growth of metastasis. The application of this approach, or an alternative approach which could provide similar information, with a spontaneous metastasis model is clearly desirable.

The development of the orthotopic transplantation approach arose from investigation of the reason for the findings that human xenografts growing subcutaneously in SCID or nude mice rarely produced metastases. Orthotopic models now often provide good correspondence with the general patterns of metastatic spread for different types of human tumour and provide for opportunities to address specific questions associated with these specific patterns. The introduction of the SCID-hu model with transplanted human tissue adds further to this approach and provides for a link between *in vitro* studies of cell growth in such human tissue and *in vivo* formation of metastases in this tissue. Orthotopic transplantation in rodent tumour models has not been so extensively studied but there is evidence that there is increased metastasis following such transplantation. The ability to manipulate the genetic background of rodent models makes them attractive for studying specific aspects of the metastatic process.

TECHNICAL CONSIDERATIONS

Many different factors can affect the performance and reliability of metastasis assays. These factors have been extensively reviewed by Welch (1997) and a summary of his analysis is presented in **Table 1**. For both spontaneous and experimental metastasis assays, important considerations include the health and care of the animals being used and whether there is an immune incompatibility between the animals and the tumour cells. For spontaneous metastases the site of the tumour can affect the number and site of metastases, as discussed previously. For experimental metastases the handling and culture of the tumour cells prior to injection into the host animal can either increase or decrease metastasis formation, depending on the conditions. For example, both high confluency in the culture and the presence of clumps of cells in the suspension can increase metastasis formation whereas poor cell viability will reduce metastasis formation. A related issue is that it is desirable to maintain the tumour cell cultures with regular passages *in vivo* alternating with those *in vitro* or by frequent return to frozen stock. Tumour cells which have been maintained in long-term culture without *in vivo* exposure may demonstrate decreased metastasis efficiency, presumably due to the development of immune incompatibilities between the cells and the host animals.

Two aspects of the above may be considered more than technical issues. The first is the finding that treatment of the host animal with drugs (particularly cyclophosphamide) can modify the formation of metastases. This was particularly observed for experimental metastasis assays in which the metastases were formed in the lung and it was possible to modify metastatic levels by greater than 10-fold (Carmel and Brown, 1977). However, the effect observed with spontaneous metastasis assays was much reduced or absent. Similar observations were reported for irradiation of the lung prior to irradiation. The explanation for these results was suggested to be the damage to the endothelium caused by the treatments leading to easier access of the cells to the interstitial space. These results suggest that any form of treatment or perhaps infection that causes inflammation in the lungs may affect metastasis formation in that environment. A similar but opposite effect was observed with agents such as heparin that reduce blood clotting. Treatment of recipient animals with such agents was found to decrease experimental lung metastasis formation significantly. It was hypothesized

Table 1 Technical factors affecting metastasis assays

Technical factor	Issues	Comments
Recipient animal	Syngeneic (rodent tumours) Immune suppressed such as SCID or nude mice (human tumours)	Tumours grown in SCID mice have been reported to have higher metastatic propensity than when grown in nude mice
Health of recipient animals	Latent or viral infections Stress of recent transport	Good health very important for reproducible results
Immunogenicity of cells	Many chemically or virally induced tumours in rodents are immunogenic	Immunogenicity can reduce metastatic potential
Animal age and gender		Variations in metastatic potential with age and sex have been observed even for tumours that are not hormonally dependent
Site of injection of primary tumour	Orthotopic vs ectopic	Orthotopic transplantation usually leads to increased metastases
Ectopic organs (human)	Transplantation into SCID mice	Human organs may demonstrate metastatic deposits from human tumour cells when same mouse organ does not
Preparation of cells for experimental metastasis assay	Level of cell viability, no. of cells injected. Presence of clumps of cells. Method of harvesting cells	All factors can modify the no. of metastases observed
Culture conditions	Confluence of culture, acidity of culture, length of time in culture	Can modify the no. of metastases observed

that the explanation for these findings was that there was reduced retention of the cells due to reduced ability to form thrombi around the tumour cells. Again, it proved difficult to reproduce these findings using spontaneous metastasis models.

The second aspect of interest is the finding that deliberate treatment of tumour cells with a growth stress, such as exposure to hypoxia, low pH or low glucose or folate levels can also lead to a transient increase in metastatic efficiency. These results are best illustrated by exposures to hypoxia which have been shown to cause large increases in experimental metastases in both rodent and human tumour cell lines (Young *et al.*, 1988; Rofstad and Danielsen, 1999). These differences can also be observed in a spontaneous metastasis model and appear to link directly to observations in patients where it has been observed that those with more hypoxic tumours are more likely to have metastases. Again, the explanation for these findings is uncertain but it is likely that changes in gene expression associated with hypoxia (such as upregulation of VEGF) play an important role. Another factor may be that a low oxygen environment in tumours may produce oxic stress (reperfusion injury), which in turn may lead to increased DNA damage and mutations in the tumour cells.

PERSPECTIVES

A clear understanding of the critical steps in the process of metastasis and the differences which exist in the abilities of different tumour cells to form metastases remains elusive. The recent work using the IVVM technology and careful cell counting techniques to track cells during experimental metastasis formation has re-emphasized the later stages of the process. Whether the ability to grow at the new site is the limiting factor in metastasis formation in all organs, or with all tumours, remains to be established but experience over the last 30 years, which has identified a wide level of heterogeneity in metastasis-related factors, suggests that this is unlikely. These studies do, however, focus attention back on the seed and soil hypothesis of Paget (1889) and on issues associated with early growth of metastases. They are consistent with the increasing recognition of the importance of cell–cell and cell–matrix interactions in the control of cellular phenotype and with the fact that

many genes that have been isolated as metastasis-specific actually code for functions which relate to cell growth.

Metastases arise from single cells (or a small clump of a few cells), so it is the properties (and interactions) of individual cells rather than of populations of cells that are critical for metastasis formation. As noted above, the environment in which a cell exists can have a significant bearing on its behaviour, thus in the context of the soil and seed hypothesis it is appropriate to think of the properties of the seed in terms of the cell and its initial microenvironment. In parallel, the concept of soil should include the idea of the metastatic cell interacting with and modifying its new microenvironment. Many micrometastases apparently do not ever grow to form macrometastases. This raises the issue of whether phenotypes associated with metastasis formation necessarily represent stable changes and further whether they are truly metastasis-specific rather than reflecting more extreme versions of properties expressed by many of the cells in the primary tumour.

The newer models for metastases, such as the SCID-hu model and the transgenic and knockout mouse models, are opening up new ways to address some of these issues. The use of new technologies, such as DNA arrays, is providing more rapid ways to identify gene expression changes in cell populations. In combination with techniques such as laser capture microdissection, it will be possible to examine gene expression in small numbers, and perhaps individual, metastatic cells. The application of these new technologies will certainly increase our understanding of the complexities of the metastatic process and provide information which can be more directly related to human disease.

- Interpretation of Experimental Results
- Biological and Technical Limitations
- Perspectives

BIOLOGICAL BASICS

The endothelial lining is distributed throughout the body, represents an organ that serves multifunctional purposes and is of approximately 1.5 kg tissue weight in an adult. The primary function of this organ is the preservation of a morphological barrier between the blood circulation and other organs and tissues. The structure is made up of a continuous but semipermeable cell layer throughout the vascular tree as well as an underlying subendothelial basement membrane. Furthermore, endothelial cells (EC) play an essential role in numerous cellular interactions, such as those involved in haemostasis, inflammation, wound healing and tissue regeneration. EC interact with platelets and leucocytes in the bloodstream and also cells from surrounding tissues, such as fibroblasts, macrophages and other immunocompetent cells. Moreover, EC take part in various haemostatic and metabolic functions, including tissue nutritional support and gas exchange.

In addition to the role of EC in angiogenesis and vascular support of primary tumours, the most obvious role of EC is in the formation of distant metastases where it is the primary cellular contact between circulating blood-borne tumour cells and host organs (Auerbach, 1992). The vascular endothelium is not a passive anatomical structure during the blood-borne spread of malignant tumours. Although the locations of many regional metastases can be explained on the basis of anatomical and/or mechanical factors, clinical and experimental observations indicate that many malignant tumours preferentially metastasize to particular distant organ sites that would not be predicted solely from mechano-anatomical considerations and blood flow patterns (Hart, 1982; Nicolson, 1982). Some organs and tissues, such as bones, adrenals and brain, are served by a small fraction of the circulating blood volume, but they are often involved in metastases from certain primary malignancies, whereas others with a high fraction of blood supply, such as heart, muscles, kidneys and others, are only sporadically colonized by cancer metastases (Sugarbaker, 1981; Nicolson, 1988).

For some time now, two major hypotheses on the organ preference of tumour metastasis have existed. Ewing (1928) proposed that the mechanical lodgment of circulating tumour cells in the first capillary system encountered was the determining factor, and that the haemodynamics of the vascular system based on specific anatomical structures predicted the locations of secondary tumours. In contrast, Paget (1889) postulated in his ‘seed and soil’ hypothesis that successful interactions of tumour cells (‘seeds’) with the microenvironment of a particular target organ (‘soil’) lead to formation of distant metastases in specific organs. These hypotheses are not mutually exclusive, and the development of distant metastases at specific organ sites is probably determined by anatomical structures with their resulting haemodynamics as well as specific interactions between unique circulating tumour cells and host organ structures.

The primary barrier between the circulation and extravascular tissues consists of the vascular endothelium and its subendothelial basement membrane (Nicolson, 1989). For the maintenance of normal function, specific interactions are required between circulating cells and these structures, and comparable interactions between tumour cells and organ EC may be necessary for organ-specific formation of secondary tumours (Weiss *et al.*, 1988). For example, specific parts of the microcirculation known as high endothelial venules (HEVs) are specialized in their interactions with other cells, such as lymphocytes, and this may allow transmigration of lymphocytes between the

bloodstream and lymphatics across the vascular barrier (Ford *et al*., 1976). The specialized HEVs, which are morphologically and antigenetically distinct from other EC and also express different antigenic patterns between HEVs from different organs, can be specifically recognized by circulating lymphocytes. Specific molecules are used by lymphocytes to initiate adhesion and migration into particular organs (Gallatin *et al*., 1983). Similarly, malignant tumour cells that preferentially colonize certain host organs must adhere to and invade in a similar way through endothelium and subendothelial basement membranes during haematogenic metastasis formation. Alternatively, for some blood-borne tumour cells it is known that they can adhere to microvascular EC and proliferate within the blood vessels (Belloni and Tressler, 1990) (**Figure 1**).

The endothelium is a single EC layer of considerable biological significance that lines the interior of blood/lymph vessels and the heart. Many of its complex functions appear to involve specific structural and biochemical characteristics of the EC surface. These specific molecular structures are found as permanent or transient, depending

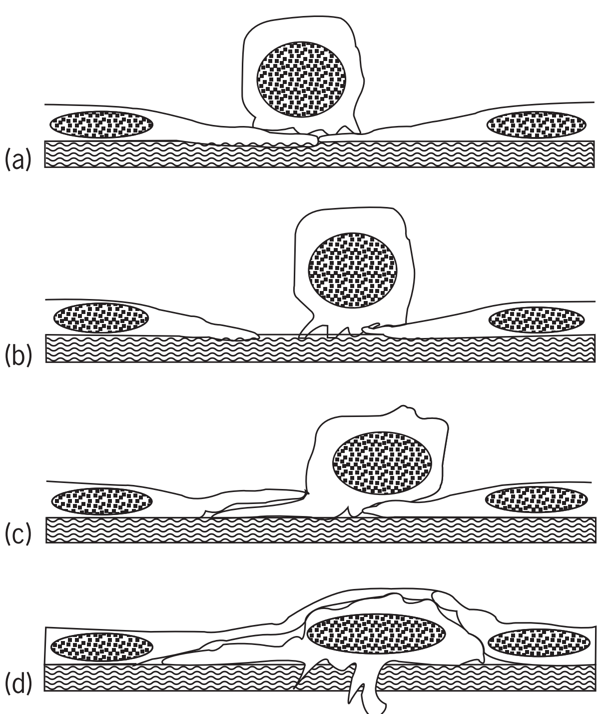

Figure 1 Sequence of events during metastatic tumour cell interactions with EC monolayer. (a) Tumour cell attachment to EC; (b) disruption of EC-EC contacts and retraction; (c) active migration of the tumour cell under the EC in contact with the underlying basement membrane; (d) invasion through basement membrane into host organ and reformation of intercellular EC junctions. (For further steps of invasion see the previous chapter, *Tumour Metastasis Models*.)

on EC functional demands and organ type (Pauli *et al*., 1990). The microcirculation is characterized by its own specific vascular structures, including differences in vessel length, diameter, wall thickness, receptors and ultrastructure that vary remarkably between different tissues and organs (Manjo, 1965; Rhoden, 1980). For example, the continuous endothelium can be either thick or thin depending on tissue and the type of EC. For example, continuous thick capillaries (thickness $>2\,\mu m$) can be found in skeletal tissue, cardiac smooth muscle and genital organs. In contrast, continuous thin capillaries (thickness $<1\,\mu m$) are typically located in tissues of the central nervous system, lung, dermis, vasa recti of the kidney, spleen, thymus, bone marrow and bone. Morphological studies *in vivo* and in cell cultures have shown that microvascular EC differ structurally according to their microvascular origin. EC from thin capillaries usually grow in culture as flat cells of hexagonal shape with large amounts of membrane-related cytoplasmic and pinocytotic vesicles on their apical and basolateral surfaces. Various EC phenotypes can be characterized according to their shape, ranging from cuboidal to elongated and stellate, and contents of vacuoles and shapes of nuclei.

The endothelium maintains its integrity and continuity through communication via gap junctions and desmosomes. The exception is in the central nervous system where tight junctions are the predominant structures. In addition to homotypic contacts, EC also have multiple points of attachment to the subendothelial basement membrane that contains various matrix proteins, such as laminin, proteoglycans (predominantly heparan sulfate proteoglycans), fibronectins, vitronectin and collagens (primarily types III, IV and V). Since variations can be found in the distribution of extracellular matrix (ECM) components within the basement membranes of different organs, such variations likely play a role in vascular heterogeneity and in the regulation of organ haemostasis and growth (Carley *et al*., 1988).

Although most EC are morphologically similar, there are distinctive regional molecular and structural differences in the vascular endothelium (Fenyves *et al*., 1993) For example, the vesiculo-vacuolar organelles, recently described organelles found only in the cytoplasm of EC that line tumour microvessels and normal venules, span the entire thickness of the vascular endothelium. These organelles provide potential trans-endothelial connections between the vascular lumen and the extravascular space. Weibel–Palade bodies, which are specific intracellular storage organelles for von Willebrand factor (vWF) in large vessel endothelia, are rarely found or absent in EC derived from the central nervous system. Moreover, differences in size and thickness of EC have been found in different organs or tissues. Generally, EC from large vessels appear to be thicker than those from microvascular endothelium. Additionally, variable surface structures that include adhesion molecules for homotypic cell–cell

interactions and for anchorage to the subendothelial basement membrane as well as other molecules, such as lectins, can be differentially expressed in large and small vessels (Simionescu *et al*., 1982; Wang *et al*., 1985).

EC in various tissues are functionally and metabolically distinct as well as structurally dissimilar (Schnitzer et al., 1994). They can participate to various degrees in metabolic and haemostatic functions, such as the following: (1) maintenance of a non-thrombogenic luminal surface, in part, via production of prostacyclins; (2) regulation of the coagulation pathway, clot formation and fibrinolysis; (3) presentation of antigens to lymphoid cells; (4) secretion of chemotactic monokines; (5) active participation in leucocyte adhesion and extravasation; (6) secretion of angiogenic factors and other growth factors that coordinately stimulate neoangiogenesis; (7) clearance and metabolism of vasoactive substances, such as bradykinin, endothelin, ADP, angiotensin I and thrombin; (8) control of vasomotion; (9) regulation of perfusion and permeability at the microvascular level and responses to and secretion of autocoids such as nitric oxide, prostaglandins, epinephrine and vasopressin; and (10) regulation of macromolecular transport between plasma and interstitial fluids via large pores, vesicular transport and specific cell surface receptors. Although the highly regulated endothelial functions associated with haemostasis and metabolism of vasoactive substances undoubtedly contribute to the metastatic process of certain tumours, we refer the reader to other reviews for more detailed information about these topics (Gerritsen, 1987; Weiss *et al*., 1988; Belloni and Tressler, 1990).

Transcapillary movements of solutes, such as hormones, drugs, sugars, amino acids, lipids and electrolytes, are regulated by the endothelium. The mechanisms responsible for the regulation of transport are (1) EC microdomains that attract or exclude molecules based on their size and charge, (2) EC surface receptor-specific membrane transport, (3) EC surface ectoenzymes that chemically alter solutes transferred into, out of or between EC and (4) EC synthesis and secretion of solutes that establish concentration gradients between blood plasma and the interstitial tissues. Thus transcapillary transport regulates vascular tone and organ blood supply as well as lymphatic flow and expression of surface receptors for the activation of leucocytes, such as during inflammation. In different organs it has additional organ-specific functions, such as regulation of the cerebral endothelial lining/blood–brain barrier and endothelium-mediated changes in renal, splenic and hepatic function and in skeletal muscle perfusion (Bassenge, 1996).

The microvascular EC membrane has been described as a static pore in some older vascular EC permeability models, with regulation of solute and fluid flow by changes of hydrostatic and hydrodynamic pressure and surface area. Although these models may be suitable for basic conditions, they cannot explain the enormous changes in secretion that occur after trauma or during inflammation. During the last two decades, the regulation of microvascular porosity has been investigated using various inflammatory mediators, vasoactive substances and intracellular signal inhibitors (Bevilacqua *et al*., 1985, 1986; Guretzki *et al*., 1994). These studies led to the development of a new concept of variable mediator-regulated pathways that control endothelial permeability (Lum and Malik, 1994). Investigation of the regulation of the permeability properties of the endothelium has yielded evidence that supports the concept of a dual regulation of EC gap formation and barrier function.

Tumours can dramatically alter the permeability and transport properties of blood vessels (Zhang and Olsson, 1997). For example, in brain tumours a common problem is vasogenic oedema that can cause subsequent neurological symptoms. The peritumoural brain parenchyma shows structural and functional changes of the intracerebral microvessels and oedema (Groothius and Vick, 1982). Additionally, the EC of peritumoral microvessels in brain tumours express glucose transporter protein in the same way as the normal tissue. However, a reduction in immunostaining for the glucose transporter occurred in the microvessels located within metastases but not in surrounding tissues. This indicates abnormalities of the blood–brain barrier in tumour vessels but normal barrier function in peritumoural regions. These effects might be related to the tumour-induced production of vasoactive substances. Reactive astrocytes and activated microglial cells produce numerous biologically active compounds, including endothelin-1, which can influence the structure and function of the peritumoural brain tissue. Structural alterations are also present in tumour-induced blood vessels and peritumoural brain microvessels, such as increased numbers of pinocytotic vesicles, large vacuoles and open junctions, which may also cause changes in permeability. Other possible mechanisms might be related to the destruction of microvessel structure and subsequent changes in hydrostatic pressure (Roy and Chitra, 1989).

One of the interesting tumour properties associated with organ-specific metastasis is that tumour cells may respond to local concentrations of growth factors produced by or present in the target organs. A likely source of organ-associated tumour cell motility factors is organ microvascular EC (Sawada *et al*., 1996) The EC-produced motility factors might interact with other soluble tissue factors to promote organ-specific tumour cell invasion (Orr *et al*., 1980; Hujanen and Terranova, 1985). Examples are nerve growth factors and neurotrophins that play an important role in migration through the blood–brain barrier (Menter *et al*., 1995). EC are also known to produce specific motility-enhancing components of the basement membrane, such as fibronectin, laminin, collagen IV, thrombospondin and fragments derived from these molecules. As described above, EC from various organs possess different amounts and proportions of subendothelial matrix

components. Therefore, tumour cell chemotaxis may be specifically influenced by the composition of the subendothelial basement membrane in the target organ (Cerra and Nathanson, 1991).

The response to various systemic and paracrine growth factors and their inhibitors determines the growth of malignant cells at particular organ sites (**Figure 2**). Differentially expressed stimulating and inhibitory factors influence tumour growth at particular organs and their ability to synthesize and secrete autocrine growth factors. These paracrine growth factors and inhibitors are produced and secreted specifically in each organ, and they appear to play an important role in organ preference of tumour cell proliferation and development of metastases. Some of the paracrine growth factors from certain tissues have been identified. For example, a lung-derived growth factor that stimulated mammary adenocarcinoma cells was purified from porcine lung-conditioned medium and later sequenced and identified as a transferrin (Cavanaugh *et al.*, 1991). Transferrin and transferrin-like factors are produced by microvessel EC, and differences have been demonstrated in the secreted amounts with the highest amounts being produced by brain EC. Liver and lung EC produced lesser amounts of transferrin-like factors (Inoue *et al.*, 1993).

Since some tumour cell lines showed growth inhibition during experiments using EC-conditioned medium, the release of inhibitory factors was assumed. Growth inhibition correlated with the metastatic behaviour of these cell lines (Nicolson and Dulski, 1986). Using organ-conditioned medium, various types of growth inhibition have been found to be mediated by the secretion of growth-inhibitory paracrine factors. One of these inhibition factors, which was first found in kidney-conditioned medium, was purified and identified as transforming growth factor-β (TGF-β) (Holley et al., 1980). TGF-β and other cytokines that are released from EC, such as interleukin-6 (IL-6), might have dual roles in the growth regulation of malignant cells (**Figure 3**). IL-6 has potent stimulatory effects in the activation of EC and enhancement of tumour cell adhesion, but it was also found that this cytokine decreased the cell growth of some tumour cell lines. Other sources of growth-inhibitory potential are immune-competent cells that are often found in the tumour

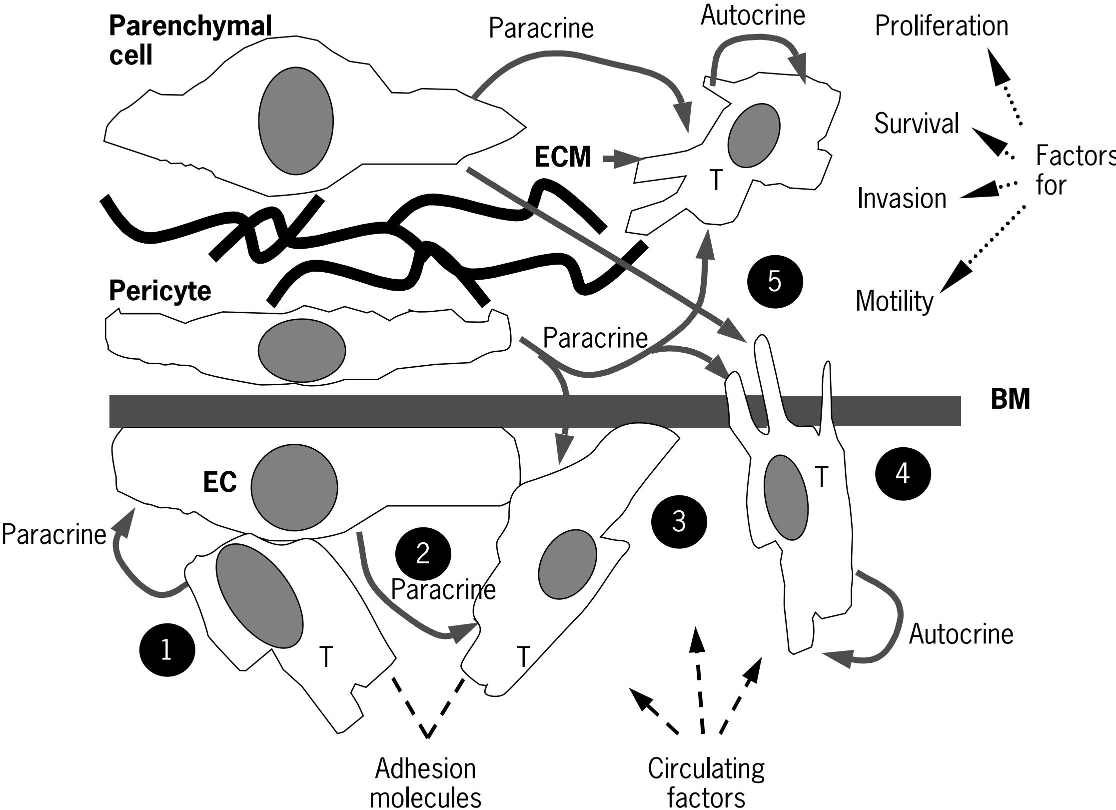

Figure 2 Paracrine and autocrine factors in tumour cell–host organ interactions during various steps of invasion and metastasis. These factors can affect tumour cell survival, proliferation, motility, invasiveness and metastatic properties.

microenvironment, such as tumour-infiltrating lymphocytes, natural killer cells and macrophages. For example, these cells as well as EC produce activated oxygen derivatives, such as oxygen free radicals (O_2^-). These radicals are rapidly converted into highly reactive radicals (H_2O_2, $HO^·$) that are cytotoxic or cytostatic.

Another mechanism has been proposed for cytostatic or cytotoxic effects of EC on circulating tumour cells (LaBiche and Nicolson, 1993). To examine whether vascular EC can be treated with various cytokines to become cytotoxic against tumorigenic target cells, mouse EC monolayers were treated with interferon-γ (IFN-γ) or tumour necrosis factor-α (TNF-α). The activated EC but not untreated control cells produced significant cell lysis of mouse reticulum sarcoma cells and two different mouse melanoma cell lines. This effect was dependent on the presence of the endothelial cells because treatment of the malignant cells with IFN-γ and/or TNF-α did not produce direct target cell lysis. Continuous presence of the cytokines was required for the activated EC-mediated tumour cell lysis (Li *et al*., 1991). However, this result was subsequently found not to be due to direct tumour cell cytolysis by activated EC. Although EC were able to inhibit the growth of tumour cells, they were not able to lyse tumour cells (Nicolson, 1999).

PRINCIPLES OF MODEL ESTABLISHMENT

Isolation and Cultivation

The data discussed above indicate that microvascular EC and ECM from different organs possess unique characteristics that are probably related to their different functions. These characteristics are dynamic and dependent on the functional requirements and microenvironmental conditions of the endothelium. First EC cultures were obtained from relatively accessible sources. For example, human umbilical vein is a useful source of EC (HUVEC) because it is easy to obtain, cells can be isolated in quantity and the cells are generally pure and grow well. However, it has the disadvantage that it is not usually a target site for metastatic involvement. Other blood vessels and tissue sources have also been used to obtain EC. For example, EC have been prepared from nasal mucosa, bovine capillary, pancreatic islet, mouse haemangioendothelioma, adrenal cortex, human dermis, bovine aorta or human neonatal foreskin. In contrast, the culture of tumour-associated EC continues to be difficult, because microvascular EC change during prolonged cultivation and growth conditions, and cellular properties can vary with their particular origin.

Cultivation of HUVEC is well established, and such cultures are widely used. Many studies on the function and interactions of EC have been performed using HUVEC cultures. However, in the evaluation of these results consideration should be given to the neonatal and macrovascular large vessel origins of these cells. As discussed above, this type of EC differs from microvascular EC. For example, the reactions of HUVEC to growth factors (ECGF, EGF, TGF-α, thrombin) and other cytokines (interleukins, TGF-β) were different from those found with microvascular EC. Additionally, differences were found between the release of cytokines by HUVEC and adult macrovascular EC. Also, organ-specific patterns of adhesion molecules expressed on microvascular EC were demonstrated *in vivo* and *in vitro*. The morphology and antigen expression of EC can also be influenced by microenvironmental conditions, such as infiltrating tumour cells. In conclusion, the use of microvascular EC cultures derived from specific target tissues for models of metastasis appears to reflect *in vivo* conditions better than EC from other sources.

The isolation of EC is generally performed using collagenase digestion of ECM and mass gradient selective centrifugation followed by several washing steps. Once cells are isolated, their identity as EC has to be confirmed by their characteristic morphology and expression of EC-specific markers, such as factor VIII, CD31 or vWF. Functional criteria, such as uptake of acetylated LDL, can also be used to confirm cell identity in EC cultures.

Activation of EC

The functions expressed by EC are strongly influenced by the extracellular environment. The presence of interleukins, interferons, tumour necrosis factor, lipopolysaccharides (LPS) and other mediators of inflammation can lead to changes in the expression of adhesion molecules on EC surfaces as well as on other cells (macrophages, monocytes, lymphocytes, etc.). This activation of EC also generates various functional changes. For example, soluble substances, such as TNF-α, IL-1, IL-4, IL-13, IFN-γ or TGF-β, initiate expression and enhanced affinity of homing receptors, such as integrins or selectins for neutrophils which results in increased adhesive interactions between these cells and EC. TGF-β, however, plays a dual role and inhibited E-selectin expression on HUVEC at the mRNA and protein levels. The basal adhesion of various tumour cells to unstimulated EC was very low, and cytokine stimulation augmented these interactions by upregulation of E-selectin expression on the EC surface. Other factors, such as plasminogen activator, released from normal or neoplastic cells cause retraction of EC with subsequent exposure of the underlying ECM. Thus, chemotactic reactions and transendothelial migration of neutrophils are possible. Furthermore, haematopoietic growth factors take part in these complex activation and inhibition processes. For example, granulocyte macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) can modulate integrin-mediated adhesion of neutrophils to activated EC.

The microvasculature is susceptible to perturbation from environmental agents, host cells and cancer cells. There is clinical and experimental evidence that physical trauma, irradiation, chemotherapeutic agents or environmental toxins can induce or enhance the metastatic process. Using established animal models of pulmonary microvasculature injury it has been shown that endothelial damage promotes the localization of circulating cancer cells to the lung with increased development of metastatic lesions, and this effect is lost after endothelial repair. These models generally use the pharmacological or chemical induction of EC damage, such as application or release of free radicals. In this example, oxidative stress is an effector of vascular damage in several of the experimental models. While endothelial cells appear to be directly susceptible to free radical attack, basement membranes are much less sensitive. However, oxidative injury of EC causes release of degradative enzymes with subsequent degradation of ECM components. This event is associated with the generation of tumour cell chemoattractants and enhanced cancer cell invasion of vascular basement membranes.

Adhesion Molecules

For investigations on the adhesive properties of various malignant cell lines, EC monolayers from human umbilical vein (HUVEC) or bovine aorta (BAEC) have been widely used. Although useful for general adhesion studies, differences were usually not observed for metastatic and nonmetastatic tumour cell adhesion to large-vessel EC. The organ preference of metastasis did correlate, however, with the adhesion of tumour cells to microvascular EC in many but not all experimental systems. For example, high lung-colonizing rat rhabdomyosarcoma, melanoma and lymphoma cell lines showed high rates of adhesion to lung-derived EC monolayers, whereas cell clones of poor metastatic potential had low adhesion rates. Metastatic tumour cells adhered to target organ EC and stimulated their retraction at cell junctions adjacent to the adherent tumour cells. Subsequently, the tumour cells penetrated the EC monolayer, adhered to components of the underlying basement membrane and eventually penetrated the subendothelial matrix. This behaviour was normally not found in most of the noninvasive, nonmalignant cells examined. Although different metastatic systems may vary in their adhesive properties to EC and their underlying matrix, their adhesive behaviours are often related to their metastatic properties (Belloni and Nicolson, 1988).

In general, the subendothelial matrix was found to be a better substrate for cell adhesion of most tumour cells than the EC surface (see the previous chapter, *Tumour*

Metastasis Models). Also, the adhesive behaviours of tumour cells could be modified by the organ-specific composition of the subendothelial ECM. Using bovine aortic EC grown on ECM preparations from various organs tumour cells showed adhesion to EC that was dependent on the organ matrix. Thus, EC behaviour can be modified by ECM composition, possibly due to changes in expression of adhesion and other molecules.

Some of the organ-associated EC surface determinants involved in the adhesion of metastatic tumour cells have been identified using affinity procedures (**Figure 4**). For example, ^{125}I-labelled lysates of EC were adsorbed on lightly glutaraldehyde-fixed tumour cells. After binding, the components were solubilized in detergent and analysed electrophoretically. In these experiments, the majority of the adsorbed radiolabelled proteins migrated in the molecular mass region known to contain integrins (~120–180 kDa). However, there were also low molecular mass proteins bound to the fixed tumour cells corresponding to the molecular masses of known glycoproteins, such as annexins, lectins and other receptors. Moreover, it was found that the individual protein profiles were unique for each EC type (Belloni and Tressler, 1990).

A similar technique for identification of adhesion molecules on EC surfaces was developed (tumour cell–Western adhesion) where detergent-solubilized EC preparations were electrophoretically separated, and EC-binding components were detected by adding viable biotinylated or radiolabelled tumour cells. For example, using this method five EC-derived glycoproteins were identified from liver or lung microvessel EC that interacted with murine large-cell lymphoma cells. These lymphoma cells bound preferentially to hepatic EC, and they adhered quantitatively based on their organ-specific metastatic behaviour. These results suggest that tumour cell adhesion is directed, in part, to specific tissue-associated surface molecules expressed by the microvascular EC in different organs. Although these adhesion molecules appear to be involved in tumour cell interactions with microvascular EC, it is unlikely that these molecules alone can confer adhesive specificity to metastatic tumour cells (Nicolson, 1988; Belloni and Tressler, 1990).

Another approach for studies of EC surface molecules that are involved in interactions with tumour cells was the development of serological procedures, including monoclonal antibodies against organ-associated antigens on EC (**Figure 5**). Hybridomas were selected from animals immunized with EC from various organs and different species. Screening and further selection using binding studies of the hybridomas and cells from different organs or species resulted in monoclonal antibodies directed against but not limited to organ-specific antigens. Using this method, antibodies reactive against EC and other cells, such as fibroblasts from one organ but not reactive against cells derived from other organs, were obtained (Doer *et al*., 1989).

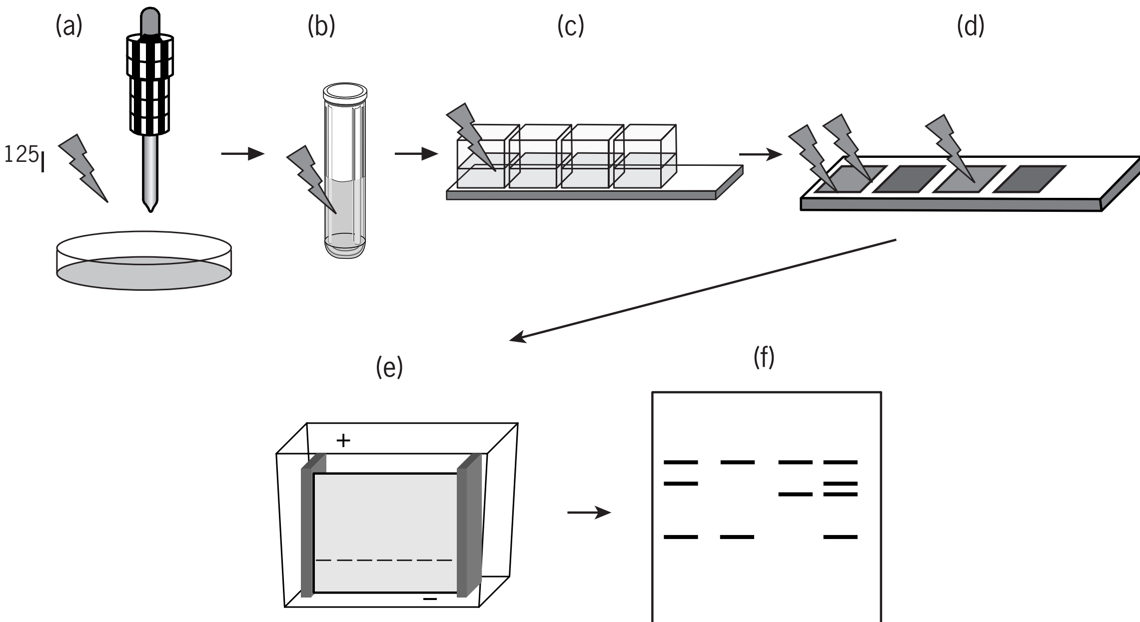

Figure 4 Principle of identification of tumour cell-binding proteins on microvascular EC surfaces. (a) Labelling (^{125}I) of microvascular EC surface molecules; (b) solubilization using sodium dodecyl sulfate or CHAPS detergent; (c) adsorption of labelled lysate to glutaraldehyde-fixed tumour cells; (d) bound EC adhesion molecules occur as radioactive sources on tumour cells; (e) electrophoretic separation of bound adhesion molecules; and (f) visualization of EC adhesion molecules by autoradiography. Microvascular EC cell lysates from different organs showed different patterns of adhesion molecule expression.

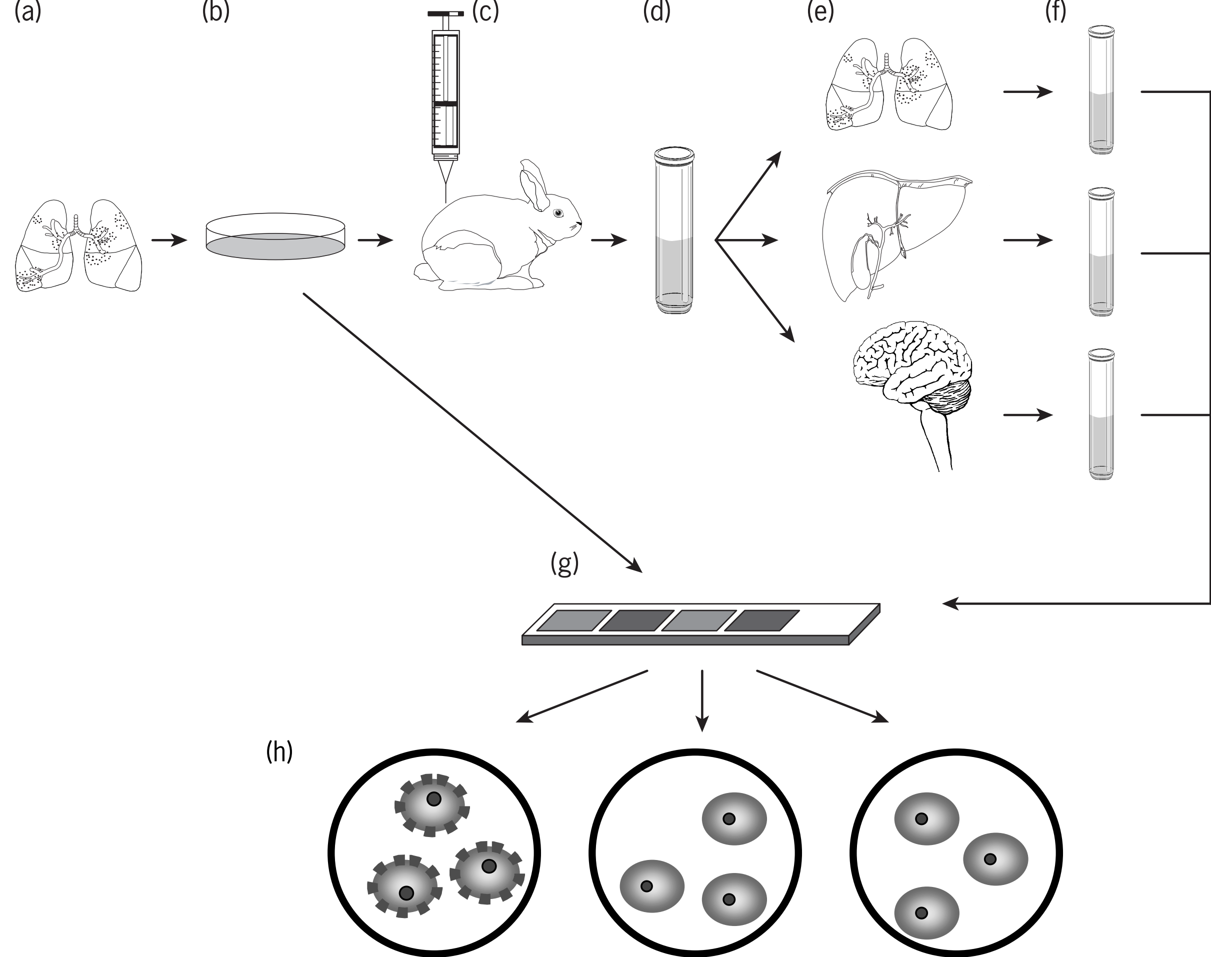

Figure 5 Selection of organ-specific antibodies against EC surface molecules. (a) Isolation of organ-specific EC (e.g. from lung); (b) culture of organ-specific EC; (c) immunization of an animal with organ-specific EC; (d) isolation of antibodies against EC; these polyclonal sera contain antibodies against organ-specific, species-specific and nonspecific EC surface antigens; (e) selection of organ-specific antibodies against EC from various organs; (f) remaining preparations contain organ-specific but not nonspecific antibodies; (g) EC monolayers from target organ can be used for immunocytochemical analysis; (h) organ-specific antibodies react with EC derived from target organ, but with EC from other organs.

Immunohistological studies using polyclonal antisera against various EC-binding glycoproteins have shown that specific organ distribution of EC adhesion molecules is quantitatively not qualitatively different in most tissues. At least one of these glycoproteins was identified as a galectin (∼33 kDa) (Lotan *et al*., 1994). Other components were identified as annexin II (∼35 kDa). Antibodies against these adhesion molecules inhibited adhesion of tumour cells to microvascular EC monolayers by about 40% (Tressler *et al*., 1993), suggesting that multiple adhesion systems (integrins, selectins, annexins) are involved in tumour cell–EC adhesive interactions.

Functional studies on adhesive interactions of EC with circulating cells can be performed using static or dynamic adhesion systems. The principles of these techniques are described in the chapter *Models for Tumour Cell Adhesion and Invasion*, and these procedures can be adapted with the modification that EC monolayers are the adhesive substrates. Since EC–tumour cell interactions appeared to be mediated primarily by glycoproteins where the binding takes place between the lectin domain of one molecule with a corresponding carbohydrate, different types of carbohydrates were assumed to be important in determining organ-specific adhesive interactions. Therefore, modification of terminal sugar moieties or blocking using antibodies against specific carbohydrates were used for identification of the involved lectins. Thus an important group of adhesion molecules identified by these methods were a type of lectins called selectins. Selectins are adhesion molecules found on tumour cells and normal cells that use carbohydrates as receptor ligands, such as leucocytes/lymphocytes (L-selectin), platelets (P-selectin) and

EC (E-selectin). The action or expression of EC selectins depends on cell activation by ILs, TNF or toxins. For example, selectins mediate the recognition of carbohydrates via Sialyl-Lewis[a], Sialyl-Lewis[x] or the MECA-70 antigen and they play a central role in targeting and initial contacts between circulating tumour cells and EC of the host organ (Irimura *et al*., 1986). (See also the chapter *Models for Tumour Cell Adhesion and Invasion*.)

The presence of platelets in adhesive interactions can also result in enhancement in EC adhesion, and their involvement in tumour cell targeting to microvascular vessel walls has been demonstrated. Platelets take part in different steps of the adhesion cascade, but they appear to be especially important in stabilization of tumour cell–EC and tumour cell–ECM adhesion. Specific interactions between tumour cells and platelets are mediated by release of activating substances and cross-linking of platelets during adhesion of tumour cells to EC and ECM.

Paracrine Motility Factors

Almost two decades ago studies showed that tumour cells can preferentially grow in medium conditioned by the target organs for metastatic colonization. For example, the ability of liver- and brain-metastasizing tumour cells to migrate towards a concentration gradient of soluble components extracted from brain or liver was demonstrated. Liver-metastasizing murine colon carcinoma cells preferentially migrated towards a concentration gradient of liver extract rather than to gradients made from extracts of lung or brain (Sawada *et al*., 1996).

Since differences in the motility and growth responsiveness to soluble factors derived from mouse liver, brain, and lung microvessel EC were found, conditioned media were used to examine the effects of secreted factors on various tumour cell systems. For example, mouse liver hepatocyte sinusoidal EC (HSE) and microvascular lung EC (MLE) were used to demonstrate organ-specific motility factors that lead to specific enhancement of motility of colon carcinoma and large-cell lymphoma cells with different metastatic potentials (Hamada *et al*., 1992; Sawada *et al*., 1996) (**Figure 6**). Highly liver-metastatic cells showed a higher stimulation of motility after exposure to HSE-conditioned medium than poorly metastatic cells. Additionally, MLE-conditioned medium failed to stimulate the motility of these cells. In contrast, the growth properties of colon carcinoma cells were not altered after stimulation of poorly and highly metastatic cell lines with conditioned medium but highly metastatic lymphoma cells were preferentially growth stimulated by conditioned medium from liver EC (Nicolson, 1988). EC derived from lung and liver secrete different tumour cell paracrine motility factors, such as C3b complement factor or monocyte chemotactic factor-1 (MCP-1) that appears to

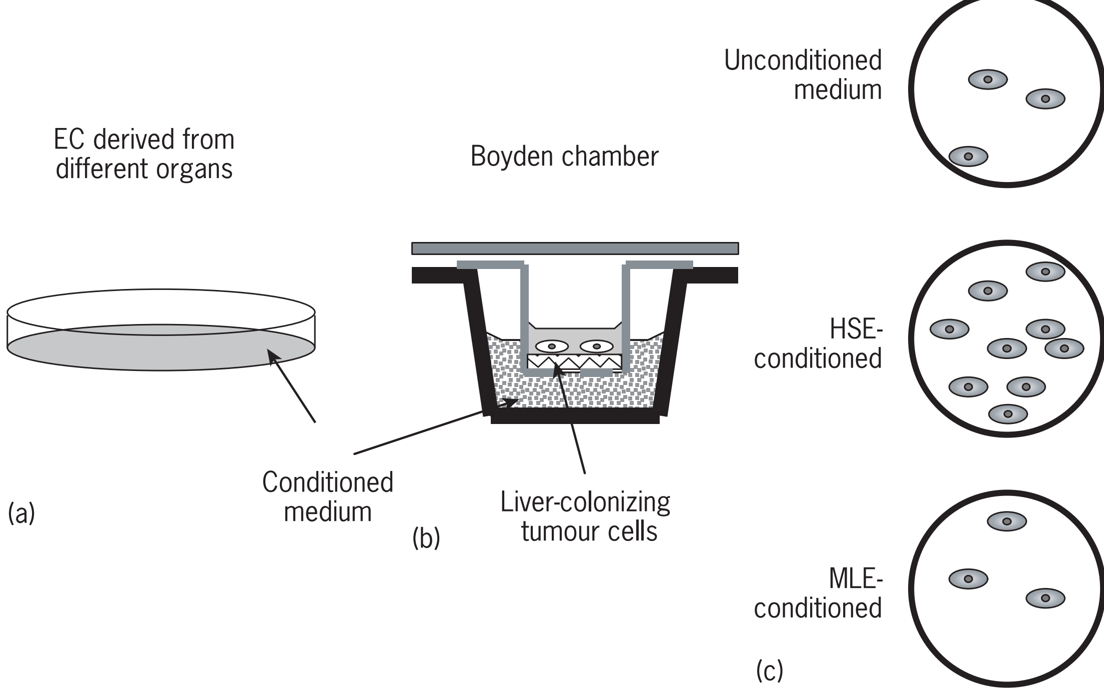

Figure 6 Paracrine motility factors secreted by microvascular EC enhance tumour cell migration. (a) Conditioned media are obtained from organ-specific microvascular EC cultures; (b) conditioned media are used as chemoattractants in the lower chamber of a Boyden chamber; (c) HSE medium from liver EC contains specific motility factor(s) and increases the number of migrated liver-metastasizing cells, whereas MLE medium from lung EC has no effect (see text).

contribute to organ preference of tumour cell invasion of these tissues by lymphoma cells (Hamada *et al*., 1992).

Various factors can influence specific steps of tumour cell adhesion, migration and invasion. Some of these have been examined using a two-chamber system separated by a porous barrier with chemoattractants in one chamber. The experimental conditions used in the Boyden chamber assay, such as various EC-conditioned media as chemoattractants, ECM components or gel preparations (as invasion barriers), determine the experimental outcome. For example, the effects of nerve growth factor (NGF) on the invasive potential of brain-metastatic melanoma cells through Matrigel (a mixture of basement membrane components that forms a gel layer in the Boyden upper chamber) were investigated during chemotactic stimulation using brain microvessel EC-conditioned medium. It was shown that the presence of brain EC motility factors was essential for invasion of the melanoma cells stimulated by NGF or other neurotrophins (Menter *et al*., 1995).

In a modification of the motility/invasion assays, possible pathways of action for these factors can be examined. For example, a possible pathway for tumour cell–EC and –ECM interactions is the stimulation of degradative enzyme secretion, such as collagenase and heparanase, and it was shown that melanoma cells exposed to NGF in the experiments described above are stimulated to release these degradative enzymes (Marchetti *et al*., 1993). Similar experimental designs can be used for the identification and evaluation of factors that determine the growth properties of tumour cells. It is known that EC can secrete growth stimulatory and inhibitory factors, and this can be obtained from the conditioned medium of organ-specific EC cultures. Tumour cell cultures can then be incubated with these conditioned media, and the number of cells or cell colonies can be measured using various detection methods.

Monolayer Wounding

A common application for the investigation of EC motility and functional consequences of disturbances of the integrity of EC monolayers is the use of wounded EC monolayers. The principle of this model is simple, and it is highly reliable. After EC are grown to confluence, the integrity of monolayers can be disrupted using sharp tools which are dragged across the monolayer. Subsequently the reconstruction of EC monolayer integrity can be observed under a microscope. Time-lapse microscopy can be applied to visualize time-dependent functions during the re-establishment of the EC monolayer integrity. This principle also allows the evaluation of cell functions which are required for EC monolayer re-establishment and the analysis of environmental conditions that are related to the presence of infiltrating tumour cells, such as paracrine growth and motility factors. Functional consequences can also be analysed by harvesting the cells for further biochemical investigations, such as examination of phosphorylation/dephosphorylation of cellular proteins.

Release of Degradative Enzymes

EC are a very important source of degradative enzymes required for the penetration of tumour and normal cells through the subendothelial basement membranes. Although tumour cells themselves are able to secrete various types of matrix degradative enzymes, they also can induce secretion and/or activation of various enzymes by surrounding EC. This stimulation occurs either directly through adhesive tumour cell–EC interactions or indirectly by release of soluble factors that modify the balance between degradative enzymes and their inhibitors to enable subendothelial basement membrane penetration by tumour cells. Models for investigation of degradative enzyme release in relation to adhesive interactions are described in the previous chapter, *Tumour Metastasis Models*. The analysis of soluble factors released by tumour cells that affect the balance between degradative activity and inhibition can be performed at the transcriptional level or by evaluation of conditioned medium. The first approach allows the investigation of surface receptors and subsequent signalling cascades that are involved in the mediation of enzyme release. EC monolayers can be incubated with different types of soluble factors, such as epidermal growth factor (EGF), platelet derived growth factor (PDGF) or various cytokines. Subsequent changes in mRNA levels of degradative enzymes and their inhibitors can be analysed, and specific drug-induced modifications of these changes allow the identification of candidate signalling mechanisms. (See also the chapters *Models for Tumour Cell Adhesion and Invasion* and *Modelling Tumour Tissue Interactions*.)

In contrast, conditioned media have been used to investigate post-translational events that are related to EC stimulation. EC monolayers can be stimulated with biochemicals (soluble factors), radiation or UV exposure or by physical interference (wounding), and the subsequent release of degradative enzymes into the culture medium can be examined at the protein level by immunological procedures, such as Western blotting. Since degradative enzymes are normally released as inactive pro-forms of the enzymes, detection of enzyme activity is required for further analysis. A common and very simple way to achieve semiquantitative results of released enzyme activity is provided by zymogram electrophoresis. This method uses different types of substrates that are added to polyacrylamide electrophoresis gels to visualize degradative activity by the disappearance of stainable substrates in the gel. Using zymogram electrophoresis the secretion of degradative enzyme can be characterized with regard to their molecular masses and substrate specificities. However, several experimental procedures, such as sodium dodecyl sulphate polyacrylamide gel electrophoresis, can

activate certain enzymes and activities observed do not necessarily represent EC function. Other experimental designs, however, allow investigators to overcome these limitations. For example, using the release of radioactively labelled heparan sulfate from ECM preparations after γ-irradiation of EC the secretion of heparanase was examined (Nicolson *et al.*, 1991). Most recently, fluorogenic substrates were introduced that allow measurements of enzyme activity, substrate specificity and kinetics. This method is based on the degradation of substrates where the resulting products are fluorogenic and can be detected using fluorescence spectrometers.

Barrier Function

The vascular endothelium is essential in maintaining proper haemostasis, selective barrier and permeability properties of blood vessels, and in mediating responses to various physiological and pathological stimuli. However, malignant tumour cells can influence EC barrier functions, including fluid exchange and selective passage of larger molecules. As an example of these changes, it is frequently seen that tumour masses are surrounded by oedema and the fluid exchange between blood circulation and tissue is disturbed (Criscuolo *et al.*, 1988; Zhang and Olsson, 1997).

Interactions with Coagulation System

Fibrin deposits in tumour beds are an unintriguing phenomenon. These deposits have been suggested to promote tumour growth by providing a provisional matrix in which tumour cells can grow, invade and induce the development of a vascular network that is crucial for tumour growth. It has been shown that procoagulant factors, such as thrombin, are not only involved in coagulation, but they can also stimulate tumour growth and neovascularization. Furthermore, the fibrin matrix can protect the newly formed micrometastases from host defence systems. Several mechanisms seem to contribute to peritumoural fibrin formation (Rickles *et al.*, 1992). For example, mechanical damage of EC integrity and subsequent exposure of the underlying subendothelial basement membrane can trigger fibrin formation by activation of the extrinsic coagulation cascade. Additionally, immunological and inflammatory stimuli in the tumour microenvironment can initiate responses of the intrinsic coagulation system. It has also been found that certain tumour cells are able to induce procoagulatory responses, and they can release proteases that activate various coagulation factors. These enzymes are serine or cysteine proteases that, for example, can cleave factor X.

The procoagulant response of EC alone or cocultured with tumour cells can be determined using conditioned media, as described above. Release or activation of different types of coagulation factors can be monitored using a variety of techniques that will not be explained in further detail in this chapter. Alternatively, fibrinolysis, or the cleavage of thrombin or plasminogen, can be investigated. The modification of plasminogen pathways by degradative activities is closely related to the degradative properties of tumour cells and/or EC (Ordinas *et al.*, 1990).

Tumour cells in addition to EC can be influenced by various circulating cells of the blood in different types of complex interactions. For example, platelets are frequently found in tumour or tumour-surrounding vessels. Their interactions with EC or tumour cells include reciprocal activation, stimulation of soluble factor release, such as growth factors or procoagulatory factors, and secretion of degradative enzymes (Honn *et al.*, 1992). For investigations of interactions between platelets, tumour cells and EC, coculture techniques have been widely used. Their principle is based on techniques where one cell type is grown to confluence (mostly EC), and other cells are added to the culture (usually tumour cells and/or platelets). Further analysis can be performed using microscopy for morphological analyses or immunological and/or biochemical methods for functional investigations. The evaluation of functional responses involves examination of signalling cascades within the different cell types and/or secretion of soluble factors into the medium. However, experiments involving several types of cells are often difficult to interpret, and slight changes in the experimental design or different cell preparations often produce different results.

GENERAL APPLICATIONS

One of the more interesting phenomena in cancer research is that tumours are collections of heterogeneous cells. Interestingly, EC are also heterogeneous in their properties to certain degrees. EC heterogeneity was apparent when immunohistochemical studies demonstrated that EC could be negative for expression of classical EC markers, such as factor VIII-related antigen von Willebrand factor. It was found that these negative EC were located in specific parts of the vascular tree, and they were functionally distinctive in sinusoidal organs, such as liver, lymph nodes or renal glomeruli. This EC heterogeneity was later also found in organ metastases. For example, EC in different tumours and sometimes within the same tumour demonstrate differential expression of surface molecules. Moreover, it has been shown that tumour cells demonstrate different adhesive interactions to EC derived from different organs, and these properties appear to be related to their metastatic behaviour.

The development of *in vitro* or *in vivo* models to study tumour cell–EC interactions should consider EC heterogeneity as well as their organ-specific microenvironments. Unfortunately, many if not all EC cell characteristics can be time dependent and transient. This includes the expression and function of various surface antigens and

secreted components and their complex interactions during the metastatic process. Furthermore, the endothelial origin of and response to various factors that stimulate or inhibit cell growth, motility and/or invasive potential must be considered. Moreover, autocrine, paracrine and hormonal mechanisms can occur transiently and change over time.

Currently, our knowledge about endothelium-dependent vascular responses, microcirculatory regulation and tissue regeneration is limited, and further investigations in these areas and their relevance to understanding pathological phenomena such as cancer invasion and metastasis are necessary. Functional responses and cellular signal transduction stimulation after tumour cell adhesion to EC are only partially understood, in addition to their downstream responses and ultimately changes in gene regulation. Exactly how EC promote lysis of their basement membrane and the subsequent penetration of tumour cells into the host organ is still under investigation, but these mechanisms appear to be very important in determining organ-specific formation of metastases.

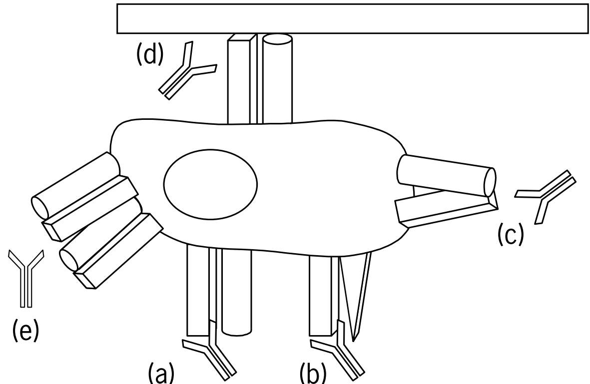

Figure 7 Detection of surface molecules by monoclonal antibodies. The scheme shows possible interference of various factors with the ability of a monoclonal antibody against one subunit of a heterodimeric molecule (for example integrins). (a) Antibody recognizes the target molecule; (b) antibody binds to a different heterodimer with the same subunit; (c) altered conformation of the molecule (e.g. after cell activation) inhibits antibody recognition; (d) steric inhibition after cell binding protects antibody-binding site; (e) 'clustering' of surface molecules results in steric inhibition.

INTERPRETATION OF EXPERIMENTAL RESULTS

Since at least some of the surface molecules on EC are able to change their activation status in relation to their functional properties, alteration of EC molecular structures under relatively native conditions is an important issue in experimental designs. For example, integrins and other adhesion molecules can be modified in their binding affinities, which can be accompanied by alterations in their quaternary structures. On the other hand, binding of antibodies is often strongly dependent on steric considerations and sometimes on the recognition of quaternary structures. Therefore, binding of antibodies to specific surface antigens is closely related to the receptor activation status. If the binding sequence is located within a critical domain, antibody attachment may not occur. In contrast, binding of antibodies to various domains of adhesion molecules can result in activation or inhibition of their function, and adhesive properties can be modified. A second problem, which is related to antibody recognition and functional consequences of antibody binding, is that various surface molecules consist of heterodimeric complexes. Therefore, antibodies against single subunits can differ in their effects compared with antibodies against more than one type of subunit in heterodimers, especially if multiple combinations of various subunits are possible, such as in the integrins. The choice of antibodies and interpretation of experimental results must consider these functional consequences of antibody binding, such as in adhesion inhibition studies used for identification of adhesion molecules involved in tumour cell attachment to EC or ECM.

Similar problems can arise if surface molecules are investigated using immunocytochemical procedures (**Figure 7**). The detection of receptor expression can depend on their functional status or the steric availability of the surface antigen. For example, surface molecules cannot be visualized by immunocytochemistry if these molecules are bound to their receptors in such a way that results in steric hindrance or occupation of the recognition domain for the antibody used. However, the ability of antibodies to recognize certain functional forms of cellular molecules can also be used in specific experimental designs for the investigation of changes in these functional properties.

BIOLOGICAL AND TECHNICAL LIMITATIONS

The organ-specific heterogeneity of EC and their potential for functional and structural alterations are among the most important problems using *in vitro* EC models. The characteristics of the EC phenotype are dependent on culture conditions, adhesive substrates and cell–cell interactions in virtually every experimental system. For example, expression of CD31 on EC surfaces is inducible by various ECM components. Additionally, the expression of various antigens (e.g. von Willebrand factor or glucosaminoglycans) and other molecules (e.g. plasminogen activator, prostaglandins or angiotensin-converting enzyme) are influenced by the age of the cultures, number of passages

and activation status of EC. Moreover, microvascular EC can deposit an insoluble ECM when cultured on plastic or collagen surfaces. Under certain culture conditions such matrices exhibit a filamentous and multilayered ultrastructure with typical characteristics of the basement membranes formed *in vivo*. Some types of EC also undergo substantial morphological and functional changes during *in vitro* culturing. For example, HUVEC cannot be used beyond passage 5–6 owing to significant changes in their phenotype. This requires frequent new preparations from different human sources. Studies on the influence of source variability on the success of EC cultures demonstrated a strong negative influence of various factors, such as smoking behaviour. EC characteristics must be frequently tested for functional criteria to obtain comparable EC. Finally, it was demonstrated that some EC lines, such as EC derived from bovine corpus luteum, express different EC types within the same vascular segments. Differentiation of these cell types by intensive cultivation resulted in EC cultures with differences in cytoskeleton structures, expression of ECM and display of adhesion molecules. Growth factors, such as EC-derived growth factor (ECGF) and cytokines (e.g. GM-CSF or interferons), can influence the growth characteristic of EC cultures, depending on the cell type.

The complex involvement of EC in microenvironmental regulation and their interactions with other cells cannot be easily mimicked by *in vitro* models. This implies that there are advantages and disadvantages in various model systems, especially if they are used for functional studies. *In vitro* systems are able to focus on individual steps in complex processes or functions but this can also result in over simplification. For example, cross-links between EC signalling cascades and cellular functions can occur and their separation may result in disparate cellular behaviour *in vitro*, which may not reflect *in vivo* behaviour. On the other hand, *in vivo* models, such as intravital video microscopy, can examine tumour cell–EC interactions under physiological conditions. However, some influencing factors might not be controllable in such *in vivo* settings, resulting in problems in reproducibility of the observed effects. Furthermore, injection of human tumour cells into animal models does not consider species-related interactions between the tumour cells and the host. For example, intravenously injected tumour cells can be attacked by the host immune system mounting a xenogenic response because many cell surface molecules demonstrate genetic and structural variability between different species. Therefore, molecular interactions between molecules of different origin may be influenced by differences in protein structure. Approaches to eliminate these problems include the injection of human tumour cells into immunodeficient animals or the use of tumour cells and animals of the same species. Also, tumour cells must maintain their tumorigenic and metastatic potentials for reliable results in these experimental designs.

In vitro culturing of EC requires specific and expensive medium to propagate the cells. Although the EC growth supplements are costly, they ensure optimal results for cell survival and growth. Other media, such as those derived from various tumour cell cultures, may vary dramatically and their effects on reproducibility can be troublesome.

Many bacterial toxins are potential inducers of EC responses, and they are common contaminants of commercial sera. They can cause release of various EC cytokines, procoagulative molecules and other factors as well as induction of EC functional changes, such as EC activation. Therefore, it is of special importance in experiments using EC to maintain an endotoxin-free environment during cell culture (media, sera) and in the experimental assays to be used.

PERSPECTIVES

Although our understanding of EC interactions with tumour cells and their involvement in organ-specific formation of metastases is increasing, much remains to be learned about the pathobiology of these interactions. Many endothelial properties are very complex, and the changes caused by tumour cell interactions, such as induction of signal transduction, and cross-talk between various signalling cascades remain to be investigated. Microcirculatory regulation and involvement of multiple cell systems, such as EC, leucocytes and platelets, in this process make relevant experimental studies a challenge. Eventually, differences between normal vascular function and pathological events may provide new therapeutic strategies for cancer treatment.

CONTENTS

- Introduction
- The Extracellular Matrix and Cell Function
- Mesenchymal–Epithelial Interactions in Embryonic Organogenesis
- Interactions in the Adult Mammary Gland
- Growth of Primary Tumours
- Metastasis
- Conclusion

INTRODUCTION

Tumours are complex tissues consisting of many variant tumour subpopulations which, if isolated, have widely differing growth rates, metastatic potential, response to therapy and genetic stability. The phenotype of an intact tumour results from interactions amongst its subpopulations and from interactions with tissue elements including, in the case of carcinoma, remaining normal and premalignant epithelial cells, stromal cells, and extracellular matrix components (**Figure 1**). Stromal cells include a number of cell types including fibroblasts, myofibroblasts (positive for alpha-smooth muscle actin and negative for cytokeratin), endothelial cells, adipocytes and infiltrating lymphocytes and macrophages. Myofibroblasts are common in cancer stroma and are probably derived from fibroblasts responding to cytokines produced by tumour cells. The extracellular matrix composition varies and contains a variety of growth factors as well as components for cellular attachment factor interactions. Premalignant progression, growth of primary cancers, invasion and metastasis are all altered by stromal interactions. The growing appreciation of the importance of orthotopic implantation in experimental oncology reflects the recognition of these interactions as critical determinants of cancer behaviour. However, far too often models to study stromal interactions simply mix tumour cells with fibroblasts. This chapter is intended to provide an overview of the interactions occurring in cancer tissues and instill an appreciation of the complexity of these tissue interactions, in those wishing to model them. Interactions occurring in the breast will often be discussed in detail but the principles apply to other organs. (See also chapter *Extracellular Matrix: the Networking Solution*.)

THE EXTRACELLULAR MATRIX AND CELL FUNCTION

Gene expression in epithelial cells is dependent upon cell shape and extracellular matrix components. Corneal epithelial cells respond to fibroblast growth factor if grown on plastic but on a collagen matrix these cells respond to epidermal growth factor, not fibroblast growth factor (Gospodarowicz *et al*., 1978). An assay for diffusible growth factors in which both producer and responder cells grow in a three-dimensional array in a collagen gel matrix (**Figure 2**) reflects the effect of normal mammary stromal and epithelial cells on neoplastic and preneoplastic cell growth *in vivo*; that is, both normal mammary epithelium and normal mammary stroma stimulate growth of mammary tumour cells but not growth of normal mammary epithelium or preneoplastic hyperplastic alveolar nodule cells (Miller *et al*., 1989). However, in parallel experiments using monolayer cultures, neoplastic cells are inhibited by normal mammary cells *in vitro*. Such results argue for the use of an extracellular matrix and allowing for three-dimensional structure in assays of cellular interactions via diffusible factors. However, the composition of the extracellular matrix is also important. For example, the prolactin and insulin response of mammary epithelium is greater on a basement membrane type extracellular matrix than on collagen type I, whereas response to epidermal growth factor is greater on collagen I than on basement membrane (Lee and Streuli, 1999).

The extracellular matrix is connected to the nucleus by a network of proteins consisting of transmembrane adhesion molecules, the cytoskeleton and the nuclear matrix. Cytoskeletal components interact with signal transduction pathways and are linked to both the extracellular matrix

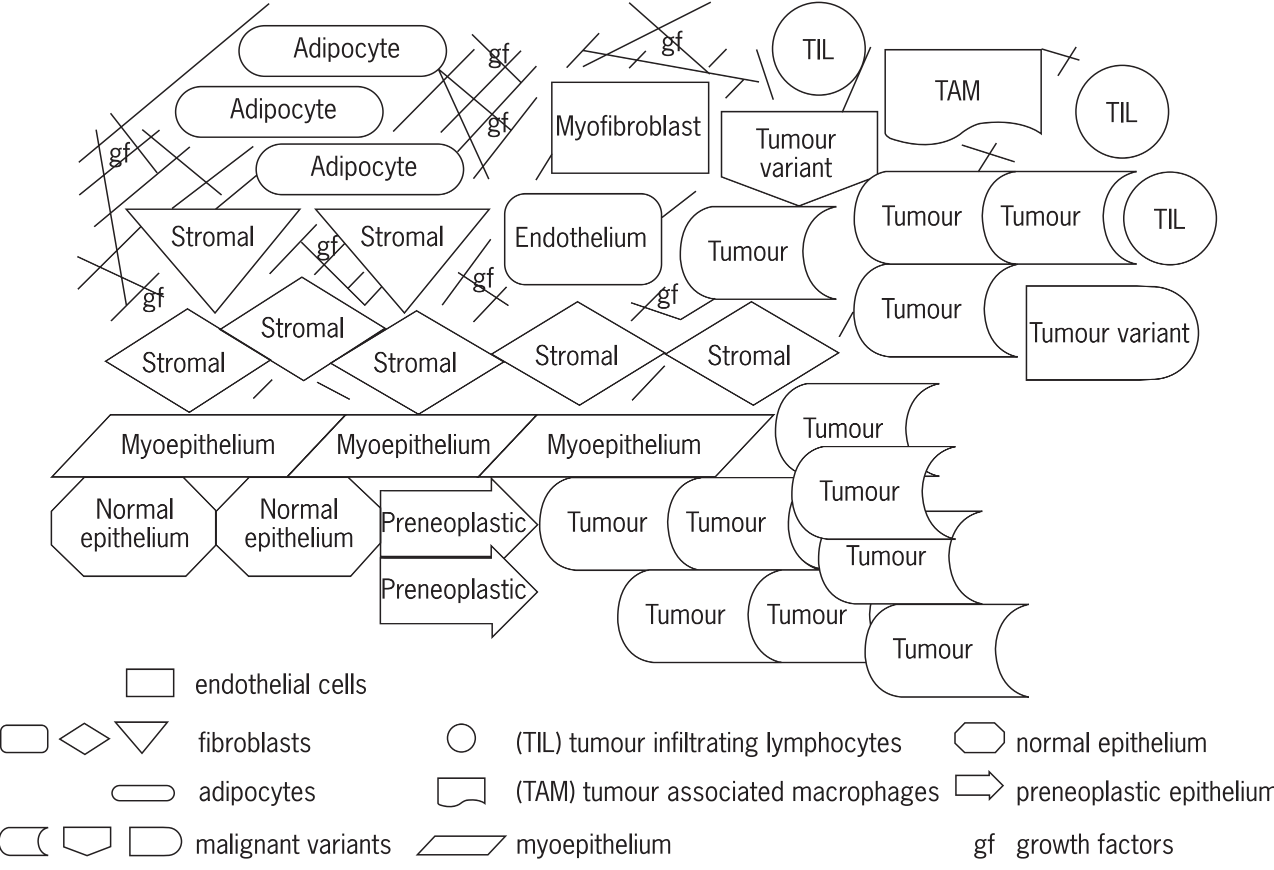

Figure 1 Interactions in a malignant tumour involve multiple cell types.

and the nuclear matrix. The matrix networks are different between normal and transformed cells and modification of the extracellular matrix environment affects the protein composition of the nuclear matrix (Getzenberg *et al.*, 1991). The nuclear matrix is associated with DNA replication and regulation of gene expression.

The stromal extracellular matrix is altered in cancer. The tumour stromal extracellular matrix contains more collagens, glycosaminoglycans and proteoglycans which may be structurally altered as well as increased in quantity. Many components which are restricted to the ductular–stromal interface in normal breast are diffusely expressed throughout the cancer stroma. Tenascin-C is highly expressed during embryogenesis, during wound healing and in tumours. Tenascin-C is weakly expressed in normal breast and varies with the menstrual cycle, being lowest during weeks three and four of the cycle. As well as increased quantities, localization is altered in breast cancer. In the normal breast tenascin-C expression is primarily in the basement membrane and just outside the ductule but in cancer tenascin is absent from the basement membrane and present diffusely in intralobular and interlobular stroma (Ferguson *et al.*, 1990).

Cell adhesion molecules involved in cell–extracellular matrix interactions include integrins which consist of an α and a β chain. Various combinations of α and β chains are receptors for different matrix components. The $\beta1$ group bind collagens, fribronectin and laminin, whereas the $\beta3$ integrins bind thrombospondin and vitronectin. The integrins $\alpha2$, $\alpha6$, $\beta1$ and $\beta4$ are decreased in most breast cancers. For example, 80% of breast cancers had complete loss of detectable $\alpha6\beta4$. Upon binding to specific matrix components, signal transduction is triggered through focal adhesion proteins to regulate proliferation, apoptosis and gene expression. Thus, alterations in extracellular matrix components and adhesion molecules in cancer result in altered gene expression in the cancer cells which can lead to altered motility and invasive properties as well as loss of attachment itself.

MESENCHYMAL—EPITHELIAL INTERACTIONS IN EMBRYONIC ORGANOGENESIS

Mesenchymal–epithelial interactions play a fundamental role in tissue development in the embryo. Developmental response of epithelium to differentiation factors, including steroid hormones, is mediated through stromal/mesenchymal cells. If the mesenchyme is unable to respond, for example owing to a genetic disorder, organogenesis is aberrant. Formation of the mammary gland epithelial bud,

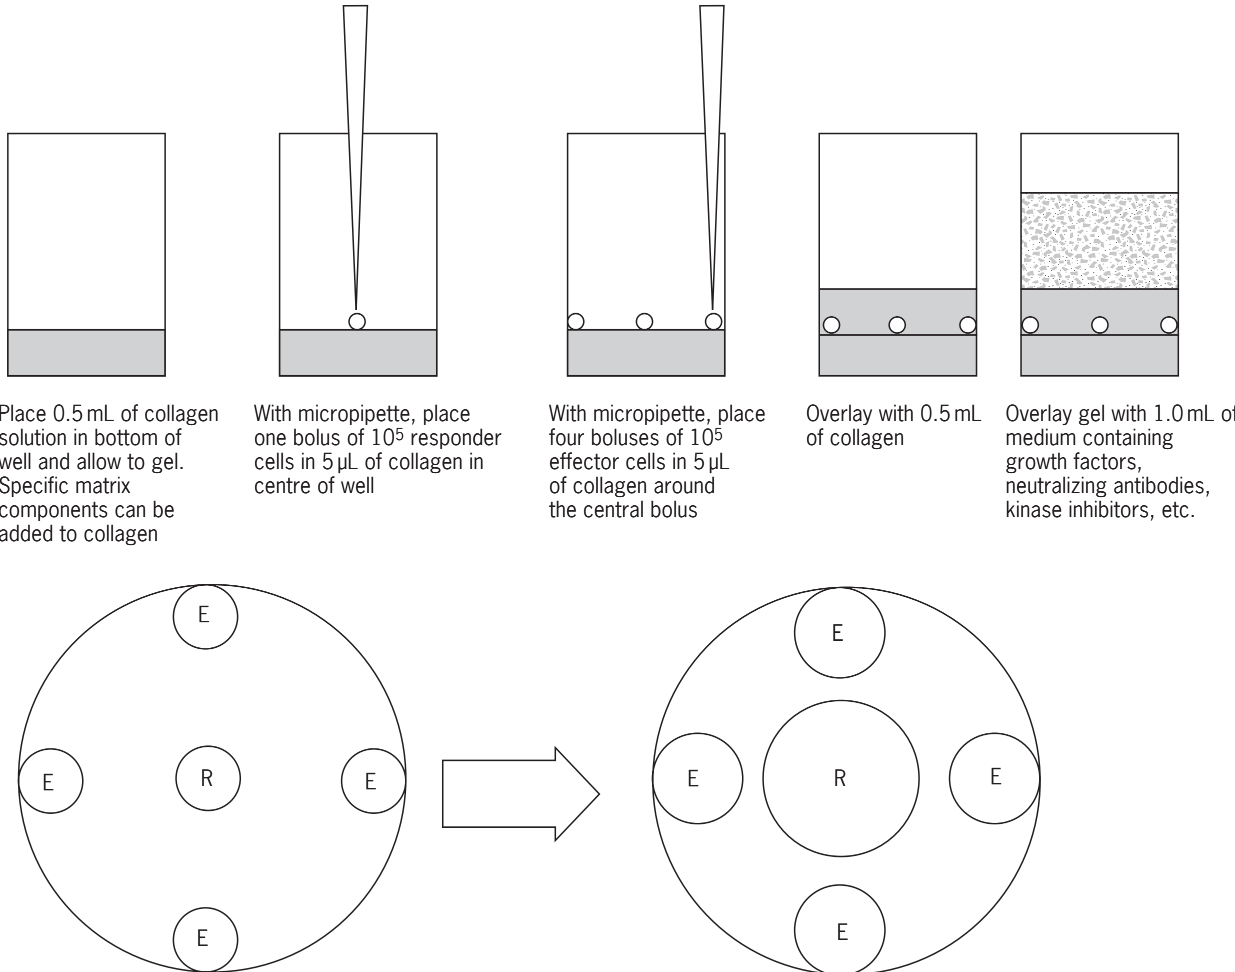

Figure 2 Assay for interactions via soluble factors in three-dimensional arrays in matrix.

appearance of hormone receptors and formation of the primary mammary sprout and ductal elongation are regulated by mesenchymal–epithelial interactions. Mesenchymal fibroblasts and mesenchymal adipocytes have separate, distinctive roles in the regulation of embryonic development of the mammary gland. Mesenchymal fibroblasts respond to testosterone to induce regression of the foetal mammary bud in developing males while the mesenchymal adipocytes regulate the initial mammary ductal elongation in females.

Most of our understanding of these interactions comes from tissue-recombination studies in which mutant or knockout mouse mesenchyme is mixed with wild-type epithelium or vice versa. Mesenchyme from *tfm* (testicular feminization) mice do not induce regression of wild-type mammary buds in response to testosterone but wild-type mesenchyme induces regression of *tfm* epithelial mammary buds. The *tfm* mutation is probably a nonfunctional androgen receptor and results in a lack of all secondary male sex characteristics in male mice. Thus, functional androgen receptors are unnecessary in the mammary epithelium but must be present in the mesenchyme for mammary bud involution in the male embryos. Tissue recombination experiments with knockout mouse tissues illustrate that epidermal growth factor receptor must be expressed by the stromal element for mammary gland ductal morphogenesis (Wiesen *et al*., 1998) and progesterone receptor is needed in the stroma for ductal development but in the epithelium for lobuloalveolar development (Humphreys *et al*., 1997).

Both mesenchyme and epithelium retain organogenic inductive response competence in the adult. The latter phenomenon has been particularly well documented with respect to the mammary gland. Morphogenetically normal outgrowths result from transplanting fetal mammary epithelium into adult mammary stroma and adult mammary epithelium responds to fetal mesenchyme. The epithelial portion of the mouse mammary gland may be surgically removed prior to the age of 21 days to obtain cleared fatpads consisting of normal stroma but lacking epithelial components. If fetal mammary epithelium is transplanted into a cleared adult mammary gland, morphogenetically normal

outgrowths result, but growth of fetal epithelia from other organs is not supported by adult mammary stroma. Thus, adult stroma retains specific inductive capacity. Adult mammary epithelium from virgin mice responds to fetal mesenchyme, and the morphogenetic branching pattern induced is dependent upon the organ source of the mesenchyme (Sakakura *et al*., 1979). The retention of organogenic inductive responses in the adult may reflect the fact that normal breast must be able to remodel glandular architecture repeatedly in response to hormonal stimuli during oestrus (mouse) or menstrual (human) cycles and successive pregnancies. However, orthotopic effects have been observed for many other types of cancer including colorectal, melanoma, prostate, lung, renal, bladder and pancreatic carcinoma, indicating that stromal–epithelial interactions persist in many adult tissues. *In vitro* studies have elucidated both contact-dependent and soluble factor-mediated mechanisms of interactions.

INTERACTIONS IN THE ADULT MAMMARY GLAND

In the mouse, both normal and preneoplastic mammary epithelia are stroma dependent, that is, they only grow in mammary fatpads and not at ectopic sites. The growth of both normal and preneoplastic cells is inhibited by normal mammary epithelium. Thus, to obtain growth, normal and preneoplastic cells must be transplanted into cleared mammary glands. Mammary tumours are obviously not mammary stroma dependent because tumours grow after subcutaneous implantation and at metastatic sites. However, tumour formation in the fatpad requires ∼10-fold fewer cells than at subcutaneous sites (Miller *et al*., 1981) and thus even tumour cells are ‘stromal-responsive.’ Furthermore, mouse mammary tumour cells are stimulated rather than inhibited by normal mammary epithelium, as evidenced by their enhanced growth in intact versus growth in cleared fatpads (Miller *et al*., 1981). Perhaps the most important orthotopic tissue effect is the enhanced metastasis displayed by mouse mammary tumour cells (Miller, 1981) and xenografted human breast cancer (Price *et al*., 1990). Fibroblasts can stimulate growth of epithelial cells as well as increase the invasiveness of malignant epithelium. Epithelium can stimulate growth of stromal cells and induce stroma to produce proteases important in invasion and release of growth factors from the extracellular matrix. Reciprocal interactions between stroma and epithelium are common.

GROWTH OF PRIMARY TUMOURS

Angiogenesis

Perhaps the most important role of stroma in the growth, invasion and metastasis of cancer is to provide additional blood vessels. Nutrients required to support a growing mass of neoplastic cells can diffuse through tissue up to a distance of only 1–2 mm. Thus, tumours will grow only to 2–3 mm in diameter unless vascularization of the tumour occurs. The ability to induce an angiogenic response is one critical difference between premalignant and malignant mammary lesions. Pieces of tissue from human ductal carcinoma *in situ* and invasive breast cancers both induce angiogenic activity when implanted in the rabbit cornea, whereas normal breast and fibroadenoma tissues do not (Brem *et al*., 1978). Thus, angiogenic activity is a stromal–epithelial interaction which is altered at an early stage in progression (i.e. carcinoma *in situ*). (See also chapter *Angiogenesis*.)

In some cases, the malignant epithelial cells produce angiogenic factors that directly induce the host to produce the vascular network. Vascular endothelial growth factor (VEGF) is one such molecule which may be released by cancer cells, possibly as a response to hypoxia. In some cases cancer cells may induce VEGF production by the stroma (Fukumura *et al*., 1998). In the latter study transgenic mice expressing green fluorescent protein under the control of the VEGF promoter show strong green cellular fluorescence in the stromal fibroblasts, but not tumour cells, of spontaneous mammary tumours. Other factors with possible roles in inducing angiogenesis include acidic and basic fibroblast growth factors, platelet-derived growth factor and angiogenin.

The angiogenic activity of specific factors can be assesssed by implanting pellets containing the factor in the cornea of mice (Kenyon *et al*., 1996). Neovascularization occurrs between days 3 and 8 after bFGF or VEGF are implanted. Systemic angiogenesis inhibitors can also be detected with this model. One advantage of the mouse cornea model is the availibilty of immunodeficient mice for xenograft studies. Some, but not all, human tumours xenografted into immunodeficient mice inhibit the angiogenic response to bFGF pellets in the mouse cornea (Chen *et al*., 1995). Transgenic and knockout mice also allow the study of the role of specific gene products in angiogenesis.

A disadvantage of using nude mice for the cornea assay is that the host defence mechanisms, which also may contribute to neovascularization of a tumour mass, are deficient. For example, a graft versus host reaction induces an angiogenic response after injecting lymphocytes intradermally into irradiated allogeneic mice (Sidky and Auerbach, 1975). Activated macrophages are also angiogenic, as indicated by the induction of vascular proliferation when injected into guinea pig corneas. Cytokines produced by monocytes that have been shown to have angiogenic activity include tumour necrosis factor alpha (TNFα) transforming growth factor beta (TFGβ) and interleukin-8. Although TNFα inhibits endothelial cells in culture, this factor induces angiogenesis *in vivo* when placed in the rabbit cornea, suggesting that the angiogenic response is due to infiltrating leucocytes induced by TNFα rather than due to a direct action of TNFα on the

endothelium. Whether a specific T cell-mediated response or a general inflammatory response is mounted, host defence efforts may be instrumental in allowing the further growth of a neoplastic lesion by inducing the neovascularization process.

Stromal Heterogeneity

Studies to understand the mechanisms of interactions have relied upon *in vitro* experiments in which fibroblasts and epithelial tumour cells are grown in mixtures or in which conditioned medium from one cell type is supplied to the other. It is important to remember that such systems are highly simplified and may not be very representative of conditions *in situ*. There are two basic problems in modeling stromal interactions *in vitro*. One is the effect of matrix and cell shape on cellular responses and interactions. Before utilizing an *in vitro* assay to study mechanisms of interactions, it should be verified that that the product of the interaction successfully models *in vivo* results. For example, mouse mammary tumour cells are stimulated by both stroma and epithelium *in situ* (Miller, *et al*., 1981). However, in monolayer cocultures, primary mammary gland cultures inhibit the growth of tumour cells, indicating that monolayer culture fails to reproduce the environment which *in vivo* results in stimulation of tumour cell proliferation by normal cells. The three-dimensional assay in collagen matrix does detect paracrine stimulation of neoplastic (but not normal or preneoplastic) mouse mammary cells by normal mammary epithelium and stromal fibroblasts (Miller *et al*., 1989). While the three-dimensional collagen gel assay is more difficult to perform than monolayer cultures and conditioned medium, it has the single advantage that it more accurately reflects tissue interactions in the mammary gland. An additional disadvantage is that production of differentiated structures and cell motility and invasion may increase the size of the cell mass being measured without an accompanying increase in cell number. Hence it is sometimes difficult to discriminate between effects of interactions on growth from those which alter differentiation state.

The other problem in modelling stromal interactions *in vitro* is the heterogeneity of the stroma and also tumour cell heterogeneity. Stroma is often represented *in vitro* by immortalized mouse fibroblast cell lines or primary skin fibroblast cultures. Mouse mammary stroma is grossly less complex than human breast stroma (**Figure 3**). In the mouse, a thin rim of fibroblasts surrounds the epithelial ducts and adipocytes constitute the majority of the stroma between the ducts. In the human breast there are many more fibroblasts with both an interlobular and an intralobular type and pockets of adipocytes. Ectoenzymes differ for inter- and intralobular fibroblasts and neutral endopeptidase is produced only by stroma from breast cancer (Atherton *et al*., 1994). In fact, based on differential gene expression, there are at least seven types of breast fibroblasts derived from normal, fibrotic and tumoural breast including fibroblasts and myofibroblasts from breast skin, normal stroma, tumour-adjacent stroma, postradiation fibrosis lesions and benign or malignant tumours (Spanakis and Brouty-Boye, 1997).

These stromal fibroblast types do not alter epithelial behaviour uniformly. Conditioned medium from malignant stroma was found to be more stimulatory for human breast cancer cell line MCF-7 than conditioned medium from normal stroma or from stroma adjacent to malignant breast tissue (van Roozendaal *et al*., 1996). Early full-term pregnancy significantly lowers the risk of breast cancer. It has been suggested that the pregnancy causes differentiation of the epithelial cells, thus reducing the number of stem cells at risk of carcinogenesis. However, the reduced risk may be due to altered stroma rather than, or in addition to, altered epithelial cells. In the rat, uniparous mammary stroma is more inhibitory to development of mammary tumours than is normal mammary stroma after carcinogen-treated rat mammary epithelium is transplanted into untreated uniparous or virgin fatpads (Abrams *et al*., 1998).

One cannot ignore stromal elements other than fibroblasts. A common perception is that host defence mechanisms act as a natural surveillance system to recognize and eradicate neoplastic cells and it is often assumed or hoped that infiltrating lymphocytes and macrophages are inhibitory or, at worst, ineffective. However, lymphocytes are more stimulatory to breast cancer cells *in vitro* than are fibroblasts (Ogmundsdottir *et al*., 1993) and tumour-associated macrophages have aromatase activity and thus may act as a local source of oestrogen (Mor *et al*., 1998). Hence, these cell types must also be regarded as potential sources of tumour growth stimulation.

The Role of the Stroma in Hormonal Responsive Tumours

The lifetime exposure to oestrogen is an important factor in breast cancer risk and it is generally thought that mitogenic activity is important in this process. Mouse mammary stroma may play an important role in the oestrogen response of mixed mammary fibroblasts and epithelium (Haslam and Counterman, 1991). A likely role of stromal cells is the local production of oestradiol within the breast so that a paracrine mechanism independent of systemic oestradiol levels can drive epithelial expansion. Breast fibroblasts plus testosterone accelerate growth of breast cancer xenografts in ovariectomized nude mice perhaps due to increased aromatase (Koh *et al*., 1998). Human breast stroma produces a 50-kDa protein which stimulates MCF-7 production of reductive 17β-oestradiol dehydrogenase activity, thus allowing the conversion of oestrone to oestradiol (Adams *et al*., 1988). The human oestrogen-dependent breast cancer line MCF-7 releases

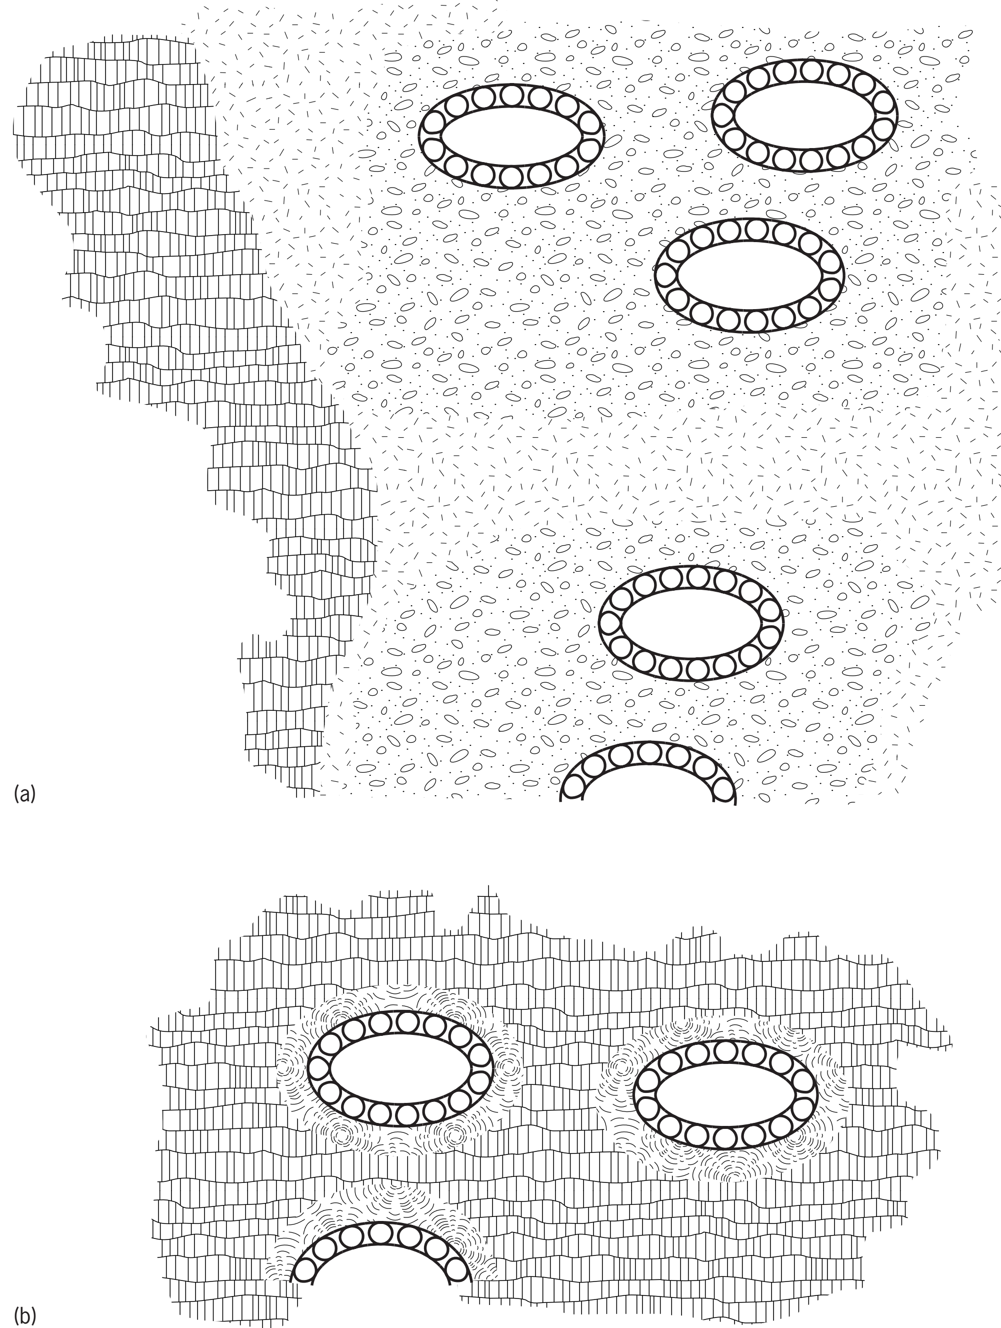

Figure 3 (a) Human breast terminal epithelial ductules (ovals with circles), intralobular stroma (), interlobular stroma (), and adipocytes (). (b) Mouse mammary gland ductules (ovals with circles), stromal fibroblasts () and adipocytes ().

both interleukin-6 and its soluble receptor to up-regulate local aromatase activity (Singh *et al*., 1995).

Stroma Stimulates Growth of Epithelium

Mammary stroma from either cancer or normal breast stimulates growth of MCF-7 *in vitro* (Gache *et al*., 1998). Normal human skin fibroblasts or Matrigel (a basement membrane extracellular matrix available commercially) mixed with human breast cancer cell lines increases xenograft incidence and decreases latency; fibroblasts plus Matrigel are even more stimulatory. Matrigel depleted of growth factors does not work. Stromelysin may be the enzyme which releases active growth factors from extracellular matrix because fibroblasts from stromelysin 3 knockout mice do not increase growth of MCF-7 xenografts (Masson *et al*., 1998). Alternatively, fibroblasts may release matrix metalloproteinases which release growth

factors from matrix (because fibroblasts added to Matrigel have no effect on xenografts of MCF-7 cells which overexpress an inhibitor of metalloproteinase (Noel *et al.*, 1998). One disadvantage of Matrigel is that it is prepared from a mouse sarcoma. It varies in growth factor composition among batches but growth factors can be depleted allowing the addition of specific factors of interest. However, when studying tumours of other species one must remember that the extracellular components are mouse and, possibly more important, are from a malignant sarcoma. A possible alternative for human cell studies is Humatrix, which is made by human myoepithelial cells (Kedeshian *et al.*, 1998). Humatrix also contains a number of growth factors, such as EGF and insulin-like growth factor I, but is reported to contain protease inhibitors and angiogenesis inhibitors rather than proteases and angiogenic factors.

Progression of various carcinomas is often accompanied by increased expression of growth factor receptors such as EGFR or erbB2. In prostate, keratinocyte growth factor, which is produced by stromal cells, is found in 65% of prostate cancer tissues but not in benign hyperplasias. The receptor is expressed by epithelium in both benign and malignant epithelium so the observed change with progression is stromal rather than epithelial (Leung *et al.*, 1997).

Reciprocal Stromal–Epithelial Interaction

Epithelium also controls stromal behaviour in tumours resulting in reciprocal interactions in which each compartment is both sending and receiving signals from the other. Stromal proliferation is a common occurrence in breast cancer and mitotic activity is increased in stromal cells near the epithelium. Cancer cells often produce growth factors the receptor for which is expressed in the stroma. Breast cancer epithelium produces basic fibroblast growth factor whereas breast stromal cells express FGFR (Hasebe *et al.*, 1997). Breast cancer cells make platelet-derived growth factor but have no receptor. Cancer makes platelet-derived growth factor which induces stroma to make insulin-like growth factors which are mitogenic for cancer cells (Yee *et al.*, 1991). Mouse mammary tumour cells produce prostaglandin E2, which induces human fibroblasts to produce hepatocyte growth factor which is mitogenic for the tumour cells (Matsumoto-Taniura *et al.*, 1999).

Normal breast fibroblasts produce insulin-like growth factor I (IGFI), not IGFII, whereas tumour-derived fibroblasts produce IGFII, not IGFI (Cullen *et al.*, 1991). MCF-7 induces normal breast fibroblasts to produce IGFII *in vitro* (Singer *et al.*, 1995) and *in situ* expression of IGF2 is localized to stroma specifically surrounding malignant breast epithelium (Rasmussen and Cullen, 1998). Since both IGFI and IGFII are potent mitogens for breast cancer cells, the advantage to the tumour cell of local production of IGFII rather than IGFI is not clear but might relate to progression to oestrogen independence (Daly *et al.*, 1991).

Contact-dependent Interactions

Cell to cell contact has long been recognized as an important element in homeostasis and loss of contact inhibition *in vitro* is a hallmark of transformation. However, growth of transformed cells may be inhibited by contact with normal cells *in vitro*. Contact-dependent regulation may involve gap junction-mediated intercellular communication (GJIC), cellular adhesion molecules, and juxtacrine growth factor/receptor binding.

Gap Junctions

Gap junctions allow the passage of small regulatory molecules such as cAMP and inositol triphosphate to diffuse among cells. A gap junction consists of localized plaques of multiple intercellular channels each of which consists of a six-protein oligomer (connexon) in the membrane of each of the communicating cells. More than a dozen of these proteins, called connexins, have been identified. Different tissues express a limited number of these connexins but an individual cell type generally expresses more than one. A connexon may be homotypic, consisting of six identical proteins, or heterotypic. Some connexins only form homotypic connexons and some combinations of connexins form nonfunctional heterotypic connexons. Passage through connexon pores is limited to molecules under 1 kDa and additional selectivity may be provided by the connexin species constituting the connexon. Loewenstein first suggested that regulatory molecules may be transmitted between cells via gap junctions. Since then, the role of GJIC in transformation, promotion and progression to a metastatic phenotype has been the subject of numerous investigations. Carcinogens and tumour promoters, such as 12-*O*-tetradecanoylphorbol-13-acetate, inhibit gap junction mediated communication. The chemopreventive agent all-*trans*-retinoic acid increases connexin 43 in renal cell cancer and prevents disruption of GJIC by 12-*O*-tetradecanoylphorbol-13-acetate and carcinogen *in vitro* (Watanabe *et al.*, 1999).

Measurement of GJIC between cells has depended upon passage of low molecular mass dyes or passage of small molecules or ions in metabolic cooperation assays. The simplest assay based on the transfer of the dye lucifer yellow from stained to unstained cells coupled by gap junctions involves scraping the monolayer with any sterile object in the presence of fluorescent dyes. Monolayers can be 'scrape-loaded' with lucifer yellow and rhodamine isothiocyanate dextran, incubated at 37°C for 20 min, and cell suspensions prepared and analysed by fluorescence cell cytometry (Kavanagh *et al.*, 1987). Lucifer yellow readily passes through gap junctions but rhodamine isothiocyanate dextran, owing to its large size, does not. Scraped cells should fluoresce at both 545 nm (lucifer yellow stained) and 590 nm (rhodamine isothiocyanate dextran stained), cells which have been coupled to scrape-loaded cells should be stained with lucifer yellow only, and

cells which did not communicate via gap junctions should contain neither dye. Metabolic cooperation assays utilize either 'kiss of death' or 'kiss of life' strategies (**Figure 4**). The kiss of death assay most commonly utilizes a mixture of hypoxanthine–guanine phosphoribosyltransferase deficient (HPRT−) and wild-type cells. The HPRT− cells are resistant to 6-thioguanine, which forms toxic thioguanine nucleotides in wild-type cells. If GJIC between the two cell types occurs, in the presence of 6-thioguanine, thioguanine nucleotides pass from the wild-type cells to the HPRT− cells, resulting in cell death. If GJIC does not occur, the wild type-cells will be killed but the HPRT− cells will survive and replicate. The number of wild-type cells needed to reduce the number of HPRT− cells in co-culture can be used as a quantitative estimate of relative efficiency of GJIC of different wild-type cells with a given HPRT− indicator cell. Kiss of life metabolic cooperation assays may utilize mixtures of HPRT− and wild-type cells in HAT medium (hypoxanthine, aminopterin, thymidine) or mixtures of ouabain-resistant and wild-type cells. HAT medium kills HPRT− cells because of the inability to salvage purines required by aminopterin block of *de novo* synthesis. If GJIC occurs with an HPRT + cell, the latter can produce sufficient purines from the active salvage pathway to rescue the HPRT− cell. Ouabain inhibits the active transport of sodium ions out of the cell via the Na^+:K^+ pump. If GJIC is established, ouabain-resistant cells can remove excess Na^+ from wild-type cells, allowing their growth in the presence of lethal levels of ouabain. In mixtures of wild-type cells which are HPRT + and are sensitive to ouabain and cells that are ouabain resistant and HPRT deficient, a reciprocal kiss of life is necessary for any growth in medium containing HAT and ouabain.

Aberrant communication competence has been described for some cancer cells. Some have been found to have a diminished ability to communicate and others have lost selectivity in communication (Fentiman *et al*., 1979) which might allow a response to improper signals. This may be the result of changed connexin species being expressed, loss of connexin expression or inappropriate processing of connexins. Loss of intercellular communication competence has been implicated during essentially all steps of initiation, promotion and progression of neoplasia. Cells transformed by oncogenes often have reduced GJIC. Transformation with H-*ras* reduced communication between transformed epithelial cells but not between transformed 3T3 fibroblasts (Vanhamme *et al*., 1989). Growth inhibition of *ras*- or *neu*-transformed cells by non-transformed cells required GJIC (Esinduy *et al*., 1995). Sequential loss of coupling was reported during progression from (1) normal rat ovarian granulosa cells to (2) immortalized cells to (3) contact independent cells to (4) cells tumorigenic in nude mice (Stein *et al*., 1991).

In addition to loss of GJIC or loss of selectivity, a third class of communication defect which might result in or allow cancerous growth is the loss of responsiveness to modulators of coupling. Activity of individual connexons may be regulated by tyrosine phosphorylation and net GJIC can be regulated by altering turnover rates (synthesis and/or degradation) as gap junctions have a half-life of 5 h (Laird, 1996). Both EGF and TGFβ may inhibit GJIC but TGFβ has also been reported to increase GJIC in keratinocytes (Madhukar *et al*., 1989) as well as in fibroblasts (Gibson *et al*., 1994). In the latter study, TGFβ treatment of quiescent 10T1/2 cells elevated proliferation and increased expression of cx43 with elevated GJIC, illustrating that increased cell proliferation can occur in the presence of GJIC. However, TGFβ more typically is involved in the GJIC-mediated inhibition of transformed cells by normal, untransformed cells (Hofler *et al*., 1993).

Hormones may function as promoters for initiated, hormone-responsive cells by altering GJIC. Because testosterone, but not oestradiol, uncouples two human transitional cell carcinoma lines, Kihara *et al*. (1990) suggested that the androgen might be an important factor in the higher incidence of urothelial cancer in males. Because communication occurs very efficiently between some tumour subpopulations and poorly between others, growth signals transmitted via gap junctions may be nonrandomly distributed throughout a tumour. Studies of mixtures of tumour cells in collagen gel culture suggest that, if cells within the mammary gland are extensively coupled, first messages, such as hormones and growth factors, might need to act directly on very few cells ($< 10\%$) to induce an effect throughout the gland (Miller, B. E., *et al*., 1986). Control of tissue in which only a few cells respond directly to a diffusible factor might be accomplished by gap junction coupling of receptor-positive and receptor-negative cells. An *in vitro* model which demonstrates this possibility uses a mixture of rat ovarian granulosa cells and mouse myocardial cells (Lawrence *et al*., 1978). Rat ovarian granulosa cells produce plasminogen activator in response to follicle-stimulating hormone but make no response to noradrenaline, whereas myocardial cells change beat frequency and action potential in response to noradrenaline but do not respond to follicle-stimulating hormone. In mixed cultures, follicle-stimulating hormone changes the beat frequency and action potential of myocardial cells and noradrenaline induces granulosa cells to produce plasminogen activator.

It is possible that GJIC in a heterogeneous tissue allows exchange of small molecules between cell types unable to communicate by GJIC directly. Although bovine mammary epithelial and fibroblasts both express cx43 and are able to self-communicate, GJIC between epithelial and fibroblastic cells does not occur. An additional cell type with properties of both epithelium (E-cadherin expression) and fibroblasts (no cytokeratin but express vimentin) also expresses cx43 and is able to communicate with both epithelium and fibroblasts. When all three cell types co-exist, GJIC occurs throughout the monolayer so that small molecules can be passed via the

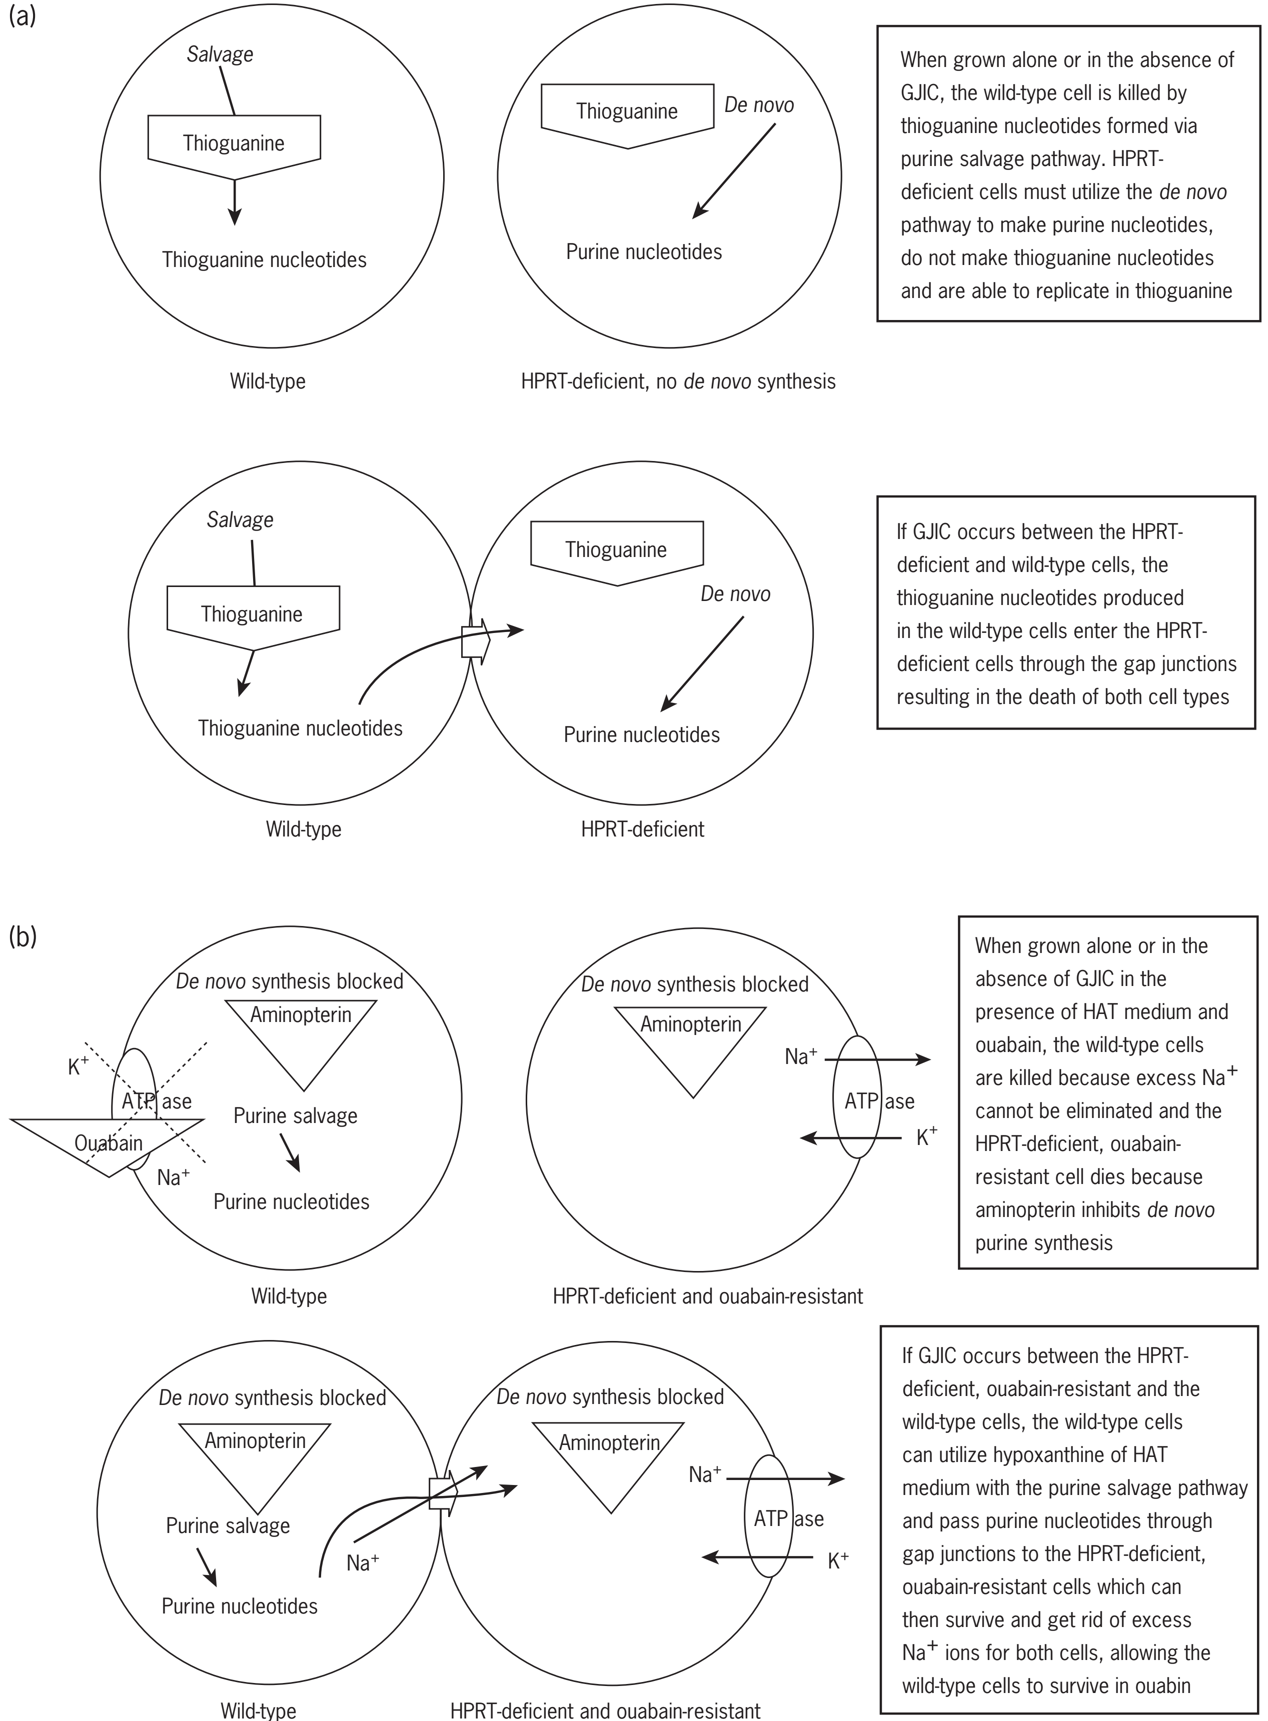

Figure 4 Metabolic cooperation assays for GJIC. (a) The kiss of death and (b) the reciprocal kiss of life.

intermediate cell between fibroblasts and epithelium (Woodward *et al*., 1998). If fibroblasts are transfected to express E-cadherin, direct GJIC with epithelium still does not occur.

Juxtacrine Signalling

Juxtacrine signalling requires contact between a receptor-positive cell and one which expresses the appropriate membrane-bound ligand. For example, the growth factors of the EGF family initially exist with a transmembrane domain and are proteolytically cleaved to form the soluble forms. In the transmembrane form, they act as both an adhesion molecule and growth factor in a juxtacrine manner. Through cell–cell contact the transmembrane form of the growth factor can activate the appropriate receptor on a neighbouring cell (**Figure 5**). Juxtacrine signalling was first demonstrated by pairing a bone marrow stromal cell line transfected with TGFα with a haematopoietic cell line transfected with EGFR to achieve both adhesion of haematopoietic cells to the stromal cells and a mitogenic response in the haematopoietic cell line (Anklesaria *et al*., 1990). Addition of EGF inhibited the adhesion. Tumour necrosis factor also exists as both a membrane integrated and soluble form, allowing both juxtacrine and paracrine signalling (Haas *et al*., 1999). Juxtacrine signalling allows very rigorous control so that the signal is delivered only to specific cells. One can imagine that shared adhesion molecules as well as a match between growth factor on one cell and receptor on the other provide a means to deliver precisely homeostatic/differentiation signals to the appropriate cell. Paracrine systems are somewhat promiscuous because no requirement for response past the expression of the growth factor receptor is necessary.

Cell adhesion molecules may also act as signalling receptors. A diverse system of transmembrane glycoproteins have been identified that mediate the cell–cell and the cell–extracellular matrix adhesion. The main families of adhesion molecules are the cadherins, integrins and selectins. The observation that the fibroblast growth factor receptor (FGFR) contains an evolutionarily conserved sequence with homology to adhesion molecules such as N-cadherin suggests they might interact with, and signal via, FGFR tyrosine kinases (Doherty *et al*., 1996). The E-cadherin–catenin complex transduces signals from the microenvironment to other molecular complexes. Signal transduction pathways starting from pp60src include E-cadherin-associated β-catenin (Noe *et al*., 1999). In addition to interactions with receptor tyrosine kinases, signal transduction via receptor protein tyrosine phosphatases (RPTPs) may be involved. The extracellular domain of RPTPs can mediate either homophilic or heterophilic interactions and a role for cadherin-mediated cell–cell adhesion has been suggested (Zondag and Moolenaar, 1997). RPTPs transduce extracellular signals by dephosphorylating tyrosine-phosphorylated intracellular substrates. For example, RPTP alpha activates pp60c-src due to direct dephosphorylation of the regulatory Tyr residue at position 527 in pp60c-src (den Hertog *et al*., 1993). Regulation of the src-related fyn protein activation by RPTP alpha appears to be important in neuronal–glial cell interactions (Zeng *et al*., 1999) and knockout mice deficient for the LAR RPTP express a deficiency in mammary gland differentiation such that lactation does not occur (Schaapveld *et al*., 1997).

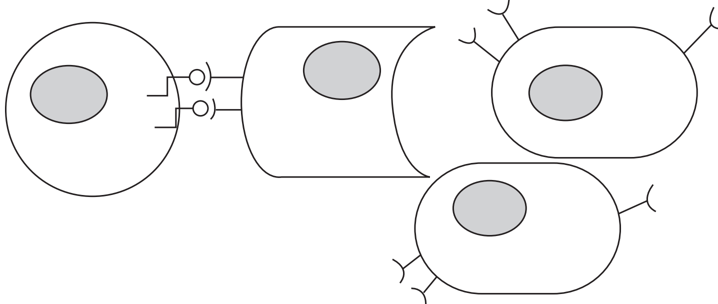
The juxtacrine mechanism may be far more important than we realize. We know of the factors which are active when cleaved from the membrane because an activity can be measured. In fact, detection and identification of the active growth factor preceded the realization that membrane-bound forms are also active in a juxtacrine configuration if cell contact is allowed. It is far more difficult to detect cleaved forms which are inactive. Perhaps the so-called orphan receptors do not have soluble ligands but act only in a juxtacrine fashion. If so, cell co-cultures or cell membranes should be screened for active ligands rather than conditioned media.

METASTASIS

The metastatic process is a complex sequence of events which involve stromal–epithelial interactions at every stage. Invasion by tumour cells in the primary site is aided by proteases made by stromal cells, sometimes in response to signals from the cancer cells. Intravasation is aided by the production of new blood vessels. Transport is a traumatic event for cancer cells moving through the circulation and survival may be aided by the formation of heterotypic emboli of cancer cells and host cells. Arrest and extravasation involves interactions between tumour cells and endothelium. Growth of extravasated cells to form metastatic deposits requires an appropriate environment, a phenomenon referred to as seed and soil. (See also chapter on *Tumour Metastasis Models*.)

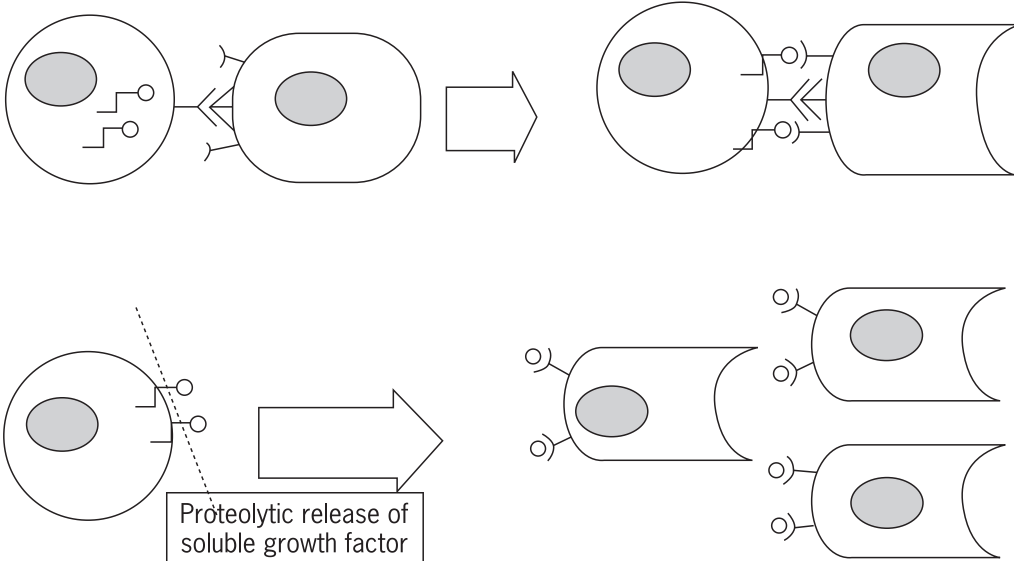
Invasion and Intravasation

Tumour cells make a variety of proteases necessary for extracellular matrix degradation and invasion but stromal cells, primarily myofibroblasts which make up the bulk of the reactive tumour stroma, also contribute several important proteases, including collagenase 1, matrix metalloproteinase 2 (MMP2) and metalloproteinase 9 (MMP9), stromelysin 1, stromelysin 3, urokinase-type plasminogen activator and cathepsin D. Tumour cells induce production by the stromal cells via release of soluble factors such as EGF, basic fibroblast growth factor and TNFα. Stromal cells other than myofibroblasts may aid in extracellular matrix degradation. In colorectal cancer, MMP2 mRNA is expressed in both peritumoural stromal and epithelial cells

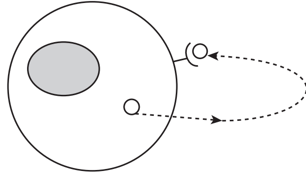


Juxtacrine interaction. Only the cell with specific receptor and in contact with cell producing the membrane-bound growth factor is stimulated.

Reciprocal juxtacrine interaction. The illustration below depicts a case in which an additional recognition molecule is necessary for production and/or transport of the growth factor to the membrane. This mechanism would allow very restrictive regulatory control to insure that only the appropriate cell expressing the appropriate adhesion/recognition molecule as well as the growth factor receptor is stimulated.



Paracrine interactions require only the presence of the growth factor receptor for response to growth factors which diffuse through the tissue. This mechanism is contact independent and allows the factor-producing cell to stimulate many more cells than possible in juxtacrine interactions but is less well controlled.



Autocrine stimulation can occur when a cell which produces a growth factor also expresses the receptor for that factor. This can occur without actual externalization of the growth factor. (See chapters *Signalling by Cytokines*; *Signalling by Tyrosine Kinases*; *Signalling by TGF beta*.)

Figure 5 Juxtacrine, paracrine and autocrine signalling.

but MMP9 is localized only in peritumoural stroma and is particularly expressed by tumour-associated macrophages at the tumour–stroma interface (Zeng and Guillem, 1996). Urokinase-type plasminogen activator in breast cancer is primarily a product of stromal myoepithelial cells, not cancer cells (Nielsen *et al*., 1996).

In some cases stroma may induce protease production by tumour cells. Mixed rat embryo fibroblasts and human cancer cell lines, neither of which produce MMP9 alone, resulted in the production of human MMP9. Fibroblast-conditioned medium contained a 30–100-kDa protein responsible for induction of MMP9 (Himelstein and Muschel, 1996).

Cathepsin D was not expressed in benign lesions (fibrocystic disease, fibroadenomas), but was positive in both the stroma and epithelium in about one half of breast cancers. About 15% of carcinoma *in situ* lesions were positive but production was found to be restricted to the epithelium (Zheng *et al*., 1999). Thus, expression in the stroma may be an important step in progression to malignancy. However, another study found that cathepsin D was increased in invasive cancer but was restricted to the epithelial component. Stromelysin 3 was mostly expressed in peritumoural stroma, and urokinase-type plasminogen activator was detected in both cancer cells and stromal cells. In normal and benign breast lesions, all three proteases were primarily found in epithelial cells, not stromal cells (Escot *et al*., 1996).

Tumour-infiltrating macrophage may result in increased release of tumour cells by releasing lysosomal hydrolases that cause necrosis, and the products of necrosis may cause an increase in the motility of neoplastic cells. Macrophages, neutrophils and lymphocytes have all been reported to induce collagenase activity *in vitro* of both cancer stromal fibroblasts and cancer cells. One should recognize that the neovascularization process in response to angiogenic factors is itself an invasive process that could augment malignant cell invasiveness. Because tumour vasculature often includes sinuses with incomplete basement membranes and because this vascularized tissue coexists with degradative enzyme-rich zones of necrosis, intravasation is greatly encouraged.

Transport

Aggregates of cells are more metastatic than single tumour cells. This may be due to more efficient arrest of the larger emboli or to protection of the inner cells to shear forces during transport. Emboli often consist of several cancer cells, but heterotypic emboli of tumour cells and lymphocytes, leucocytes or platelets might also enhance metastasis.

Arrest and Extravasation

In some cases the arrest of tumour cells is organ specific, suggesting that cell-surface receptors may exist on tumour cells and target organ endothelium. *In vivo* phage display has revealed that a number of peptide motifs selectively homed (3–35-fold increased localization over background) to the endothelium of specific organs (Rajotte *et al*., 1998). It has been reported that tumour cells and endothelial cells form gap junctions prior to extravasation and that the expression level of the receptor/ligand pair that mediates adhesion between tumour cells and the endothelium is rate limiting (el-Sabban and Pauli, 1995).

Seed and Soil

Depending upon the organ site of the primary cancer, certain organs are most likely to be involved with metastatic disease. Vascular connections are clearly very important in determining which sites have metastases, as increasing numbers of tumour cells which reach an organ increase the likelihood of the establishment of proliferative metastatic nodules. Preferential arrest due to organ-specific endothelial cell adhesion molecules may determine metastatic sites and there are differential abilities of organs to provide an appropriate environment (soil) for growth of the tumour cell (seed) and different seeds have specific soil requirements found only in certain organs. Stroma may promote metastasis by increasing cancer cell migration and invasion in addition to stimulating growth. For example, osteonectin produced by bone marrow stroma is chemotactic for breast and prostate cancer cells, both of which commonly metastasize to bone, but not for cancer cell types which do not metastasize to bone (Jacob *et al*., 1999). Of course, the metastatic tumour cells release a number of factors which alter the host organ. In particular, bone structure may be altered significantly. Breast cancer forms osteolytic metastases whereas prostate cancer forms osteoblastic metastases.

Dormancy and Recurrence

Therapy sometimes appears to cure cancer but recurrences of dormant tumours, both at the surgical site and at distant metastatic sites, may occur years later. It is not known whether dormancy represents a balance of tumour cell replication and death or whether the tumour cells simply go into an extended period of cell cycle arrest. It has been suggested that the immune system is responsible for holding these malignancies in a dormant state and that subsequent weakening of immunity, possibly via an additional disease, emotional stress or simply ageing, allows the deposits of tumour cells to regrow. Other evidence suggests that extracellular matrix components may be involved in allowing tumour cells to avoid apoptosis. Vitronectin inhibits topoisomerase-induced apoptosis in glioma cells (Uhm *et al*., 1999) and $\beta 1$ integrin-binding suppressed chemotherapy-induced apoptosis in small cell lung carcinoma (Sethi *et al*., 1999). Tumour dormancy in

human cancer xenografts was induced by low-level expression of urokinase receptor and involved reduced integrin $\alpha5\beta1$ binding to fibronectin and subsequent low basal levels of extracellular regulated kinase (ERK) (Hiragun *et al*., 1985).

CONCLUSION

The complexity of cancer is far greater than described in this chapter. New factors and interactions are being discovered rapidly. Cytotoxic agents are still the first line of defence following surgical ablation of primary cancers, but the understanding of cellular and matrix interactions provides new therapeutic targets. Anti-angiogenic factors and inhibitors of proteases are obvious candidates for chemoprevention and therapeutic targets. Chemopreventive agents such as retinoic acid altered the composition of the extracellular matrix in rat mammary glands with increased tenascin and fibronectin but decreased laminin (Schedin *et al*., 1995). Effects on GJIC are also a likely target. The chemopreventive agent all-*trans*-retinoic acid increases connexin 43 in renal cell cancer and prevents disruption of GJIC by promoters and carcinogens *in vitro* (Watanabe *et al*., 1999). Perhaps the chemotherapeutic index could be improved if $\beta1$ integrin-mediated protection from apoptosis could be blocked. Tumour cells might be held in the dormant stage by reagents which interfere with plasminogen activator receptor-$\beta1$ activation of ERK. The complex nature of cancer tissue provides ample opportunities to intercede in the disease. However, the same complexity allows for multiple paths of cancer evolution. If therapy blocks one route, a variant cell which is not dependent upon that mechanism takes a different route in progression. Nevertheless, it may be possible to identify relatively few interactions which are bottlenecks in cancer progression, allowing efficient therapy.

CONTENTS

- The Drug Development Process
- Criteria for Selecting Candidate Lead Compounds
- Models for New Drug Screening and Testing
- The High-throughput Strategy
- Genetic Approaches for Drug Development
- Resistance to Anticancer Drugs
- Multidrug Resistance (MDR)
- Expression of *MDR1* Gene in Health and Disease
- Therapeutic Application of the *MDR1* Gene
- Apoptosis and MDR
- Reversal of Anticancer MDR
- Assessment of MDR Reversing Agents
- Multi-hit and Multi-target Approach Against MDR: Drug Combinations
- Quantitation of Synergism and Antagonism
- Experimental Design for Drug Combinations
- Selectivity of Synergism and Antagonism
- Rational Approach to the Clinical Protocol Design for Drug Combinations

THE DRUG DEVELOPMENT PROCESS

There are two basic elements for anticancer drug development: efficacy and selectivity. The search for highly efficacious compounds may be achieved by a rational approach or an empirical approach. After the selection of a candidate compound with *in vitro* and preliminary *in vivo* testing, extensive preclinical pharmacological and toxicological studies need to be performed to assess the possible therapeutic potential. The toxicological profile and selectivity of effect play a crucial role in determining the success or failure of a drug development.

In the United States, the Food and Drug Administration (FDA) plays an important role in each stage of evaluation, monitoring and approval from investigational new drug (IND) application for phase I to phase III clinical trials, to new drug application (NDA) and to postmarketing surveillance (Food and Drug Administration, 1995). The approximate time period required for each step of the process is given in **Table 1**.

The evaluation of new anticancer agents starts from *in vitro* experimentation, usually with small quantities of compounds. Preliminary testing in rodents allows the selection of the lead candidate compound(s) for further preclinical pharmacological and toxicological studies (**Table 1**) using mice, rats and dogs. At this stage, scale-up synthesisis required and compliance with the regulatory guidelines for good manufacturing practice (GMP) and good laboratory practice (GLP) should be enforced. In clinical trials, the guidelines for good clinical practice (GCP) need to be followed.

An IND application to the FDA consists of the following: an introductory background statement; general investigational plan; the clinical trial protocol including investigator data, facility data and institutional review board (IRB) data; chemistry, manufacturing and control data; environmental assessment; pharmacological and toxicological data; and previous human experience. The following information is usually part of the protocol: study design, criteria for patient eligibility, recruitment

Table 1 The new drug development process

Preliminary testing	Preclinical research and development	Clinical studies	NDA review	Postmarketing surveillance
Time range Vary	Range: 1–3 years Average: 18 months	Range: 2–10 years Average: 5 years	Range: 2 months–7 years Average: 24 months	Adverse reaction reporting
		Phase 1 →		
Discovery and evaluation		Phase 2 →		
Design		Phase 3 →		Survey
Targeting	Scale-up Synthesis and purification			Sampling
Modelling	Animal testing: Pharmacokinetics	Accelerated development and review →	→	Testing Inspections
Synthesis Mechanism	Toxicology Short term →			Sponsor answers any question from review
In vitro and preclinical *in vivo* testing	Long term →	→		
		↑ IND Submission to FDA 30-day safety review	↑ NDA Submission to FDA	↑ NDA Approval by FDA

plan, pretreatment evaluation, treatment/intervention plan, grading toxicities/side effects, criteria for therapeutic response/outcome assessment, criteria for removal from study, biostatistics, subject registration and randomization procedures, quality assurance, protection of human subjects, informed consent procedures and references.

When an IND application is submitted to the FDA, there will be a 30-day safety review period before phase I clinical trials can be started (**Table 1**). The phase I trial is mainly a dose-finding study to explore the safety, the tolerated doses, pharmacokinetics and toxicities. It usually enlists 20–100 patients and takes several months to complete the study. The phase II trial uses up to several hundred patients with specified tumour type(s). In this phase, the aims are to determine therapeutic effects, toxicities and any unexpected complications. The study may take up to 2 years to complete. The phase III trial is an expanded study enlisting hundreds to several thousand patients and usually involves multiple medical centres. Efficacy and toxicity are evaluated for a range of tumours under specified regimens of treatment. The phase III trial may take 2–4 years to complete (**Table 2**). When safety and therapeutic efficacy are established, the new drug application (NDA) can be submitted to the FDA for review and approval. Postmarketing surveillance is an important aspect for the manufacturers and FDA and involves adverse reaction reporting, sampling, testing and inspections. (See also chapter on *Translational Research*.)

The rational approach of drug development includes selecting a molecular target and the development of molecular entities of drugs. Owing to the similarity of biological and molecular make-up between tumour and normal cells, the strategies for developing agents for cancer therapy include (1) inactivation or blocking the molecular process that leads to carcinogenic transformation, (2) exploiting the differences between normal and tumour cells at the molecular, biochemical and cellular levels and gaining a selective advantage towards therapeutic aims, (3) eliminating or inhibiting tumour cells with cytotoxic agents, cytodifferentiating agents or reversing agents of multidrug resistance (MDR) and (4) approaches of combination therapy with therapeutic agents with different modalities of treatments.

Table 2 Clinical trials in humans

Phase	No. of patients	Length	Purpose	Approximate percentage of drugs successfully tested
I	20–100	Several months	Dose-finding Safety Toxicity	70
II	Up to several hundred	Months to 2 years	Short-term safety and effectiveness	33
III	Hundreds, up to several thousand	2–4 years	Safety, dosage and effectiveness	25–30

In this chapter we will concentrate on the methods and models of new drug development and overcoming the drug resistance that would affect the therapeutic end results of cancer treatment.

CRITERIA FOR SELECTING CANDIDATE LEAD COMPOUNDS

It is usually difficult to select a candidate compound for further development. The decision is of great importance since drug development takes a long period of time to test, to evaluate and to meet regulatory requirements and it might easily cost as much as 50 million dollars to market a new drug.

For every 10 000 compounds screened, approximately 500 may show antitumour activity *in vitro*. Among these, 100 may be worthy of testing in animals. Of these 100 compounds, 10 may meet the criteria to perform extended pharmacological and toxicological studies to obtain enough information to warrant clinical trials in humans. Past experience (Food and Drug Administration, 1995) suggests that for the phase I trial only 70% of drugs are successfully tested. For the phase II and phase III trials only about 33% and 25% of drugs are successfully tested, respectively (**Table 2**).

There are several criteria for selecting a candidate compound, including potency, pharmacological properties, toxicity, feasibility of formulation, and degree of difficulty of synthesizing or producing a sufficient quantity.

MODELS FOR NEW DRUG SCREENING AND TESTING

The US National Cancer Institute (NCI) has played a very important role in antitumour screening and testing for the past four decades. Its approach and policy have evolved through the decades and created models that have a long-lasting impact (Driscoll, 1984; Chabner, 1990; Johnson, 1990; Sikic, 1991).

Historical Models and Their Evolution

The NCI established the Cancer Chemotherapy National Service Center (CCNSC) to support research efforts of investigators in the discovery of new agents for cancer treatment. The main models used then were murine leukaemias, e.g. L1210 and P388, as index tumours for *in vivo* screening. This was followed by additional tumour models used to follow up the initial lead.

In 1985, the NCI changed its cancer drug-screening programme by (1) emphasizing primary *in vitro* screening using an organ-site oriented approach, (2) using human solid tumour cell lines, (3) using small amounts of compounds for the primary screening, and (4) a renewed commitment to use screening as a method for exploring natural products from diverse sources (e.g. plants, marine organisms and microbes)

During 1990–1992, the NCI Cancer Drug Screen was established. The main feature is *in vitro* exposure (48 h) of a panel of 60 human tumour cell lines at five different concentrations with 10-fold serial dilution. Crude extracts are usually evaluated at a single concentration. The SRB (sulforhodamine B) protein stain assay (see below) was used to generate 60 dose–effect curves for each compound. It should be noted from the mass-action law principle that 1000-fold dilution with five or more dose densities would be too broad to have smooth dose–effect curves, although it would provide some efficacy indications. This programme also provides: the development of the ‘mean graph’ (Paull *et al*., 1989) to interpret the relative sensitivities of each of the tumour cell lines to an individual agent and the development of computer-based ‘Compare Program’ (Paull *et al*., 1989) for recognition of these patterns of effectiveness. By comparing the correlation with a representative seed compound, such as taxol, vinblastine or adriamycin, potential clues to understanding the mechanism of antitumour action may be obtained.

For example, vinblastine, taxol and numerous compounds that target microtubules showed similar patterns in the ‘mean graph’ and a strong correlation in the ‘Compare Program,’ although inhibitors and promoters of tubulin polymerization were both present.

Molecular Targeting and Cell-based Drug Screen

In early 1990, the NCI launched a major effort to characterize and define molecular targets with the 60 human tumour cell lines (Chabner 1990; Johnson, 1990; Sikic, 1991). The data suggest that a combination of biological patterns of effectiveness with information on specific molecular targets will enhance the recognition of novel agents. So far, the molecular targets that have been characterized in the screen include *mdr-1*, *H*-, *N*- and *K-ras*, *bcl-2*, *SKC*, *p53*, *MDM2*, G_1 and G_2 checkpoints, DT diaphorase, thymidylate synthase, etc. The length of the list is increasing.

The tumour cell lines used for experiments are usually obtained from various sources: (1) generated by individual laboratories from experimental animals whether they are spontaneous tumours or carcinogen-induced tumours, and from human tumour specimens; and (2) cell lines generated by transgene procedures. Large collections of animal and human tumour cell lines are available commercially from the cell bank of the American Type Culture Collection (ATCC) (Rockville, MD, USA), but they are mainly unmodified cells. Drug-resistant cells are usually generated either *in vivo* in animals or *in vitro* in tissue culture by continuous exposure with gradually increasing sublethal doses or concentrations of an antitumour agent. Depending on the drug and tumour type, the time required for generating a drug-resistant tumour cell line ranges from several months to several years. If the selecting agent is from a natural source, frequently MDR cell lines can be obtained. So far, the panel of 60 human tumour cell lines used by the NCI are not MDR cell lines.

A Model for Solid Tumours In Vitro: Hollow-fibre Assay

The traditional xenograft models of human tumours in nude mice or scid mice are rather expensive, time consuming and require 20–500 mg of compounds, depending on the potency. In the newly adopted hollow-fibre assay system (Casciari, *et al*., 1994) human tumour cell lines are implanted within a polyvinylidene hollow fibre. The fibres are heat-sealed before implantation into i.p. or s.c. compartments in the same nude mouse. Three fibres are simultaneously inserted into both compartments in the same mouse. Thus, antitumour effect of an agent can be simultaneously evaluated against three individual tumours growing in two separate physiological compartments of the same animal. The hollow fibres are removed after 1 week to examine the tumour cell viability using SRB or XTT assays (Skudiero *et al*., 1998; Skehan *et al*., 1990).

Cytotoxic effects of an antitumour agent on the growth of various tumour cell lines *in vitro* are evaluated under specified conditions. Typically, the cells are cultured at an initial density of 5×10^4 cells/mL. They are maintained in a 5% CO_2-humidified atmosphere at 37°C in RPM I medium 1640 (or other medium) containing penicillin (100 units/ml), streptomycin (l00 μg/mL) and l0% heat-inactivated fetal bovine serum. For cell suspension cultures, cytotoxicity assays are performed by using the 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-(carboxanilide)-2*H*-tetrazolium hydroxide (XTT) microculture tetrazolium method (Scudiero *et al*., 1998) in duplicate in 96-well microtitre plates. XTT is prepared at 1 mg/ml in prewarmed (37°C) medium without serum. Phenazine methosulfate (PMS) and fresh XTT are mixed to obtain 0.025 mmol/L PMS–XTT solution (27 μL of the stock 5 mmol/L PMS is added per 5 mL of 1 mg/mL XTT). After a 72 h of incubation, 50 μL of assay aliquots are added to each well of the 200 μL cell culture. After incubation at 37°C for 4 hr, the absorbance at 450 nm and 630 nm is measured with a microplate reader. For the monolayer cell cultures, they are determined in 96-well microtitre plates by the SRB method described by Skehan *et al*. (1990) for measuring the cellular protein content. Cultures are fixed with trichloroacetic acid and then stained for 30 min with 0.4% SRB dissolved in 1% acetic acid. Unbound dye is removed by acetic acid washes, and the protein-bound dye is extracted with an unbuffered Tris (tris(hydroxymethyl) aminomethane) base for determination of the absorbance at 570 nm in a 96-well microtitre plate reader. The experiments are usually carried out in duplicate or triplicate. Each run entails 5–6 concentrations of the drug being tested. The IC_{50} values are determined by the median-effect equation and plotted (Chou, 1991a; Chou and Talalay, 1984) using computer software.

The Knockout Models for Multi-drug Resistance

To assist in the understanding of the mechanism of action and physiological functions of the transporter proteins, the generation of gene knockout models is often very useful. Borst and co-workers have obtained mice with single and double knockout in *mdr1a* and *mdr1b* genes (Schinkel *et al*., 1997). They found that the recognition of the P-glycoprotein (Pgp, see below) as an important component of the blood–brain barrier and its involvement in the absorption and elimination of several clinically used drugs. The fact that the multidrug resistance protein (MRP) is ubiquitously expressed, although at very low levels, in the liver and some other organs suggests that it exerts a common function. The development knockout mice for MRP and other transporters would greatly improve the understanding of their mechanisms and physiological functions.

Several physiological functions of MRP have been suggested. These include protection against environmentally present heavy metal oxyanions, modulation of the activity of ion channels, transport of leukotriene C_4

and glutathione, glucuronate and sulfate conjugates and transport of GSH through a co-transport mechanism (Rappa *et al*., 1999). The importance of MRP in the protection of normal tissue from the toxicity of anticancer agent such as etoposide had been established. A total block of MRP has been found to be compatible with life, suggesting that MRP inhibitors can be safely used for treating cancer patients (Rappa *et al*., 1999).

Recently, the transporter was found in drug-resistant cell lines with low level Pgp and MRP, but with high levels of drug transport, particularly for mitoxantrone. This was designated BCRP, MXR and ABCP by different groups of investigators (Kuska, 1999; Ross *et al*., 1999). Today, by searching a computerized database looking for sequences similar to a signature ATP-binding motif found in the known ABC genes, at least 50 human ABC genes have been found. Because the expression level of BCRP/MXR/ABCP is so low in adult tissues, it might be an excellent candidate to target for an inhibitor and enhance the effect of chemotherapy without affecting normal cells (Higgins, 1995; Kuska, 1999). (See also chapter on *Drug Resistance and Reversal*.)

THE HIGH-THROUGHPUT STRATEGY

The large number of compounds from biodiversified sources and combinatorial chemistry libraries require high-efficiency assays. In recent years, high-throughput assay systems have been developed from 96-well microplates for optical, colorimetric and fluorescence readers to microplates consisting of as large as a 1536-well format for multimode analysers. The availability of robotic systems is replacing labour-intensive manual work with increased workload and efficiency. The efficiency of drug development is also facilitated by the identification of small molecules that bind with high-affinity acceptor molecules (e.g. cell-surface receptors, enzymes, antibodies) so to mimic or block their interaction with natural ligands. Assuming that peptides can be used as antitumour agents, on the basis of a ‘one-bead, one peptide’ approach (Lam *et al*., 1991), one can greatly enhance the production and rapid evaluation of random libraries of millions of peptides so that receptor-binding ligands of high affinity can be rapidly identified and sequenced. By using the split synthesis approach, the first cycle consisted of distributing a pool of resin beads into separate reaction vessels each with a single amino acid, allowing the coupling reaction to go to completion, and then repooling the beads. This cycle was repeated several times to extend the peptide chain. In this fashion, each bead should contain only a single peptide species. To develop a rapid approach for screening the library to find beads containing peptides able to bind to any particular acceptor molecule, acceptor molecules were coupled to an enzyme (alkaline phosphatase) or to fluorescein and added in soluble form to the peptide bead library.

Typically, a few beads were intensely stained and were visible to the naked eye and easily seen with a low-power dissecting microscope (bead diameter 100–200 μm against a background of countless nonactive beads. With the aid of tiny forceps coupled to a micromanipulator, the intensely stained beads could be remove for analysis. Each bead was washed with 8 mol/L guanidine hydrochloride to remove the acceptor complex and then the peptide sequence contained on the bead was determined by placing it on a glass filter which was inserted into a peptide microsequencer. A library containing several million beads could be screened in about 10 Petri dishes in half a day. Subsequently, it could be washed with 8 mol/L guanidine hydrochloride and subsequently reused for screening new acceptors. This micromethod is likely to be extended to other applications, such as polynucleotides or desoxypolynucleotides.

GENETIC APPROACHES FOR DRUG DEVELOPMENT

The process of therapeutic drug development evolved from the experience-based herbal medicine to evidence-based pharmaceuticals. In the modern era, it has further progressed to gene-based biotechnological products and gene therapy. The combinatorial chemistry and platform technology aided by computer modelling of chemical molecules and chiral properties and structural folding hold new promise and challenges in the new millennium.

Large genetic databases now include portions of all of the human genome. A variety of technologies make it possible to catalogue the expression of large numbers of genes in specific organs and tissues and to compare healthy and disease states, and drug-sensitive and drug-resistant conditions. Disease- or pathology-associated and mutated genes isolated through biotechnologies are now numbered in the thousands. In addition, the scientific success in positional cloning has been impressive, and the number of positionally cloned disease genes is increasing (Darby, 1997). With the rapid rate of accumulation of genetic information, new drug-screening models and targets will facilitate the discovery of new and better drugs.

Expression profiling technologies and positional cloning are the two main approaches to the drug targeting (Scangos, 1997). Expression profiling technologies include subtraction hybridization, computerized comparisons of gene libraries from different tissues, serial analysis of gene expression and differential displays. Differential expressions have been correlated with disease states, but it has been difficult to determine which differentially expressed genes are cause rather than effect, and which, if targeted by a drug, could reverse the disease process. The positional cloning approaches have identified and cloned genes involved in human diseases, including cancer,

Alzheimer's disease, obesity, diabetes and asthma. The problem is that although these genes provide insight into the cause of disease, they are limited in what they can deliver for therapeutic intervention. For example, positionally cloned genes often encode proteins of unknown biochemical or physiological function, leading to a situation where it is difficult or impossible to set up screening assays for inhibitors. More important, positionally cloned genes often contribute to a disease phenotype by virtue of being defective. Since drugs most often are inhibitors of their targets, these genes most often are inappropriate screening targets. However, one may be able to use the identified gene to understand the biochemistry and regulatory process of the pathway and, thereby, identify an optional point of intervention (Skangos, 1997). An important question for drug development is what genes and proteins exist in the target cells which, when inhibited by a drug, will reverse the effects of the disease gene and restore homeostatic balance.

RESISTANCE TO ANTICANCER DRUGS

Innate or acquired resistance in chemotherapy remains a serious obstacle towards the chemotherapeutic treatment of cancer and infectious diseases. Various mechanisms of drug resistance exist which include drug metabolism (decrease in drug activation or increase in drug inactivation), transport (decrease in drug influx or increased drug efflux), drug target alteration (increased target levels, altered function of target or decreased affinity of drug for target), DNA repair (increased repair of DNA damage or mutations in mismatch repair genes) and apoptosis (altered function and regulation that change the ability of tumour cells to execute programmed cell death). Among these mechanisms, the best characterized mechanisms of MDR involves P-glycoprotein 170 (Pgp) (Kartner and Ling, 1989; Juliano and Ling, 1996; Ueda *et al*., 1999).

MULTIDRUG RESISTANCE (MDR)

The original concept of MDR was introduced in 1970 by Biedler and Riehm of the Sloan-Kettering Institute in New York (Biedler and Riehm, 1970). They found that cells resistant to drugs that had no structural or mechanistic similarities showed cross-resistance. In some cases the resistant cells expressing Pgp show collateral sensitivity to unrelated compounds and become more sensitive, when compared with the parent (non-MDR) cells (Chou *et al*., 1998). However, there is apparently no unifying theory for a simple explanation of the MDR problem (Laing and Tew, 1997).

There are at least three types of MDR that have been characterized: (i) classical Pgp-mediated MDR, in which the causal relationship between resistance and overexpression of Pgp and resistance has been clearly demonstrated *in vitro*; (ii) atypical MDR, which involves drugs that interact with DNA topoisomerase that has decreased enzyme levels and/or a mutated structure, and (iii) non-Pgp-mediated MDR, in which resistant cells do not show elevated Pgp levels of expression, but instead, with increased level of MRP, lung resistance protein (LRP) or the expression of other members of the ABC transporter gene family (Gottesman and Pastan, 1993; Kuska, 1999).

Despite an overwhelming number of papers on MDR_1 expression and Pgp activity in tissue culture systems of multidrug resistance, the relationship of MDR_1 with the clinical observation of multidrug resistance remains weak. Although a strong correlation has been obtained in haematological malignancies, it is premature to generalize the association in solid tumours (Kellen, 1994; Antoney and Kayl, 1999; Robert, 1999). The fact that MDR_1 is just one of many polypeptides in the ABC superfamily related to drug resistance may weaken the correlation since the contribution of multiple factors such as Pgp, MRP, apoptosis antagonist, Bcl-2, Bcl-X_L and compartmentalization were not simultaneously analysed.

EXPRESSION OF *MDR1* GENE IN HEALTH AND DISEASE

The identification of Pgp as an ATP-dependent pump, which could confer resistance to a variety of hydrophobic compounds cytotoxic to cancer cells, raised the possibility of normal function of Pgp (Kellen, 1994; Antoney and Kaye, 1999; Bates *et al*., 1999; Robert, 1999). Monoclonal antibody labelling of the tissue distribution of Pgp revealed the plasma membrane localization on the positive cells. For the epithelial cells of jejunum, ileum and colon, the major location was on the mucosa. For the brush border of proximal tubule cells of the kidney and the biliary face of the hepatocytes of the liver, and also placenta, the Pgp expression was most evident. Although *mdr* knockout mice are viable, mice in which *mdr* genes have been intentionally inactivated have major alterations in pharmacokinetics and tissue distribution of substrates for Pgp. The physiological role of Pgp in health and disease has therapeutic implications for pharmacological inhibition of Pgp. The importance of Pgp in MDR in cancer suggests that the efficacy of administered chemotherapeutic agents can be enhanced and MDR can be reversed by Pgp blockers. An alternative procedure to the pharmacological approach to circumvent Pgp-mediated MDR in cancer cells is to prevent the biosynthesis of transporter by selectively affecting its transcription. These include the use of antisense, ribozymes and triplex-forming oligonucleotides targeted against different regions of the *MDR1* gene. In either cases, exploitation for selectivity against

tumour over normal tissues is an important determinant for beneficial therapeutic effects.

THERAPEUTIC APPLICATION OF THE *MDR1* GENE

Cloning and sequencing (**Figure 1**) of *MDR1* cDNA provide the tool to confirm that the phenotype of MDR can be conferred on drug-sensitive cells by expression of Pgp. The possibility of using genetic materials for gene therapy has promoted the development of *MDR1* gene transfer and expression methodologies (Aran *et al*., 1999). One of the goals is to protect drug-sensitive cells (such as bone marrow progenitor cells) from cytotoxic effects in cancer chemotherapy. *In vitro* and animal models have been established. However, it remains to be seen whether the genetic advantage gained by cells expressing transgenic *MDR1* will be sufficient to fulfil the expected goals. Clinical trials have already been performed to determine the stability of expression of the *MDR1* gene and its ability to confer chemoprotection on bone marrow cells. To date, the success of these studies has been limited by the inefficiencies of delivery of genes into human bone marrow cells. As a dominant selectable marker, the *MDR1* gene still has to prove its efficacy *in vivo* to ascertain stable expression of non-selectable genes of interest by drug selection in the appropriate disease animal model (Aran *et al*., 1999).

Since the *MDR1* gene confers multidrug resistance *in vitro* and *in vivo*, *mdr1* transgenic mice could be serve as an *in vivo* model for new anticancer drug evaluation. Unfortunately, these *mdr1* transgenic mice have not lived up to the original expectation because after several generations of inbreeding, the level of expression of human *MDR1* became too low (Aran *et al*., 1999).

APOPTOSIS AND MDR

Programmed cell death (apoptosis) is mediated by degradation of DNA and a number of cellular proteins. The discovery of the Bcl family of proteins by Tsujimoto and Croce (1986) as apoptosis antagonists suggested a novel mechanism of MDR and a new approach to therapeutic interventions.

The *bcl-2* (B-cell leukaemia/lymphoma 2) gene products are one subfamily of proteins that determine how particular cells die in response to particular physiological or pharmacological environments. Bcl-2 in widely expressed in human tumours, and by inhibiting cell death it may allow tumour cells to accumulate the mutations which in turn may cause the cell to become invasive. Studies of the programmed cell death in the nematode *Caenorhabditis elegans* have provided many important leads to the understanding of apoptosis. Recent findings in the JNK pathway, cell death signalling via Fas and TNF receptors, Bcl-X_L for protecting cancer cells *in vitro*

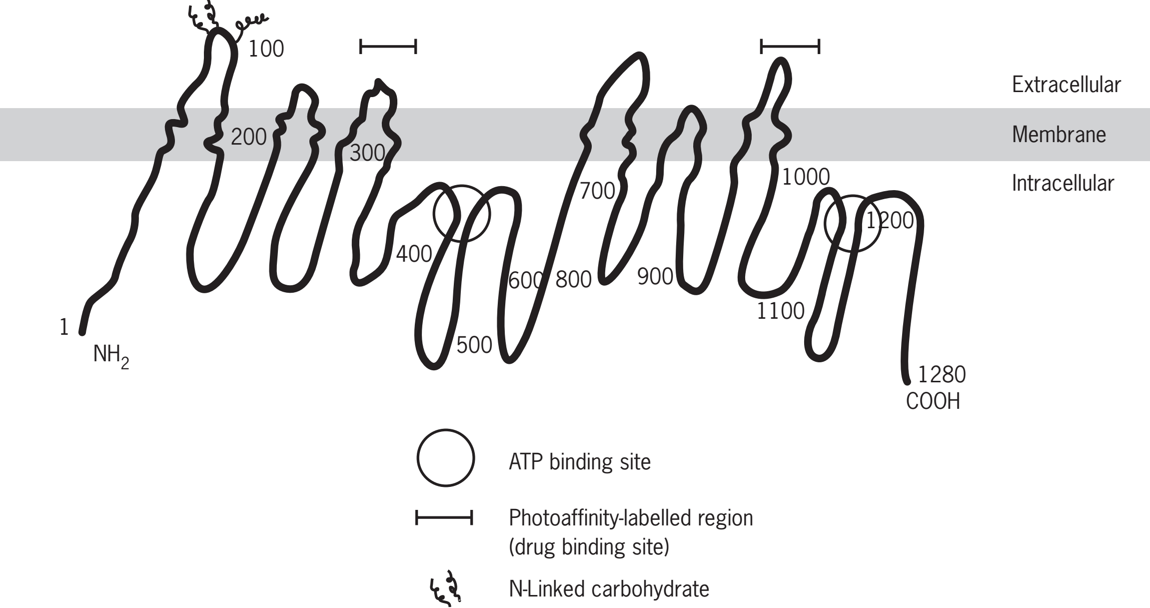

Figure 1 Model of human P-glycoprotein (Pgp). A two-dimensional drawing of Pgp with numbers referring to amino acid residues in the linear sequence. The ATP-binding domains and the putative drug-binding domains are shown for each half of the molecule. Pgp is a single polypeptide consisting of 12 transmembrane and helical segments. Putative N-linked carbohydrates, located in the first extracellular loop, are indicated in the diagram. (From Lam *et al*., 1991, Gottesman and Pastan, 1993, Kellen, 1994 and Robert, 1999.)

against drug-induced apoptosis and the enhancement of chemosensitivity of cancer cell apoptosis by over-expression of Bcl-X_s have all added to the complexity in this field (Clynes *et al.*, 1998).

REVERSAL OF ANTICANCER MDR

A plethora of agents have been developed that modify, modulate or reverse the MDR phenotype (Chou *et al.*, 1998). There are diverse classes of compounds that interact with Pgp (**Table 3**). Many anticancer agents from natural sources, such as vinblastine, vincristine, doxorubicin, paclitaxel, actinomycin D and their analogues, are MDR substrates. Other natural products, such as colchicine, rhodamine 123, erythromycin, ardeemin and gypsetin also interact with Pgp (Kellen, 1994). Steroid hormones such as aldosterone, cortisol and dexamethasone, calcium blockers such as verapamil and dilitiazem, quinolines such as quinidine, quinine and quinicrine, immosuppressants such as cyclosporin A, rapamycin and FK506, peptides such as gramicidin D and valinomycin, and calmodulin antagonists such as trifluoperazine and chlorpromazine are also modulators of Pgp. These resistance modifiers have undergone structural modification to reduce undesirable side effects, such as from verapamil to dexverapamil, and from cyclosporin A to SDZ PSC 883, (**Table 4**). Of these, verapamil, trifluoperazine, cyclosporin A, nifedipine and verapamil have been subjected to phase I/II clinical trials (Volm, 1998).

Table 3 Diverse classes of compounds that interact with Pgp

Antineoplastic drugs	Modulators/chemosensitizers
Vinblastine, vincristine	Verapamil, diltiazem, bepridil
Doxorubicin, daunomycin, mitoxantrone	Azidopine, nitrendipine, nifedipine
Bisantrene	
Etoposide, teniposide	
Topotecan	Quinidine
Mitomycin C	Cyclosporin SDZ PSC-833
Paclitaxel, taxotere	FK506
Mithramycin	Rapamycin
Actinomycin D	Terfenadine
	Trifluoperazine
Other agents	Quinine, quinicrine
Colchicine	Reserpine
Rhodamine 123	Forskolin
Ethidium bromide	
Erythromycin	
Ketoconazole	**Peptides**
Ardeemin	Gramicidin D
Diketopiperazine	Valinomycin
Gypsetin	
Steroid hormones	**Photoaffinity drug analogues**
Aldosterone	Azidopine
Cortisol	Iodoarylazidoprazosin
Tamoxifen	*N*-(*p*-Azido-3-iodophenethyl) spiperone
Megestro	
Dexamethasone	Tamoxifen aziridine

Table 4 Resistance modifiers

First generation	Second generation
Verapamil	Dexverapamil
Cyclosporin A	SDZ PSC 833
Calmodulin inhibitors	SDZ 280-446
Quinine	XR 9051
Progesterone	GF 120918
Tamoxifen	S-9788
Amiodarone	Ardeemin
Trifluoperazine	

ASSESSMENT OF MDR REVERSING AGENTS

Evaluation of a new MDR-reversing agent consists of many important aspects. Using 5-*N*-acetylardeemin (NAA) as an example (Chou *et al.*, 1998), these include the following:

1. *Reversing efficacy*: whether it completely or partially reverses drug resistance to a certain drug in a given MDR cell line. For CCRF-CEM and CCRF-CEM/VBL_{100} cells, the IC_{50} values for VBL are 0.000 83 and 0.632 μmol/L, respectively. In the presence of 15 μmol/L of NAA (IC_{50} values are 29.8 and 20.8 μmol/L, respectively), the IC_{50} for VBL became 0.000 21 and 0.000 11/μmol/L, respectively. Thus, NAA completely reversed the VBL drug resistance in CCRE-CEM/VBL_{100}. cells. The analogue of NAA 5-*N*-acetyl-8-demethylardeemin (NADMA) showed a similar effect to NAA (**Figure 2**).
2. *Improvement of therapeutic efficacy*: how much it improves the therapeutic effect *in vivo* in B6D2F_1 mice bearing P388/0 and P388/DX leukaemia. For P388/0, 2 mg/kg Q D×4 i.p. of doxorubicin increased the life span by 178%. In combination with NAA, 70 mg/kg, the increase in life span became 189%. However, in doxorubicin-resistant P388/DX tumour-bearing mice the increases in life span were 106% and 151% in the absence and presence of NAA, respectively. In nude mice bearing MX-1 mammary carcinoma xenograft, treatment with doxorubicin 1.5 mg/kg Q D×5 i.p. reduced the tumour size by 44%, whereas with doxorubicin and NAA (50 mg/kg) combination, the tumour size was reduced by 75%; two of eight mice were tumour free but one mouse died of toxicity.
3. *Toxicity toward the host*: whether it has little or no cytotoxicity or side effects when compared with other MDR-reversing agents. For NAA there was no apparent toxicity other than the reversible body weight drop at

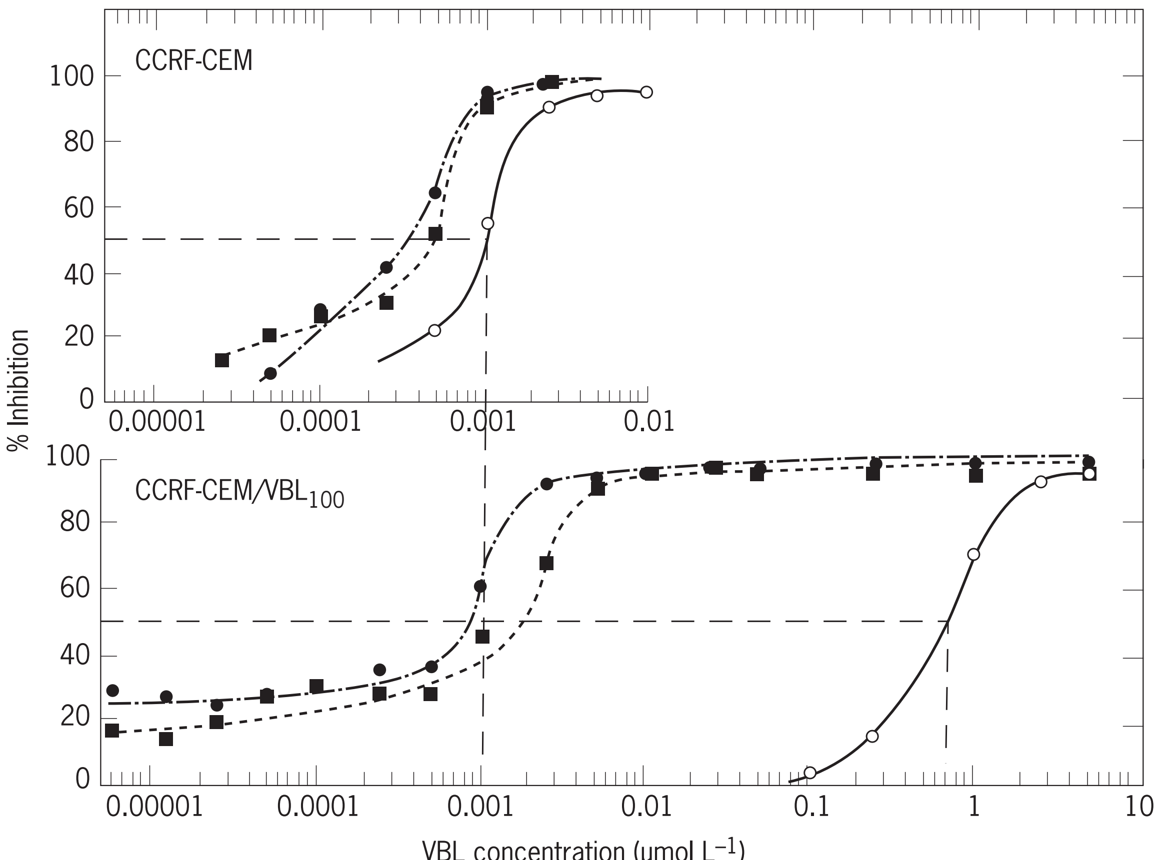

Figure 2 Dose–effect curves for vinblastine (VBL) against the cell growth of human leukaemic cells in the absence and presence of MDR reversing agents, with (○) varying [VBL] alone; (●) varying [VBL] with constant [NAA] (15 μmol/L); (■) varying [VBL] with constant [NADMA] (15 μmol/L). Top, CCRF-CEM lymphoblastic leukaemic cells; bottom, CCRF-CEM/VBL_{100} leukaemic cells 760-fold resistant to VBL. The concentrations of the ardeemins used were about half of their IC_{50} values toward CCRF-CEM cells. (From Chou *et al.*, 1998, *Proceedings of the National Academy of Sciences of the USA*, **95**, 8369–8374.)

150 mg/kg Q D×8 i.p. By contrast, verapamil at 150 mg/kg Q D×3 i.p. led to a 40% lethality towards the mice.

4. *Preferential synergism in MDR over the parent tumour cells*: in our earlier studies, we observed that NAA is slightly more potent in inhibiting CCRF-CEM/VBL_{100} cells than in inhibiting the parent CCRF-CEM cells (i.e. collateral sensitivity) (Chou *et al.*, 1998), and we conducted classical drug combination studies for VBL and NNA. As shown in **Figure 3**, VBL + NAA showed much stronger synergism in CCRF-CEM/VBL_{100} cells than in CCRF-CEM cells. These results suggest an extra therapeutic value of NAA in combination with VBL, a classical MDR substrate.
5. *Increase intracellular accumulation of drugs*: whether and how much an MDR-reversing agent increases intracellular accumulation of cancer chemotheraputic agents. Intracellular accumulation of [^{3}H]VBL in CCRF-CEM cells was increased twofold by 30 μmol/L of verapamil and threefold by 30 μmol/L of NAA.
6. *Efflux kinetics*: whether the MDR-reversing agent alters the elimination (efflux) kinetics of a drug under investigation. For the efflux kinetics for preloaded [^{3}H]VBL in CCRF-CEM cells, drug elimination was biphasic with an initial half-life of 12 min and β-phase half-life of 105 min. In the presence of 30 μmol/L of verapamil, the half-lives for the two phases were prolonged to 18 and 210 min, respectively. In the presence of 30 μmol/L of NAA, these half-lives were extended to 29 and 380 min, respectively (**Figure 4**). Thus, NAA not only resulted in a higher intracellular concentration of vinblastine but also prolonged the retention half-life of the preloaded vinblastine.
7. *Selective binding*: whether an MDR-reversing agent binds specifically to a particular MDR pump protein. Evidence that NAA interacts directly with the transporter, Pgp, was obtained by examining its effect on the inhibition of photoaffinity labelling of [^{3}H]azidopine, a photoactivatable substrate of Pgp (Sikic, 1991). The membrane functions from CCRF-CEM parent cells showed little or no [^{3}H]azidopine binding, whereas the binding to the membrane fractions isolated from

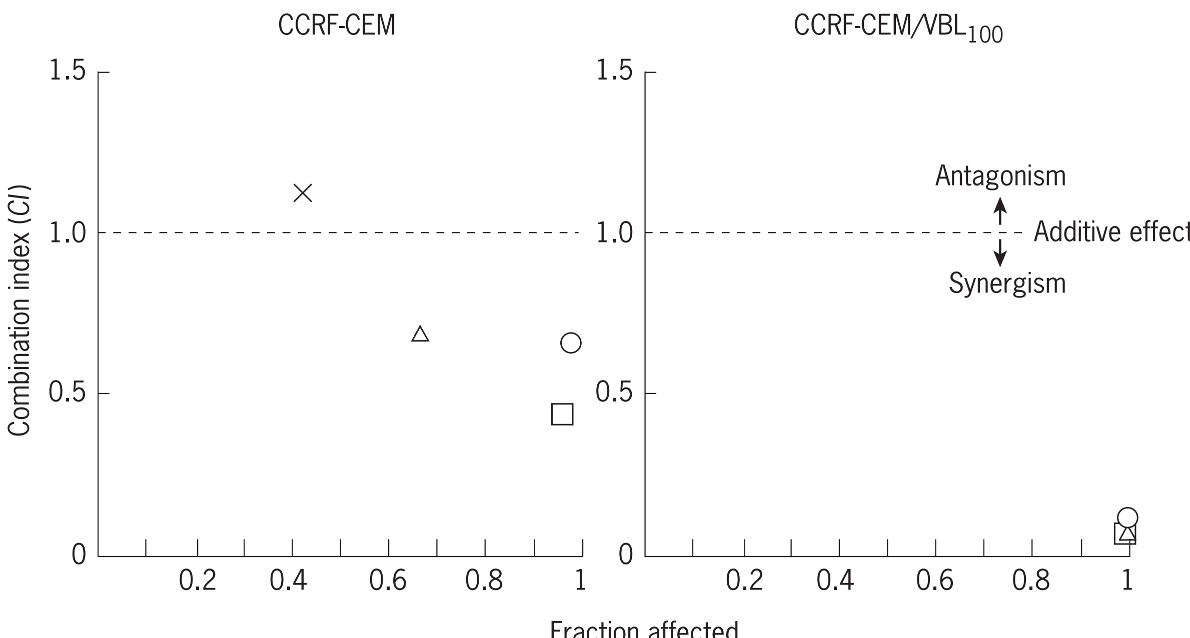

Figure 3 Synergism between vinblastine (VBL) and MDR reversing agent, 5-*N*-acetylardeemin (NAA), in combination against the growth of CCRF-CEM and its subline resistant to VBL, CCRF-CEM/VBL_{100}. $CI < 1$, $CI = 1$, and $CI > 1$ indicate synergism, additive effect and antagonism, respectively (Chou and Talalay, 1984; Chou 1991a).

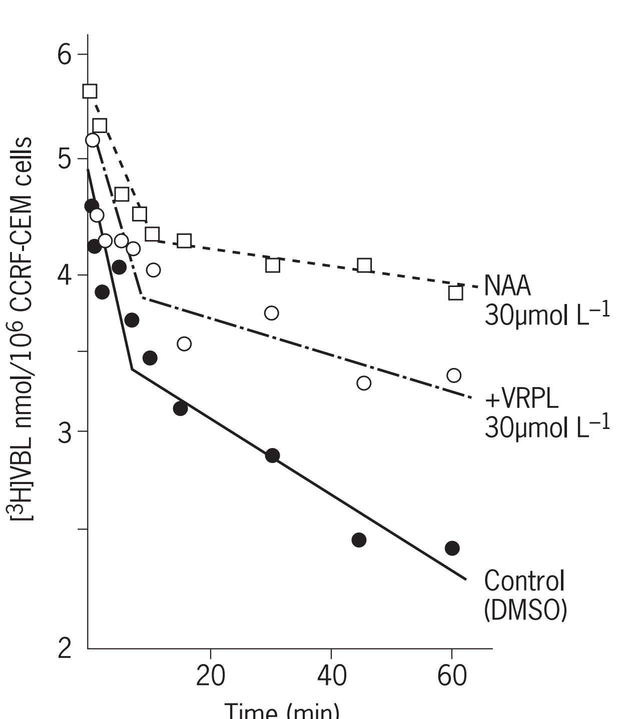

Figure 4 Reduced rates of efflux of preloaded [^{3}H]vinblastine (VBL) in CCRF-CEM cells by the MDR reversing agents 5-*N*-acetylardeemin (NAA) and verapamil (VRPL). [^{3}H]VBL was preloaded for 30 min at 37°C and, washed twice at 4°C with fresh medium. NAA or VRPL was added at 0 min and incubated at 37°C for various time periods. (From Chou *et al*., 1998, *Proceedings of the National Academy of Sciences of the USA*, **95**, 8369–8374.)

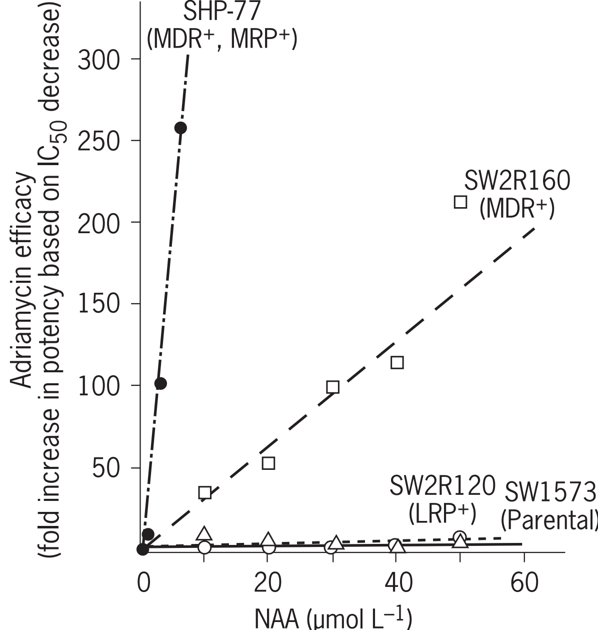

Figure 5 Enhancement of doxorubicin (DX) cytotoxicity by NAA. Six concentrations of DX were tested for cytotoxicity in (●) SHP77 ($MDR^+ + MRP^+$); (△) SW2R120 (LRP^+); (□) SW2R160 (MDR^+); and (○), SW1573 (wild-type) cells in the presence and absence of NAA. The concentrations required for 50% inhibition of cell growth (IC_{50} in μmol/L) were determined by the median-effect plot using computer software (Chou and Hayball, 1996). Fold of increase in efficacy of DX is based on fold of decrease in IC_{50}. NAA alone showed little or no cytotoxicity in these cell lines.

CCRF-CEM/VBL_{100} cells expressing Pgp were competitively displaced.

8. *Selective effects of the MDR-reversing agent*: whether the reversing agent sensitizes the cells of various subtypes of MDR such as Pgp, MRP and LRP. Enhancement of doxorubicin cytotoxicity by NAA (1–50 μmol/L) in human cancer cell lines expressing different MDR phenotypes was studied in culture (**Figure 5**). For SHP-77 (MDR-Pgp^+ + MRP^+) cells, the IC_{50} of doxorubicin was reduced 260-fold to 0.009 μmol/L by 6 μmol/L of NAA. In contrast, for SW1573 (parent), SW2R120 (LRP^+) and SW2R160 (MDR-Pgp^+) cells, the doxorubicin IC_{50} values were reduced three-, seven-, and 50-fold, respectively, by 20 μmol/L of NAA. Therefore, NAA markedly enhanced the efficacy of doxorubicin against SHP-77 (MDR-Pgp^+ + MRP^+) and SW2R160 (MDR-Pgp^+) cells, but had little effect in enhancing the efficacy of doxorubicin against SW2R120 (LRP^+) or SW1573 (parental cells).

MULTI-HIT AND MULTI-TARGET APPROACH AGAINST MDR: DRUG COMBINATIONS

As indicated above, there are many possible mechanisms that confer drug resistance. For multidrug resistance, there are mdr_1, mdr_2, MRP_1, MRP_2, MRP_6, LRP, etc. In addition, the ATP-binding cascade (ABC) superfamily has numerous genes (Higgins, 1995; Kuska, 1999) that may be relevant to drug resistance. It is reasonable to expect that a single agent alone is insufficient to overcome multifactorial multidrug resistance. Therefore, multidrug combination is a logical way to combat drug resistance.

This approach can be divided into the following categories: (1) combining drugs with different mechanisms of action; (2) combining MDR substrates with non-MDR substrates; and (3) combining MDR substrates belonging to different subclasses.

The outcomes of drug combination can be synergistic, antagonistic or additive. There is no simple way to predict the outcome quantitatively even at the *in vitro* level, and in animal models or clinics it will be much more complex.

The goal of drug combination is to (1) increase therapeutic efficacy by synergism, thus lowering the dose(s) of the drugs, (2) reduce toxicity or side effects against the host by reducing the dose; (3) minimize or reverse the drug resistance or delay the development of drug resistance; increased therapeutic efficacy leads to a decrease in the length of therapy, which in turn decreases the risk of developing resistance; and (4) achieve selective synergism against the target and/or selective antagonism toward the host, hence increasing the therapeutic index.

There are general rules that can be generated from past experience with drug combination studies. First, drugs with different mechanisms of actions or different modes of effect usually generate more synergism than those with similar modes of action. Second, based on the mass-action principle, synergism is usually more prominent at high dose or high effect levels than at low dose or low effect levels. Third, one should not attempt to predict or to interpret synergism or antagonism based on individual drug mechanisms alone since it tends to be oversimplified. Synergism or antagonism can be due to drug transport, metabolism, etc., unrelated to mechanism *per se*. For a simple case such as inhibition of tumour cell growth *in vitro*, it can be the combined results of cytocidal and cytostatic effects, and nobody knows from a live cell to a dead cell how many steps there are involved that can be the target step(s) for the component drugs.

Although the main focus for the pharmaceutical industries and academic drug discovery programmes is to search for individual new chemical entities or new therapeutic modes of action, in the treatment of neoplastic disease and infectious disease such as AIDS, monotherapy has been proved inadequate and combination therapy should be used (Chou, 1991a). The main problem, however, is that most clinical trials are still at the stage of trial-and-error in which there is no direct evidence that a particular combination may give a beneficial synergistic effect even *in vitro*. In addition, there is a great deal of confusion regarding data analysis and interpretation owing to a lack of a clear definition of 'synergism' (Chou, 1998).

Since synergism is an effect that is more than an additive effect and antagonism is less than an additive effect, a clear definition of 'additive effect' is of crucial importance in any meaningful quantitation of synergism or antagonism. So far, only two methods, namely the isobologram (Chou and Talalay, 1983) and the combination index method of Chou and Talalay (1984), involve a vigorously derived equation for defining what 'additive effect' is.

QUANTITATION OF SYNERGISM AND ANTAGONISM

The median-effect equation of Chou (Chou, 1976; Chou and Talalay, 1984) and the median-effect plot of are derived on the basis of the mass-action law principle:

$$(f_a/f_u) = (D/D_m)^m \quad [1]$$

where D is the dosage or concentration of a drug, f_a and f_u are the fraction affected and unaffected, respectively, by the drug, D_m is the the median-effect dose, signifying the 'potency' of the drug, and, the exponent m signifies the 'shape' or sigmoidicity of the dose–effect curve (i.e. $m = 1$, hyperbolic; $m > 1$, sigmoidal; $m < 1$, negative (flat) sigmoidal). The linear correlation coefficient of the median–effect plot, r signifies the 'conformity' of the data to the

method of analysis. Rearrangement of eqn. [1] gives

$$f_a = 1/[1 + (D_m/D)^m] \quad [2]$$

and

$$D = D_m[f_a/(1 - f_a)]^{1/m} \quad [3]$$

Thus, as the m and D_m values are known, the dose and effect can be interchanged. The logarithmic form of eqn [1] gives a linear equation:

$$\log(f_a/f_u) = m \log D - m \log D_m \quad [4]$$

Therefore, Chou's median-effect plot of log D against log (f_a/f_u) yields an x-intercept of log D_m and thus the D_m value and the slope of the plot (i.e. the m value) can be easily obtained (Chou and Talalay, 1984).

The median-effect principle has been extended to the analysis of the dose–effect relationship for multiple drugs. The multidrug effect equation was derived from the inhibition of the enzyme kinetic models via mathematical induction and reduction. The resulting general equation was then used to define the combination index (*CI*) equation of Chou and Talalay (1981, 1984):

$$CI = (D)_1/(Dx)_1 + (D)_2/(Dx)_2 \quad [5]$$

for a two-drug combination, where the denominators are the doses of each drug alone that produce x% effect and the numerators are the dose of the two drugs combined that also produce x% effect. Equation [5] allows the determination of the *CI* value, where $CI < 1$, $CI = 1$ and $CI > 1$ indicate synergism, additive effect and antagonism, respectively (Chou and Talalay, 1984). Computer software has been developed for automated analysis (Chou, 1991b; Chou and Hayball, 1996; Chou *et al*., 2000). This mass-action law-based method has gained popularity in the past two decades. Based on the *Citation Index* (Institute for Scientific Information, Philadelphia, Pa, 1982–1999), the median-effect principle of Chou and the combination-index equation of Chou-Talalay and its computer software have been used in scientific papers published in over 270 different biomedical journals.

EXPERIMENTAL DESIGN FOR DRUG COMBINATIONS

Because each drug may have different 'potencies' and may have different 'shapes' of dose–effect curves, it is essential to have a dose–effect curve (dose–effect relationship) for each drug before contemplating drug combination analysis. A typical old-fashioned experimental design is to vary the dose of each drug alone for the dose–effect curve parameters, and then use a 'non-constant ratio' design of combination (e.g. keeping the dose of one drug constant while varying the doses of the second drug). In this design, the *CI* value at each combination of data points can be calculated (Chou and Talalay, 1984; Chou, 1991a). However, the most efficient design is to vary the dose of each drug alone and then make a mixture of the drugs, and then serially dilute it. Thus, the combination is at a 'constant ratio' of combination. In effect, the mixture is treated as the third drug in the two-drug combination. In this design, not only can the *CI* values at each combination of data points be calculated, but we can also simulate the *CI* values at all effect levels. In addition, the classical isobologram can be automatically generated. By contrast, in a one-constant ratio design, only the normalized isobologram can be constructed (i.e. the dose (D) is normalized by Dx for x% inhibition) (Chou and Talalay, 1984; Chou, 1991a; Chou *et al*., 2000).

SELECTIVITY OF SYNERGISM AND ANTAGONISM

Most researchers have paid attention to the synergistic efficacy against the target (e.g. tumour cells, HIV), but neglected the possibility of synergism against the host which produces side effects or toxicity. In a series of classical studies by Chang *et al* (1985, 1987), 4-hydroperoxycyclophosphamide (4-HC) was combined with another anticancer agent, etoposide (VP-16), for purging leukaemic cells in autologous bone marrow transplantation. At high dose–high effect levels, the combination showed a synergistic effect against the proliferation of human promyelocytic leukaemic cells (HL-60), but showed antagonism towards the bone marrow progenitor cells as measured by CFU-GM and BFU-E (Chang *et al*., 1985). In another study, 3′-azidothymidine (AZT) and interferon-alpha$_{2A}$ (IFN) showed strong synergism against HIV proliferation, but showed only moderate synergism against bone marrow progenitor cells (Berman *et al*., 1989).

RATIONAL APPROACH TO THE CLINICAL PROTOCOL DESIGN FOR DRUG COMBINATIONS

With a quantitative method for synergism and antagonism readily available, we no longer take the risk of trial-and-error methods for conducting drug combination clinical studies. Although *in vitro* data under simple and defined conditions may not be fully applicable for *in vivo* or clinical situations, the quantitative method at least provides directions as to answering the following questions

(Chou, 1991a, 1998):

1. *Selection of candidate combination*: among many antineoplastic drugs with different mechanisms of action, which pair, triplet or quadruplet of drug combination has better synergism than others?
2. *Pattern of synergism/antagonism*: if synergism is observed, does synergism occur similarly at different effect levels or different dose levels?
3. *Combination ratio*: does an equimolar ratio of combination yield a greater synergistic effect than other combination ratios?
4. *Schedule dependency*: do two drugs that are administered simultaneously or in a sequential order or reverse order produce similar degrees of synergism?

All of the above questions are important and relevant to the rational approach to clinical drug combination protocol design. For a more detailed review and discussion see Chou *et al*. (1994, 1997) and Chou (1998).

BIOLOGICAL BACKGROUND

Why Immunotherapy?

The greatest limitation to the successful treatment of cancer is the ability of tumours to form distant metastases. These are often located in vital organs and are either inaccessable or refractory to conventional forms of cancer treatment such as surgery, chemotherapy or radiotherapy. A further limitation of conventional cancer treatment is the necessity to balance the toxicity and side effects with the dose-dependent beneficial antitumour effects of these modalities. The ideal form of cancer therapy would be selective for the tumour and thereby nontoxic to the host, able to circumvent heterogeneity within a given tumour and be able to reach tumour metastases in all anatomical sites. High expectations have arisen that the immune system can be exploited for immunotherapeutic anticancer treatment because of its exquisite specificity. This is associated primarily with T lymphocytes and antibodies, but also with professional antigen-presenting cells (APCs), such as dendritic cells (DCs), and with cytotoxic effector cells such as NK cells, macrophages and others. (See also chapters on *Antibodies and Recombinant Cytokines* and *Genetic and Cellular Vaccines*.)

Biology of Metastasis Formation

For the design of immunological interventions to be successful in the treatment of metastases it seems essential to be aware of basic concepts and aspects of metastasis formation which have been known for many years (Fidler and Radinsky, 1990; Kerbel, 1990; Nicolson, 1993). These are, for example, clonal selection of metastatic cells, heterogeneity of metastatic subpopulations, organ specificity of metastases and the role of angiogenesis. Proteolysis and alterations in adhesive functions are the most obvious and thus one of the most thoroughly investigated processes. Various proteases and precursors and their inhibitors exhibit a complex interplay of a highly regulated nature. The same holds true for adhesive and 'de-adhesive' tumour–host interactions, involving adhesion molecules from the immunoglobulin superfamily, integrins, cadherins, selectins and hyaluronic acid receptors as well as their ligands. The control of the metastatic cascade by these extracellularly acting molecules is delicately balanced. Slight changes could affect any balance and consequently promote metastasis formation.

Molecular Targets of Metastases

Upon ligand binding, cell surface receptors transmit signals into the cell, activating multiple metabolic and signal transduction pathways which can promote cell growth, cell differentiation or programmed cell death (apoptosis) (Hart *et al*., 1989; Fodstad, 1993; Khazaie *et al*., 1993). Metastatic cancer cells may become more resistant to apoptosis than their non-metastatic counterparts (Glinsky, 1998). Although the nature of the stimulatory molecules is highly variable, the principles involved in propagating the signals seem to be ubiquitous. Thus, such different stimulators as antigens, cytokines, hormones and growth factors (Khazaie *et al*., 1993) use similar transduction principles including ligand induced receptor internalization of receptor–ligand complexes, activation of G proteins, oligomerization, increases in calcium uptake, activation of tyrosine kinases or other kinases and phosphatases, protein

phosphorylation or dephosphorylation and the triggering of oncogenes and transcription factors. The signalling molecules interact with each other through universal 'zippers' such as SH2 and SH3 domains. Many of the currently described metastases-related molecules are confined to distinct cellular compartments such as the extracellular space, the cell membrane, the cytoplasmic signalling network and the nuclear regulatory system. Promising new therapeutic approaches try to use recombinant soluble metastases-related molecules which interfere with ligand interactions.

Tumour-associated Antigens (TAAs) and the Immune System

In recent years we have also seen an increase in biological therapies which incorporate new insights from immunology and molecular biology (Eibl *et al*., 1997, 1998). The process of selection and expansion of mutant clones that occurs during progression of human malignant disease leads to a wide range of random mutational, recombinatorial, deletional and regulatory gene changes. Neoantigens may be produced (1) by up-regulation of lineage-specific markers (e.g. differentiation antigens) and/or oncofetal antigens to immunologically 'visible' levels and (2) by the occurrence of nonlethal mutations in widely expressed proteins. Thus, tumours may express both unique TAAs and cross-protective antigens (Coggin *et al*., 1998). Together, such new TAAs make a strong case for the use of autologous tumour cell vaccines (rather than defined antigenic peptides) to ensure the recognition of unknown but potentially targetable TAAs generated by random mutational processes (Ellem *et al*., 1998).

The immune system is a complex system with several functional components and powerful information-processing capabilities. It employs a multilevel defence against invaders through nonspecific (innate) and specific (acquired) immune mechanisms. The immune system has learned through evolution to distinguish between foreign antigens (e.g. bacteria, viruses, etc.) and the body's own cells or molecules. The lymphocyte is the main type of immune cell participating in the immune response and responsible for specificity, diversity, memory and adaptivity. Other cells called phagocytic cells – neutrophils, eosinophils, basophils, monocytes – are accessory immune cells whose primary function is to provide facilities to eliminate antigens. Different populations of lymphocyte recirculate at primary and secondary lymphoid organs and are carefully controlled to ensure that appropriate populations of B and T cells (naive, effector and memory) are recruited into different locations. This differential migration of lymphocyte subpopulations at different locations (organs) of the body is called trafficking or homing.

The key features of the immune system which are of great interest to the field of information processing (Dasgupta, 1999) are as follows:

- *recognition* of patterns (antigen) and generation of selective responses;
- *feature extraction*: each APC, by processing and presenting antigenic peptides, serves as a filter and a lens: a filter that destroys molecular noise, and a lens that focuses the attention to the lymphocyte receptors;
- *diversity generation* in lymphocyte receptors by genetic combinatory processes involving basic elements;
- *learning* by experience and associations mediated by changes in specific lymphocyte concentrations;
- *memory*: using short- and long-term memory mechanisms, the immune system keeps an ideal balance between economy and performance in conserving a minimal but sufficient memory of the past (Ahmed and Gray, 1996);
- *self-regulation*: immune responses are self-regulatory although there is no central organ for this; the regulation can be either local or systemic, depending on the route and property of the antigenic challenge;
- *threshold mechanisms*: immune responses take place above a certain matching threshold (strength of chemical binding);
- *co-stimulation*: activation of T and B cells is closely regulated through second signal co-stimulation; the second signal (often from helper T cells) helps to ensure tolerance and judge between dangerous and harmless invaders or false alarm.

In order for immunological approaches to the treatment of cancer to live up to their expected potential, it seems essential to investigate systematically in appropriate model systems the parameters required for optimum stimulation of effector activities and for selective accumulation of effector cells and/or molecules at the sites of metastases. Because of the complex nature of metastasis formation, of tumour–host interactions, of antitumour immune responses and of tumour immune escape mechanisms (Schirrmacher *et al*., 1982; Ellem *et al*., 1998) it is very important that such experimental model systems fulfil certain criteria, such as: (1) reproducible formation of metastases at distinct organ sites, (2) protocols for reproducible induction of antitumour immune responses and (3) reproducible sensitivity of the tumour system to immune manipulation and immunotherapy.

PRINCIPLES OF MODEL ESTABLISHMENT

A prerequisite for basic research in cancer metastases is the availability of a tumour line with the capacity to metastasize. In order to find out which properties enable a metastasizing cancer cell to metastasize, it is advantageous to compare it with a related cancer line which has either no or a very reduced metastatic capacity. Many of the molecules that were found to play a role in metastasis were

identified in such a way. For studies on immune recognition by T lymphocytes such tumour lines should be typed for cell surface expression of major histocompatibility complex (MHC) molecules of class I or class II. These molecules are used to present intracellular peptides to immune CD8 or immune CD4 T lymphocytes, respectively. Further molecules of importance are TAAs, cell adhesion molecules (CAM) and differentiation antigens (DA). These molecules may play important roles in cell–cell interactions, cell–matrix interactions and cellular signalling. Degradative enzymes are important for tumour cell invasiveness and are regulated by respective inhibitors.

Establishment of Related Tumour Sublines with Different Metastatic Capacity

The model system we have been studying most intensively is the Eb/ESb/ESb-MP mouse tumour (Schirrmacher, 1982). ESb cells represent a spontaneous highly metastatic variant of the chemically induced T cell lymphoma L5178 Y (Eb) of DBA/2 mice and arose most likely following fusion of Eb cells with a host macrophage. The ESb-MP subline is an adhesion variant of ESb which grows *in vitro* attached to plastic whereas Esb cells grow in suspension. *In vivo*, ESb-MP cells grow progressively but show a less aggressive phenotype, metastasizing more slowly than ESb and involving multiple organs. The following sublines of ESb were also established: ESbL, a line reisolated from a single liver metastasis after spontaneous metastasis of ESb from an intradermal site; ESb-TA$^-$ cells, an immune escape variant resistant to syngeneic ESb-TA$^+$ specific cytotoxic T lymphocytes. The phenotype and characteristics of the tumour lines of this model system are summarized in **Table 1**.

Gene Tagging

We decided to use the bacterial *lacZ* gene to tag genetically our tumour cells and at the same time to use this foreign gene as a model tumour-associated antigen (TAA). ESbL-lacZ cells represent a gene transfectant of ESbL retrovirally transduced with *lacZ* vector BAG, selected for high expression via fluorescence-activated cell sorter (FACScan) and cloned (Krüger *et al*., 1994a, b). Since its description almost 40 years ago, the *lacZ* gene has become particularly useful in phage and bacterial genetics and in molecular DNA cloning. In the early 1980s the *lacZ* gene together with the chromogenic substrate 5-bromo-4-chloro-3-indoyl-β-D-galactopyranoside (X-Gal) was also introduced into cell biology, developmental biology and finally into metastasis research. Lineage studies or detection of individual tumour cells in the context of normal tissue could then be attempted since the tag was transmitted to subsequent generations upon cell division. X-Gal

Table 1 Phenotype and characteristics of tumour lines used

	Eb	**ESb**	**ESb-MP**
Aetiology	Chemically induced T lymphoma (L5178Y)	Spontaneous metastasis variant	Adhesion variant
Phenotype[a]			
MHC class I, II	I^+, II^-	I^+, II^-	I^+, II^-
TA	Eb-type (K^d)	ESb-type (K^d)	ESb-type (K^d)
CAM	LFA-1	ICAM-1	LFA-1, ICAM-1, L1
DA	Thy1, CD8, CD45R	Lyt1, CD2, CD45R	Mac-1, CD2, CD45R
Invasiveness[b]	Low	High	High
Degradative enzymes	MTSP-1	MTSP-1, u-PA, heparanase	MTSP-1, u-PA, heparanase
Malignancy	Low	High	Low
Primary tumour (size)	1.5 cm	0.8 cm	2.0 cm
50% survival time (t_{50})	28 days	10 days	42 days
Dissemination	—	Fast	Slow
Involved organs	—	Liver, bone marrow, lung, spleen	Liver, bone marrow, lung, spleen, kidney, spinal column
Sublines			
Liver selected[c]		ESb-L	
LacZ transfected[d]	Eb-lacZ	ESb-L-lacZ	
Immune escape[e]		ESb-TA$^-$	

[a]MHC = major histocompatibility molecules; TA = tumour antigen; CAM = cell adhesion molecules; DA = differentiation antigens.
[b]Through endothelium and subendothelial extracellular matrix, matrigel, fibrin gel, collagen gel and lung cubes; MTSP-1 = murine T cell related serine proteinase; u-PA = plasminogen activator of urokinase type.
[c]After spontaneous metastasis from intradermal site, reisolated from a single liver metastasis.
[d]Retrovirally transduced with *lacZ*, *neo*^{R} vector, selected via G418 and FACS and cloned.
[e]Immune escape variant ESb816, resistant to ESb-TA$^+$ specific cytotoxic T lymphocyte (CTL).

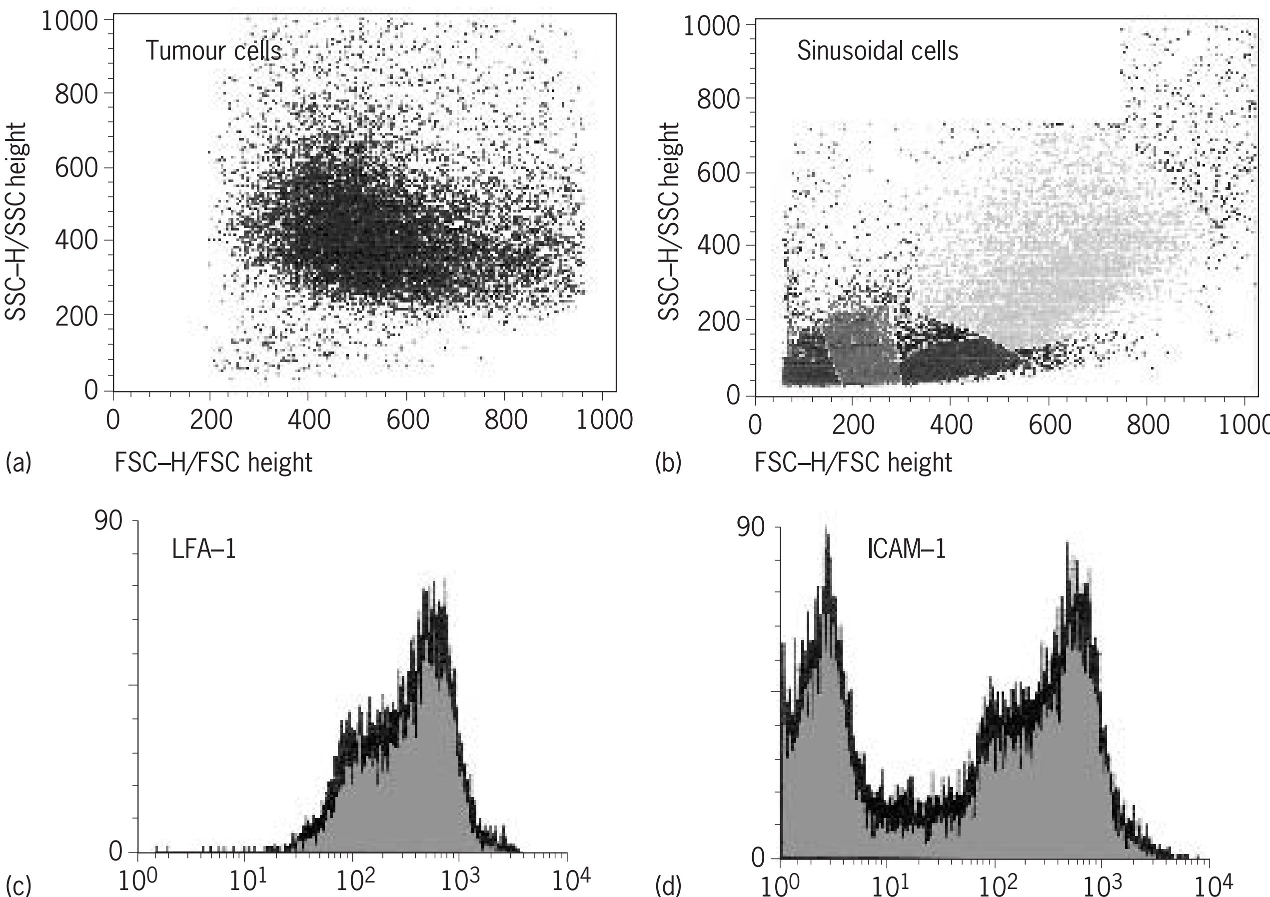

Figure 1 Flow cytometric analysis of FDG-loaded isolated liver sinusoidal cells and tumour cells. Tumour cells expressing the *lacZ* gene were identified as green fluorescence-positive cells (a) and sinusoidal cells as green fluorescence-negative cells (b). (c, d) monoparametric frequency distribution of red fluorescence (FL2) in tumour and sinusoidal cells. An example is given with LFA-1 expression on tumour cells (c) and ICAM-1 in sinusoidal cells (d).

staining is usually performed on fixed cells or tissues with the consequence that stained cells are not viable. This limitation was overcome by the development of another substrate for β-galactosidase, namely fluorescein-di-β-D-galactopyranoside (FDG), making the detection of viable lacZ expressing cells possible by flow cytometry. This added a new dimension to cancer research as it allowed not only the histological description of early metastases by X-Gal staining but also the reisolation of FDG-stained tumour cells and purification from host cell populations making *ex vivo* characterization and molecular analysis of metastatic cells possible. With these new technologies, quantitative and qualitative studies permitted new insights into individual steps of the metastatic cascade, in modulated host environments and in evaluating the effectiveness of cancer therapies (Krüger *et al*., 1994a, b, 1999).

Visualization of Micrometastases

Micrometastases are secondary tumour cell colonies below the detection threshold of conventional technology in the clinic. They are important targets for adjuvant therapies. In primary operated breast cancer, for instance, there is an uncertainty whether micrometastastes are left behind which are a potential risk factor for tumour recurrence. Because of this uncertainty adjuvant chemotherapy is given to most breast-cancer patients. If one were able to visualize micrometastases, not every patient would need to receive such additional therapy which has considerable side effects.

Detection of micrometastases and small numbers of dormant tumour cells has only recently been possible in this model when using the genetically tagged tumour lines. X-Gal staining allowed single ESb-lacZ tumour cells to be detected in infiltrated organs such as lymph nodes, bone marrow or liver (Krüger *et al*., 1994a). Despite expression of the *lacZ* gene, the tumour cells were still tumorigenic, metastatic, unchanged in phenotype and therefore comparable to the parental ESb cells. After spontaneous metastasis, whole-organ staining revealed metastatic foci at the surface of the liver, while X-Gal staining of frozen tissue sections revealed micrometastasis in the form of

clusters and diffusely disseminated single cells (Krüger *et al*., 1994b). It was also possible to reisolate cells from metastases and to quantify them in metastasized organs via loading with the substrate FDG, which allowed tumour cell fluorescence staining and quantitative FACScan analysis. In a typical experiment, 12 days after intradermal tumour cell inoculation, 55% of the reisolated cells from the liver and 13% of the cells from the spleen were tumour cells.

The visualization and quantification of micrometastases gives important information about the type and degree of cellular spreading. For instance, it may be focal or diffuse, a distinction that may influence the patient's prognosis. **Figure 1** shows an example of flow cytometric analysis of tumour cells which had metastasized to the liver. Tumor cells (a) could be distinguished from normal sinusoidal cells (b) by green fluorescence following hypotonic FDG loading. Further staining with monoclonal antibodies allowed the detection of LFA-1 adhesion molecules on the tumour cells (c) and of ICAM-1 cell adhesion molecules on sinusoidal cells (d).

Visualization of Macrometastases

With nuclear magnetic resonance (NMR) imaging, it was possible in mice to detect the formation of focal metastasis in the liver and kidneys noninvasively and without contrast agents. The NMR studies were performed at high magnetic field strength (7.0 T) using a Bruker AM 300 spectrometer and a superconducting magnet with a 15-cm diameter vertical bore. During the measurements, mice were anaesthesized with chloral hydrate for 1–2 h in the case of ^{31}P-NMR spectroscopy of primary tumours or with isofluorane inhalation narcosis for 2–3 h in the case of ^{1}H-NMR imaging and kept at a temperature of about 32 °C. Metastases with a diameter $>$0.3 mm could usually be detected by day 21–23 after ESb-MP inoculation. This noninvasive imaging procedure in live tumour-bearing mice enabled us to follow the effect of immunotherapy (Fichtner *et al*., 1997).

GENERAL APPLICATIONS

Model Vaccination Studies Against Tumour Challenge

The field of human cancer vaccines is currently undergoing a revival. In a special issue of *Seminars in Oncology* (Cancer Vaccines, *Seminars Oncology*, **25**, No. 6, December 1998), some of the underlying principles are summarized as follows: (1) human cancers are weakly immunogenic or not immunogenic at all; (2) cell-mediated immune responses, mainly those of T-lymphocytes, are critical to tumour rejection; (3) almost nothing is known about the nature of the rejection antigens on human tumours; (4) it is not clear whether these antigens are different for each case of human cancer or whether there are clinically useful antigens that are shared by all or most tumours of a given histological type; and (5) the effectiveness of vaccines is greatly limited by excessive tumour burden. Examples of the most advanced clinical studies with human cancer vaccines are presented in this special issue. Most cancer vaccines use live tumour cells or lysates thereof. Some others use tumour-derived proteins, peptides or gangliosides. The use of DNA or RNA vaccines in general is relatively new. Its application to cancer was tested in our own laboratory.

Vaccination with DNA or RNA Encoding a Model Tumour Antigen and a Cytokine

Three different vaccination sites were compared for efficiency of immunization with naked DNA or self-replicating RNA (Förg *et al*., 1998; Schirrmacher *et al*., 2000a). Using the bacterial *lacZ* gene as a model, three injection sites of the mouse (skeletal muscle, dermis of the abdominal skin and ear pinna) were used for inoculation. Gene expression varied in expression time with muscle tissue showing the longest expression. Expression time, however, did not correlate with immune response intensity. The ear pinna was by far the most effective and muscle the least effective priming site for specific humoral and cytotoxic T cell-mediated immune responses (Förg *et al*., 1998). *Lac-Z* DNA immunization was also compared with cell based vaccination with *lacZ* transfected tumour cells, in which case again the pinna was the best site for inducing strong immune responses. Tumour-specific T cell responses could also be well induced in the pinna, leading to cytotoxic T lymphocyte induction and protective antitumour immunity (Schirrmacher *et al*., 2000a). Gene expression following pinna inoculation of either nonreplicating DNA plasmids or self-replicating RNA (Schirrmacher *et al*., 2000a) was similar, lasting for 2–3 weeks. Higher antibody responses were obtained with RNA than with DNA. β-Gal peptide-specific CTL memory responses to *lacZ* DNA or RNA were similar. They lasted for more than 6 weeks whereas the respective responses induced by *lacZ* tumour cells lasted for only 2 weeks.

The extent of protective antitumour immunity depended not only on the gene dose used for vaccination but also on the aggressiveness of the *lacZ* transfected tumour line used for challenge (Schirrmacher *et al*., 2000a). In comparison with *lacZ*-transfected tumour cells as vaccines, polynucleotide vaccination also demonstrated superiority with regard to cross-protection. Protective antitumour immunity could be strongly increased upon co-inoculation of *lacZ* DNA with IL-2 DNA or IL-12 RNA. These new model studies demonstrate efficient protective antitumour immunity after intra-pinna *lacZ* TAA polynucleotide vaccination and show additional immunomodulatory

effects by co-administration of cytokine polynucleotides (Schirrmacher *et al*., 2000a).

Vaccination with Live Tumour Cells; Establishment of Tumour Dormancy and Immune Memory

With the low metastatic Eb lymphoma, also genetically tagged with *lacZ*, we were able to visualize the rapid migration of tumour cells from a primary inoculation site such as the skin or the ear pinna to the lymphatic circulatory system and to the bone marrow (Khazaie *et al*., 1994). Live proliferation-competent and irradiated proliferation-incompetent Eb-*lacZ* cells were compared for their potency to induce after intra-pinna inoculation systemic antitumour immunity in syngeneic DBA/2 mice. Inoculation of nontumorigenic doses of live tumour cells led to long-lasting specific and systemic T cell-mediated antitumour responses requiring both CD4 and CD8 T lymphocytes. Irradiated cells as vaccines offered only limited short-term protection which could be marginally improved by local secretion of interleukin-4 following respective gene transfer (Khazaie *et al*., 1994). The more effective protection offered by vaccination with live tumour cells correlated with rapid migration and persistence of small numbers of tumour cells in the bone marrow of host animals. In contrast, irradiated Eb-*lacZ* cells had a short persistence. These observations indicated that in the course of vaccination with live tumour cells, a fraction of these cells escaped destruction by host mechanisms and persisted in a dormant state in the bone marrow for long periods of time. Persistence of dormant cells in the bone marrow correlated with the duration of antitumour immunity (Khazaie *et al*., 1994). We recently provided evidence for an important role of CD8 immune T cells in the control of tumour dormancy in the bone-marrow compartment. The bone-marrow residing tumour cells expressed the proliferation associated Ki-67 antigen and expanded upon CD8 T cell depletion. Upon transplantation of bone marrow from tumour-dormant to naive recipients, the co-existence of low numbers of tumour cells and CD8 immune memory T cells provided transient protection against further tumour cell challenge (Müller *et al*., 1998). The bone marrow thus appears to be a privileged site where protective immune T cells keep tumour cells in a dormant state. The use of *lacZ* tagging thus allowed us to study in detail tumour dormancy and the role of tumour–host interactions in this phenomenon.

Intra-pinna inoculation of live aggressive ESbL tumour cells also led to the induction of specific long-term systemic protective immunity rather than tumour growth. The ear pinna appeared to be the only site in syngeneic mice where these tumour cells which express a distinct TAA recognizable by specific CTL cannot grow. Induction of anti-ESbL immunity could be shown *in vivo* by rejection of a second tumour cell challenge or *in vitro* by killing of ESbL tumour cells in a ^{51}Cr-release assay using *in vitro* re-stimulated spleen cells from syngeneic immunized mice as effector cells. Both CD4 and CD8 T cells were required for induction of CTL (Schirrmacher *et al*., 1992) and protective immunity. Since we had a tumour model at hand in which we could compare experimental situations of tumour resistance (e.g. after pinna inoculation) with tumour susceptibility (e.g. after subcutaneous inoculation), we decided to examine the activation of cytokine genes directly *ex vivo* and to compare cytokine profiles with tumour resistance or susceptibility. The results revealed a superiority of the ear pinna over a subcutaneous inoculation site for induction of a Th1-type cytokine response (Jurianz *et al*., 1998).

Vaccination with Fusion Products of Tumour Cells and Dendritic Cells

If tumour cells express a tumour-associated antigen but no costimulatory molecules for activation of T lymphocytes, the interaction of such tumour cells with respective specific T cells could induce anergy rather than T cell activation. That means that such T cells will be shut off from responding to that same antigen upon further contact. This problem is particularly relevant for tumours arising from cells which are not professional antigen-presenting cells and are therefore devoid of costimulatory molecules. Carcinomas are such an example. They are derived from epithelia and represent the majority of human cancers. Dendritic cells are the most competent professional antigen-presenting cells and are the only cells able to prime nonantigen-experienced specific T lymphocytes. A concept has therefore been developed to fuse carcinoma cells with dendritic cells in order to introduce into the cancer cells all the properties which are necessary for costimulation of T cells.

Using *lacZ*-tagged cells, we also performed immunization experiments with carcinoma cells in the mouse. For this purpose we used the DA3 line of a chemically induced mammary carcinoma of BALB/c mice which we transfected with *lacZ* to generate the clone III-25 which was used in all further experiments. Whereas the immunogenicity of the parental carcinoma line was very low, possibly linked with the low expression of MHC I molecules, the *lacZ* transfectant showed a slight increase in immunogenicity and a reduced tumour growth *in vivo* due to the immune recognition of β-galactosidase as model TAA. Also in this model the ear pinna appeared to be the best site for immune response induction. Preimmunizing mice with fusion products of tumour cells and DCs led to the induction of systemic protective immunity against the parental DA3 cell line which was revealed by delayed tumour growth after challenge. In case of using fusion products with the *lacZ* transfectant, a very clear-cut protection was achieved in the majority of tumour-challenged animals. The immunization led to β-galactosidase-specific

memory CTLs which still existed 10 weeks after immunization. Immune spleen cells from such preimmunized mice were able to transfer protective antitumour immunity into nude mice preinoculated with respective tumour cells. These new and not yet published results reveal the special immunotherapeutic efficiency of fusion products of tumour cells and DCs in situations of low tumour immunogenicity (Lindner, 1998).

Model Immunotherapy Studies Against Established Metastases

Active Specific Immunotherapy (ASI) with Cancer Vaccines for Treatment of Micrometastases

Major contributions to the understanding of the principles of therapeutic tumour vaccination and ASI were made in the L10 guinea pig hepatocarcinoma (Key, 1981) and in the ESb-mouse lymphoma model. A number of similarities existed between the optimum protocols developed in these two metastasizing tumours and the therapeutic results obtained. Whereas in the L10 tumour postoperative immunotherapy with irradiated autologous tumour cells admixed with BCG protected against lymph node and lung metastases, in the ESb tumour model postoperative treatment with irradiated Newcastle disease virus (NDV)-infected autologous tumour cells protected against haematogenous metastases (Heicappell *et al*., 1986). Important variables for optimum therapeutic effects were the time of operation of the primary tumour, their residual disseminated tumour burden and the dose of virus or BCG added to a standard dose of 10^7 irradiated tumour cells. The site of vaccination also appeared to be important: In the L10 guinea pig model, three vaccinations injected intradermally protected against lymphatic spread, whereas in the ESb mouse model, intraperitoneal administration of the vaccine had the strongest protective effect against visceral metastastes. In both models, postoperative vaccination with inactivated viable tumour cells without viral or bacterial adjuvants had no therapeutic effect (Key and Hanna, 1981, Heicappell *et al*., 1986).

In both tumour models it was shown that vaccination leads to a local inflammatory reaction which extends to the draining lymph nodes and eventually leads to a systemic immunity and inflammatory reaction at sites of metastases. In the guinea pig, the interconnections between local vaccine reactions and systemic immunity were evaluated by means of removal of the local reaction sites of the skin or of the draining lymph nodes at different times and testing the effects on postoperative survival. The stronger the local reaction, the better was the extent of systemic immunity induced. The combination of autologous tumour cells and BCG in the vaccine had a synergistic effect both on the intensity of the local reaction and on the protective immunity. In both models it was documented that the viability of the inactivated tumour cells was of decisive importance and that the cells had to be frozen under controlled conditions otherwise their immunogenicity was greatly decreased. In the Esb–tumour system, we found that simple shock freezing/thawing of the tumour cells completely destroyed their immunogenicity with regard to stimulating tumour-specific CTL in mixed lymphocyte–tumour cell (MLTC) cultures (Schirrmacher *et al*., 1993). This defect could not be restored by the addition of cytokines such as IL-1, IL-2 or interferon-γ. The stronger immunogenicity of intact tumour cells compared with membrane preparations could be due to accessory adhesive and signalling molecules.

In a comparative study we found that vaccination with either L10/BCG or with L10-NDV vaccine induced similar protective antitumour immunity (Bier *et al*., 1989). A combination of the two types of vaccine did not lead to better protective immune effects. BCG induces long-lasting ulcers in animals and patients whereas NDV does not. Another advantage of NDV may be its more precise localization at the tumour cell surface where immune cell–tumour cell interactions take place. When we analysed the immune responses of animals inoculated in the pinna with either live ESb or live ESb-NDV cells we found three levels at which NDV exerted an amplifying effect on the immune response: (1) an increased CD4 T cell-mediated helper response, (2) an increased frequency of tumour-specific CTL precursors and (3) an increased stimulatory capacity of NDV-modified ESb cells for activating tumour-specific CTL precursors to mature CTL *in vitro*. Advantages of NDV are its good cell-binding properties, its selective replication in tumour cell cytoplasm, which is independent of cell proliferation, and its relative safety (Schirrmacher *et al*., 1998). Most important for its use as an adjuvant in human cancer vaccines are its ability to introduce T cell costimulatory activity, to prevent anergy induction and to induce locally chemokines (e.g. RANTES, IP10) and cytokines (e.g. interferon-α, T-β) that affect T cell recruitment and activation. A further development consists in attachment, via NDV-derived haemagglutinin–neuraminidase (HN) membrane anchoring molecules, of universal defined bispecific reagents such as T cell activating anti-CD28 antibodies (Haas *et al*., 1998).

Clinical ASI Studies

The present status of our clinical studies with the autologous NDV-modified high-quality live tumour cell vaccine ATV-NDV which have been ongoing since 1988 has recently been updated. These include Kaplan–Meier probability plots of postoperative survival of cancer patients from five different phase II vaccination studies. Comparisons are made between groups of patients with similar prognostic parameters. In one study (glioblastoma), the vaccinated group (ASI) was compared with a historical control from the same clinic. In the other four studies

(colorectal carcinoma Dukes' C (Ockert 1996); primary operated mammary carcinoma (Ahlert, 1997); melanoma and ovarian carcinoma (Ahlert *et al*., 1997)), both groups of patients received ASI treatment simultaneously. The ATV-NDV vaccine, prepared after purification starting with 10^7 cells, differed with respect to tumour cell number and cell viability (Ahlert *et al*., 1997). Therefore, retrospectively, groups were formed and compared with similar prognostic parameters that differed only with respect to postulated quality parameters of the vaccine. In all five studies, postoperative treatments with high-quality ATV-NDV vaccine showed a strong trend for improval of survival in comparison with patients treated with low-quality vaccine or in comparison with historical controls (Ockert *et al*., 1996). In addition, there were various signs of systemic effects which support the notion of effectivity. A prospective randomized, controlled phase III study with the ATV-NDV vaccine in primary operated breast-cancer patients in the medium risk category has recently been started. The design of this study is shown in **Figure 2**.

Adoptive Cellular Immunotherapy (ADI) with Immune Cells for Treatment of Macrometastases

We established in the ESb/ESb-MP lymphoma model a cellular cancer therapy with unique efficiency even in late-stage advanced metastasized cancer. *In situ*-activated tumour immune T cells, induced in allogeneic, tumour-resistant, MHC-identical but superantigen-different donor mice (B10.D2), could transfer strong graft versus leukaemia (GvL) effects accompanied by only mild graft versus host (GvH) reactivity. Systemic immune cell transfer into 5 Gy-irradiated DBA/2 mice bearing up to 4 week established syngeneic tumours and macro-metastases led to massive infiltration of the tumour tissues by CD4 and CD8 donor T lymphocytes. Upon interactions of these T cells with host antigen-presenting cells, primary tumours (>1 cm diameter) were encapsulated and rejected from the skin and liver metastases were eradicated. The effects of this effective ADI therapy could be followed in individual animals by ^{31}P-NMR spectroscopy of primary tumours and by ^{1}H-NMR imaging of metastases. An approximately 25 000-fold excess of metastatic tumour cells could be rejected, as revealed quantitatively by FACSscan analysis of *lacZ* gene-transfected tumour cells.

This T cell-mediated therapy caused recruitment and activation of a distinct host macrophage population into the liver bearing the lymphocyte adhesion molecule sialoadhesin (Sn) (Umansky *et al*., 1995a). We demonstrated *in vitro* that these Sn^+ macrophages were capable of processing and presenting human C-reactive protein via MHC class II to a CD4 T helper clone specific for an identified MHC II associated C-reactive protein-derived peptide (Umansky *et al*., 1995a). Furthermore, Sn^+ macrophages which were isolated from the liver of ADI-treated animals could directly restimulate *in vitro* CD8 T lymphocytes primed against the tumour cells, suggesting that they could process and present exogenous TAA to T lymphocytes (Rocha *et al*., 1997a). Moreover, using as *in vitro* model the antigen β-galactosidase, for which a dominant MHC class I L^d restricted peptide epitope is known to be recognized by specific CD8 CTLs, we demonstrated that purified Sn macrophages can process

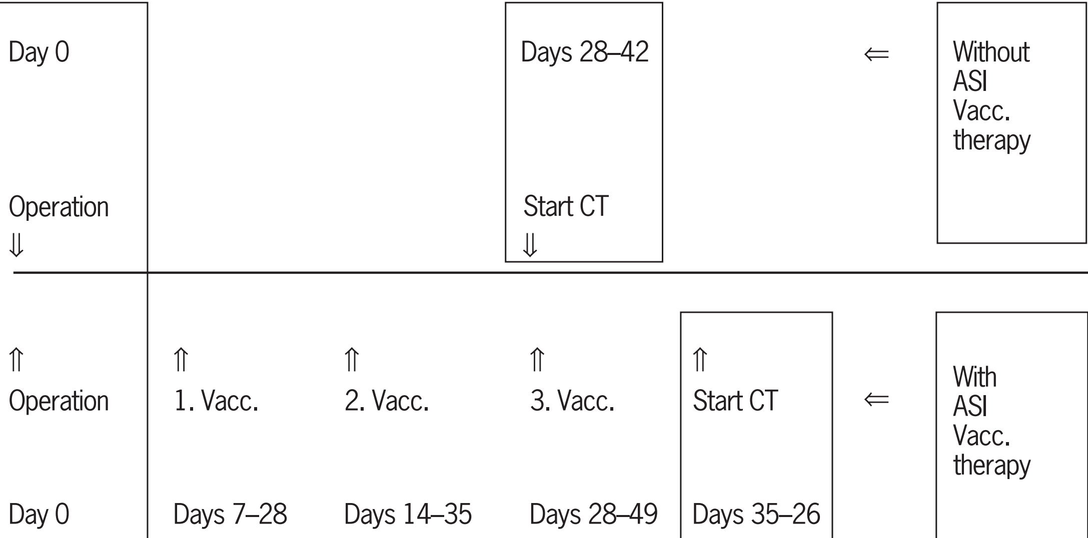

Figure 2 Protocol of a phase II/III clinical study to test for efficacy of active specific immunotherapy (ASI) of the autologous virus-modified tumour vaccine ATV-NDV in primary operated breast-cancer patients. It is a multicentre, prospective, double-blind, placebo-controlled, randomized parallel-group study (protocol No. ASI A-01). CT = chemotherapy.

exogenous β-galactosidase and stimulate peptide specific class I MHC restricted CTL responses (Muerköster *et al.*, 1999). Sn macrophages which are significantly increased in the liver after ADI played an essential role in GvL reactivity (Muerköster *et al.*, 1999). They appeared to be able to process tumour-derived proteins via the MHC class I and also via the MHC class II pathway and present peptide epitopes to CD8 and to CD4 immune T cells, respectively. The synergistic interactions demonstrated before between immune CD4 and CD8 T cells during ADI could thus occur in the observed clusters (Rocha *et al.*, 1997a) in the liver between such T cells and host Sn^+ macrophages.

Breaking Tolerance via GvL Reactivity

A major goal in tumour immunotherapy consists in breaking potential tumour-specific T cell unresponsiveness (tolerance) that may explain tumour growth in cancer patients. In the above GvL/GvH/ADI model we were able to demonstrate that immunological tolerance to a tumour-associated viral superantigen (SAG) is overcome by transfer of allogeneic T cells expressing SAG-reactive Vβ6 T cell receptor chains (Schirrmacher *et al.*, 2000b). DBA/2 mice and the derived tumour ESb-MP express vSAG-7 (Mls^a), an endogenous viral superantigen which is absent in B10.D2 mice. In DBA/2 mice, virtually no Vβ6 SAG-reactive cells can be detected owing to central tolerance established by negative selection in the thymus. In contrast, in B10.D2 mice, about 10% of peripheral CD4 and CD8 T cells express Vβ6 T cell receptor chains. Upon contact with SAG-expressing lymphoma cells, these Vβ6 T cells became activated rather than tolerated (as reported previously) and developed SAG-specific cytotoxic T lymphocyte activity and secreted IL-2 and interferon-γ. The grafted T cells infiltrated liver metastases, formed close contact and clusters (Muerköster *et al.*, 1998) with SAG-expressing tumour cells and caused significant GvL effects. Selection for tumour resistance among the progeny from a cross between SAG-negative donor and SAG-positive recipient strains revealed a strict correlation between loss of the endogenous SAG tolerogen, rescue of Vβ6 T cells from SAG-mediated deletion and leukaemia resistance. These findings suggest that immune responses to superantigens can be exploited to break tolerance and augment immune responses to tumours (Schirrmacher *et al.*, 2000b).

BIOLOGICAL LIMITATIONS

Specific cancer immunotherapy approaches also have their limits. Tumour genomic instability, heterogeneity and plasticity allow the selection of immune escape variants. Major restrictions to the effectivity of specific immunotherapy relate to complex phenomena such as (1) tumour epitope loss, (2) immunosuppressive tumour products and (3) defective tumour capillaries. It is beyond the scope of this chapter to go into more detail on tumour immune escape mechanisms and readers are therefore referred to literature reviews (Eibl *et al.*, 1997, 1998; Coggin *et al.*, 1998; Ellem *et al.*, 1998; Glinsky, 1998). The capillary endothelium of the intratumour neovasculature is frequently defective, particularly in presenting the homing signals that facilitate the massive diapedesis of tumour-reactive T cells into tumour tissue (Ellem *et al.*, 1998).

TECHNICAL CONSIDERATIONS

Dissection of Tumour Microenvironment of Liver Metastases for Studies on Tumour–Host Interactions

The interaction between tumour and host cells determines to a large extent the outcome, namely tumour growth and progression towards metastases or tumour arrest, dormancy or rejection. Most of the studies published so far on interactions of tumour cells and host cells were made *in vitro* and dealt with aspects such as cell adhesion, proliferation, invasiveness, cytotoxicity or cytokine production. Cells which are taken out from their respective tissues may suffer from mechanical stress during cell isolation. When subjected to tissue culture they are in an entirely different situation from *in vivo*. Often they lack cell–cell contact or contact with surrounding extracellular matrix. Since the microenvironment in tissue culture differs in many respects from that *in vivo*, new approaches for *in vivo* studies or tumour–host cell interactions are of utmost importance in cancer research. To elucidate the metastatic phenotype, approaches have been made to relate, for instance, cell surface molecules expressed on the tumour cell lines from tissue culture to their propensity to generate metastases *in vivo*. Several authors have reported that certain steps of the metastatic cascade are rate limiting (Fidler and Radinsky, 1990; Kerbel, 1990; Nicolson, 1993). To produce metastases, tumour cells must complete each of the sequential steps in the pathogenesis of cancer metastasis. Each discrete step appears to depend on the interaction between tumour cells and multiple host factors (i.e. the microenvironment of the tumour) and to be regulated by transient or permanent changes in DNA, RNA or proteins of multiple genes. With this background, the need for comprehensive *in vivo*/*ex vivo* studies on tumour–host interactions and their kinetics in relevant model systems becomes obvious. (See also chapter on *Modelling Tumour Tissue Interactions*.)

We have established a new method allowing the *ex vivo* isolation of tumour and host cells (tumour microenvironment) at any time point during the metastatic process and without any further *in vitro* culture. We chose as a model the ESbL lymphoma, transduced with the *lacZ* gene

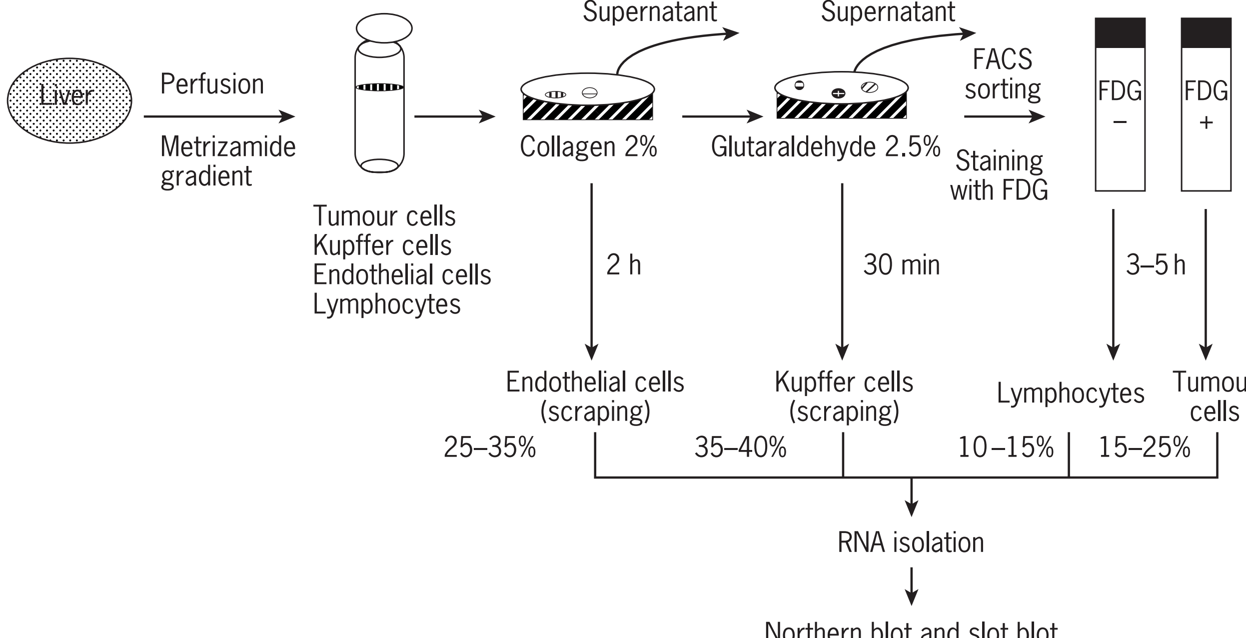

Figure 3 Method of *ex vivo* separation of cells from a liver metastasis for preparation of total RNA. Sinusoidal cells and tumour cells from livers were fractionated into subpopulations by differential adhesion (endothelial and Kupffer cells) and by FACS (lymphocytes and tumour cells). Numbers indicate the range in percentage of cells obtained in each purification step relative to the total number of live recovered cells.

(**Figure 3**). In this ESbL-*lacZ* tumour model, intradermal tumour growth and liver metastasis development followed three distinct phases: a first exponential growth phase, a transient plateau phase and a second expansion phase (Krüger *et al*., 1994a, b). The plateau phase was characterized by a constant tumour diameter, correlating with a constant small amount of metastasis in the liver. This phase was followed by an aggressive second expansion phase leading to macroscopic metastases in multiple visceral organs and to death of the animals within a few days (Krüger *et al*., 1994b). These different phases of the metastatic process provide a good model for the investigation of the influence of tumour–host interactions during metastasis and of means for its modulation. The plateau phase allows one to study mechanisms of immunoresistance and tumour control. The second tumour expansion phase allows the study of mechanisms of breakdown of immunoresistance and perhaps molecules of importance in metastatic progression.

Isolation of Tumour and Sinusoidal Cells from Liver Metastases

Livers from anaesthetized tumour-bearing mice were washed *in situ* by perfusion through the portal vein and tissue digestion was carried out during perfusion with pronase and collagenase. Tumour and sinusoidal cells were separated by a metrizamide gradient as described (Rocha *et al*., 1996b).

Isolation of Liver Endothelial Cells

Liver endothelial cells were isolated by co-culturing liver sinusoidal and tumour cells on collagen-coated plastic Petri dishes. The purity of endothelial cell populations was evaluated as described (Rocha *et al*., 1995).

Isolation of Kupffer Cells from Livers

Kupffer cells were isolated after differential adhesion on 2.5% glutaraldehyde Petri dishes (Umansky *et al*., 1995b). The purity of Kupffer cell population was evaluated as described (Umansky *et al*., 1995b).

Isolation of Lymphocytes and Tumour Cells from Liver Metastases

Separation of tumour cells from lymphoid cells was performed as described (Krüger *et al*., 1994b). A window for sorting was defined in the FDG-positive cells (tumour cells) excluding dead cells and debris with propidium iodide. The flow rate was 3000–5000 cells s^{-1} and sorted cells were collected in sterile tubes containing RPMI with 20% FCS.

Flow Cytometry Analysis of Tumour and Host Cells

Antibody Staining of Tumour and Sinusoidal Cells

As a standard protocol, 1×10^6 cells were incubated at 4 °C for 10 min with the first antibodies following a described protocol (Rocha *et al*., 1996a). To test the purity of the separated populations, the following rat anti-mouse monoclonal antibodies were used as culture supernatants: anti-CD4 (clone GK 1.5); E-selectin (clone 21KC10), specific for endothelial cells; anti-macrophage antibody (F4/80). After washing, the cells were incubated with the second antibody ($F(ab')_2$ goat anti-rat, mouse Ig absorbed, (R)-phycoerythrin conjugated) and analysed.

FDG Staining and FACS Analysis of Tumour and Host Cells

After antibody staining, liver metastases were quantified at the single cell level by loading and staining with FDG as described (Rocha *et al*., 1996a). Samples were simulaneously measured for FSC and integrated side scatter (SSC) as well as green (FL1) and red (FL2 and FL3) fluorescence (expressed as logarithm of the integrated fluorescence light). Recordings were made only on propidium iodide-negative (viable) cells of the red (FL3) fluorescence, excluding aggregates whose FSCs were out of range. *Ex vivo* expression of cell surface molecules was analysed by histograms of red fluorescence (FL2) distribution plotted as number of cells (y-axis) against fluorescence intensity (x-axis) for the different tumour and sinusoidal cell populations (Rocha *et al*., 1996a).

Gene Expression Studies: RNA Extraction, Hybridization and Densitometric Quantitation

RNA extraction was performed by the chloroform–phenol technique. Extracted RNA was precipitated with propan-2-ol and the pellet washed in ethanol, dried under vacuum and resuspended in 0.1% diethyl pyrocarbonate solution. The quantity of RNA was determined by measuring the absorbance at 260 nm. Total isolated RNA was denatured and spotted on to a nitrocellulose filter using a dot blot apparatus and fixed by UV cross-linking under vacuum. The following cDNA probes were used for hybridization: MHC class II, α and β chain, ICAM-1 and integrin $\alpha4$ chain. cDNA inserts were labelled with ^{32}P to a specific activity of about 2×10^8 cpm mg^{-1} DNA with an oligo-labelling kit. After hybridization, the filters were washed three times for 30 min with sodium chloride (3 mol L^{-1})–trisodium citrate (0.3 mol L^{-1}) solution and sodium dodecyl sulfate at 68 °C. Membranes were exposed to O-MAT films at −70 °C. Expression of the mRNA was quantified by densitometry of autoradiograms using the Adobe Photoshop program and the SCAN analysis program from Macintosh with each sample measurement calculated from the ratio of the average areas between the specific mRNA transcripts and the β-actin mRNA transcripts (Rocha *et al*., 1996b). An application of this technology revealed *in situ* downregulation of VLA-4 integrin cell surface expression during lymphoma growth and liver metastases (Rocha *et al*., 1997b).

PERSPECTIVES

We have tried in this review to demonstrate how the use of model systems can lead to the development of new strategies for the immunotherapy of metastases. We have primarily focused on our own research relating (1) to the virus-modified autologous live cell vaccine ATV-NDV developed for ASI-treatment and (2) to cell-based ADI studies in a GvL/GvH animal model system. Both ASI- and ADI-type immunotherapies are being evaluated in clinical trials. Positive results have been reported recently from a randomized controlled ASI study (Vermorken *et al*., 1999) and also from ADI studies in particular when using allogeneic donor lymphocyte infusions (DLI) to obtain graft versus leukaemia (GvL) effects (Slavin *et al*., 1996; Collins *et al*., 1997). ADI with autologous lymphokine-activated killer (LAK) cells or with tumour-infiltrating lymphocytes (TIL) was reported to have an overall response rate of about 25% in metastatic melanoma (Rosenberg *et al*., 1993) and renal cell carcinoma patients (Osband *et al*., 1990). Gene-modified cell therapies (Gage, 1998) are also being developed for gene therapy of cancer.

Apart from ASI and ADI immunotherapies, a variety of other interesting new strategies have been developed which could not be discussed because of space limitations. With regard to antibody-based therapies, including apoptosis-inducing monoclonal antibodies (mAbs), recombinant antibody-fusion proteins, bispecific antibodies and antibodies engineered for tumour targeting and pro-drug activation, we refer to our review from 1996 (see Further Reading). Some mAbs have already been proved clinically effective for adjuvant immunotherapy (Riethmüller *et al*., 1994).

New techniques are being developed for the identification and cloning of genes for T cell targets and the identification of T cell epitopes (Bona *et al*., 1998) and mimotopes (Chen, 1999) by sequencing peptides eluted from HLA molecules of tumour cells or from peptide libraries (Chen, 1991). Based on such specific information about genes and peptides of TAAs, new gene and/or peptide vaccination strategies are likely to be developed. When combined with our increasing ability to manipulate the immune system via cytokines, costimulatory molecules, delivery systems and new adjuvants, these advances

provide hope for effective immunotherapy and vaccination against cancer.

Two other developments open further exciting perspectives for the future: DCs (Steinmann, 1991) and heat-shock proteins (HSPs) (Srivastava, 1997). Since DCs are a unique leukocyte population which control the primary immune response, it is to be expected that many new technologies will be developed for dendritic cell-based vaccines to be used for immunotherapy of cancer. This can involve the loading with peptides or tumour lysates (Nestlé *et al*., 1998), transfection with tumour-associated DNA or RNA (Boczkowski *et al*., 1996) or fusion of DCs with carcinoma cells (Gong *et al*., 1997). HSPs of different molecular mass have been demonstrated to carry representative peptides of tumour cells and are highly efficient for the induction of protective immunity based on oligoclonal T cell priming. It can be expected that standard protocols will allow the preparation of HSPs from individual cancer patients for autologous vaccination purposes (Srivastava, 1997).

Another future perspective relates to the new technologies of MHC-peptide tetramers for the direct visualization of TAA-specific T cells (Crawford *et al*., 1998; Romero *et al*., 1998) and of quantitative ELISPOT assays for cytokine-producing T cells. Both assays provide new diagnostic tools to evaluate the immune status of cancer patients and their response to therapy.

All these new approaches for immunotherapy can be expected to have an effect on microdisseminated carcinoma cells. As the disease progresses towards macrometastatic disease, the risk increases that the tumour may develop immune escape variants and immunosuppression which could be formidable barriers to effective cancer immunotherapy. Perhaps combined T cell and antibody-based immunotherapy approaches may outsmart even such tumour cell variants (Abken *et al*., 1998). Anyway, it is extremely important that clinical experiments are well thought out, are started early enough and are carefully designed. Immune monitoring should include measurements of the immune response and characterization of HLA expression on tumours. Only in this way will immunotherapy of metastases eventually receive the attention that it undoubtedly deserves.

SUICIDE GENE THERAPY

Suicide genes are negative selectable markers encoding for enzymes that convert prodrugs into compounds that are toxic to the genetically modified cell. This approach, designed to alter the drug-sensitivity profile of tumours, is a two-step process: in the first step the gene for the foreign enzyme is delivered and targeted within a viral vector or using a naked DNA fragment to the tumour where it is to be expressed. Thereafter the prodrug is administered, which is converted to the active cytotoxic compound by the foreign enzyme expressed by the tumour cells. An inherent limitation of most viral-based cancer gene-therapy protocols is the inability to transduce the entire population of a tumour mass; this may be overcome (at least partly) by the ability of gene-modified cancer cells to mediate the killing of adjacent untransduced cells (the so-called bystander effect, discussed below). (See also chapter on *Genetic Prodrug Activation Therapy*.)

The best characterized 'suicide gene' is the herpes simplex virus thymidine kinase (HSV-*tk*) gene, which mediates phosphorylation of the prodrug ganciclovir 1000 times more efficiently than its mammalian counterpart. The phosphorylated forms of ganciclovir bring about DNA chain termination and cause single-strand breaks, leading to cell death. Similarly, the *Escherichia coli* gene cytosine deaminase (CD), when expressed in mammalian cells, can convert the nontoxic compound 5-fluorocytosine (5FC) to the cytotoxic compound 5-fluorouracil (5FU).

Both the *CD* and HSV-*tk* genes have been validated in multiple *in vitro* systems, wherein tumour cell lines tested demonstrate dose-dependent inhibition of proliferation upon exposure to the prodrugs 5FC and ganciclovir, respectively. In their *in vivo* model, Bentires-Alj *et al*. (2000) used either parental or *CD* transfected DHD/K12 colorectal cancer cells to establish peritoneal carcinomatosis in BDIX rats. Following 3 weeks of intraperitoneal 5FC injections, rats treated with the *CD* transfected cell line demonstrated total regression of their peritoneal tumours, as opposed to rats treated with parental DHD/K12 cells, who showed extensive disseminated peritoneal carcinomatosis. Six of eight rats treated with the DHD/K12-CD cells were alive at 360 days, as opposed to all control rats, which died between days 45 and 71.

The 'bystander effect' is a phenomenon defined by the ability of gene-transduced tumour cells to mediate cytotoxicity to adjacent untransduced tumour cells. Although there is no single explanation for this phenomenon, a number of alternative hypotheses have been generated. These include direct drug transfer, immune-mediated responses and intercellular induction of apoptotic signals. First is the proposal for cell–cell transfer of ganciclovir metabolites through intercellular gap junctions made up of proteins called 'connexins;' other mechanisms include phagocytosis of 'apoptotic vesicles' containing phosphorylated ganciclovir metabolites by untransduced tumour cells, or the disruption of tumour vasculature leading to a haemorrhagic tumour necrosis mediated by the release of cytokines such as TNF-α from transduced cells.

Mesnil *et al*. (1996) established the importance of intercellular gap junctions (connexins) with their studies conducted on HeLa cancer cells, which express very low basal levels of connexins. Upon transfection of the HSV-*tk* gene, the HeLa cells became highly sensitive to the cytotoxic effect of ganciclovir; however, they failed to mediate killing of untransfected HeLa cells in 'mixing'

co-culture studies, i.e. no *in vitro* bystander effect was observed. When HeLa cells were transfected with the gene encoding for the gap junction protein connexin 43, significant killing of HSV-tk^{-} cells occurred with the presence of only 10% HSV-tk^{+} cells in the co-culture, suggesting a powerful *in vitro* bystander effect.

An immune response may also occur. In an *in vivo* model of CNS glioma in Lewis rats, Dewey *et al*. (1999) were able to inhibit effectively the growth of established syngeneic gliomas using intratumoural injections of an adenoviral vector expressing the HSV-*tk* gene followed by systemic ganciclovir treatment, with 100% survival at 3 months and no evidence of residual glioma assessed by weekly magnetic resonance imaging. However, when survivors were killed at 100 days, evidence of diffuse perivascular inflammatory infiltrates and secondary demyelination was observed, along with persistent transgene (HSV-*tk*) expression in both cerebral hemispheres. (See also chapter on *Modelling Tumour–Tissue Interactions*.)

To improve the efficacy of the suicide gene therapy system, Black *et al*. (1996) used random sequence mutagenesis to create HSV-*tk* mutants, which significantly increased the sensitivity of transduced cells to acyclovir and ganciclovir. One of these mutants, the HSV-*tk* 30 (Qiao *et al*., 2000), has been tested in various human cancer cell lines, and renders these cells 9–500-fold more sensitive to ganciclovir than the wild-type (wt) HSV-*tk*, and appears to be a promising candidate for evaluation in gene therapy trials.

TUMOUR-SUPPRESSOR GENE THERAPY

Most of the known mutations in cancer lead to either gain of function of transforming oncogenes or loss of function of tumour-suppressor genes. Despite the presence of multiple genetic mutations in cancer cells, correction of a single critical lesion is often sufficient to abrogate the malignant phenotype. The *p53* tumour-suppressor gene is an attractive target for gene therapy replacement strategies, because of the central role it plays in determining the cellular response to genomic stress and DNA damaging agents. Depending upon the degree of DNA damage, p53 can either mediate p21-induced cell cycle arrest at the $G_1 \rightarrow S$ interphase, or induce apoptosis through its influence on genes such as *bax* and *fas*. p53 also may play an anti-angiogenic role through its regulatory effects on VEG-F and thrombospondin.

Multiple models (both *in vitro* and *in vivo*) validate the rationale for p53 gene therapy in a broad spectrum of tumour types, either alone or in combination with radiation or chemotherapeutic agents. Most investigators currently favour replication-defective (E1 deleted) adenoviruses because they do not integrate into the host chromosome, can infect a wide range of tissue types and can be generated in high titres. Although most strategies have focused on cell lines or established *in vivo* tumours with a mutant p53 status, some groups have demonstrated efficacy even in the presence of tumours with a wt p53 status, when used in conjunction with radiation therapy.

Kock *et al*. (1996) used adenoviral-mediated *p53* gene transfer (Ad *p53*) into p53 mutant glioma cell lines and demonstrated dose-dependent inhibition of proliferation (by [^{3}H]thymidine incorporation assays), accompanied by significant DNA fragmentation (apoptosis) and induction of p21. Similarly, p53 mutant glioma xenografts were established in the flanks of nude mice, and a significant reduction in tumour volume, retardation of tumour progression and improved survival were seen in mice treated intratumourally with Ad *p53* compared with a control vector. Similar results were observed using stereotactic injections of Ad *p53* in an intracerebral orthotopic rat glioma model. Ad *p53* did not, however, exert the same inhibitory effect on U87 glioma xenografts (characterized by a wt *p53* status). However, when used in combination with radiation, there was significant reduction in tumour volume and improved survival compared with mice treated with Ad *p53* or radiation alone; this radiosensitizing effect was associated with increased apoptotic cell death determined by the TUNEL assay (Lang *et al*., 1998).

Nielsen *et al*. (1998) demonstrated significant synergy between Ad *p53* gene therapy and paclitaxel (which stabilizes microtubules and mediates a $G_2 \rightarrow M$ arrest) in xenograft models of ovarian cancer ($p53^{null}$SK-OV-3), prostate cancer ($p53^{mut}$DU-145) and breast cancer ($p53^{mut}$MDA-MB-231). In all these models, a significant reduction in tumour burden (60–90%) was seen in animals treated with the combined modality as opposed to Ad *p53* or paclitaxel alone.

The combination of Ad *p53* gene therapy with immunotherapy based on Ad IL-2 has revealed impressive results in the murine mammary adenocarcinoma (PyMT) model with regression of 65% of established tumours (Putzer *et al*., 1998). Upon rechallenge with tumour cells, 50% of mice demonstrated long-term tumour-free survival, suggesting the development of antitumour immunity. Injection of mice with either vector alone resulted only in a delay in tumour growth, and no evidence of an antitumour cytolytic T lymphocyte response, as was evident in mice treated with both vectors. (See also chapter on *Models for Immunotherapy and Cancer Vaccines*.)

An inherent limitation of current gene transfer methods is the lack of regulation of gene expression following transfer. Some groups have recently described the use of trans-splicing ribozymes simultaneously to repair mutant *p53* transcripts and restore translation of wt p53 protein in the Saos-2 osteosarcoma and the SW480 colon carcinoma models (Watanabe and Sullenger, 2000). (See also chapter on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Cells*.)

Based on the above-reviewed data, and a plethora of other preclinical data, *p53* gene therapy is currently being investigated in the setting of a number of phase I and phase

II trials in non-small cell lung and squamous cell head and neck cancers. Although most of these trials are focused on safety and dissemination issues, and the efficacy of gene transfer into tumour tissue, some are noteworthy for responses in a subset of treated patients. Ultimately, this therapy will succeed if there are data to suggest a better response rate, potentiation of other agents and selectivity of efficacy in cancer cells. (See also chapter on *Regulation of the Cell Cycle*.)

ONCOLYTIC VIRUSES

Enhanced understanding of the biological processes involved in viral life cycles and virus–host cell interactions has led to novel strategies for gene therapy. Significant achievements have been attained in the development of both nonviral agents and replication-incompetent viral vectors for gene replacement, drug-resistance gene delivery and prodrug-activating enzymes. However, limitations in gene expression levels, viral titre and target cell specificity have limited the efficacy of these agents in the setting of cancer gene therapy. Novel attempts to overcome limitations in cancer gene therapy involve the use of natural or recombinant viruses that selectively replicate in human tumour cells. The ability of these viruses to replicate in cancer cells leads to increased gene expression via transcription from nascent viral genomes and subsequent infection of neighbouring cells. Although virus replication can directly lyse cells as a result of the viral load exceeding the cellular capacity, induction of inflammatory cytokines, interferon response pathways, CTL activation and accumulation of cytotoxic proteins can enhance their oncolytic activity. Currently, the most promising oncolytic viral agents include reovirus (Type 3 Dearing), and recombinant versions of vaccinia viruses, adenoviruses and herpes simplex viruses (HSV-1). These viruses are able to replicate selectively in cancer cells as a result of constitutively active signalling cascades, inactivated tumour-suppressor gene functions, or elevated pools of polymerase substrates in highly proliferative cells.

Strategies employing the use of adenoviruses as tumour-selective oncolytic agents have targeted mutations in the early region 1A or early region 1B genes (E1A and E1B) located in the E1 segment of the adenovirus genome. E1A proteins interact with pRB, releasing the E2F transcription factors needed for expression of genes involved in entry into S phase and transactivation of the viral E2 promoter. E1A proteins have also been shown to associate with p300/CBP to promote E2F-mediated transcription. The E1B gene products E1B55K and E1B19K act to suppress apoptotic pathways in the infected cell. E1B55K inhibits p53-mediated cell cycle arrest or apoptosis, and serves as a transporter of viral mRNAs from the nucleus to the cytoplasm, while the 19-kDa E1B gene product mimics the antiapoptotic activity of Bcl-2. Since almost half of all human cancers are defective in p53 tumour-suppressor function, Bischoff *et al*. (1996) used an adenovirus with an E1B55K gene deletion (*dl1520*), subsequently designated ONYX-015, to target these malignancies. A screen of several human cell lines demonstrated that the mutant virus elicited its cytotoxic effects only to those cells lacking functional p53. In addition, the ONYX-015 virus caused significant size reduction and complete regression in a majority of human cervical carcinoma ($p53^{-/-}$) xenografts in nude mice, while having no effect on the tumour volume of human glioblastoma multiforme ($p53^{+/+}$) xenografts. The specificity of the ONYX-015 virus for p53 null cells has been questioned, but the efficacy of this virus as an oncolytic agent has now been demonstrated clinically. In addition, treatment of squamous cell carcinomas of the head and neck with combined intratumoural ONYX-015 injection, cisplatin and 5FU have improved response rates in phase II clinical trials (Khuri *et al*., 2000). Additional adenovirus mutants have recently been constructed that lack E1B55K and deliver prodrug-converting enzymes, or target pRB-deficient tumour cells.

HSV-1 is a double-stranded DNA virus and, typical of all herpes viruses, has the capacity for both lytic and latent life cycles. HSV-1 latency is established in neurons, but these viruses can be reactivated to cause encephalitis and lesions at the primary site of infection. The first replication-competent HSV-1 mutant (*dlsptk*) consisted of a 360-bp deletion within the thymidine kinase (*tk*) gene (UL23) (Martuza *et al*., 1991). The *tk* deletion makes virus replication dependent on elevated thymidine triphosphate pools, which are found in highly proliferative cells. The dlspk HSV-1 mutant was shown to inhibit tumour growth and prolong survival in nude mice containing subcutaneous and subrenal xenografts of U87 human gliomas, but HSV-1 *tk* mutants are not devoid of the capacity for neurovirulence and removal of *tk* eliminates the ability to treat with antiviral agents, such as ganciclovir. Other HSV-1 viruses have been safety-modified by deleting both copies of the *γ34.5* gene (*RL1*) that is responsible for neurovirulence (Chou *et al*., 1990). Mineta *et al*. (1994) created an HSV mutant containing a *lacZ* insertion in place of the ribonucleotide reductase gene (*UL39*), making virus replication depend on cellular proliferation, allowing reporter gene assessment, and *tk* to be maintained for sensitivity to antiviral agents. The same group subsequently generated an HSV-1 mutant (G207) that included both *RL1* deletions and the *LacZ* insertion into UL39 to combine the advantages of the single mutants. The G207 virus was also shown to reduce U87 human glioma xenograft growth and prolong survival of mice bearing these tumours. Toxicity studies in HSV-sensitive owl monkeys have further demonstrated the lack of neurovirulence of the G207 virus (Hunter *et al*., 1999). Recently, the G207 virus and an HSV-1 virus (1716) lacking both copies of *RL1* have been evaluated for dose-escalation

safety trials in patients with incurable malignant brain tumours.

Reovirus is being investigated as an oncolytic agent as a result of its selective replication in cells with activated Ras signalling pathways. This selectivity is due to the fact that activated Ras signalling leads to dephosphorylation and inactivation of the double-stranded RNA-activated protein kinase (PKR) (Strong *et al*., 1998). PKR serves as an intracellular antiviral agent by its ability to detect double-stranded RNA, unique to specific viral genomes and transcripts. Activated PKR phosphorylates eIF-2 alpha, a component of the cell translation machinery, preventing its ability to initiate translation on viral transcripts. Ras-activated signalling leads to inactivation of PKR, allowing primary viral products to accumulate and carry out the lytic life cycle of the virus, but the mechanism by which Ras inactivates PKR is unknown. To date, reovirus has been found to be capable of infecting a wide range of human tumour cell lines (Norman and Lee, 2000) and induce regression of both SCID tumour xenografts, and tumours in immunocompetent mice (Coffey *et al*., 1998). The large proportion of human tumours having constitutively active signalling cascades upstream of Ras, or activating mutations in Ras itself, exemplifies the potential of reovirus as an oncolytic agent. Furthermore, the wide distribution of the virus receptor (sialic acid) over a variety of cell types and the nonpathogenic nature of reovirus infections makes it a promising therapeutic candidate.

Vaccinia virus belongs to the Poxviridae family of complex DNA viruses that encode all replication factors necessary for their cytoplasmic life cycle. The ability of the virus to tolerate large insertions of foreign DNA ($\leq$25 kb) and infect a wide variety of cell types has led to the development of vaccinia expression vectors. As with HSV-1 *tk* mutants, vaccinia virus *tk* mutants require elevated thymidine triphosphate pools for replication and are less pathogenic than the wild-type virus. Puhlmann *et al*. (2000) demonstrated the enhanced ability of *tk*-deleted vaccinia viruses to selectively replicate in tumour cells and inserted a luciferase reporter that allowed them to detect significant expression levels in tumour cells compared to normal tissue. Recently, prodrug-activating enzymes, including purine nucleoside phosphorylase and cytosine deaminase, have been engineered into the *tk*-deleted viruses to improve tumour cell-specific killing and to provide a mechanism to inhibit viral replication in pathogenic situations. Both of these recombinant viruses demonstrated significant oncolytic activity and enhanced tumour regression following addition of prodrug but the efficiency of tumour cell-killing mediated by the *tk*-deleted virus replication required significant decreases in the amount of virus used in order to see the effect of prodrug conversion. Although these vaccinia agents have been used to demonstrate impressive oncolytic activity, the extent of viral pathogenicity will need to be reduced before considering these viruses for clinical use.

Table 1 Cancer-directed gene therapy strategies

Suicide gene delivery
HSV-tk: Converts prodrugs, such as acyclovir and ganciclovir, into nucleoside analogues that inhibit DNA replication
Cytosine deaminase: Converts 5-fluorocytosine into the cytotoxic compound 5-fluorouracil

Tumour-suppressor gene delivery
p53: Mediates cell cycle arrest and/or apoptosis in p53-deficient tumour cells
pRB: Binds E2F family of $G_1 \rightarrow S$ entry transcription factors
p21: Prevents cyclin D/cyclin-dependent-kinase mediated phosphorylation (inactivation) of pRB

Oncolytic viruses
Adenovirus: E1B55K-deletion mutants selectively replicate/kill p53-deficient malignancies
HSV-1: Thymidine kinase (UL23) and ribonucleotide reductase (UL39) gene deletion mutants require elevated nucleotide pools, found in highly proliferative cells, for viral replication. Deletion of γ34.5 (RL1) genes prevents neurovirulence
Reovirus: Malignancies with constitutively active Ras signalling pathways have inactive double-stranded RNA-activated protein kinase (PKR), allowing eIF-2 alpha to initiate translation of viral proteins
Vaccinia virus: Thymidine kinase gene deletion mutants require elevated nucleotide pools for viral replication (see HSV-1)

Viruses with tumour-selective replication hold great promise as oncolytic agents; however, further understanding of host–virus interactions and the aberrant pathways associated with specific malignancies will be essential for improving upon the specificity and efficacy of these agents. Future improvements will undoubtedly include the use of viruses that target tumour-specific receptors and/or contain tumour-specific promoters. (See also chapters on *Human DNA Tumour Viruses* and *RNA Viruses*.)

To summarize the above sections, cancer-directed gene therapy strategies are outlined in **Table 1**.

ANTIANGIOGENIC GENE THERAPY

Survival and growth of a tumour in living organisms are dependent on two factors, its ability to escape immune surveillance and its capacity to maintain a continuous supply of oxygen and nutrients. Angiogenesis, the process in which new blood vessels grow from existing vessels, must occur within solid tumours in order for tumour cells to acquire the oxygen and nutrients that they need for proliferation. Tumour growth may be limited to 1–2 mm^2 by the diffusion of nutrients without recruitment of new blood vessels. In addition, neovascularization of a solid tumour appears to be required before formation of metastasis can occur. Angiogenesis is a multistep process which

includes recruitment and activation of nearby endothelial cells, degradation of the vascular basement membrane, proliferation and migration toward the angiogenic stimulus and formation of new capillaries by linkage to the preexisting capillary network. Either tumour cells or accessory cells within the tumour stroma can trigger angiogenesis by the secretion of angiogenic factors such as basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF). These factors, along with platelet-derived growth factor (PDGF), transforming growth factor beta (TGF-β) and angiopoietins, are also involved in maturation and stabilization of newly formed vessels. The angiogenic switch during tumorigenesis appears to be caused by the disruption of a complex balance between angiogenesis stimulators and inhibitors, both of which fluctuate over the course of tumour development. (See also chapters on *Angiogenesis* and *Angiogenesis Models*.)

Delivery of antiangiogenic agents to tumours by means of gene therapy has become an attractive new approach since it has been difficult to mass produce stable recombinant forms of endogenous angiogenesis inhibitors; for a detailed review, see Feldman and Libutti (2000). Antiangiogenic gene therapy of cancer is currently designed either to target the tumour directly, by increasing local concentrations of antiangiogenic agents within the tumour, or by a systemic delivery approach whereby the patient's normal tissues would function as a 'factory' to increase circulating levels of a particular agent. While the tumour-directed gene therapy approach avoids systemic toxicity of the antiangiogenic gene product, its effectiveness may be limited by blood supply within the tumour for efficient distribution of the vector. Furthermore, systemic gene delivery seems to be an attractive method for delivery of antiangiogenic agents owing to their apparent lack of toxicity.

Antiangiogenesis gene therapy strategies to date include the use of endogenous angiogenesis inhibitors, or those that target the production or action of endogenous proangiogenic agents. VEGF is a known tumour-derived cytokine that promotes angiogenesis. Hence much attention has been focused on inhibiting transcription or translation of VEGF and its receptors through the use of neutralizing antibodies. Vitaliti *et al*. (2000) demonstrated that single-chain antibody fragments directed against VEGF effectively blocked angiogenesis in the chorioallantoic membrane of chick embryos. In addition, these antibody fragments were effective in reducing the growth of subcutaneous tumours in nude mice.

The majority of antiangiogenic therapies have focused on rapidly growing, highly vascularized tumours or tumour cell lines. Interestingly, angiostatin, a fragment of the plasminogen protein, has been shown to inhibit significantly the growth of tumours in mice which were derived from both slow and rapidly growing human bladder carcinoma cell lines (Beecken *et al*., 2001). Thus, the responses of slowly growing, poorly vascularized and rapidly growing, highly vascularized tumours to this angiogenesis inhibitor appear to be similar.

Endostatin, a protein fragment derived from the C-terminal noncollagenous domain of the basement membrane constituent Type XVIII collagen, has been shown to inhibit tumour growth *in vivo*. The potential of the systemic gene therapy approach was evaluated in murine VEGF implant angiogenesis and orthotopically implanted human colon/liver metastasis xenograft models after adenovirus-mediated gene delivery of endostatin (Chen *et al.,* 2000). In the VEGF implant model, mice were treated with the adenoviral construct by tail-vein injection, and 13 days later Teflon chambers containing $VEGF_{165}$ were implanted subcutaneously. Angiogenesis was then measured by analysis of vascularized tissue that formed around the implants. Mice in the human colon/liver xenograft model were also pretreated with the adenovirus, and colon tumour fragments were orthotopically transplanted 13 days after treatment. Circulating endostatin levels increased and lasted longer in both models in response to treatment. Furthermore, partial inhibition of VEGF-induced angiogenesis was shown in the VEGF implant angiogenesis model, and complete inhibition of tumour growth was achieved in 25% of mice in the human colon/liver metastasis xenograft murine model.

In order to augment the inhibitory effects of antiangiogenic agents on tumour growth, a new combination therapy approach has emerged using simultaneous treatment with two different agents. In a murine leukaemia model, Scappaticci *et al*. (2001) demonstrated complete loss of tumorigenicity in 40% of animals that received tumours retrovirally transduced with a combination of both angiostatin and endostatin.

Antitumour effects have also been observed using specific interferons, endogenous glycoproteins that participate in triggering cellular antiviral mechanisms. Retroviral delivery of murine class I interferons (IFNs) -α and -β to endothelial-like cells *in vitro* significantly inhibited migration and invasion in chemotaxis and chemoinvasion Matrigel assays, respectively (Albini *et al*., 2000). In addition, a Matrigel morphogenesis assay showed that cells transduced with IFN-β were completely inhibited from growth and formation of capillary-like structures. However, IFN-α was unable to inhibit the endothelial cells from growing and forming capillary-like structures, suggesting that whereas IFN-β seems to exert an effect on endothelial cell differentiation, IFN-α does not. These IFNs were also tested in both immune-competent and athymic nude mice using the Matrigel sponge model. In this model, cells expressing IFN-β strongly inhibited angiogenesis whereas partial inhibition was observed with cells expressing IFN-α.

Antiangiogenic gene therapy has emerged as an alternative strategy to deliver antiangiogenic agents to cancer patients. The optimal method of gene delivery is still undetermined, as the immunogenicity and toxicity of many

viral vectors used for *in vivo* studies remains a concern regarding their clinical use. Use of viruses as gene therapy agents appears to be efficient in terms of cell entry and gene expression, whereas nonviral gene delivery using transporters such as liposomes offers lower risk of toxicity and immunogenicity, but may only offer suboptimal transgene expression. Molecular mechanisms of angiogenesis seem to vary among different tumour types, thus the efficacy of specific antiangiogenic agents is expected to vary in accordance with the tumour type. Systemic gene therapy may prove to be a method that can be used to alleviate the need for chronic drug treatment, which may be necessary with the tumour-directed approach. Further progress will require a more complete understanding of the mechanisms involved in the angiogenesis process and also improvements in gene vector technology.

CYTOKINE GENE THERAPY

Cytokine gene therapy of cancer is rooted in host immune defences, especially host T cell-mediated immunity involving cytotoxic T lymphocytes (CTLs) and T-helper cells (Th1s) (Lattime and Stanton, 1999). Tumours can be, and often are, recognized by T cells as abnormal. However, this recognition rarely leads to a fully activated immune response because the Th1 cells most often fail to secrete the cytokines necessary for sustaining proliferation and activation of the CTL cells. When a fully activated CTL response is initiated, the results can be dramatic and often correspond to cases of spontaneous remission or extended latency time to development of metastases after primary tumour removal. Efforts to enhance the CTL response by systemic administration of cytokines have been unsuccessful largely owing to serious side effects, rapid degradation and/or rapid elimination of the cytokine from the circulation, and in older patients with an immune system that is generally less responsive to cytokine stimulation (Hsueh *et al*., 1996). Cytokine gene therapy for cancer seeks to circumvent the systemic dosing problems by delivering the appropriate cytokine stimulation directly to the tumour site and thus support, elicit and enhance a full host CTL immune response in a more natural paracrine milieu. (See also chapters on *Models for Immunotherapy and Cancer Vaccines*; *Signalling by Cytokines*.)

Several gene therapy approaches are being pursued in order to deliver the appropriate cytokine to the tumour site and/or the most immunologically relevant site for induction and enhancement of antitumour immunity (Fernandez *et al*., 1998). Studies have shown that, under various circumstances, the list of relevant cytokines that promote an antitumour immune response include TNF-α, G-CSF, GM-CSF, IFN-γ, IL-1, IL-2, IL-4, IL-6, IL-7, IL-12 and IL-18 while TGF-β actually appears to suppress antitumour immune responses. Of these cytokines, IL-2 and IL-12 have perhaps shown the most promise owing to their specific mode of action via T cell-mediated immunity, but they also have significant difficulties. Cytokines that primarily stimulate immunity via T cells include GM-CSF, IL-6, IL-7 and IL-18. Eosinophils are a major effector cell for IL-4 and IL-2 while neutrophils are involved in G-CSF mode of action. In addition, G-CSF, IFN-γ, TNF-α, IL-2, IL-4 and IL-7 significantly enhance antitumour macrophage activity. Dendritic cell activity is also significantly enhanced, both at the tumour site and in surrounding tissue, by G-CSF, GM-CSF, IL-2, IL-18 and especially IL-4. Endothelial cells may also be involved as an effector cell for most of these cytokines since several are known to induce vascular adhesion molecule expression profiles in such a way as to promote inflammatory cell invasion at the site of cytokine expression. Obviously, with the range of mechanisms represented by the major effector cell types upon which these cytokines act, finding the optimal cytokine(s) for enhancing and stimulating antitumour immunity against any particular tumour will be critical to the underlying success or failure of these approaches.

Finding the right delivery method is also critical. The most common method of delivering the cytokine gene is to deliver cells that have been engineered *ex vivo*, via transfection or transduction, to produce the cytokine of interest. Live attenuated virus has also been used in order to infect a local tissue indiscriminately. Tumour cells, lymphocytes, endothelial cells and fibroblasts have all been tried as specific cellular targets. In the case of tumour cells, both engineered primary tumour cells from patients and engineered allogeneic, established tumour cell lines have been used as inoculums. There are many advantages and disadvantages to either tumour cell source, but generally, the use of autologous primary tumour cells guarantees the presentation of host tumour antigens as part of the antitumour response while established tumour cell lines provide a simpler, less labour-intensive method of delivering the cytokine but has the disadvantage of reducing the chances of a shared antigen profile. Lymphocytes are also an attractive target for gene therapy using cytokines because of their natural functions – proliferation and activation in response to immunogenic stimulation and accumulation at the site of immunogenicity. Unlike lymphocytes, endothelial cells are a potentially renewable source from which engineered endothelial cells could specifically expand into the growing vasculature of a solid tumour. In fact, endothelial cells have been shown to tolerate genetic engineering, migrate into and survive in an angiogenic site after intravenous injection (Ojeifo *et al*., 1995). Still, primary tumour cells, lymphocytes and endothelial cells are difficult to isolate, expand and manipulate *in vitro*. Fortunately, dermal fibroblasts are a readily available source of autologous cells that can be isolated and grown *in vitro* with relative ease, thus making it simpler to retrovirally transduce and select them. This means that fibroblasts are superior to other cells from an

ex vivo manipulation standpoint – whether they are superior, compared with the other possible target cell types, in their ability to deliver and stimulate antitumour immune responses when expressing the relevant cytokine remains to be seen. Still, there is clearly preclinical and clinical evidence that delivering immunomodulating cytokines in this manner enhances host antitumour activity resulting in significant suppression of tumour growth, although to date none have shown complete remission and/ or protection.

Since normal immune responses involve a highly coordinated effort involving numerous cell types and a veritable orchestra of cytokines, merely overexpressing a particular cytokine, or even two, is unlikely to provide the most effective antitumour response. With this in mind, dendritic cells (DCs) are being pursued as yet another target for cytokine gene therapy. Because of their role in directly presenting tumour antigens to and activating T cells, DCs are absolutely critical to a robust cell-mediated immune response. Many of the difficulties in obtaining and growing DCs have been overcome and numerous reports have outlined the successful transduction and maintenance of DC function after *ex vivo* manipulation (Szabolcs *et al*., 1997). The display of tumour antigen by DCs coupled with enhanced cytokine stimulation provided by gene therapy holds significant promise for increasing the already encouraging results obtained by cytokine gene therapy with other targets.

GENE-MODIFIED DENDRITIC CELLS

There have been a number of gene therapy approaches to fighting cancer by genetically modifying immune system cells to enhance their antitumour effect. One approach utilizes modification of CTLs for adoptive T cell therapy, and the other utilizes dendritic cells to enhance either presentation of tumour antigens or provide stronger costimulatory signals to activate antigen-specific CTLs more efficiently. Dendritic cell-based gene therapy has shown progress and several animal studies have provided encouraging results.

Dendritic cells are targets for cancer gene therapy because they are potent antigen presenters and possess high levels of various costimulatory molecules important for activation of $CD4^+$ and $CD8^+$ T lymphocytes. The cytotoxic T lymphocyte response is critically important for tumour rejection and eradication, and means to enhance this response through modification of dendritic cells are being vigorously pursued. Gene transfer of a tumour-specific antigen to dendritic cells *ex vivo* and infusion into the patient have the advantage of providing a renewable supply of antigen for presentation and preclude the need to identify specific peptides within the protein that induce strong CTL responses. Adenoviral vectors are commonly used for this purpose, although other viral and nonviral vectors have been used. (See also chapter on *Models for Immunotherapy and Cancer Vaccines*.)

In a study by Kaplan *et al*. (1999), a murine B16 melanoma tumour model was used to test the ability of modified dendritic cells to induce an antitumour immune response. B16 cells express murine homologues of human melanoma-associated antigens such as gp100, TRP-1, TRP-2 and MART-1. Therefore, murine dendritic cells isolated from the bone marrow were transduced with gp100 or TRP-2 using an adenoviral vector and infused into animals before or after tumour formation. The pre-immunization model showed substantial protection from tumour-induced death after infusion of 5×10^5 gp100 or TRP-2 expressing dendritic cells and challenge with a lethal dose of B16 tumour cells at 15 days post-immunization. Within 30 days, 100% of control mice died whereas in mice immunized with dendritic cells expressing gp100 or TRP-2, only 20% and 0% developed tumours with delayed kinetics, respectively. The effect was long lasting as 75% of mice receiving a second injection of B16 cells 50 days after the first B16 injection remained tumour free. Although the results with preimmunization were impressive, a more clinically relevant model involves treatment of pre-existing tumours. To this end, the authors injected a lethal dose of B16 cells into mice 4 days before treatment with transduced dendritic cells. Surprisingly, only 20% of the mice given gp100 expressing dendritic cells and 60% of mice given TRP-2 expressing dendritic cells remained tumour free. The outcome was improved by infusion of a mixture of the two dendritic cell populations.

Similar results were observed by Wan *et al*. (1999), who used the same murine tumour model. Immunization with dendritic cells transduced by adenovirus with gp100 could prevent tumours in 70% of mice challenged with B16 cells. In addition, treatment after establishment of pulmonary tumours resulted in an 80% reduction in lung metastases.

Less impressive results were obtained using non-immunogenic mouse fibrosarcoma cell (NFSA) tumours stably expressing MART-1, a melanocyte lineage-specific antigen expressed by many malignant melanomas (Ribas *et al*., 1999). When these mice were challenged with tumour cells after preimmunization twice with dendritic cells transduced with MART-1, only 21% were completely protected. Treatment of established tumours resulted in only a small delay in tumour growth. These results may be due to the poor immunogenicity of MART-1. A strong and sustained antitumour response may ultimately require transfer of more than one tumour antigen gene to dendritic cells to confer a more antigenically diverse immune response and to guard against poorly immunogenic antigens and development of tumour resistance due to down-regulation of specific tumour antigens.

$CD4^+$ T cells appear to be important for development of antitumour immunity. Depletion of $CD4^+$ T cells from animals before immunization with modified dendritic cells

significantly abrogates the antitumour response (Kaplan *et al*., 1999; Ribas *et al*., 1999; Wan *et al*., 1999). The central effecter role of $CD4^+$ T cells was demonstrated by Wan *et al*. (1999). They found that protective immunity conferred by transfer of gene modified dendritic cells could be maintained after $CD8^+$ T cell depletion. Furthermore, tumour rejection was independent of signals from IL-12 and CD40. These data may reflect a shift in our understanding of the antitumour response due to $CD8^+$ and $CD4^+$ cells and factors which influence generation of strong immunity to weakly immunogenic tumour antigens.

The second approach to cancer gene therapy utilizing dendritic cells involves transfer of the gene for CD40 ligand (CD40L). CD40L is usually expressed on activated $CD4^+$ T cells, whereas its receptor, CD40, is expressed predominantly on B cells, activated macrophages and dendritic cells. Stimulation of dendritic cells through CD40/CD40L is important for activation of dendritic cells, which then in turn up-regulate various T cell costimulatory molecules such as ICAM-1 and B7. The eventual result is stimulation of $CD8^+$ CTLs.

Enhancing the activation of dendritic cells is hypothesized to increase the CTL immune response against tumours and forms the basis for gene transfer of CD40L into dendritic cells. It is thought that CD40L expressed on dendritic cells will interact with CD40 in a *cis* fashion, to cause autoactivation and more potent activation of CTLs. This hypothesis was recently tested by Kikuchi *et al*. (2000). Using B16 and CT26 (undifferentiated colon adenocarcinoma) tumour models, dendritic cells transduced with CD40L were administered to mice bearing established tumours. For both models, significant and sustained tumour growth delay was observed, as was a significant increase in survival. Additionally, a two-tumour model in which tumours were established in each flank was tested for antitumour CTL activity. When CD40L transduced dendritic cells were injected into one of the tumours, both the left and right tumours were growth suppressed. Immunohistochemical analysis of the tumours showed high-level $CD8^+$ T cell infiltration and some $CD4^+$ T cells, whereas control mouse tumours had very low levels of T cell infiltration.

There are a number of advantages to the CD40L system compared with transduction of tumour antigens to dendritic cells. The most obvious is that in the CD40L system, a tumour antigen does not have to be identified. Furthermore, modified dendritic cells have the potential to present many tumour antigens owing to their interaction with tumour cells, thus allowing the immune system to respond to a variety of tumour antigens.

DRUG RESISTANCE GENE THERAPY

Transfer of drug resistance genes into haematopoietic stem cells is used as an approach to circumvent chemotherapy induced myelosuppression. The major goal of drug resistance cancer gene therapy is selective survival of haematopoietic progenitors while concurrently inhibiting tumour growth. This strategy results in the selection of drug-resistant cells and thus may allow more dose-intensive chemotherapy regimens to treat drug-resistant tumours. Bone marrow stem cells are the ideal target for this approach based on their multilineage differentiation potential and their capacity for self-renewal. The majority of the gene transfer studies have used recombinant murine leukaemia retrovirus-based vectors. However, this class of retrovirus requires a breakdown of the nuclear membrane for integration, limiting the transduction efficiency of quiescent stem cells. More recently, HIV-based lentiviral vectors have been shown to transduce nondividing cells stably, increasing the potential for gene transfer into stem cells. Despite the difficulties in transducing stem cells, studies have shown that transduction of only a few early progenitors with a drug resistance gene is adequate for selection and repopulation of the marrow.

Gene transfer of the multidrug resistance gene-1 (*MDR-1*), O^6-methylguanine–DNA methyltransferase (*MGMT*) and dihydrofolate reductase (*DHFR*) have each demonstrated the ability to increase cellular resistance to chemotherapeutic agents (see chapter on *Models for Drug Development and Drug Resistance*). The most widely studied drug resistance gene is *MDR-1* that encodes the 170-kDa ATP-dependent multipass-transmembrane efflux pump P-glycoprotein which can expel a number of lipophilic compounds from the cell. MDR-1 provides resistance to a variety of drugs including the anthracyclines, *Vinca* alkaloids, actinomycin D and paclitaxel. Increased drug resistance following *MDR-1* gene transfer into human and murine haematopoietic cells has been documented in many studies and is the basis for clinical trials that are now under way. Initial murine studies demonstrated that human *MDR-1* transduced haematopoietic cells had preferential survival *in vivo* after treatment with MDR drugs. Expression of human MDR-1 in long-term repopulating stem cells was shown by serial transplantation of transduced marrow with paclitaxel selection and resulted in MDR-1 expression 17 months after the initial transduction. This demonstrated that continuous expression can be maintained with *in vivo* selection. Simultaneous resistance of *MDR-1* transduced haematopoietic cells *in vivo* and sensitization of murine tumour cells was shown in Balb/C recipients following treatement with paclitaxel. The mice tolerated high doses of paclitaxel while demonstrating a significant decrease in tumour growth (Hanania and Deisseroth, 1997).

The O^6-alkylguanine–DNA alkyltransferase enzyme, encoded by the *MGMT* gene, increases cellular resistance to alkylating agents including the chlorethylating agent BCNU and the methylating agent temozolomide. Mutant forms of MGMT are resistant to the alkyltransferase modulator O^6-benzylguanine (BG) and provide a greater

resistance to the chemotherapeutic agents compared with wild-type forms. Two well-characterized mutants, G156A and P140K, have been shown to protect transduced marrow from BG and BCNU or temozolomide-induced myelosuppression and result in significantly improved survivial *in vivo* (Ragg *et al*., 2000; Sawai *et al*., 2001). Following drug treatment, an increase in MGMT transduced cells reached nearly 100% in bone marrow (Ragg *et al*., 2000) and peripheral blood (Ragg *et al*., 2000; Sawai *et al*., 2001) and secondary transplant experiments proved that selection occurred at the stem cell level (Ragg *et al*., 2000; Sawai *et al*., 2001). MGMT-associated enrichment was best demonstrated in a model in which G156A transduced marrow was selected up to 1000-fold, even when initially present at a repopulation disadvantage (Davis *et al*., 2000). In a tumour xenograft study, G156A transduced marrow was transplanted into *nu/nu* athymic mice bearing a tumour cell line expressing high levels of AGT. Here, mice were protected from a dose-intensive regimen of BG and BCNU while the tumour exhibited a significant growth delay (Koc *et al*., 1999). These results provide strong evidence that MGMT transduced marrow may increase the therapeutic index of BG and BCNU to allow aggressive cancer treatment. Clinical trials using G156A *MGMT* gene transfer have also been proposed. In contrast to MDR substrate drugs, BCNU is more toxic to early haematopoietic progenitors and therefore may facilitate stronger selection for MGMT transduced cells.

Table 2 Host-directed cancer gene therapy strategies

Antiangiogenic gene therapy

Angiostatin: Proteolytic fragment of plasminogen protein that serves as an endogenous inhibitor of angiogenesis

Endostatin: Proteolytic fragment derived from the C-terminus of collagen XVIII that serves as an endogenous inhibitor of angiogenesis

Localized cytokine gene therapy (enhancing cell-mediated immunity)

Cytokines that promote an antitumour immune response: TNF-α, G-CSF, GM-CSF, IFN-γ, IL-1, IL-2, IL-4, IL-6, IL-7, IL-12, IL-18

Effector cell targets of cytokine gene delivery: Tumour cells, lymphocytes, endothelial cells, fibroblasts

Gene-modified dendritic cells (enhancing cell-mediated immunity)

Tumour-specific antigens displayed on dendritic cells: gp100, TRP-1, TRP-2, MART-1

CD40L gene delivery to dendritic cells: CD40L expression on dendritic cells serves to activate cytotoxic T cells, allowing multiple antigen recognition without prior knowledge of the antigens involved

Drug resistance gene therapy (haematopoietic protection/ enhancing the chemotherapeutic index)

MDR-1: Efflux pump providing resistance to anthracyclines, *Vinca* alkaloids, actinomycin D and paclitaxel

MGMT: Encodes O^6-alkylguanine–DNA alkytransferase protein: resistance to cytotoxic alkyl lesions arising from BCNU and temozolomide treatment. Mutant forms of MGMT are resistant to the endogenous MGMT inhibitor, O^6-benzylguanine (BG)

DHFR: Dihydrofolate reductase is required for thymidine synthesis. Mutant forms of DHFR are resistant to inhibitors of the endogenous enzyme (methotrexate, trimetrexate)

Gene transfer of the *DHFR* gene is used to protect haematopoietic cells from antifolate chemotherapeutic agents such as methotrexate (MTX) and trimetrexate (TMTX), which bind DHFR and inhibit nucleotide synthesis. Certain mutant forms exhibit reduced affinity for antifolates, and therefore gene transfer of these variants is used to provide increased cellular protection from these agents. Mice transplanted with haematopoietic cells retrovirally expressing the human DHFR mutants L22R and L22Y were protected from MTX- and TMTX-induced cytopenia, respectively. Recently, gene transfer of a nucleoside transporter, hENT2, which is insensitive to the nucleoside analogue NBMPR, was shown to confer resistance in murine cells to antifolate drugs which target other key enzymes involved in purine/pyrimidine synthesis. In this model, tumour cells that express high levels of a sensitive nucleoside transporter are sensitized, whereas haematopoietic cells are protected, thereby increasing the antitumour activity of folate analogues (Patel *et al*., 2000).

These murine models indicate that drug-resistant gene transfer can lead to enrichment of drug-resistant bone marrow, which may allow more intensive chemotherapy regimens to treat tumours resistant to conventional chemotherapy. However, the success of this strategy will ultimately be determined in clinical trials which are ongoing. Of note, this powerful selection strategy can also be used to co-select for a second therapeutic gene in the treatment of genetic disorders of the haematopoietic system and studies to investigate this possibility are also in progress.

Finally, to summarize the above sections, host-directed gene therapy strategies are outlined in **Table 2**. (See also chapters on *Antisense and Ribozyme Therapy*; *Gene Therapy–Tumour Suppressor Replacement/Oncogene Suppression*.)

- Conclusions and Perspective

INTRODUCTION: BASIC BIOLOGY OF EPITHELIAL CANCERS

All adult tissues are derived from three embryonic germ layers: ectoderm generates the likes of epidermis and nervous system, mesoderm connective and supportive tissues and endoderm the many epithelial organs. Although tissues of mesenchymal origin account for up to 80% of the mass of an individual, over 90% of adult human tumours are epithelial carcinomas. This may be explained by the fact that many such tissues (e.g. skin, respiratory, urogenital and alimentary tracts) are exposed to environmental carcinogenic hazards. Common examples include ultraviolet rays in sunlight (skin cancers), air pollution and cigarette smoke (lung cancers), asbestos (mesothelioma) and less well defined dietary risk factors which may contribute to the development of gastrointestinal (GI) tract cancers. Internal organs such as mammary gland, liver, kidney and bladder may also be affected by toxic agents, some of which (such as aflatoxin, which affects the liver, and aniline dyes, which target the urinary tract) may exhibit tissue-specific effects. Viruses are also involved in the aetiology of certain carcinomas (e.g. papilloma virus, cervical cancer; hepatitis virus, hepatocellular carcinoma; and Epstein–Barr virus, nasopharyngeal carcinoma). (See also chapter on *Cell and Tissue Organisation*.)

Normal Epithelial Organisation

The evolution of complex multicellular organisms required the development of highly coordinated and specific cell interactions. During embryogenesis, cell contacts with other cells and extracellular matrix (ECM) components play major roles in directing morphogenesis, migration and differentiation in exquisitely orchestrated developmental processes. These processes are also modulated by soluble factors (generally termed 'growth factors') in the environment. Epithelial cells are the first to develop in the embryo, with motile, nonadhesive mesenchymal cells differentiating from them. Throughout history, the notion that malignant cells represented some form of embryonic stem cell has been a recurring theme. It was debated whether these were occult fetal tissues or cells which *de novo* recapitulated the proliferative and invasive character of such cells. It is now known that remodelling of tissues following injury and oncogenic progression can involve transient epithelial–mesenchymal phenotypic conversions and re-expression of genes normally only active in the embryo.

In the adult, normal epithelial cells are polarized and organized broadly into squamous sheets or secretory structures via intercellular attachments including desmosomes, tight junctions and adherens junctions (**Figure 1**). The basal cell layer secretes proteins that constitute the basement membrane, with which close contact is maintained by further adhesive interactions. The cell shape, rigidity and structure are maintained by a complex system of epithelial-specific intermediate cytokeratin filaments. Aggregations of epithelia are separated and supported by a connective tissue stroma incorporating blood vessels and loosely associated, more mobile mesenchymal cells. Although the cell–cell and cell–matrix contacts maintain tissue structure and integrity, it is becoming clear that the adhesion molecules involved provide far more than a mere physical supporting role. Recent studies have provided evidence that a cell's differentiation, gene expression, motility and even survival depend upon correct interactions with its immediate

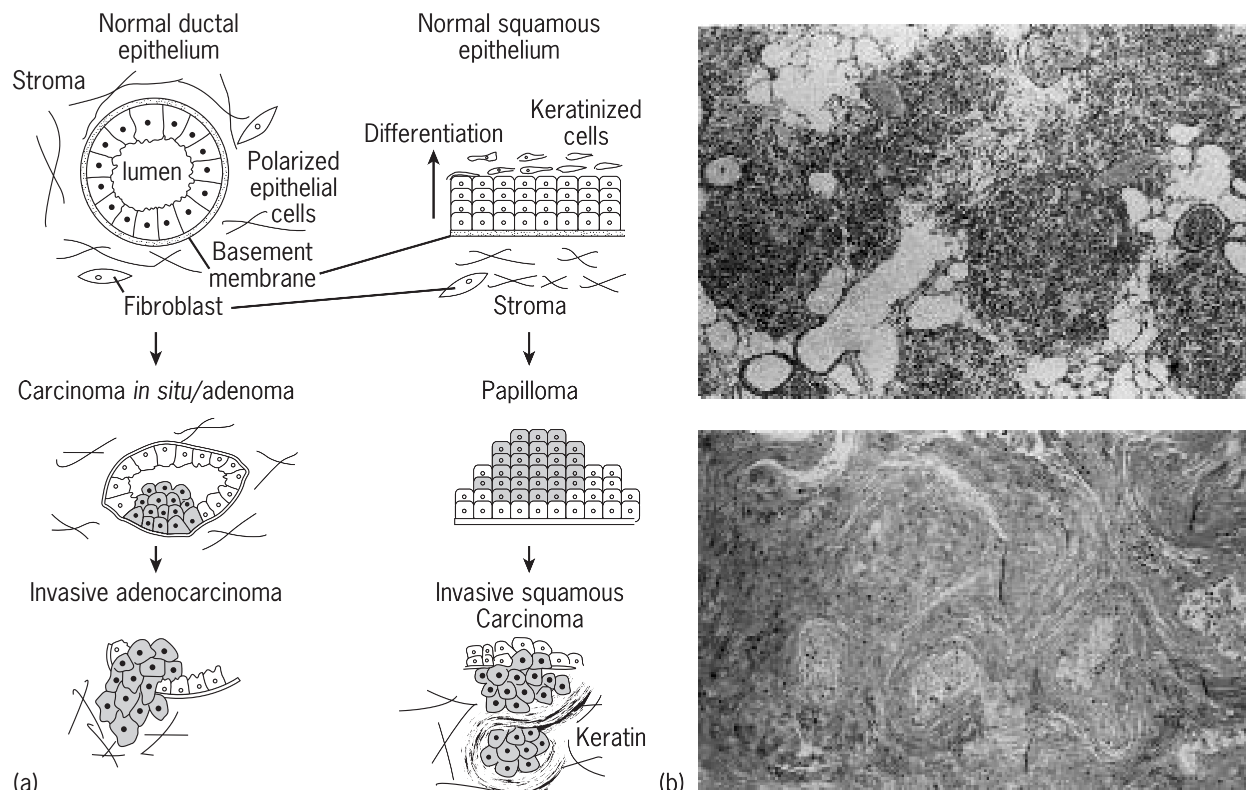

Figure 1 (a) Epithelial organisation; (b) examples of carcinomas: (top) lung adenocarcinoma and (bottom) oral squamous carcinoma.

environment. Many safeguards exist to ensure that cells which are incorrectly positioned do not survive (a process known as apoptosis or anoikis), and cancer cells are those which fail to respond to these normal social regulatory signals. (See also chapter on *Extracellular Matrix: the Networking Solution*.)

Regulation of Tissue Structure and Function: Homotypic Epithelial Adhesion is Down-regulated in Invasive Cells

One of the adhesion molecules important in maintaining the integrity of epithelial structures is the calcium-dependent glycoprotein E-cadherin. It is functionally inactivated in nearly all epithelial human cancers by a variety of mechanisms (**Figure 2**). Germ-line mutations in the E-cadherin gene are linked with predisposition to invasive gastric cancer, and in a transgenic mouse model of pancreatic carcinoma, loss of E-cadherin is causally linked with benign to malignant conversion. In human squamous carcinomas of the head and neck, E-cadherin expression is inversely correlated with the presence of lymph node metastases; similar findings have been reported in gastric and hepatocellular carcinomas. In some experimental studies, when the E-cadherin gene was introduced into carcinoma cells, which lacked expression, their invasive potential was lost and intercellular adhesion enhanced. In other cases, such as the human breast carcinoma cell line MCF-7, invasive variants continued to express high levels of E-cadherin, suggesting either that some function of the molecule was impaired, or alternatively that other 'positive' invasion signals may over-ride its influence in certain cell types (Christofori and Semb, 1999).

The intracellular domains of cadherins associate with catenins and the actin cytoskeleton. β-Catenin, when released from E-cadherin, can move to the nucleus and in association with transcription factors can induce expression of genes involved in the cell cycle. Although the mechanisms are far from fully elucidated, the circumstantial evidence in favour of an important regulatory role for E-cadherin in tumour progression is compelling. In developmental processes, it is clear that migratory cells must first detach from their neighbours, and this must involve a change in their adhesive status. It seems that the transient, orderly control of molecules such as the cadherins, if misregulated, could lead to the evolution of epithelial cells which have acquired the properties more usually associated with mesenchymal cells; lack of polarization and differentiation and a motile, migratory phenotype. (See also chapter on *Modelling Tumour–Tissue Interactions*.)

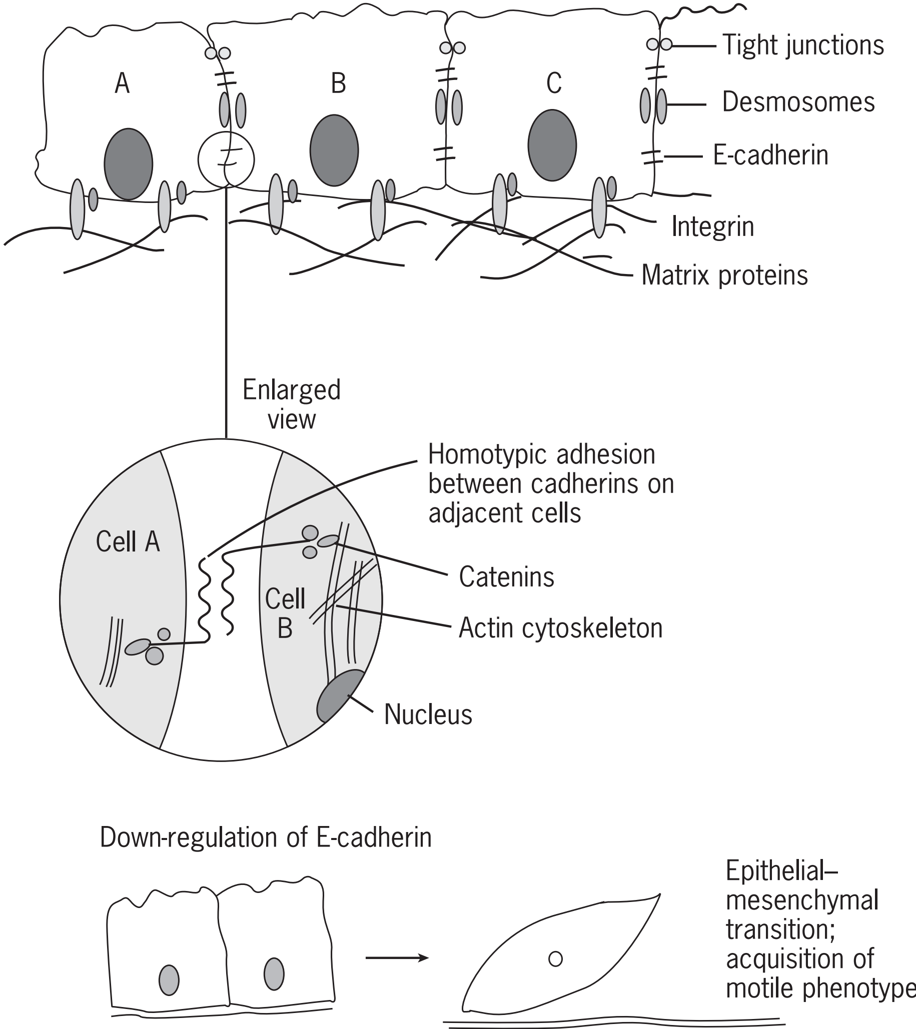

Figure 2 Mechanisms of inactivation of E-cadherin.

Epithelial–Mesenchymal Transformations in Embryogenesis and Metastasis

The transient phenotypic conversion of epithelial cells to a mesenchymal morphology is a common event during embryonic development. In the adult, epithelial cells normally only migrate during wound healing or tissue repair. In one experimental system utilizing a rat bladder carcinoma cell line, the epithelial–mesenchymal transition could be induced by fibroblast growth factor 1 (FGF-1) (a-FGF) or by culturing the cells on collagen type 1 fibres. The resulting cells showed a rapid down-regulation of cadherins, loss of their ability to form aggregates and acquisition of motility (**Figure 2**). Interestingly, an early response to FGF-1 was the production of matrix metalloproteinases, illustrating how such a phenotypic shift could provide the range of abilities required for invasion by either the embryonic or malignant cell (Valles *et al*., 1991).

Mesenchymal–Epithelial Interactions

During organ development, many morphogenic interactions between epithelia and mesenchyme occur and organogenesis has been studied *in vitro* in tissue explants. Mesenchymal factors have been found to be essential for growth and morphogenesis of epithelial cells in most if not all systems studied (Birchmeier and Birchmeier, 1993). The paracrine (indirect) signals may be transmitted by three different modes: cell–cell contact, cell–matrix interactions or diffusion of soluble factors. Direct contact between epithelial and mesenchymal cells has been shown to be important in the developing mammary gland and in the induction of new epithelia during kidney development. However, separation of the two cell types by filters has shown that mesenchymal induction of morphogenesis in other tissues (e.g. salivary gland) does not require direct contact. Components of the extracellular matrix such as collagens can support branching morphogenesis of

mammary epithelial cells, and soluble mediators such as 'scatter factor' and a variety of growth factors can also participate in morphogenesis (see below).

Fibroblasts, the classical mesenchymal cells, are nonpolarized, motile and generally found surrounded by extracellular matrix. They interact with components of the ECM via adhesion molecules such as integrins for which they express a variety of receptors. They secrete a variety of ligands that interact in a paracrine fashion with epithelial-specific receptors. In addition, it is known that several proteases can be produced by mesenchymal cells which bind to receptors on epithelial cells to mediate directed proteolysis, e.g. during tooth eruption, capillary sprouting or ductal branching. Coordinated expression of matrix-degrading proteases and their inhibitors is also involved in involution of the mammary gland. (See also chapters on *Mammary Tumour Induction in Animals as a Model for Human Breast Cancer*; *Modelling Tumour Tissue Interactions*.)

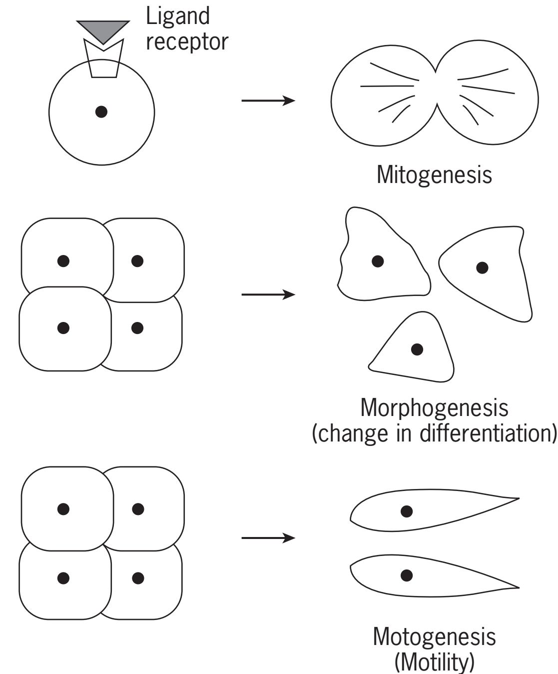

Figure 3 Pleiotropic effects of 'growth factors' (e.g. EGF, HGF).

Matrix and Growth Factors

Tissue development, renewal and repair occur with the assistance of a wide variety of regulatory growth factors that may provide both inhibitory and stimulatory signals. The responses induced depend upon interplay between the origin and state of differentiation of the target cell, the number and types of receptors it expresses and the concentration of growth factor(s) in its environment. In order to respond to these molecules, cells must express specific transmembrane receptors that can bind the growth factors. This process transmits signals via a cascade of intracellular activation events that culminate in a number of responses in the target cell, the most common of which is mitosis. However, the term 'growth factor' may be misleading since it is evident that these ligands induce pleiotropic responses and may alter states of differentiation, cytoskeletal organisation, motility and other cellular functions. The same growth factor may produce varying responses in either different cell lineages, or the same cell type at different stages of differentiation – again emphasizing the importance of 'context' in developmental decisions. For example, 'scatter factor' is secreted by fibroblasts and induces epithelial cells to dissociate (scatter) in culture; the cells also become dedifferentiated and more invasive (**Figure 3**). This molecule was found to be identical with hepatocyte growth factor (HGF) (a mitogen for liver cells) and to induce these diverse responses via a single receptor – the product of the c-*met* proto-oncogene – in all cell types. HGF has been implicated in acquisition of an invasive phenotype in many types of carcinomas.

A factor may also evoke different responses depending on the quantity available; fibroblasts respond to low concentrations of FGF-1 by proliferation and to high concentrations by movement towards it (chemotaxis). Once tissue architecture is defined, further growth and the replacement of those tissues (such as skin, intestine and haematopoietic system) which are self-renewing depends upon the proliferation of a limited number of multipotent 'stem' cells. These generate developmentally restricted progenitor cells whose progeny finally yield differentiated, fully functional, nonproliferative mature cells. This coordinated process must be closely regulated in order to maintain tissue integrity and function, and indeed it is the imbalance of proliferation and differentiation/cell death that is at the heart of malignant transformation. Many tumours have been shown to secrete growth factors and/or to over-express their receptors and indeed many of the oncogenes recently identified have been shown to encode these molecules or other components of the mitogenic signalling pathway. The potential of certain viruses to cause malignant transformation of cells is due to the integration of such oncogenes into their genomes. (See also chapters on *Human DNA Tumour Viruses*; *RNA Viruses*.)

Such observations led to the 'autocrine' hypothesis of tumour development, i.e. the idea that a tumour cell survives because it is no longer dependent on endocrine or paracrine growth stimulatory signals, but can produce its own. This leads to an autostimulatory loop and increased autonomy from normal growth controls. In the most extreme cases the receptor may be constitutively activated independently of ligand binding and hence constantly transmitting stimulatory signals to the cell. There is now

compelling evidence that mutation or overexpression of growth factors and/or their receptors may provide a growth advantage for tumour cells, indirectly stimulate vascularization on which the continued expansion of the tumour mass depends, and potentiate processes involved in invasion and dissemination.

Benign or Malignant? Carcinoma *In Situ*

As Virchow is supposed to have remarked, 'no man even under torture can say what is a tumour,' and even modern pathologists have to use an armamentarium of criteria to classify tumours and to discriminate benign from malignant lesions. In the past, diagnosis was ultimately determined only by the eventual outcome (survival or death), although then, as now, certain features of the location and appearance of the tumour provided clues as to its probable behaviour. We now like to think that tumour classification and staging have evolved to a sophisticated art, and there is a general tacit understanding of the difference between benign tumours (which are generally indolent, well-differentiated, circumscribed and localized masses) and malignant lesions with a tendency to develop more rapidly, invade locally and spread to distant sites.

For certain carcinomas there are defined premalignant or benign lesions which may represent stages in the evolution of a malignant tumour from its normal tissue of origin; other hyperplastic conditions do not appear to predispose to the later development of cancer, and for some tumours (e.g. pancreatic and renal carcinomas) there seems to be no premalignant state. Until recently, these lesions were described in morphological terms, but increasingly, molecular probes are being used to dissect the multiple genetic defects thought to be necessary to produce fully metastatic tumours. Since many tumours are known to have a long occult phase prior to detection, it is not surprising that the early stages of malignant conversion have been so elusive. The prime example of this is the case of so-called 'unknown primaries' where the first and only manifestation of cancer is a metastasis.

Although cancer is often described as the abnormal growth of cells, over-proliferation *per se* does not define malignancy. Hyperplasia represents the increased proliferation of essentially normal cells, e.g. after injury (physiological) or in psoriasis (pathological). Dysplasia may generate atypical or abnormal cells, but these generally do not proliferate indefinitely and are not invasive. Metaplasia is defined as a major switch in phenotype and these metaplastic cells may eventually overgrow and replace other cellular elements in the affected tissue; it is this latter category which may represent one of the earliest steps in oncogenesis, e.g. squamous cell metaplasia in the airways of the lung. At this point the lesion remains *in situ*, has generally not breached the surrounding basal membranes and may be encapsulated in a zone of connective tissue.

Tumour Progression, Heterogeneity and Clonal Dominance

It is generally accepted that most cancers arise from a single aberrant cell. The clonal nature of several malignant diseases has been demonstrated by examining genetic and biochemical markers such as the presence of chromosomal abnormalities, secretion of a single species of immunoglobulin (plasma cell tumours) and isoenzyme patterns. One possibility is that the progenitor cell is transformed (perhaps by the presence of an aberrant gene or exposure to an environmental carcinogen) and that this then proliferates to generate the clinically detectable tumour. An alternative hypothesis suggests that many cells undergo 'initiation,' but that only one or a few 'progress' to full malignancy. Certainly there are genetic traits where an individual is at a high risk of developing cancer in one or more organ systems, and in some instances this is due to mutation or the loss of genes important for the regulation of mitosis, repair of DNA damage or programmed cell death (apoptosis). In these individuals certain tissues may be primed and require only a single further event to generate a tumour. In such cases multiple primary tumours are not unusual.

Foulds first formulated the concept of tumour progression in 1975. At about this time, experimental models of carcinogenesis were demonstrating that certain compounds could cause cancer only if animals were exposed to sequential treatments with other compounds. Some chemicals worked if administered initially ('initiators'), followed by others that acted to 'promote' the oncogenic potential of the former, but were not themselves carcinogenic. Some complex mixtures (such as cigarette smoke) were described as 'complete carcinogens' because they contained both initiators and promoters. Nowell, in his clonal evolution theory, proposed that the carcinogenic event induced 'genetic lability' which permitted 'stepwise selection of variant sublines and underlies tumour progression.' This model, and its experimental background, formulated the concept of the multistep nature of carcinogenesis and the progression from normal cells through premalignant lesions to fully malignant cancers capable of metastasis. Tumours therefore can acquire increased heterogeneity of a variety of phenotypic and genotypic traits (some of which will provide a growth advantage to particular cell subpopulations) but can retain the unique markers that identify their monoclonal (single cell) origin. Recent work has begun to define the molecular genetic bases for some of these steps in the tumours where premalignant lesions are identifiable and accessible, notably colorectal carcinoma, squamous cell carcinomas and to a

lesser extent melanoma and breast carcinoma. (See also chapter on *Overview of Oncogenesis*.)

Metastasis

For some common tumours such as lung, breast and colon carcinoma and malignant melanoma there is a correlation between the size of the primary lesion and the probability of metastasis. For an individual tumour, size generally equates with time, and this observation probably reflects the fact that 'older' tumours have had longer in which to acquire multiple genetic alterations, now thought to underlie the well-recognized multistep nature of oncogenesis and progression. The cell population as it enlarges will generate increasing heterogeneity from which subpopulations with relatively greater autonomy from host environmental controls will emerge by adaptation or selection. It is clear that genes controlling tumour growth can be distinct from those controlling metastasis, since some tumours that are capable of indefinite growth fail to spread to distant organs. It is this aspect of cancer that is the most challenging both in terms of producing accurate models for the better understanding of the processes involved, and also in the development of effective systemic therapies. The importance of neoangiogenesis, not only in development of primary tumours, but also in facilitating metastasis and as a valuable therapeutic target is now fully appreciated (Fidler and Ellis, 1994). (See also chapters on *Angiogenesis Models* and *Tumour Metastasis Models*.)

EPITHELIAL CANCER MODELS

Given that there are over 200 different types of cancer, most of which are epithelial in origin, it is clearly not possible to discuss models of more than a fraction of them. The general principles involved in malignant transformation have been described above, and now it is possible to discuss in more detail specific cases where these processes can be mimicked *in vitro* and/or *in vivo*. We accept that much of cancer is genetically determined, but even when a specific gene (e.g. *APC* or *BRCA1*) is known to predispose to cancer, the host genetic background can contribute significantly to its effects. This means that the same gene in mouse and humans will never give exactly the same incidence, types and spectrum of behaviour of cancers. Nevertheless, manipulation of genes either by mutation, or overexpression or the 'knockout' of tumour-suppressor genes has proved very useful in both providing experimental cancers for study and also determining the function of these genes. (See also chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*.)

Similarly, animals can be exposed to carcinogenic chemicals, toxins, irradiation, viruses, etc., and cancers may ensue. In many cases the exposures are acute and high dose, and this may give different (often more highly immunogenic) tumours to those which arise from chronic, lower dose exposure as is usually the case in humans. More recently, cultured animal and human epithelial cells have been exposed to agents identified as having carcinogenic potential in order to simplify analysis, although this reductionist approach cannot match the complexity of interactions that can lead to metastatic cancer in the body.

It is important to define from the outset what the 'model' is designed to model (see chapter on *Advantages and Limitations of Models for Cancer and Malignant Cell Progression*). This may seem to be stating the obvious but there are very different imperatives if one is aiming to study, for instance, oncogenic transformation of a particular epithelial cell lineage *in vitro*, the process of chemical or viral carcinogenesis, chemoprevention or the biology or therapy of primary or secondary cancers. The next sections will cover models of several common cancers, and these will be cross-referenced to other cancer types where general principles can be defined.

SKIN AND SQUAMOUS CELL CARCINOMAS

Chemical Carcinogenesis–Squamous Cell Carcinomas: the Mouse Skin Model

Many of the classical concepts of multistage carcinogenesis have been derived from the mouse skin model in which the three basic stages of carcinogenesis (initiation, promotion and progression) have been demonstrated. The historical reasons for this approach are readily apparent since observations on scrotal skin cancer in chimney sweeps led Percival Pott to elaborate the first theories on environmental/chemical causes of cancer in the eighteenth century. Suspect substances could be 'painted' on to animal skin where the effects on the epidermal cells were readily observed. This system has led to the extraction and identification of substances from complex mixtures that are carcinogenic in humans, notably 1,2,5,6-dibenzanthracene and 3,4-benzo[*a*]pyrene from coal tar, polycyclic aromatic hydrocarbons (PAHs) from cigarette smoke and the diterpene esters from croton oil. However, this model has some limitations as a predictor of risk factors in humans. Marked differences in susceptibility exist not only between different species but also between strains of mice, and the structure of mouse skin is different from that of human skin in terms of morphology, hair cycle and permeability to exogenous compounds. Arsenic can cause skin cancers in humans but has not done so in any animal so far tested, and only about 70% of known carcinogens cause cancers when applied to the skin (reviewed in Eccles, 1987).

Nevertheless, this simple model has over many decades yielded vital information about which agents act at different stages of carcinogenesis, what their genetic targets are, the role of cofactors and epigenetic influences and finally has provided test systems for evaluating potential inhibitors of these events.

The 'initiation' stage is generally considered to require the direct interaction of the compound with DNA in stem cells leading to an irreversible genetic defect, often involving *ras* oncogenes. The H-*ras* locus has been shown to undergo many different changes that can lead to malignancy including mutagenic activation, amplification of the mutant allele and loss of the normal allele (Akhurst and Balmain, 1999). The way that skin tumour promoters seems to work is by expansion of the initiated stem cells offering the potential for buildup of further genetic changes, genomic instability and the conversion of a benign papilloma to a malignant carcinoma. In the absence of an initiation event, tumour promoters merely induce hyperplasia – overgrowth of nonmalignant cells (Slaga *et al*., 1996). H-ras induces a 'papilloma' phenotype, characterized by a high rate of cell proliferation and aberrant differentiation. This phenotype has been ascribed to activation of the epidermal growth factor receptor (EGFR) and effects on different protein kinase C (PKC) isoforms (these are intracellular signalling molecules). Premalignant progression requires additional genetic events which at this stage are inhibitable by transforming growth factor beta (TGFβ). Cells that have low levels of TGFβ are more readily transformed, exemplifying the fact that progression can be linked to gain of oncogene function and/or loss of suppressor gene function. Interestingly, at later stages of progression, TGFβ can act to stimulate tumour invasion, indicating that cellular context is important to gene function (Ackhurst and Balmain, 1999) (**Figure 4**).

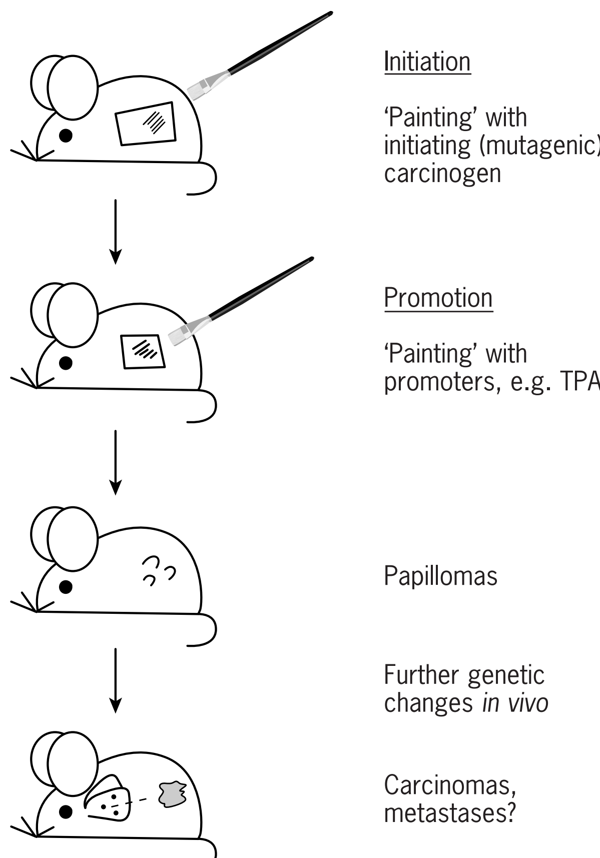

Figure 4 Skin carcinogenesis model.

Intervention/Therapy Studies

Inositol hexaphosphate (IP6) has been demonstrated to prevent carcinogenesis in a variety of experimental systems (Shamsuddin, 1999), although it seems that its metabolism and biodistribution may be different in mice and humans. Its mechanisms of action are not fully understood, but it appears to have several interesting properties: inhibition of cell proliferation, enhanced differentiation of malignant cells, down-regulation of mutant p53 and stimulation of DNA repair. In a classical two-stage initiation–promotion model using the initiator 7,12-dimethylbenzanthracene (DMBA) and the promoter TPA, it was shown that giving IP6 in the drinking water was able to inhibit papilloma formation significantly if given in the initiation (first 3 weeks) period, but not if administration was delayed until the promotion period (weeks 4–23).

In Vitro Models of Skin Tumour Progression

More recently, murine and human cell lines have been derived from keratinocytes (the skin epithelial cells) at various stages of progression. One of the most widely used is the human HaCaT series (Fusenig and Boukamp, 1998). The original cell line was obtained from normal human skin cells. Nonmalignant cells will grow in culture, but generally undergo senescence and die after 60–70 cell divisions. Immortalization (one of the first stages in malignant progression) may occur spontaneously in rare clones, or can be induced by various means. These include overexpression of the telomerase (*hTERT*) gene which acts to keep chromosomal 'ends' or telomeres long enough to allow repeated DNA replication and cell division, mutation of the *p53* 'guardian of the genome' gene involved in DNA repair or introduction of viral genes which also overcome senescence by interfering with cell cycle control. Similar cultures can be made from oral, bladder, rectal and oesophageal squamous epithelial cells.

By exposure of early cultures of HaCaT to various agents, a panel of cell lines has been obtained which show different genetic changes and malignant potential. Ultraviolet (UV) B (exposure to which is known to be a

risk factor for skin cancers, including melanoma which does not arise from epithelial cells) induced p53 mutations and loss of senescence genes on chromosome 3p. Interestingly, exposure of the HaCaT cells to inorganic arsenic (which as noted above causes skin and other cancers in humans) also reduced p53 levels and increased the levels of another gene, *mdm2*, which regulates p53 in normal cells (Hamadeh *et al*., 1999). This suggests that different risk factors for skin carcinogenesis may impact on key cell regulatory elements, notably the p53–Mdm2 loop which regulates cell cycle arrest in damaged cells. The loss of this control enables cells with DNA mutations to continue to proliferate. It is now also possible to reconstruct human skin epidermis *in vitro* by growing keratinocytes either on dead de-epidermized dermis (DED), dermal equivalent (collagen–fibroblast lattices) or synthetic substrates (Lenoir-Viale, 1996). Although primarily developed for skin graft research and cosmetic testing, these systems may also lend themselves to studies of malignant progression and therapeutic interventions.

In Vivo Xenograft Models of Squamous Cell Carcinoma Tumour Progression

So far, examples have been given of how normal human keratinocytes in tissue culture can be immortalized by various different agents, and some of the genes involved. At this point the cells are only able to generate benign papillomas, and not tumours when transplanted into immunodeficient mice. However, tumorigenic transformation can be induced by either introduction of mutant H-ras or exposure to heat. Growth of HaCaT cells at 40 °C induced chromosomal alterations including gains of regions of chromosome 11 which contains genes such as cyclin D1, involved in cell cycle control (Boukamp *et al*., 1999). This is interesting since it suggests that the effects of sunburn could be due to both UV exposure and high temperatures which produce different, but potentially complementary, genetic changes in skin epithelial cells. Malignant conversion was also associated with loss of chromosome 15 and a decrease in expression of the thrombospondin (*TSP*) gene. This molecule is important in controlling angiogenesis (the development of new blood vessels) on which tumour growth and metastasis depend. It is now thought that the ‘angiogenic switch’ is a key element in the conversion of benign to malignant tumours, since if a focus of cells is unable to induce a new blood supply, its growth and invasion are limited. The cells that had become malignant could be prevented from forming tumours by restoring chromosome 15 or the *TSP* gene to them. These procedures have now generated cell lines which together encompass all of the stages of human skin tumour progression from hyperplasia through to invasive cancers.

When cell lines of increasing malignancy (HaCaT, A5, II4RT) were compared, it was found that specific matrix metalloproteinases (MMP3, 9 and 10) increased coordinately (Bachmeier *et al*., 2000). These enzymes are very important in many aspects of tumour growth and invasion, releasing sequestered tumour growth factors and angiogenic factors, breaking down the ECM, thus potentiating tumour cell invasion, and MMP-9 has also been suggested to be involved in the angiogenic switch by releasing active vascular endothelial growth factor (VEGF) (Bergers *et al*., 2000). Xenografts can also be established directly from human cancers, or via cell lines derived from human cancers, although they rarely metastasize and recapitulate all of the malignant features of the original tumour. It is now appreciated that the malignant phenotype is best expressed if the tumours are grown in orthotopic (anatomically correct) sites rather than the convenient subcutaneous (s.c.) site in athymic mice. In some cases the latter site has been shown to downregulate key genes involved in invasion and angiogenesis. When a human basaloid oral SCC was transplanted s.c. or in the oral submucosa of athymic mice, the resulting lesions showed clear differences, with preferential growth of either the basaloid or squamous cells, which each exhibited different malignant features.

Microenvironmental/Host Influences in Skin Carcinogenesis

It is clear that the microenvironment and cell–cell interactions play a key role in tumorigenic conversion although the processes involved are not fully understood. Vaccariello *et al*. (1999) used an organotypic tissue model which mimics premalignancy to monitor genetically tagged malignant II4 cells cultured with either normal human keratinocytes or immortal HaCaT cells. Clonal expansion of these cells was prevented by direct contact with the former. Further progression of the tumorigenic HaCaT clones was found to require the *in vivo* environment which induced further genetic changes and selection of tumour cell subpopulations with enhanced autonomous growth. Various growth factors were induced which acted in an autocrine manner to stimulate both tumour cell proliferation and migration, which is a key element of an invasive phenotype (Fusenig and Boukamp, 1998). HaCaT cell clones capable of either benign or malignant (invasive) growth can be placed as surface transplants on to the subepidermal stroma of athymic (immunodeficient) mice to explore tumour–host interactions further. At 1 week after seeding, both types of transplants appear similar to healing wounds, but later the malignant cells revealed loss of cell polarity and defective basement membranes and cell–cell contacts.

In humans, UV irradiation is the main cause of skin tumours and the effects of UVB and chemical carcinogens

have been investigated in relation to the role of the extracellular matrix. Stenback *et al*. (1999) showed that these two agents induced different stromal reactions, notably in the synthesis and deposition of collagen types I and III. Further reproducible changes occurred during tumour development and progressive loss of differentiation. In a syngeneic model of squamous cell carcinoma similar to the HaCaT system, Dong *et al*. were able to explore differential gene expression during tumour progression in immunocompetent hosts. They used primary Balb/c mouse keratinocytes, a spontaneously transformed cell line (Pam 12) and metastatic cell lines derived from lymph nodes (Pam LY) and lung (Pam LU). A variety of genes were upregulated in the metastatic cell lines including the Growth Regulated Oncogene (GRO) alpha family and other genes linked to cell shape, motility and chemotaxis, signal transduction and angiogenesis (Dong *et al*., 1997). GRO alpha is a member of the C–X–C family of chemokines which promote chemotaxis of granulocytes and endothelial cells by binding to CXC receptor 2. Tumours overexpressing GRO alpha were fast growing, highly angiogenic and metastatic, but this advantage was diminished in hosts with defective CXC receptor 2, indicating that tumour malignancy depends on critical interactions with the microenvironment (Loukinova *et al*., 2000).

One of the genes which showed changes in expression (e.g. *Ly-6A/E*) is homologous to the human E48 SCC antigen which is implicated in cell–cell recognition, and hence may contribute to tumor progression via immune escape mechanisms. Upregulation of this gene would not be selected for *in vitro* or in immunodeficient hosts, indicating the importance of including syngeneic animal systems in tumour modelling. Both human and murine squamous cell carcinomas (SCC) have been shown to express cytokines involved in inflammation, e.g. interleukins 1α, 6 and 8 and granulocyte–macrophage colony-stimulating factor (GM-CSF). This is associated with a metastatic phenotype and only occurs *in vivo* and not during *in vitro* transformation, again emphasizing the role of the host environment in potentiating later stages of tumour progression.

Transgenic and ‘Knockout’ Mouse Models for Squamous Cell Carcinomas

These systems are covered in depth in other chapters (see *Transgenic Technology in the Study of Oncogenes and Tumour Suppressor Genes*; *Gene Knockouts in Cancer Research*), but a few observations are worthy of note. As stated previously, tumour growth and invasion are sustained partly by the binding of ‘growth factors’ to their receptors on the cell membrane. Key signalling systems in epithelial carcinomas include the c-erbB family (EGFR, c-erbB 2, 3 and 4) which are activated by various ligands including EGF, transforming growth factor alpha (TGFα) betacellulin and the heregulins (Eccles *et al*., 1995; Eccles, 2000) and also the insulin growth factor receptor. To determine the role of receptors and ligands in tumour development, transgenic mice have been made which express either amplified or mutant genes. The ability to introduce genes stably into the germ line of mice has converted the study of multistage chemical carcinogenesis to multistage molecular carcinogenesis. By combining genes with regulatory sequences that target expression to specific tissues, scientists can study neoplastic progression in animals with defined genetic traits. Cooperativity between different genes can be tested by crossing different transgenic lines, and effects of environmental agents can also be included. The epidermis is an attractive tissue for such studies, as it is accessible and can stand as a model for epithelial cancers in general.

Transgenic mice overexpressing insulin-like growth factor 1 under the control of the keratin 5 (epidermal basal cell specific) promoter develop squamous papillomas, some of which convert to carcinomas (DiGiovanni *et al*., 2000), thus illustrating at least two of the major phases of tumour development, although metastases were not reported. In another model, mutant p53 was targeted to the epidermis of transgenic mice using a keratin -1 promoter, and their skin was treated with the classical promoter TPA. In control mice papillomas developed and regressed following cessation of treatment, whereas in the transgenic mice the papillomas progressed to metastatic carcinomas. The accelerated tumorigenesis was ascribed to increased genomic instability and abnormal amplification of centrosomes. Microarray analysis may be able to determine which genetic changes are linked to this ‘progressor’ phenotype. In another double (TGFα + v-fos) transgenic model generated by the same group, TPA also accelerated carcinoma progression, but additional genetic events were required and a high incidence of c-Ha-ras mutations (but not p53 mutations) were found in the papillomas. Interestingly, not all double transgenics show enhanced tumour formation, since in some systems loss of p53 can paradoxically be inhibitory, although this can be overcome by other specific genetic synergies or additional genetic changes (Wang *et al*., 2000) (**Table 1**).

Human papillomaviruses (HPVs) are DNA viruses that have been implicated as immortalizing agents which induce hyperplasia in cutaneous and mucosal epithelia, and they have a role in the development of certain human squamous cell carcinomas, e.g. cervical carcinoma. They act by interfering with the function of the *p53* and retinoblastoma (*Rb*) tumour-suppressor gene products since two of the viral proteins E6 and E7 can bind to these molecules. Recently, transgenic mouse models have been produced in which the HPV E6 or E7 genes have been delivered to specific epithelial cell populations to explore their role in more detail, and their interactions with other genes implicated in malignant progression (Eckert *et al*., 2000).

Table 1 Some transgenic models for epithelial neoplasia and preneoplasia

Transgene	Promoter	Result
IGF-1	Keratin 5	Skin papillomas and carcinomas
Mutuant *p53*	Keratin 1	Increased incidence of metastatic carcinomas with TPA
TGFα + v-*fos*	Keratin 1	Spontaneous papillomas, increased sensitivity to TPA promotion to carcinomas; endogenous H-ras activated
SV40 Tag	WAP	DCIS and progression to breast carcinomas in mice
TGFα	MMTV	Preneoplasias and cancers in rats
v-Ha-*ras* + c-*myc*	MMTV	Synergistic induction of breast carcinomas
Wnt-1	MMTV	Breast carcinomas, some metastases
Polyoma virus mT	MMTV	Rapid development of breast carcinomas
c-*neu*	MMTV	Breast carcinomas
SV40 Tag	C(3) 1	Prostate cancers, no metastases
SV 40 Tag	Probasin	Prostate cancers + metastases
c-*myc*	C(3)1	PIN but no carcinomas

Mice deficient in certain genes have also been produced to explore potential susceptibility factors. NAD (P)H:quinone oxireductase 1 (NQOI) is a flavoprotein involved in the detoxification of quinones and hence protects against their mutagenic effects. NQOI −/− mice treated with a classical two-stage carcinogenesis protocol (skin painting with benzo[*a*]pyrene followed by repeated applications of TPA) developed a much higher incidence of skin tumours than wild type mice, indicating that NQOI can act as an endogenous factor in protection against certain carcinogens. Similar studies with other candidate genes may one day explain why certain individuals exposed to high levels of carcinogens (e.g. cigarette smoke) may be more likely than others to develop cancers.

GASTROINTESTINAL TRACT TUMOURS

Colorectal cancers appear to arise as a result of a combination of activation of oncogenes and inactivation of tumour-suppressor genes – a scenario that is likely to be common to other tumour types also. It has been calculated that mutations in at least four or five genes are required to produce a fully malignant cancer. Although genetic changes may occur predominantly at ‘preferred’ stages of tumour evolution, it seems to be the accumulation of acquired defects rather than their chronological appearance that determines tumour behaviour (Cho and Volgelstein, 1992). It has long been known that certain malignancies are associated with particular chromosomal aberrations. More recently, nonrandom ‘loss of heterozygosity’ (i.e. allelic deletions of specific chromosomal regions) has proved a powerful pointer to the presence of tumour suppressor genes. This type of analysis led to the identification of the *DCC* gene (Deleted in Colon Carcinoma), whose product turns out to be a cell adhesion molecule important in intestinal cell differentiation. The gene (*APC*) for familial adenomatous polyposis (FAP) when mutated in the germ line is associated with the development of multiple benign colorectal tumours and similar somatic mutations have been found in sporadic colorectal cancers.

During the search for the *APC* gene, another gene was found which is also frequently mutated somatically in colorectal carcinomas – the *MCC* gene. Also, a mutational ‘hotspot’ has been found in the *p53* gene (which plays a crucial role in cell cycle regulation) in some human liver cancers that could be a consequence of exposure to the hepato-carcinogenic agent aflatoxin B_1 (Paraskeva and Williams, 1992). These observations show how classical epidemiology and cytogenetic analyses are being translated into an understanding at the molecular level of how our ‘nature and nurture,’ i.e. hereditary and environmental influences, may conspire to render us more or less susceptible to particular cancers. In addition, the accumulation of genetic alterations at a particular point in time may determine if the neoplasm is benign or malignant.

Spontaneously Arising Animal GI Tumours and Chemically Induced Tumours

Colorectal carcinomas are rare in rodents, although incidences of 30–40% have been recorded in rats with bacterial infections or acute colitis (both possible risk factors in humans). Occasional lymph node metastases, but not liver metastases, were found. Most chemical carcinogens, when administered to rodents by oral or other routes, induce tumours in the gut but also other sites. The most commonly used agents are dimethylhydrazine, dibenzanthracene, methylcholanthrene, heterocyclic amines, azoxymethane, *N*-methyl-*N*-nitro-*N*-nitrosoguanidine (MNNG) and *N*-methyl-*N*-nitrosurea (NMU). In all cases the incidences and rate of development are unpredictable, rendering the models unsuitable for general use. However, cell lines have been derived from some tumours, and where the primary hosts were an inbred

strain, the tumours can be passaged into genetically identical hosts (e.g. colon 26 in Balb/c mice, MCA38 in C57BL/6J mice, PROb in BDIX rats and CC531 in WAG/Rij rats). In this case, the growth of the tumours (and in some cases metastasis) can be more readily controlled, and the effects of various interventions more easily measured.

The Min Mouse Model

Min (Multiple Intestinal Neoplasia) is a mutant allele of the mouse *Apc* gene with a nonsense mutation at codon 850. Mice carrying this mutation, like humans, develop multiple intestinal adenomas (benign colorectal tumours), although their frequency is significantly influenced by 'modifier' genes such as *Mom-1* carried by different inbred strains, and can be increased by treatment with chemical carcinogens such as ethylnitrosourea (Moser *et al*., 1995). The female mice also develop breast cancers. This model provides an interesting system in which to study the role of *Apc* and modifier genes in initiation and progression of two major cancer types. A second model Apc1638N is also available in which tumour multiplicity is also modified by *Mom-1*, but several other X-ray responsive loci are also involved. In this strain the female animals develop ovarian carcinomas (van der Houven van Oordt *et al*., 1999).

Intervention and Therapy Studies

In addition to studying genetic modifiers, these models are also extremely useful for exploring the potential role of agents which might prevent cancers developing in genetically prone individuals, and possibly eventually in the general population if effective, safe dietary supplements could be found. The identification of upregulated levels of prostaglandins in colorectal and other cancers has led to the suggestion that inhibitors such as aspirin may be beneficial. Daily doses of aspirin reduce the numbers and sizes of polyps developing in the small intestine, but not the colon of Min mice. The Min mice have also been crossed with mice transgenic for the human carcinoembryonic antigen (CEA) gene to generate tumours expressing a human antigen. Such animals are ideal for testing CEA-directed immunotherapy (Thompson *et al*., 1997) since the target antigen is expressed on appropriate normal tissues in addition to the tumour, whereas in xenograft models only the tumours are 'positive.'

Xenograft Models

Many human GI tumours have been established as xenografts, either directly from clinical material or from cell lines, and some of the most commonly used are SW480, LS174T, KM12, HT29, HCT116 and COLO 320. In general, the tumours grow best when they are implanted in the correct anatomical location (the caecal wall) rather than subcutaneously. Although different congenitally immunodeprived hosts have been used, it is not clear if doubly or triply deficient mice are generally more susceptible to tumour growth and metastasis than the generally used athymic (T-cell deficient) mouse (**Table 2**).

Table 2 Colon carcinoma xenografts + metastasis models

Tumour	Injection site	Host	Metastases
WiDR	Spleen	Athymic mice	Liver
GX-39	Spleen	Athymic mice	Liver
GX-39	Intravenous	Athymic mice	Lung
LS174T	Intraportal vein	Athymic rats	Liver
LS174T	Spleen	Athymic mice	Liver
HT-29	Spleen	Athymic mice	Liver
HT-29	S.c.	SCID mice	Lung
TK3, TK-4, TK-9	Caecal wall	Athymic mice	Liver
HM-7	Spleen	SCID mice	Liver
C-1H	Spleen	SCID moce	Liver
LS180	Intraportal	Athymic mice	Liver, nodes

Metastasis Models

The commonest sites of metastasis of GI tumours are the liver and mesenteric lymph nodes. Tumours grown in the caecal wall are generally able to colonize these sites, while failing to spread from s.c. sites. This is technically demanding, and various 'short cuts' have been devised, notably the introduction of cells directly into the portal circulation via a mesenteric vein, or into the spleen, whence cells also rapidly enter the portal circulation. The spleen can be left *in situ* or removed a few minutes after injecting cells to avoid overgrowth of tumour at the primary site. These procedures have proved invaluable both for selecting cells with a higher propensity for metastasis by repeated cycling through the liver, and for testing therapeutic interventions or the effects of introducing genes into the cells by transfection prior to transplant.

LUNG AND BRONCHIAL CARCINOMA

In most Western countries, lung cancer is the main cause of cancer deaths, and even in Japan it has now overtaken stomach cancer as the most frequent malignant disease. In the last 50 years the death rates from cancer have increased by 200% in males and 300% in females; 90% of this is accounted for by smoking. The predominant type of cancer is adenocarcinoma, and it generally spreads to the contralateral lung, mediastinum, pleural cavity and lymph nodes.

In Vitro Models

In addition to a plethora of rodent and human tumour cell lines, a three-dimensional *in vitro* organ culture model for bronchial carcinoma has been designed using human bronchial mucosa organ cultures and lung cancer cell lines. This system offers opportunities for various *in vitro* investigations on therapeutic and diagnostic modalities of lung cancer, and invasion can also be quantified (Al-Batran *et al*., 1999).

Chemically Induced Tumours

Benign and malignant laryngeal cancers have been induced in hamsters and bronchogenic cancers in other species; urethane and PAHs are potent initiators of lung tumours in mice. Nicotine-derived nitrosamino ketone (NNK), a tobacco-specific carcinogen, induces lung cancers in rats by whichever route it is administered. These tumours have been examined for genetic alterations, and these have been found to include K-*ras* activation and loss of the *p16* and *Rb* tumour-suppressor genes. Alterations of these genes are also common in human lung cancer. Genetic linkage analyses to identify human lung cancer susceptibility genes is difficult owing to population heterogeneity and variable exposure to carcinogens. The mouse lung tumour model has become a valuable alternative in this search and also as a vehicle for chemoprevention studies.

Chemoprevention and Intervention Studies

A/J mice administered benzo[*a*]pyrene or the tobacco-specific carcinogen 4-(methylnitrosamino)-1-(3-pyridyl) butan-1-one (NNK) develop pulmonary adenomas. This model has proved useful in exploring the potential of compounds to inhibit carcinogenesis in the postinitiation period – which is what would be required for any realistic cancer intervention studies in humans. Myo-inositol and dexamethasone have been shown to reduce the formation of lung neoplasms in this model, and when coadministered there was an additive inhibitory effect.

Transplantable Models: Lewis Lung Carcinoma

One of the oldest and most widely used syngeneic transplantable tumours is the Lewis lung carcinoma (3LL) which grows in C57BL mice. It is highly malignant and metastatic. Although its natural primary site is the lung, it has been generally used as a model of lung metastasis. In common with many tumours, it grows well in the lungs following intravenous injection, and may also spread to the liver; it is also capable of metastasis from subcutaneous sites. It has featured in hundreds of publications testing agents as diverse as cytotoxic drugs, proteinase inhibitors, vaccines, vitamins, gene therapy and immunotherapy. Recently, it has also been used as a model of primary lung cancer with metastasis to mediastinal lymph nodes.

Xenograft Models

A wide variety of human lung carcinomas have been grown as xenografts in athymic mice, although generally at the s.c. site. Recently, intrapleural inoculation of cells was shown to result in a high incidence of lung tumours and lymphatic metastasis, compared with low take rates when cells were injected intravenously. An athymic rat lung cancer xenograft model has also been described, although since these animals have more residual immunity than athymic mice, preirradiation was necessary to enhance tumour growth. Metastasis to lymph nodes has been observed in these models. Although interesting, tumour growth quantitation is difficult and the animals can suffer from cachexia. With the development of green fluorescent protein- or genetically tagged cells, or polymerase chain reaction (PCR)-based methods to detect low numbers of human cells in mouse tissues, these problems may be resolved (Chishima *et al*., 1997).

BREAST CARCINOMA

Although the earlier detection of breast cancer through screening programmes and improvements in surgery and adjuvant therapy have improved survival rates, there are still around 15 000 deaths from this disease in the UK each year and 43 000 in the USA. This is due to the development of metastatic disease that is refractory to therapy. It is still the leading cause of death from malignant disease in Western women. The majority present with apparently localized disease, but many relapse owing to presence of occult micrometastases.

Changes within breast lobules, notably atypical lobular hyperplasia and lobular carcinoma *in situ* (LCIS) are generally recognized as risk markers for subsequent development of carcinoma. Ductal carcinoma *in situ* (DCIS) appears to predispose to cancer at the same site, whereas there is no evidence that invasive carcinomas arise directly from LCIS. However, it is still not clear whether all *in situ* carcinomas are inherently capable of evolving into malignant metastatic cancers, but in view of the heterogeneity observed within these lesions, it is unlikely. With an increasing number of cases of DCIS being identified by mammography, it is important for further analysis at the molecular level to try to define those most likely to progress.

Recently, a number of genetic alterations have been identified that are beginning to shed more light on the

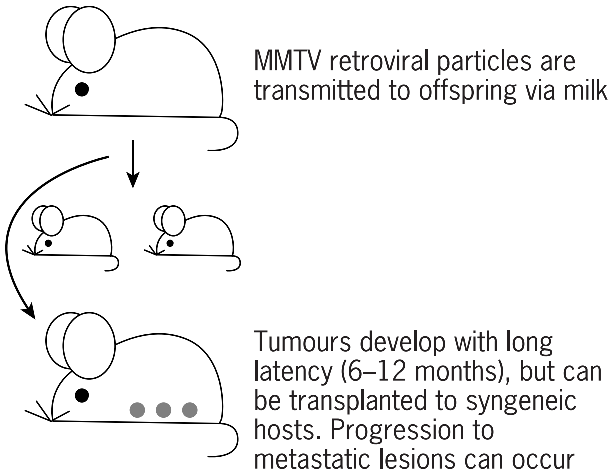
aetiology and progression of breast cancer. The identification of two genes (*BRCA1* and *-2*) associated with familial breast cancers may seem of little relevance to most cases, which are not genetically linked (see chapter on *Inherited Predispositions to Cancer*). However, by analogy with *APC* (see chapter on *Lower Gastrointestinal tract*) it is likely that their isolation and cloning will yield insights into the control of proliferation and differentiation of epithelial cells in the mammary gland. Secondly, overexpression of the proto-oncogene c-*erb*B-2 has been shown to be an independent prognostic indicator in breast cancer. Its presence in primary tumours has been linked with a higher probability of brain and visceral metastases, shorter survival and a poor response to therapy.

Breast cancer models will be discussed in other sections (see chapter on *Mammary Tumour Induction in Animals as a Model for Human Breast Cancer*), so in this chapter only a brief outline will be given. The reader is referred to two excellent special issues of journals: The *Journal of Mammary Gland Biology and Neoplasia* (1996) featured ‘Experimental Models of Development, Function and Neoplasia’ and a recent issue of *Oncogene* (2000) has been devoted entirely to ‘Mouse Models for Breast Cancer.’

Syngeneic Rat and Mouse Tumour Models

About 60–70 years ago, some of the first mouse tumour models were developed from inbred strains found to have a naturally high incidence of breast cancers. This was subsequently shown to be due to the transmission of the mouse mammary tumour virus (MMTV). The tumourigenicity is due in part to the activation of proto-oncogenes such as *Wnt-1* by proviral insertion into the host DNA. Although metastasis in the primary host is rare, when transplanted into syngeneic recipients, metastasis to lungs, nodes and viscera can be promoted by selection, producing useful experimental models, and the cells can also be readily grown *in vitro* (Barnett and Eccles, 1984). Human breast tumours show varying degrees of oestrogen responsiveness, and *in toto* the various MMTV mouse models span the spectrum from highly endocrine dependent (growing only during pregnancy and regressing following birth) to hormone-independent (**Figure 5**).

Rat mammary tumours may occur sporadically at low incidence and can be induced by the use of chemical carcinogens such as DMBA and NMU, and also by high doses of oestrogen (**Figure 6**). The primary hosts generally developed multiple lesions of varying malignancy and hormone dependence, and these proved useful for intervention studies with tamoxifen and other oestrogen antagonists. Metastases were again rare, and owing to the effects of the carcinogen, lung primary tumours



Oncogenesis is due to insertional activation, by the virus, of cellular oncogenes such as *Wnt-1*, *Wnt 3*, *Int2/FGF3*, *hst1/FGF4*, *Int-3*

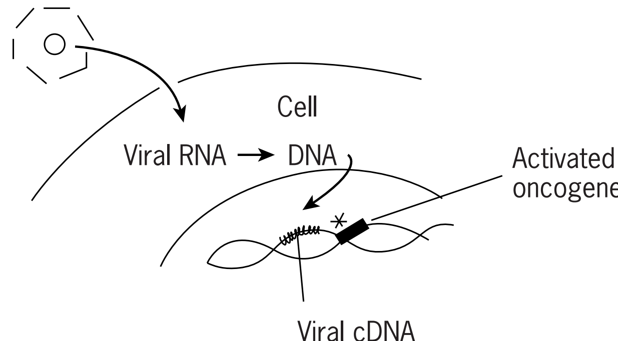


Figure 5 Mouse mammary tumour virus oncogenesis.

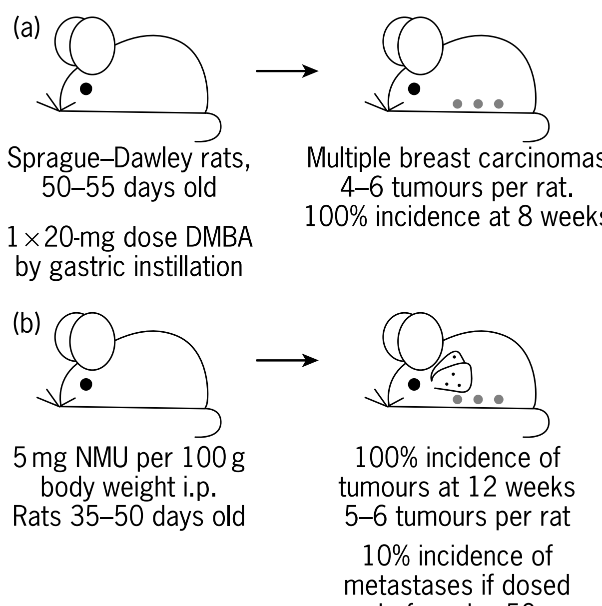

Figure 6 Rat mammary carcinogenesis. (a) ‘Huggins’ model; (b) NMU model.

were sometimes mistaken for secondary tumours. Again, these tumours could be transplanted and developed into useful models of hormone-dependent or independent growth and metastasis (Briand, 1983; Nicolson, 1988; Noble *et al*., 1975; Eccles *et al*., 1994). However, chemically induced tumours tend to have high levels of *ras* mutations, which are rare in human breast cancers, and since the human aetiology is complex (with a multiplicity of risk factors but no primary causative agent identified), it has been hard to model the natural history accurately. Now that genetic changes implicated in human breast cancer are emerging, it is possible to model these in rodents to study their effects.

Human Cell Lines and Xenografts

There are a relatively small number of commonly used human breast carcinoma cell lines, but these have been well characterized. The most popular is MCF-7, which is also reliably oestrogen sensitive, and generally only grows as a xenograft if the athymic mice (which have naturally low oestrogen levels) are hormonally supplemented. Other common cell lines are the MD Anderson (MDA) series, some of which (e.g. MDA MB 435) will metastasize from mammary fat pads in athymic mice. Breast carcinomas are not particularly easy to grow from clinical material (the success rate is around 30%), but this has been improved by the use of tissue fragments, co-inoculation with host fibroblasts and/or Matrigel and transfection of angiogenic cytokine genes into cell lines (Price *et al*., 1990). In addition, three-dimensional mammary primary culture models, as in other systems (e.g. skin and prostate), have proved invaluable for analysing important interactions controlling gene expression and differentiation (Ip and Darcy, 1996). Recently, breast cell lines which will metastasize to bone have been developed, which should prove very useful for studying this difficult clinical problem (Sung *et al*., 1997) (**Table 3**).

Transgenic Models and 'Knockouts'

Some excellent transgenic models of breast carcinoma have been developed which seem to mimic many aspects of human tumour biology including, in some cases, metastasis. The genes of interest (c-*erb*B-2, TGFα, c-*myc*) can be readily and specifically targetted to the mammary gland using breast specific promoters or by fusing genes to the long terminal repeat of the mouse mammary tumour virus. Both transgenic rat and mouse models have been established, and also a system in which cells from the mammary epithelium are removed, transfected with genes of interest using retroviruses and returned to the fat pad of the donor animal, avoiding the necessity for germ-line transduction (Edwards *et al*., 1996) (**Figure 7**). (See also chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*.) Some transgenic animals have been designed specifically to produce lesions, which mimic early-stage disease (DCIS) with the intention of studying determinants of cancer progression to invasive disease. Recently, targetted mutagenesis has been used to delete specifically the gene *Brca1* from the mouse mammary gland. *BRCA1* mutations are thought to be responsible for a significant proportion of familial breast cancers. The studies were complex because the homozygous 'knockout' mouse fails to survive, and the heterozygote does not develop tumours. However, if the second allele in these mice is mutated in the glands, they proceed to develop abnormalities and later mammary cancers, which, like their human counterparts, show increased genetic instability (Xu *et al*., 1999). This is still not a perfect model since in women loss of only one allele is

sufficient to confer a very high risk of developing breast cancer.

PROSTATE CANCER

Prostate cancer has the highest incidence of any non-cutaneous malignancy in the West, and is the second highest cause of cancer deaths in males in Europe and the USA (Foster *et al.*, 1999). The incidence is greater than 30% in men over 50 years and 80% in men over 80 years. The incidence is also steadily rising, and at diagnosis around 75% of patients have locally extensive or metastatic disease. In 1978, Isaacs *et al.* listed the ideal criteria for an animal model of prostate cancer, which could equally well be applied to most epithelial cancers. The list was comprehensive and included features such as morphological and biochemical profiles similar to human disease, slow growth, appropropriate sites of metastasis (lymph nodes and bone), hormone and drug responsiveness similar to humans, progression towards hormone independence, etc. For practical purposes, the cells should also be transplantable in syngeneic hosts, be able to grow *in vitro*, and should express markers such as prostate-specific antigen (PSA).

Rodent Models

The best known series of rat prostate tumours (the 'Dunning' model) was derived from a spontaneous tumour (R3327) which arose in a Copenhagen male rat in 1961.

It has subsequently spawned multiple sublines of varying hormone dependence, metastatic capacity and marker profiles which together mimic most aspects of the human disease spectrum. It is probably the most widely used model available, and has been used to test antiandrogens, immunotherapy and vaccines, and many other novel therapies, and most recently has been used to discover important tumour- and metastasis-suppressor genes including *KAI1* and *MKK4/SEK1* (Tennant *et al*., 2000). It has also been used to develop a bone metastasis model. A second rat model system originated in a closed colony of Lobund–Wistar rats maintained by Dr Morris Pollard. This is the only rat strain that is inherently predisposed to spontaneous metastasizing hormone-sensitive prostate carcinomas. These animals have been widely used for intervention studies since they show progression from benign lesions (prostatic intraepithelial neoplasia (PIN) to fully malignant, hormone-independent tumours (Bostwick *et al*., 2000).

Xenograft Models

To date, about 25 xenograft models of human prostate cancer have been described, although the most commonly used are the PC3 (M), DU145 and LNCaP since these (unlike some other xenografts) also grow *in vitro*; of these only the latter is androgen sensitive (**Table 4**). Human prostatic carcinoma cells are generally very slow growing, and this has hampered their establishment as models, with only about 5% of implants yielding progressively growing, transplantable tumours (van Weerden and Rominj, 2000). Again, with the appreciation of the importance of orthotopic sites of growth, models which, when grown in the prostate, will disseminate to lymph nodes and other sites including bone have now been developed (Pettaway *et al*., 1996; Zhau *et al*., 2000).

Transgenic and Reconstitution Models

Several transgenic models have been developed using oncogenes such as those derived from the SV40 virus and polyoma virus, *ras* and *myc*. Prostate-specific gene expression has been achieved using regulatory elements of the rat probasin gene, the PSA antigen and the androgen-responsive rat *C3* gene (reviewed in Green *et al*., 1998). One of the most useful models has been the TRAMP (transgenic adenocarcinoma mouse prostate) in which rat probasin promoter elements drive expression of SV40

large T antigen. The transgenic mice develop PIN by 8–12 weeks of age that progress to adenocarcinomas with distant metastases by 24–30 weeks of age. Cell lines have been derived from tumours at various stages of progression, and since the mice are inbred, the tumours can be transplanted to new hosts.

A mouse prostate reconstruction (MPR) model has also been developed over the last decade. Fetal urinogenital sinus (UGS) tissue is dissected and can be separated into epithelial and mesenchymal cells. These cells can then be infected in short-term cultures with retroviruses carrying genes of interest prior to reimplantation into syngeneic mice. The MPR model was one of the first transgenic organ systems to study the effects of specific genes or gene combinations within the context of the prostate *in vivo* (Thompson *et al*., 2000). The cells do not have to be cultured *in vitro*, eliminating the selection of cell types with the capacity to grow under these artificial conditions (**Figure 7**). The effects of many genes have been studied, including TGFβ, *ras* and *myc*. The cells are effectively genetically 'tagged' by the unique retroviral insertion sites, allowing clonal evolution to be followed as the tumours progress.

Cells can also be derived from genetically mutated mouse strains to measure their susceptibility to oncogenesis. Ras + myc transduction leads to the development of localized tumours in normal mice, but when UGS was derived from p53 'knockout' mice, the resulting tumours gave a very high incidence of bone and soft tissue metastases. Early-passage cell lines derived from primary tumours and metastases in the same animal can be analysed for differential gene expression, which might be related to progression. This approach has identified several important candidate genes, including caveolin 1, which has been found to be overexpressed in both mouse and human prostate carcinoma metastases and to potentiate survival of tumour cells in the absence of androgens.

CONCLUSIONS AND PERSPECTIVE

Over the last several decades, *in vitro* and *in vivo* models of increasing sophistication have been designed to assist in the elucidation of the nature of cancers. Epithelial cancers, because of their major social and economic importance, have been particularly well represented. While it is clear that no single model will suffice to encompass all aspects of the human cancer counterpart, there are now a great variety of systems which together provide most of the necessary tools for studies of basic cancer biology, the underlying genetic and molecular mechanisms, tumour–host interactions and therapeutic interventions. For most of the major cancer types, we have available both rodent and human tumour cell lines, and in some cases panels of cells ranging from normal through immortalized to fully malignant. Increasingly complex *in vitro* models are being devised whereby tumour cells can be made to interact with or invade normal tissues, bridging the *in vitro–in vivo* divide. In terms of *in vivo* models, there are a wide range of syngeneic and xenogeneic tumours available, and the increasing use of orthotopic (anatomically correct) sites of implantation, and of 'tagged' cells for sensitive detection of disseminated cells has enhanced our ability to study and treat metastatic disease.

Finally, the most dramatic breakthroughs have come from the development of genetically engineered mice in which oncogenes targeted to specific tissues, or knockout of suppressor genes has led to transgenic strains with high incidences of cancers. These can be used for primary intervention/prevention studies or, if on a suitable inbred genetic background, can yield new transplantable tumour models for studies of progression. Furthermore, the crossing of transgenic strains enables interactions between oncogenes, suppressor genes and modifier genes to be explored, since it is clear that full malignant conversion requires cooperation of multiple genetic and epigenetic factors. Once the models which best mimic human cancers have been defined (and this must await a fuller understanding of the latter), we will have ideal systems in which to test new therapies specifically targeting the underlying molecular abnormalities, and ultimately preventative treatments which will short-circuit the oncogenic process in those at risk due to hereditary factors or lifestyle.

Institute for Molecular Medicine, Huntington Beach, CA, USA

CONTENTS

- Introduction
- Haematopoiesis
- Role of some Tumour Viruses in Malignant Transformation
- Oncogenes and Tumour-suppressor Genes
- Models for Haematological Pathogenesis
- Principles of Haematological Tumour Models and their Application in Haematology
- Some Problems of Animal Models
- Clinical Relevance of Experimental Results

INTRODUCTION

Carcinomas account for approximately 90% of human cancers, whereas malignancies that arise from blood-forming cells and from cells of the immune system, leukaemias and lymphomas, account for about 8% of malignancies in humans. Acute leukaemia is the most common malignancy in children, affecting approximately 2000 children each year in the United States. The lymphomas are the seventh most common cause of death from cancer in industrialized countries, with more than 40 000 new cases annually in North America.

The leukaemias and lymphomas provide particularly good examples of the relationship between defective differentiation and malignancy. Since all of the different types of blood cells are derived from a common stem cell in the bone marrow, the descendants of these cells form the various lymphoid cell lineages by commitment to specific differentiation pathways. For example, some cells differentiate to form erythrocytes whereas others will differentiate to lymphocytes, platelets, macrophages, granulocytes, etc. Cells of each of these types undergo several rounds of division as they differentiate, but once they become fully differentiated, cell division ceases. In contrast, leukaemic or lymphoma cells fail to undergo terminal differentiation. Instead, they become arrested at early stages of maturation, and they retain their capacity for proliferation and continue to reproduce (**Figure 1**).

Compared with other cancers, haematological cancers are well disseminated near their inception, and they are capable of being transported throughout the body in the lymph and blood. Although they are disseminated, the leukaemias and lymphomas still show certain preferences of organ colonization and growth (**Figure 2**). Some of these malignancies, such as chronic lymphocytic B cell leukaemias and small-cell lymphocytic lymphomas, are found extensively in the liver, whereas others (acute lymphocytic T cell leukaemias, acute lymphocytic B cell leukaemias and prolymphocytic B cell leukaemias) are found predominantly in the bone marrow, and a few (polylymphocytic B cell leukaemias and immunoblastic sarcomas) are found in both compartments.

HAEMATOPOIESIS

There are basically three types of cellular elements present in the blood: red blood cells (erythrocytes), white blood cells (leucocytes), and platelets (thrombocytes). Since platelets do not contain a nucleus, sometimes they are not considered true cells. Each of these cells has its own function, differs morphologically from the others and has a lifespan characteristic for that particular cell type. In normal healthy people the destruction and production of lymphoid cells is balanced and, therefore, the number of cells present in the blood at any particular time is relatively constant. In the same way that ontogenesis occurs for the whole organism, the blood cells must also undergo certain stages of maturation to carry out their intended functions. In a healthy person, only the mature adult cells are found in the peripheral blood, whereas in many diseases, immature and abnormal forms of the cells may be present.

During human development there are changes in the sites of production, type and distribution of haematopoietic

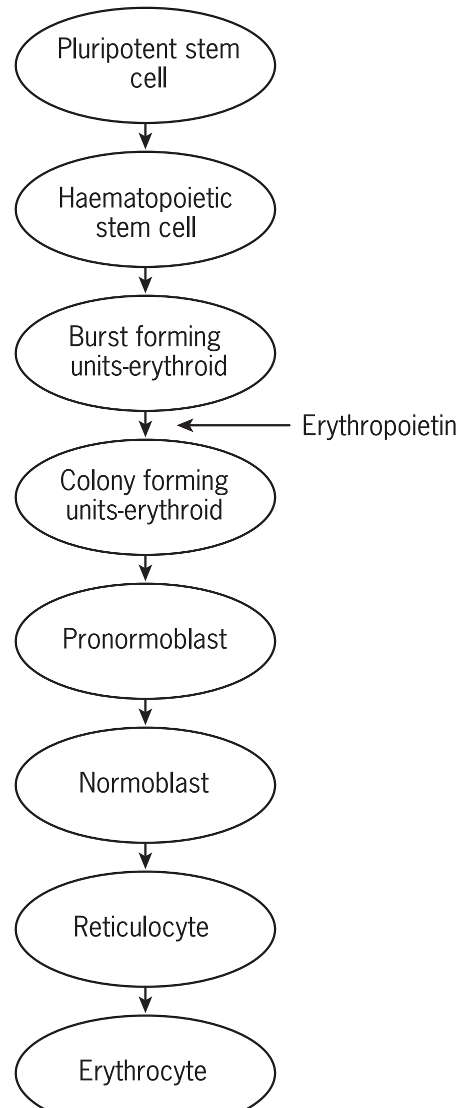

Figure 1 Stimulation of erythropoiesis by erythropoietin. Erythropoietin stimulates growth and differentiation of erythroid progenitor cells in the regulation of red cell production. Simplified scheme of erythroid precursors.

cells. In the fetus, haematopoiesis takes place at various intervals in the liver, spleen, thymus, bone marrow and lymph nodes. Within 2 weeks of embryonic life, primitive red blood cells are produced in the yolk sac. By the second month, granulocytes and megakaryocytes begin to appear and the liver and spleen become primary sites of cell development. Lymphocyte production starts at approximately the fourth month and monocytes are produced by the fifth month. At the end of the third trimenon the bone marrow becomes the primary organ of haematopoiesis. At birth, and continuing into adulthood, major blood cell production is confined to the bone marrow and is known as medullary haematopoiesis.

In children, the haematopoietic bone marrow (red marrow) is located in the flat bones of the skull, clavicle, sternum, ribs, vertebrae and pelvis and also in the long bones of the arms and legs. After puberty and during the adult life, the red marrow is normally confined to the flat bones (skull, clavicle, sternum, ribs, vertebrae, pelvis and the proximal ends of the long bones femur and humerus). The remaining marrow space is occupied by fat cells (yellow marrow), which can be replaced by haematopoietic cells under certain situations of intensive stimulation.

Haematopoiesis is tightly controlled by numerous cytokines/growth factors. In certain disease states, such as haemolytic anaemia, the bone marrow is unable to produce sufficient numbers of haematopoietic cells, and the secondary organs of haematopoiesis, such as liver and spleen, become reactivated as sites of extramedullary haematopoiesis. However, in haematological malignancies the primary and secondary organs of haematopoiesis may be infiltrated with malignant cells, resulting in a loss of the haematopoietic capacity.

Lineage-specific responses, such as increase of the number of erythrocytes during hypoxia or neutrophil production during bacterial infection, are governed by three generic categories of cellular competencies: (1) the capacity of haematopoietic stem cells to give rise to progenitors committed to a particular haematopoietic lineage; (2) the capacity of progenitors of a lineage to give rise to a differentiated progeny; and (3) the ability of the organism to perceive environmental stimuli by generating both extracellular and intracellular signals that either permit or repress these pathways of differentiation.

The production of blood cells in haematopoietic tissues involves the establishment, in early embryogenesis, of pluripotential haematopoietic stem cells. These cells are capable of a high degree of self-replication and have not yet committed themselves to the production of any specific lineage. Haematopoietic stem cells remain in residence in haematopoietic niches for the entire life of the host. They can also be removed from the original carrier and establish haematopoiesis for another lifetime in recipient organisms that have been lethally irradiated. Therefore, stem cells are (1) pluripotential and (2) can reconstitute the haematopoietic system because of their capacity for both self-renewal and production of committed progeny. Although committed progenitor cells cannot be distinguished morphologically, they can be quantified *in vitro*, because in semisolid medium (e.g. soft agar or methylcellulose) they form colonies containing morphologically recognizable, differentiated progeny cells. Committed progenitor cells are immediate precursors of blast forms, the earliest morphologically recognizable precursor cells of the stem cell lineage. The cell progeny of the blast forms, such as erythroblasts, can be identified morphologically and undergo predictable phenotypic changes as they progressively acquire attributes of the functional, terminally differentiated cell.

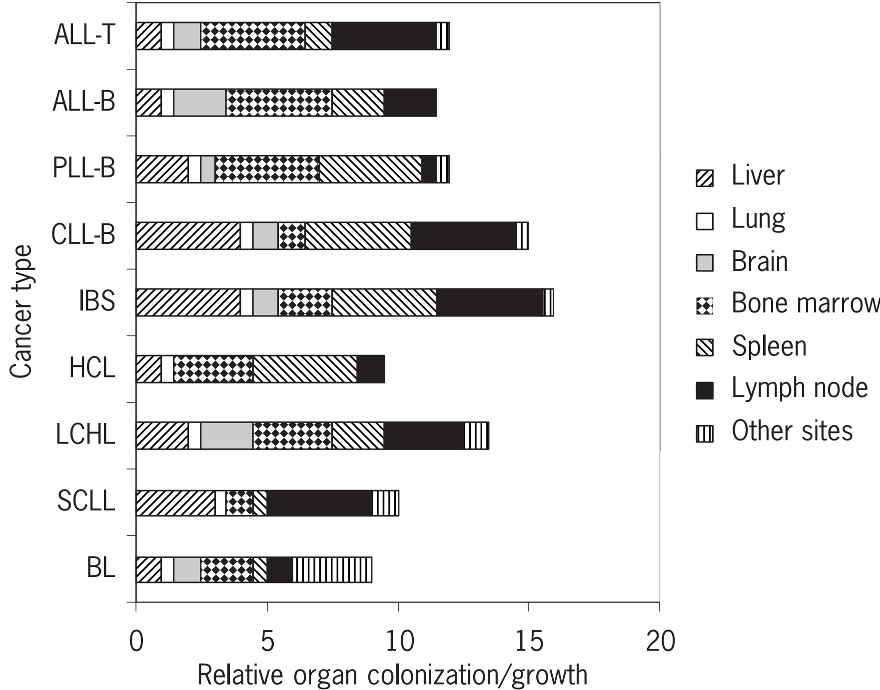

Figure 2 Organ preference of colonization/growth of selected human leukaemias and lymphomas. Organ colonization is scored as follows: 0, none; 0.5, organ sometimes involved; 1, organ involved; 2, organ moderately involved; 3, organ heavy involved; 4, organ replacement by disease. ALL-T, acute lymphocytic T cell leukaemia; ALL-B, acute lymphocytic B cell leukaemia; PLL-B, prolymphocytic B cell leukaemia; IBS, immunoblastic sarcoma; HCL, hairy cell leukaemia; LCHL, large cell histiocytic lymphoma; SCLL, small cell lymphocytic lymphoma; BL, Burkitt lymphoma. (From Nicolson, 1988, *Biochimica et Biophysica Acta*, **948**, 175–224.)

In the normal adult, all of these steps of replication and maturation take place exclusively in the bone marrow, an environment that provides growth factors, growth inhibitory factors, differentiation factors and adhesion molecules that aid in the retention, survival and growth of stem cells and progenitors in that particular niche. In the past 30 years, many factors involved in regulating growth and differentiation of haematopoietic cells in the bone marrow have been identified, usually in mouse models prior to their discovery in human systems. It should be recognized that murine models are highly relevant to human haematopoietic physiology. For example, virtually all *in vitro* assays for human haematopoietic progenitor cells were derived from similar methods established using murine cells. In fact, the first clear evidence that hematopoietic stem cells exist was derived from the seminal studies of Till and McCulloch (1961).

Current models of haematopoiesis propose that uncommitted pluripotent stem cells in the bone marrow maintain the ability to proliferate, reproduce themselves and differentiate. These stem cells are also able to repopulate the bone marrow after lethal damage and reconstitute normal haematopoiesis in the recipient organism. The first step of differentiation divides into lymphoid stem cells and haematopoietic stem cells, which are still considered multipotential cells. The haematopoietic stem cell is the precursor for red cells, granulocytes, monocytes and megakaryocytes (platelets). Progression of the multipotential cells to unipotential stem cells occurs through stimulation by various environmental factors within the different compartments of the organism. For example, the lymphocyte precursor or lymphoid stem cell leaves the bone marrow and undergoes differentiation into B lymphocytes in the lymph nodes or T lymphocytes in the thymus. In many cases the differentiation signals responsible have been identified. In the case of the primitive red blood cells that have been termed burst forming unit-erythroid cells that differentiate into colony-forming erythroid units, this occurs under the influence of the differentiation/growth factor erythropoietin (**Figure 1**). Similarly, colony-forming cells that are driven by specific differentiation/growth factors can be found for eosinophils, megakaryocytes, monocytes or granulocytes in response to Eos colony-stimulating factor (CSF), macrophage colony-stimulating factor (M-CSF), thrombopoietin, granulocyte colony-stimulating factor (G-CSF) or macrophage/granulocyte colony-stimulating factor (GM-CSF), respectively.

During the differentiation and maturation of haematopoietic stem cells, the cells undergo considerable changes in cell structure, size and shape. Progression from one stage to another does not appear to have discrete boundaries, but the expression of different cell surface molecules allows distinction between different precursor stages. In addition, metabolic pathways, cytoplasmic contents and nuclear chromatin structure differ between the different stages and are dependent on the committed lineage.

The lineage-specific differentiation of haematopoietic cells is determined to a large degree by specific haematopoietic growth factors and their cellular receptors. Once these haematopoietic growth factors bind to their receptors, specificity is mediated by the specific activation of their subsequent intracellular signalling pathways. This permits only a limited number of cells at certain differentiation stages to respond to the growth factors in the cellular environment. This ability to detect differentiation/growth factor signals can be introduced into non-haematopoietic cells by gene transfer of specific receptors (Roussel *et al*., 1987). Most growth factors interfere with more than one step of progenitor cell replication and cellular differentiation. In normal cells, replication and differentiation occur simultaneously. For example, the growth/differentiation factor G-CSF can stimulate growth of neutrophil progenitors and precursor cells, but this factor can also stimulate differentiation of these cells into mature neutrophils. Hence investigating and interpreting the actions of haematopoietic growth/differentiation factors can be difficult. Although there are additional limitations, such as unusual expression and availability of signalling proteins, our current understanding of the mechanisms of haematopoietic growth/differentiation factors has been achieved through the use of various models of transformed or leukaemic cell lines.

The control of haematopoiesis requires not only stimulation of cell proliferation and directed differentiation, but also tight regulation of its inhibition. Mitogenesis can be inhibited by various inhibitory factors, such as transforming growth factor-β (TGF-β). This antiproliferative factor interferes with tumour-suppressor gene products, such as Rb protein inhibiting the cell cycle progression from G_1 to S phase during the proliferation of progenitor cells (Laiho *et al*., 1990; Zentella *et al*., 1991). In addition, TGF-β can suppress the expression of growth factor receptors, such as the receptors for G-CSF, GM-CSF and interleukin-3 (IL-3) (Musso *et al*., 1990; D'Angeac *et al*., 1991). Other inhibitory factors of haematopoietic growth/differentiation include IL-4, IL-10, prostaglandins, interferon alpha and gamma (IFNα and IFNγ) and ferritin. (See also chapters on *Signalling by Cytokines* and *Signalling by TGF beta*.)

The ability of haematopoietic stem cells to undergo haematopoietic growth/differentiation in specific environmental compartments has been known for some time, but the mechanisms involved in this localization or 'homing' required a better understanding of adhesion molecules and their organ-specific distributions, mechanisms and activities. For example, it was known for some time that donor stem cells can be intravenously infused, but they repopulate only haematopoietic compartments in the bone marrow where they interact with stromal cells and then undergo further replication, proliferation and differentiation.

The organ-specific adhesive interactions involved in haematopoietic growth and differentiation are mediated by various types of adhesion molecules at the cell surface of haematopoietic cells, such as integrins and CD44, and their ligands on host organ stromal cells and their extracellular matrix that contain proteoglycans, heparan sulfate, fibronectin and vitronectin, among other molecules (Long, 1992). Adhesive interactions of circulating cells are discussed elsewhere in this section and the reader is referred to the relevant chapters (*Tumour Metastasis Models and Models for Tumour Cell–Endothelial Cell Interactions*). The expression of adhesion molecules at the haematopoietic cell surface is closely related to cell activation by various soluble growth factors or interleukins. Many interleukins or CSFs can modulate the expression of adhesion molecules and therefore interfere with the adhesive properties of stem cells at various stages of differentiation. This in turn, is an important point of hematopoietic regulation and lineage specific differentiation. In addition to the organ-specific expression of adhesion ligands, some CSFs or growth factors, such as GM-CSF and TGF-β1, can bind to extracellular matrix components resulting in localized regulatory activity of these factors (Mooradian *et al*., 1989).

ROLE OF SOME TUMOUR VIRUSES IN MALIGNANT TRANSFORMATION

Tumour viruses have been extremely important as models for cellular and molecular investigations of malignant cell transformation, and in some specific cases they appear to be involved in the formation and progression of human haematological malignancies (**Table 1**). The relatively small size of their genomes has allowed the discovery of various viral genes or oncogenes that have cellular homologues that play important roles in cell signalling and regulation of cell proliferation, survival and growth. Tumour viruses of six different families are capable of causing malignant transformation of mammalian cells, and one of the five DNA tumour viruses and the single known RNA tumour virus are important in haematological malignancies either as co-carcinogens or complete carcinogens. For example, the Epstein–Barr virus (EBV), which belongs to the Herpes virus group, is involved in the induction of Burkitt lymphomas or B cell lymphomas in AIDS patients, and the human T-cell lymphotropic virus (HTLV-1) is related to the appearance of adult T-cell

Table 1 Viruses associated with human malignancies

Virus group	Virus	Malignancy
DNA viruses		
Herpesviruses	Ebstein–Barr virus	African Burkitt lymphoma Nasopharyngeal carcinoma
Adenoviruses	Rarely in humans	
Hepadnaviruses	Hepatitis B virus	Hepatocellular carcinoma
Papovaviruses, Papillomaviruses	Human papillomaviruses (HPV 5, 8, 16, 18, 31, 33)	Squamous cell carcinoma Cervical carcinoma
Polyoma/SV40	Polyoma	Not in humans
RNA viruses		
Retroviruses	Abelson murine leukaemia virus (ALV)	Not in humans
	Moloney murine leukaemia virus (Mo-MLV)	Not in humans
	Human T cell lymphotropic virus type I (HTLV-1)	Adult T cell leukaemia
	Human T cell lymphotropic virus type II (HTLV-2)	Hairy T cell leukaemia
	Rous sarcoma virus (RSV)	Not in humans
	Avian erythroblastosis virus (AEV)	Not in humans

The retroviral group contains various examples of tumour viruses that do not directly cause malignancies in humans, but this group has contributed significantly to the discovery of various cellular oncogenes.

leukaemias. EBV is able to transform human B lymphocytes in culture, but the mechanism of this transformation remains incompletely understood. Multiple gene changes appear to be required to induce transformation, and the presence of a transformation-related viral gene may be only the first step in a multistep genetic process resulting in malignancy. Other viruses are also related to malignant transformation of haematological cells. For example, HTLV-1 is thought to be one of the causative agents of adult T cell lymphomas, whereas another related retrovirus (HTLV-2) is associated with the relatively rare formation of hairy T cell leukaemias. As a third virus from this group, HIV-1 does not appear to directly cause cancers, but it is likely to be responsible for the higher incidence of malignancies in AIDS patients, such as lymphomas or Kaposi sarcomas, possibly as a consequence of immunosuppression and loss of immune surveillance. Papillomaviruses, polyoma/SV40 viruses and adenoviruses appear to be important in certain malignancies, especially those involving certain epithelial cells, and can induce cell transformation by a common pathway that includes the alteration of cell cycle regulation by interfering with the key nuclear suppression proteins Rb and p53. (See also chapters on *Human DNA Tumour Viruses* and *RNA Viruses*.)

ONCOGENES AND TUMOUR-SUPPRESSOR GENES

Oncogenes and tumour-suppressor genes are large groups of genes that can together cause or contribute to the abnormal behaviour of malignant cells (**Table 2**). Suppressor genes were originally identified as genes whose expression was related to the suppression of tumour formation or progression. Elevated expression or uncontrolled activity of oncogene products or their normal cellular gene counterparts or proto-oncogene products can result in excess proliferation of tumour cells or inhibition of their differentiation to terminal phenotypes and cell death, whereas loss of function or expression during malignant transformation is characteristic for tumour-suppressor gene products. Oncogenes and suppressor genes related to malignant transformation have been identified in certain haematological malignancies, and some examples will be described in the following sections.

Oncogenes

The first well characterized example of oncogene activation by chromosome translocation was the c-*myc* oncogene involved in human Burkitt lymphomas and mouse plasmocytomas, which are malignancies of antibody-producing B lymphocytes. Both of these malignancies are characterized by chromosome translocations involving the genes that encode immunoglobins. For example, virtually all Burkitt lymphomas have translocations of a fragment of chromosome 8 to one of immunoglobulin gene loci on chromosome 2, 14 or 22. The fact that the immunoglobulin genes are actively expressed in these tumours suggested that the translocations activate a proto-oncogene from chromosome 8 by inserting it into the immunoglobulin loci. This possibility was investigated by analysis of tumour DNAs with probes for known oncogenes, leading to the finding that the c-*myc* proto-oncogene was at the chromosome 8 translocation breakpoint in Burkitt

Table 2 Oncogenes and tumour-suppressor genes involved in haematological malignancies and their proposed cellular functions

Type	Name	Malignancies in humans	Cellular function of gene product
Oncogenes	*abl*	Chronic myelogenous leukaemia Acute lymphocytic leukaemia	Nonreceptor protein tyrosine kinase
	Bcl-2	Follicular B cell lymphoma	Regulation of apoptosis
	DEK-CAN	Acute myelogenous leukaemia	Transcription factor
	E2A/pbx1	Acute lymphocytic leukaemia	Transcription factor
	ErbA	Avian erythroblastosis	Thyroid hormone receptor
	ErbB	Avian erythroblastosis	Receptor protein tyrosine kinase (growth factors)
	ets	Avian erythroblastosis	Transcription factor
	evi	Acute myelogenous leukaemia	Transcription factor
	fms	Stem cell leukaemia	Receptor protein tyrosine kinase
	Gp55 SFFV	Erythroleukaemia	Receptor ligand
	Hox gene family	Acute T cell lymphoma Myeloid leukaemias	Regulation of apoptosis Transcriptions factors
	IL-3	Pre B cell leukaemia	Receptor ligand
	lyl	Acute T cell lymphoma	Transcription factor
	mpl	Myeloproliferative leukaemia	Receptor protein tyrosine kinase
	Myb	Avian myelocytoblastosis	Transcription factor
	myc	Burkitt lymphoma	Transcription factor
	PML/RARα	Acute promyelocytic leukaemia	Retinoic acid receptor
	rasN	Acute myelogenous leukaemia Acute lymphocytic leukaemia	GTP-binding protein
	rel	Non-Hodgkin lymphomas	Transcription factor
	scl	Acute T cell lymphoma	Transcription factor
	tal	Acute T cell lymphoma	Transcription factor
	ttg	Acute T cell lymphoma	Transcription factor
Tumour-suppressor genes	*Rb*	Chronic megaloblastic leukaemia	Cdk4/cyclin D-dependent regulation of G_1 cell cycle phase
	INK4	Leukaemias	Cdk4/cyclin D regulation of G_1 cell cycle phase
		Lymphomas	
	p53	Leukaemias Lymphomas	Cdk cell cycle inhibitor p21 Apoptosis induction by DNA damage
	tan-1	Acute lymphocytic leukaemia	Receptor ligand

lymphomas. The translocations inserted c-*myc* into an immunoglobulin locus, where it was expressed in an unregulated manner. Such uncontrolled expression of the c-*myc* gene, which encodes a transcription factor normally induced in response to growth factor activation, is sufficient to drive cell proliferation and contribute to tumour development.

Translocations of other proto-oncogenes frequently result in rearrangement of coding sequences, leading to the formation of abnormal gene products. A prototype of this process is the translocation of the *abl* proto-oncogene from chromosome 9 to chromosome 22 in chronic myelogenous leukaemia forming the morphologically characteristic Philadelphia chromosome. This translocation leads to fusion of *abl* with its translocation partner, the *bcr* gene. The result of this gene fusion is production of a Bcr/Abl fusion protein in which the normal amino terminus of the Abl proto-oncogene protein has been replaced by Bcr amino acid sequences. The fusion of Bcr sequences results in aberrant activity and altered subcellular localization of the Abl protein tyrosine kinase, an important event leading to cell transformation.

Although most oncogenes stimulate cell proliferation, the oncogenic activity of some transcription factors results from inhibition of cell differentiation. For example, thyroid hormone and retinoic acid induce cell differentiation in a variety of cell types. These hormones diffuse through the plasma membrane and bind to intracellular receptors that act as transcriptional regulatory molecules. Mutated forms of the retinoic acid receptor (PML/RARalpha) can act as oncogene proteins in chicken erythroleukaemia and human acute promyelocytic leukaemia cells, respectively. The mutated oncogene receptors appear to interfere with the action of their normal proto-oncogene homologues,

thereby blocking cell differentiation and maintaining the leukaemic cells in an active proliferating state. As a consequence of this knowledge, high doses of retinoic acid can overcome the effect of the PML/RARalpha oncogene protein in acute promyelocytic leukaemia cells and induce their differentiation. Therefore, patients with this type of leukaemia can be treated effectively by administration of high doses of retinoic acid, which can induce differentiation and block continued cell proliferation. Such treatment with retinoic acid results in remission of the leukaemia in those patients, although this favourable response is temporary and patients eventually relapse with retinoic acid-resistant leukaemia. The use of this treatment is thus of substantial benefit in the initial treatment of acute promyelocytic leukaemia, providing the first example of a clinically useful drug targeted against an oncogene protein (**Figure 3**).

Another example of the role of differentiation in development of haematological malignancies involves the E2A gene products, E12 and E47, which are critical for proper early B cell development and commitment to the B cell lineage. Loss of E2A activity also results in a partial block at the earliest stage of T cell lineage development. The E2A gene products play a role early in thymocyte development that is similar to their function in B cell lineage determination. Furthermore, the lack of E2A gene products can result in the development of T cell malignancies, and it has been proposed that E2A inactivation is a common feature of a wide variety of human T cell proliferative disorders, including those involving the E2A heterodimeric protein partners tal-1 and lyl-1. The tal oncogene proteins are phosphorylated exclusively on serine and act as a substrate for the mitogen-activated signaling protein kinase ERK-1, resulting in alterations in DNA-binding affinity and modifications of their transcriptional activities (Yunis and Tanzer, 1993; Prasad and Brandt, 1997). Another example is the *HOX11* proto-oncogene that is normally expressed in embryogenesis where it directs the synthesis of the lymphoid cells in the spleen. In adult tissues, HOX11 expression is silenced by an unknown mechanism. Aberrant expression of HOX11 occurs in T cell acute lymphoblastic leukaemia, where it is thought to be involved in T cell immortalization. The *HOX11* gene may be repressed in normal T cells and erythroid cells by the action of negative elements which may be deleted or mutated in leukemia cells (Brake *et al*., 1998). Other members of the *HOX* gene family may be also involved in haematopoietic cell differentiation where they act as transcriptions factors (Crooks *et al*., 1999; Daga *et al*., 1999).

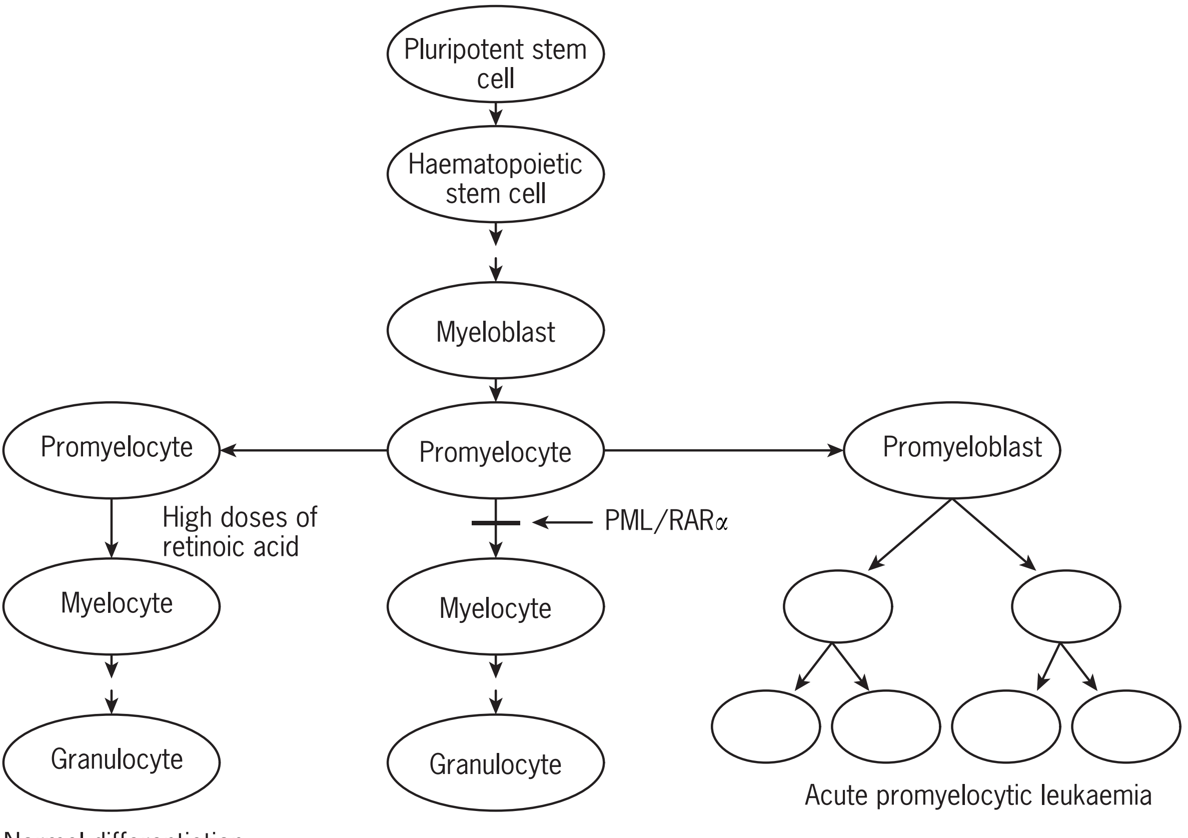

Figure 3 Pathogenesis of acute promyelocytic leukaemia and its treatment with high doses of retinoic acid.

Tumour-suppressor Genes

A different mechanism of abnormal tumour cell growth and survival is the loss of genes or gene products that regulate cell proliferation and programmed cell death (apoptosis). For example, the *bcl-2* oncogene product is involved in the regulation of apoptosis, but its generation by chromosome translocation with subsequent abnormal amplification results in protection against programmed cell death and formation of lymphomas. Abnormal Bcl-2 expression inhibits apoptosis and maintains cell survival leading to reduced environmental dependence on tumour cell growth and survival, such as that found in lymphomas that are growth stimulated by their organ factors found in their environment.

Inactivation or lost expression of tumour-suppressor genes results in the loss of negative regulators of cell proliferation or programmed cell death. The classical example for tumour-suppressor genes is the retinoblastoma *Rb* gene, which is involved in cell cycle regulation. Instead of acting only in haemotological malignancies, most of the tumour-suppressor genes are involved in many types of human tumours. For example, INK4, which regulates cell cycle progression from G_1 to S phase, is often lost in leukaemias and lymphomas, but also in melanomas, brain tumours and carcinomas. This gene encodes the Cdk inhibitor p16 that normally regulates Rb inactivation by the Cdk4/cyclin D kinase necessary for the release of G_1 cell cycle progression. Therefore, inactivation of INK4 results in increased activity of Cdk4/cyclin D complexes, hyperphosphorylation of Rb and loss of an important cell cycle restriction point. (See also chapter on *Regulation of the Cell Cycle*.)

DNA damage normally causes induction of the p53 gene product that activates transcription of the Cdk inhibitor p21. This inhibitor blocks cell cycle progression and DNA replication. Reduced expression or loss of function of p53 therefore prevents DNA damage-induced cell cycle arrest with a subsequent accumulation of mutations and genetic instability in these cells. In addition, p53 regulates DNA damage-induced apoptosis and inactivation of this tumour-suppressor gene product can result in resistance of transformed cells against radiation, chemotherapy, growth factor deprivation or hypoxia, treatments that normally induce apoptosis.

MODELS FOR HAEMATOLOGICAL PATHOGENESIS

Haematological malignancies provide several particularly good examples of the relationship between cell differentiation, uncontrolled proliferation and malignant transformation. As mentioned above, infections with the HTLV-1 virus can induce the formation of acute T cell leukaemia (ATL). Since the molecular mechanisms of the HTLV-1-induced ATL are such good examples of oncogenic transformation, the mechanisms of viral tumorigenesis and its investigation from clinical background to molecular pathways will be described in the following section.

Epidemiological, serological, experimental and molecular biological evidence supports the viral pathogenesis of ATL. This evidence is that: (1) the incidence of HTLV-1 infections and the occurrence of ATL are similar with regard to their geographical distribution; (2) infections with HTLV-1 can be found in most patients with ATL (Kozuru *et al*., 1996; Tamiya *et al*., 1996); (3) proviral HTLV-1 DNA is integrated into the genome of leukaemic cells; (4) clonal proliferation of infected leukaemic cells has been demonstrated (Yoshida *et al*., 1984); and (5) infection of T cells with HTLV-1 can immortalize these cells (Miyoshi *et al*., 1981; Yoshida *et al*., 1982). The integration of HTLV-1 proviruses into the genome of leukaemic cells appears to be random, which suggests a role of HTLV-1 in malignant transformation independent of the integration site of the provirus. In contrast, viral oncogenesis in carcinoma cells is normally associated with a close relationship of viral integration and activation of oncogenes or suppression of tumour-suppressor genes. The viral gene expression also results in a transcription of the *trans*-activation protein Tax that can initiate viral gene expression and replication. In addition, this protein can interfere with transcription of cellular genes, such as those for IL-2, IL-2 receptor α, GM-CSF, c-*fos* or c-*jun*. Many proteins with an increased Tax-induced expression are involved in the regulation of cellular proliferation. Furthermore, expression of Tax proteins can lead to immortalization of T cells in an IL-2-dependent matter (Grassman *et al*., 1989). However, additional genetic or epigenetic alterations and clonal selection appear to be required for leukaemogenic transformation and the clinical occurrence of ATL.

PRINCIPLES OF HAEMATOLOGICAL TUMOUR MODELS AND THEIR APPLICATION IN HAEMATOLOGY

Availability of Blood Cells

Blood represents a ‘renewable resource’ for obtaining human cells. Therefore, normal and malignant cells may often be obtained using relatively easy procedures used for the isolation and maintenance of these cells from peripheral blood. Large numbers of human lymphocytes (1–2 million per millilitre of blood) can be isolated by simple and inexpensive techniques. For example, lymphocyte preparations can be obtained by density-gradient centrifugation, further isolation of monocytes/macrophages utilizes their ability to adhere to plastic. In addition,

monoclonal antibodies bound to magnetic beads and recognizing specific surface molecules of haematological cells can be used to select enriched or depleted T or B cell subpopulations. The latter cells also allow the generation of continuously growing cell lines via retroviral transformation, using viruses such as Epstein–Barr virus.

Murine bone marrow cells are usually isolated from femoral bones using standardized preparation techniques. The ease of isolation and high yield of cells without loss of viability provide excellent cell cultures for experimental studies. Similarly, human bone marrow aspirates or preparations from bone after their surgical removal can be used, but the potential risk for viral infections has to be considered when using human tissues.

In addition to the isolation of primary cells from patients or animals with malignant haematological diseases, other techniques are available to obtain haematological cells for experimental investigations. For example, short-term culture of human lymphocytes can be established from peripheral blood (Hungerford *et al*., 1959). With a few modifications, this technique has become a standard procedure for human genetic analyses. However, these cells can be cultured for only a few days, and the resulting cell cultures are heterogeneous in their cellular characteristics. Therefore, primary cultures are often not suitable for experimental procedures. Alternatively, diploid stem cell and permanent cell lines can be established or they are available commercially (from the American Type Culture Collection (ATCC) and the European Collection of Animal Cell Cultures (ECACC). Such diploid nontransformed cells are more homogeneous and demonstrate stable proliferation for up to 50 passages in culture. Permanent cell lines can be obtained by viral transformation of untransformed cells, resulting in immortalized cells. In addition, specific genetic modifications have been introduced that result in mutational changes in oncogenes/tumour-suppressor genes, knockouts of these genes or specific retroviral transformation by gene insertion. The disadvantage of these cells is that they often lose characteristics of normal cellular behaviour, such as cell growth and differentiation properties, availability of metabolic pathways, and expression of surface molecules, among other changes. (See also chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*; *Models for Tumour Growth and Differentiation*.)

Cell Culture Techniques

Modern haematological research requires the use of cell cultures that exist as more or less complex cellular systems. Various techniques have been established for the establishment and maintenance of these cell cultures (see chapter on *Basic Tissue Culture in Cancer Research*). Although principles of mammalian cell culture can be transferred to haematological cells, some specific problems have to be considered because of the specific nature and behaviour of these cells. First, as described above, the formation of leukaemias and lymphomas is closely related to disturbances in cell differentiation and maturation, which are strongly dependent on microenvironmental factors, such as the presence of cytokines or growth factors. For example, addition of serum (horse or fetal bovine) to cell cultures can result in variation of cellular behaviour since serum contains numerous growth factors with significant variations among different batches. Use of serum-free culture conditions in colony-forming assays can support colony formation and overcome these difficulties. In addition, specific conditions usually provided by the bone marrow matrix may influence proliferative properties and differentiation of blood progenitor cells. Therefore, culture conditions have to be adapted to the requirements of the specific cells. Second, blood provides specific conditions of circulating fluid where haematological cells occur as single cells in a complex solution. Consequently, culture of haematological cells frequently requires nonadherent culture techniques and cell suspensions.

Although this chapter cannot do justice to some of the specific technical problems of cell culture, the following will discuss some of the specific problems in haematological cell culture. Cell culture in suspension is required for cells that do not show cell adhesion to plastic surfaces or matrix components under normal culture conditions. This technique can be used for tumour cells that do not require or have reduced requirements for cell adhesion for their survival and growth. Culture as single cells in suspension has some advantages compared to the culture of adherent cells. The suspension cell cultures can be easily subcultured by simple dilution without the requirement of degradative enzymes, such as trypsin. As long as culture conditions (fresh medium) provide sufficient nutrients and toxic metabolic waste products are removed so that they do not accumulate, these cultures more or less grow continuously without a lag time after their dilution into fresh medium. In addition, homogeneous suspensions are available in large culture volumes and high cell densities.

Short-term culture of peripheral lymphocytes is a standard technique in human genetics and provides an almost unlimited source of diagnostic material for mutational analysis, investigation of chromosomal abnormalities and identification of hereditary alterations in genome structure. However, since the cells originate from cancer patients, special considerations of biological safety are required to prevent infection with viral agents, such as HBV, HCV or HIV-1. Isolation of peripheral lymphocytes is based on density gradient centrifugation (usually in a density gradient of Ficoll) of heparinized whole blood. Subsequently, addition of mitogens stimulates cell proliferation to obtain large numbers of lymphocytes for chromosomal analysis by staining techniques, *in situ* hybridization or isolation and direct sequencing of DNA.

Frequently, haematological cells need specific conditions for cell proliferation or maintenance of their differentiation properties. This can be obtained only by addition of other cells that normally provide the specific microenvironmental signals required by the haematological cells. These feeder cell layers frequently consist of embryonic fibroblasts, macrophages or thymocytes that have been inactivated for cell proliferation but not survival by radiation or mutagen treatment, leaving feeder cells that contain the necessary metabolic activity. These feeder cells secrete matrix proteins, growth factors and/or other stimulating factors, and they provide specific surfaces for cell–cell contacts and cell adhesion. In addition, bone marrow matrix has been used for haematological cell cultures.

In contrast to cellular differentiation found in the complex environment of *in vivo* models of cellular differentiation, in haematological malignancies analysis of single cells or cell lines permits the identification of specific cellular interactions and allows for their manipulation or modulation. The advantage of these model systems for cellular differentiation is at the same time one of their disadvantages. Neglecting the complex interactions of haematological cells with their microenvironment, such as bone marrow matrix and the presence of specific growth factors and cytokines, the relevance of *in vitro* results to human pathobiology may be limited. The haematological development from totipotent cells to pluripotent stem cells and finally to terminal differentiated blood cells is characterized by the loss of proliferative activity.

Various *in vitro* model systems have been developed for studying different steps of haematological cell differentiation, where the cellular differentiation can be induced by physiological or artificial substances and cell–cell or cell–matrix interactions. For example, growth factors, such as TGF-β, EGF or HGF, hormones, such as corticoids, glucagon or thyroxin, vitamins, such as all-*trans*-retinoic acid, or various inorganic ions can be used for induction of cellular differentiation (Osborne *et al*., 1982; Nakamura *et al*., 1989; Massague, 1990; Bonicinelli *et al*., 1991). In addition, induction of cell differentiation can be achieved by homologous or heterologous cell–cell interactions. Homologous cell–cell interactions require a high cell density to permit efficient cell–cell communication. However, for the investigation of haematological cell differentiation, heterologous stimulation by fibroblasts and thymocytes, among other cell types, is more frequently used. Current *in vitro* models in haematology have been based on the development of major experimental techniques. Earlier Burgess and Metcalf (1980), Metcalf (1989) and Cross and Dexter (1991) developed various cloning methods for haematopoietic cells based on semisolid agar culture containing colony-stimulating growth factors. The usage of feeder layer-cell culture was introduced by Dexter *et al*. (1977). Lymphoblastoid (such as HL-60 cells) and erythroid cell lines (such as Friend–erythroleukaemia cells (MEL)) are widely used examples of established progenitor cells for studying haematopoiesis (Rossi and Friend, 1967). Depending on the stimulating agents, their cellular differentiation into various terminal differentiated blood cells can be induced and studied (**Table 3**).

Table 3 Cellular differentiation of haematopoietic progenitor cell lines depending on the differentiation inducing agent

Cell line	Inducing agent	Terminal differentiated cell type
Friend-erythroleukaemia (MEL)	DMSO	Erythrocytes
HL-60	DMSO	Granulocytes
	Vitamin D_3	Monocytes
	Phorbol ester	Monocytes
	GM-CSF	Eosinophils

Animal Models for Haematological Malignancies

Animal models based on knockout or transgenic technology are now widely used in basic and applied haematological research (see chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*). The evaluation of animal models for haematological malignancies has to take into account various aspects of host and donor organisms as well as the target process(es) in the malignant tumour cells that is under investigation with a particular model. For example, for investigating the metastatic properties of leukaemia cells, the following aspects of the metastatic cascade have to be considered: (1) the natural site of leukaemogenesis, which in most cases is the bone marrow; (2) the exit site of the leukaemia cells from the bone marrow; (3) the effects of natural immune response of the host in the bone marrow and during the metastatic spread in the circulation; (4) the homing of leukaemic cells to other organs, including the bone marrow; and (5) the growth and elimination of leukaemic cells in the target organ(s).

The establishment of animal models for haematological malignancies currently relies on transgenic technology and retroviral infection of target cells. As technological advances become available they offer an opportunity to inactivate or modulate various endogenous genes in mice (or rats), leading to new possibilities in haematological research on the various steps of transformation and progression. In general, perturbations of gene expression in transgenic systems often lead to measurable alterations of physiological functions within the animal model. The technical details of this are described elsewhere in this section (see chapter on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*), but for an understanding of haematological models we will

discuss a few important features that have to be considered in the evaluation of these models. Little is known about the stepwise deregulation of specific genes leading to haematological malignancy, but aberrant gene expression in transgenic mice has been correlated with the formation of various haematological malignancies. For the investigation of these processes, specific target genes are usually dysregulated using transgenic modifications. However, frequently transgenic dysregulation of intracellular signalling pathways can result in activation of alternative pathways or interfere with signalling that is not directly involved in the regulation of the target gene (Sheppard *et al*., 1998). This can lead to cellular behaviour normally not found in evolving human malignancies. Therefore, the careful characterization of transgenic or infected cell clones has to include evaluation of morphological criteria, histopathological appearance, cytoskeletal architecture, expression of cell surface molecules, clonality and immunological properties of the resulting cells. For example, the expression of p210Bcr/Abl in haematopoietic progenitor cells in transgenic mice can contribute to two clinically distinct haematopoietic malignancies, CML and ALL, indicating that this transgenic system provides a novel transgenic model for human Philadelphia chromosome-positive leukaemias. In addition, proliferation of blast cells can occur in the lung or other secondary organs, which might represent an extramedullar blast crisis comparable to the natural clinical occurrence in humans (Honda *et al*., 1998).

Chromosomal translocations are found as primary or secondary mutations in patients with leukaemias. As a result of these translocations, fusion can occur between various genes that encode transcription factors or other potential oncogenes/tumour-suppressor genes. The role of these fusion genes in leukaemogenesis is often unknown. For functional studies of the fusion genes *in vivo*, they can also be expressed in mouse bone marrow cells via retroviral transduction (Cuenco *et al*., 2000). The clinical features of these animals are important, and such morphological investigations can increase our knowledge about the role of affected genes in haematological malignancies.

Multipotential progenitor and stem cells occur at a low frequency in haematopoietic tissues. Therefore, it is often difficult to obtain sufficient numbers of cells for experimental studies that delve into the molecular events involved in the regulation of lineage-affiliated genes within these multipotent cells. As an example to solve this problem, the myeloproliferative leukaemia virus (MPLV) has been used to generate a phenotypically diverse array of haematopoietic progenitors from adult mouse bone marrow and embryonic blood. These cells can be expanded to perform further investigations previously impossible using analogous primary cells (Thompson *et al*., 1999).

In some cases it is preferable to use animal models of human haematological malignancies for some studies. For example, rabbit models of lymphoma with specific chromosomal abnormalities have proved to be very useful for clarifying the role of EBV in human EBV-associated lymphoma and provide a means for studying prophylactic and therapeutic regimens. Another example is the Si-IIA-EBV or Cyno-EBV that can be inoculated intravenously, orally, subcutaneously or intraperitoneally and can subsequently induce T cell lymphomas in rabbits in about 2–5 months (Hayashi and Akagi, 2000).

SOME PROBLEMS OF ANIMAL MODELS

Although animal models of human haematological malignancies have proved to be useful, especially for *in vitro* studies, there are also some limitations that must be considered. Long-established leukaemia and lymphoma cell lines from mice or other animals and their sublines are heterogeneous in their malignancies, resulting in variations in their behaviours. For example, cells of high malignant potential are often less susceptible to lysis by the complement-dependent natural immune response than less malignant cells. The more malignant cells also have higher affinities for adhesion within the bone marrow and are less dependent on the microenvironment for their survival, differentiation and proliferation. This phenotypic diversity or heterogeneity is not specific to haematological malignancies, but because of the single cell characteristic of tumour cell–host organ interactions this phenomenon requires specific consideration when using haematological malignancies.

Host factors influencing metastasis formation have been attracted research attention for several decades. These studies have shown that there are important systemic and local environmental factors, such as immune resistance mechanisms that impact on tumour properties. For example, the antitumour T cell response, natural killer cells and macrophages can influence the metastatic process. It has been known for some time that malignant haematological cells are more susceptible to host immune mechanisms than cells from carcinomas. Therefore, many models of haematological malignancies use immunodeficient animals as the host. Furthermore, coagulation factors and platelets interact with circulating cells, particularly in the microcirculation. As discussed above, growth factors, cytokines and/or hormones are involved in the regulation of differentiation, proliferation and survival of leukaemia and lymphoma cells. Many of these factors are also very important regulators of host defence, inflammation and wound repair mechanisms. Thus these environmental factors can result in the selection of malignant cells that escape the above environmental controls. The complexity of the relationship between tumour cells and animal hosts is further discussed elsewhere in this section. (See also chapter on *Human Tumours in Animal Hosts*.)

Major problems for the investigation of tumour immunology in haematological malignancies are the reliability

and reproducibility of antitumour effects in spontaneously arising and nonimmunogenic haematological malignancies (see chapter on *Models for Immunotherapy and Cancer Vaccines*). For example, B cell malignancy-derived Ig may be considered a model tumour antigen for vaccine development. However, as a nonimmunogenic self-antigen, it must also be first rendered immunogenic by chemical or genetic fusion to carriers that enable the induction of protective antitumour immunity in murine tumour models. For example, multiple injections of intact irradiated murine B cell leukaemia/lymphoma cells (BCL1) has been used to trigger a dose-dependent antitumour immune response in syngeneic mice. However, Newcastle disease virus (NDV) infection or transfer of cytokine genes into these cells for investigation of their role immune response did not affect tumorigenicity or immunogenicity of BCL1 cells (Morecki *et al*. 1998). Administration of these vaccines as fusion proteins or the use of naked DNA vaccines may allow efficient targeting of antigen-presenting cells *in vivo* (Biragyn and Kwak, 1999).

In summary, the very complex interactions of haematological cells with different physiological processes, such as immune response, host defence and inflammation, among others, require consideration of many factors influencing the experimental systems. Therefore, the use of experimental systems requires careful investigation of these factors for reproducible and reliable results. Moreover, these complex interactions are frequently neglected in experimental design of *in vitro* investigations. Finally, the translation of these observations to *in vivo* systems often yields unexpected results.

CLINICAL RELEVANCE OF EXPERIMENTAL RESULTS

Molecular analysis of malignant transformation in haematological malignancies has led to significant contributions in clinical treatment strategies. For example, as a consequence of the molecular understanding of leukaemogenesis in patients with acute promyelocytic leukaemia (APL) the development of differentiation-inducing therapy by all-*trans*-retinoic acid (RA) is now a standard clinical procedure. Nearly all patients achieve complete remission by the treatment of all-*trans*-RA; however, clinical remissions are usually of brief duration, and these patients often subsequently develop RA-resistant disease. The mechanisms of RA resistance in APL cells are poorly understood and most clinical approaches have not been successful in overcoming RA resistance. Therefore, further understanding of the complex regulatory mechanisms of progenitor cell maturation and differentiation will be necessary for successful long-lasting treatment. Using this example, studying RA-resistant APL model systems *in vitro* and *in vivo* may be useful for investigating the molecular aspects of blocking leukaemic cell differentiation and the molecular mechanisms of RA resistance (Kizaki *et al*., 1999).

MODELS FOR MELANOMA

Malignant melanoma is a common human cancer with high mortality rates. The incidence of this disease is currently increasing faster than that of any other malignancy. The primary cause of melanoma is thought to be exposure to ultraviolet (UV) radiation (Fountain *et al*., 1990). Other risk factors include fair skin, a hereditary predisposition toward the disease, increased age and race. In the white population, for example, the disease is increasing rapidly and was projected to affect approximately one in 75 persons by the start of the twenty-first century (Ahmed, 1997). The steady overall increase has been attributed to various causes ranging from the reduction of the stratospheric ozone to the changing lifestyles and attitudes that affect sun exposure. Although it is easily diagnosed and wholly curable if detected early, the high mortality rate (6700 deaths each year in the United States) is due to the propensity for melanoma to metastasize if left untreated (Dooley, 1994).

Most human malignant melanomas develop as a consequence of a lengthy multistep process. This process involves formation of naevi from normal melanocytes, a radial growth phase (RGP) and a subsequent vertical growth phase (VGP; metastatic phenotype), which results in decreased dependence on growth factors, reduction of contact inhibition and diminished anchorage dependence (Lu and Kerbel, 1994). The prevalent working model for melanoma metastasis development defines it as a series of interrelated, sequential steps involving the survival and growth of unique subpopulations of cells with metastatic properties that preexisted within the parental neoplasm (Fidler, 1990).

The molecular steps leading to human malignant melanoma and subsequent metastasis are not well known.

Several animal models have been established to study the progression of melanoma. **Table 1** summarizes the major melanoma models of both human and nonhuman origin. Each model will be discussed here for its relevance to study the human disease.

Table 1 Experimental models in melanoma research

Type	Site	Description
Mouse models		
DMBA + UV-induced melanoma	*In vivo*	Mouse skin treated with carcinogen and UV irradiation
Allografts	*In vivo*	Murine melanoma cell lines (B16, K-1735) transplanted into syngeneic mice
Transgenic: SV-40	*In vivo*	Tyrosinase proporter-driven SV-40 induced-melanoma
Transgenic: c-Ret	*In vivo*	Metallothionein-driven c-Ret induced-melanoma
Transgenic: HGF	*In vivo*	Metallothionein-driven hepatocyte growth factor-induced melanoma
Transgenic: $p16^{INK4a}$ + H-ras	*In vivo*	Tyrosinase-driven Ha-ras in $p16^{INK4a}$ knockout mice
Human/mouse xenografts	*In vivo*	Human tumours injected s.c. or i.v. into nude or SCID mice
Human models		
Artificial skin reconstructs	*In vitro*	All components of human skin cells are cocultured to simulate human skin
Xenografts of human skin	*In vivo*	Human skin grafted on to SCID/RAG mice and melanomas are induced
Other animal models		
Monodelphis domestica (opossum)	*In vivo*	Melanomas are induced by UV irradiation
Sinclair swine	*In vivo*	Pigs develop spontaneous melanomas
Syrian hamster	*In vivo*	DMBA-induced or spontaneous melanomas
Guinea pig	*In vivo*	DMBA-induced melanomas
Xiphophorus fish	*In vivo*	UV-induced or spontaneous melanomas

Mouse Models

Currently there are no spontaneous murine melanoma models, and the existing models consist of induced melanomas. The induced murine melanoma models can be divided into two groups: (1) induction of melanomas by means of UV radiation and carcinogens and (2) induction of melanoma by specific genetic manipulations (transgenic mice). These models are syngeneic and have the advantage of an intact immune system. This allows the investigators to study not only the molecular events within the tumours, but also to look into the immune responses against these tumours. Since the murine skin differs from the human skin in its architecture, these models, however, may not represent the actual molecular events involved in the progression of human melanoma.

In group (1), investigators used the carcinogen 7,12-dimethylbenz[*a*]anthracene (DMBA) as an initiator followed by UV radiation, croton oil or TPA as promoters to induce melanomas in mice. Nearly all of the mice developed skin cancer, and around 20% of the animals developed primary cutaneous melanoma (Donawho *et al.*, 1992). Several melanoma cell lines have been generated (B16 and K-1735) and established in culture. These cell lines were injected as allografts to generate several sublines with different metastatic capabilities (Epstein *et al.*, 1967; Romerdahl *et al.*, 1989; Donawho *et al.*, 1992). These syngeneic models are extensively in use to study the molecular changes associated with the acquisition of the metastatic phenotype.

Recently, transgenic models to generate melanomas has been the subject of renewed research. Indeed, several transgenic mouse models are available. All of these mice were generated by utilizing the expression of viral or human oncogenes under inducible or tissue specific promoters (**Table 1**). For example, Mintz and her colleagues used the tyrosinase promoter-driven SV-40 antigen to induce melanoma in mice (Bradl *et al.*, 1991). Other investigators used the c-*Ret* or hepatocyte growth factor/scatter factor genes driven by the metallothionein promoter to generate melanomas (Iwamoto *et al.*, 1991; Takayama *et al.*, 1997). Recently, transgenic mice bearing melanomas were established by crossing knockout mice for $p16^{INK4a}$ with mice expressing activated H-ras in mouse melanocytes using the tyrosinase promoter (Chin *et al.*, 1997). In general, these transgenic animal models suffer the disadvantage that the genes they utilized to induce melanoma were not necessarily have been shown to be involved in the progression of human melanoma *in situ*. In addition, these models provide limited potential to study the aetiology and the genetic events involved in the progression of human melanoma because unlike in the human skin, mouse melanocytes are localized deep in the hair shafts in the dermis.

Human/Mouse Xenografts

This is the most widely used model to study the regulation of human melanoma tumour growth and metastasis. There are close to 50 human melanoma cell lines available to the scientific community at large. These cell lines represent several stages in the progression of human melanoma. Most of the cell lines were established from metastatic lesions (lymph nodes, brain or skin metastases) and as such they fall under the category of VGP. Several other cell lines were established from skin tumours at the RGP, while very few cell lines representing primary cutaneous melanoma are available owing to the difficulties of growing them in culture. This wide range of cell lines (sometimes from the same patient at different stages of the disease) enables us to compare their gene expression *in vitro*, to manipulate their gene expression pattern *ex vivo* and subsequently to analyse the effect of this manipulation *in vivo* by implanting them as xenografts in an orthotopic model (subcutaneous injections) (Huang *et al.*, 1996, 1998; Xie *et al.*, 1997). The human cell lines are injected into the immunocompromised nude or SCID mice. In general, there is a good correlation between the tumourigenicity of the tumours in patients from which they originated and their ability to grow subcutaneously in nude or SCID mice. The incidents of spontaneous metastasis from the primary tumours to other organs in these animal models are very low. An alternative approach has been utilized to study the metastatic potential of these cell lines by using the experimental lung metastasis assay. In the assay, melanoma cells (usually 1×10^6 or 2×10^6) are injected into the tail vein of nude mice and a few weeks later the number of lung colonies counted under a dissecting microscope. Our experience with this assay shows that in most cases a direct correlation exists between the behaviour of tumour cells in the patient and their metastatic potential in nude mice. Unlike the environment setting in the patient, however, the environment in these models is lacking certain components of the immune response. In addition, growth and angiogenic factors released by the implanted human tumour cells may not work efficiently on the stroma cells within their immediate host environment. Despite these deficiencies, these models are widely used to study the effect or the role of target genes on tumour growth and metastasis of human melanoma.

Human Models

Artificial Skin Reconstructs

In this artificial model (Meier *et al.*, 2001), all cell types of the human skin are cultured together to mimic the skin environment. It involves coculture of terminally differentiated epidermal cells, a basement membrane layer and a dermal compartment consisting of fibroblasts embedded in collagen. All layers are arranged in a physiological context

that functions like the human skin. The model has been used as an alternative means to animal testing for skin irritation (cosmetic products), wound healing and UV-induced damage (Ponec and Kempenaar, 1995; Simonetti *et al*., 1995; Kuroyanazi *et al*., 1996). Recently, however, Herlyn and his colleagues have utilized this model to study the biology of melanocytes and the progression of human melanoma. When normal melanocytes were applied to these reconstructs, they retained their dendritic morphology and did not divide for a period of 35 days. Melanoma cells, on the other hand, exhibited the same biological properties of human melanoma cell *in vivo*. For example, RGP melanoma cells when incorporated onto the reconstructs, grew as single cells or small nests within the epidermis/dermis junction and did not invade into the dermis. VGP melanoma cells formed clumps and clusters within the epidermis/dermis junction with some of the cells crossing into the dermis. Metastatic melanoma cells exhibited accelerated proliferation with the majority of the cells invading deep into the dermis (Satyamoorthy *et al*., 1999). These data point to the usefulness of this model to study the behaviour of melanoma cells in the nonanimal setting. As in the xenograft/nude/SCID mice model, the skin reconstructs are ideal to study altered gene expression with respect to melanoma.

Mouse/Human Chimaera: Xenografts of Human Skin on to SCID Mice

Using the same principles to induce melanomas in mice, i.e. DMBA coupled with UV radiation, Herlyn's group has tried to induce human melanoma in human skin grafted on to SCID/RAG mice. The combination treatments of DMBA followed by UVB irradiation produced high incidents of squamous cell carcinomas and a human nodular malignant melanoma in one mouse. Grafting skins from normal donors or from patients with melanoma could be a valuable tool to study the molecular mechanisms associated with the progression of human melanoma (Soballe *et al*., 1996; Attilasoy *et al*., 1998).

Other Animal Models

Other animal models to generate melanomas have been the subject of considerable research. Among the models worth mentioning are those in the opossum (Ley *et al*., 1989), Sinclair swine (Millikan *et al*., 1974), Syrian hamster (Chernozemsai and Raichev, 1966), guinea pig (Clark *et al*., 1976) and the *Xiphophorus* hybrid fish (Setlow *et al*., 1989) (**Table 1**). In the South American opossum, melanomas were induced by UV irradiation and were found to metastasize spontaneously to other organs. The Sinclair swine model is interesting in the sense that the pigs developed spontaneous melanomas at birth, which also regressed spontaneously in adult life. The mechanisms by which these tumours regress are still unknown and may provide valuable information for the progression of the human disease as the skin of the pig resembles the structure of the human skin. The drawbacks in all these animal models are the requirement to clone the species-specific human-homologous genes in each case. This challenge causes difficulties in comparing human melanoma with those developed in these animal models.

MODELS FOR SARCOMAS

Osteosarcoma is a primary bone malignancy that usually occurs during the adolescent and young adult years when the long bones are undergoing rapid growth. Current therapy consists of preoperative chemotherapy, surgical intervention (either amputation or limb-sparing surgery depending upon the resectability of the tumour) followed by postoperative chemotherapy. Despite this aggressive therapy, 30–40% of patients will relapse, usually within 1 year after diagnosis. Although some patients will develop local recurrence of the tumour or metastases at other bony sites, the majority of patients will relapse in the lung. Patients who relapse have a poor prognosis. Salvage chemotherapeutic regimens have had limited success. Consequently, new chemotherapeutic agents and novel therapeutic approaches are needed.

As a result, investigators are using osteosarcoma cell lines and developing animal models in which to identify new therapies for testing in clinical trials. In the following sections the benefits and disadvantages of various cell lines and xenographic and syngeneic animal models of osteosarcoma will be discussed. Finally, the canine model of osteosarcoma, the only spontaneously occurring animal model will be described.

Cell Lines

A large number of osteosarcoma cell lines are available through the American Type Culture Collection (ATCC) (see www.ATCC.org). An advantage of using cell lines to assess the effect of chemotherapeutic and immunomodulatory agents is that a large number of agents can be screened relatively rapidly. Three human cell lines, SAOS-2, MG-63 and TE-85, have been well characterized with regard to their sensitivity to chemotherapeutic and immunomodulatory agents. For example, the antitumour effects of the chemotherapeutic agents etoposide, adriamycin, amsacrine, topotecan, vinblastine and cisplatin and the immunomodulating cytokines TNF-α, interleukin-1 and interferon-γ were assayed for their cytotoxic effect on these three cell lines (Jia *et al*., 1995). Interestingly, SAOS-2 cells were most sensitive to the effects of TNF-α and interferon-γ, while MG-63 cells were most sensitive to interleukin-1, and TE-85 cells were resistant to TNF-α and IL-1, but sensitive to interferon-γ (Jia and Kleinerman,

1991). This heterogeneous response is similar to what happens in a tumour when only a portion of cells making up the tumour are sensitive to a particular agent. The population of cells that are sensitive die off while the resistant population continues to grow and ultimately results in the death of the patient. So if a single cell line is used to assess a new agent, it is not clear if other cell lines will also be sensitive or if a human tumour will be sensitive.

In the analysis of chemotherapeutic agents in combination with cytokines, interleukin-1α (IL-1α) enhanced the activity of etoposide in all three cell lines (Jia *et al.*, 1999a). Based on this result, a clinical trial was undertaken in patients with relapsed osteosarcoma (Worth *et al.*, 1997). Although the study had to be stopped prematurely because IL-1α production was halted, analysis of the patients treated on this study indicated that the combination of IL-1α and etoposide was effective in some patients. The number of osteosarcoma cell lines available for *in vitro* and *in vivo* studies is very limited and there is a need to establish more cell lines.

Animal Models

Human–Murine Xenografts

Xenografts have several advantages over cell lines. The most commonly used model introduces human cells in a murine host. A major drawback of xenograft models is that human cells will not grow in immunocompetent animals, the immune system of an animal will recognize the human cells as foreign and reject the tumour. Consequently, as in the melanoma models, immunocompromised mice must be used, and the effect of the immune system on therapy cannot be adequately assessed.

MNNG/HOS is human cell osteosarcoma line that produces tumours when implanted subcutaneously in nude mice (Chen *et al.*, 1997) (**Table 2**). This model is useful in that the tumours are well circumscribed and the effect of therapy can be easily quantified. However, this cell line does not grow in bone and does not metastasize. The effects of therapy observed on tumours growing subcutaneously may not be the same on tumours growing in the bone or in the lung.

A model devised by Meyers *et al.* (1990) is unique in that it uses surgical specimens, not cell lines, and immune-deprived mice, not nude mice. In this model, CBA/CaJ inbred mice are subjected to infant thymectomy and total body irradiation with subsequent marrow reconstitution. Tumour specimens obtained at the time of surgery are directly implanted into flank muscle. Tumour cells grow at the site of inoculation; however, the tumour does not metastasize, and this limits the usefulness of this model.

Another model (Berlin *et al.*, 1993) requires the v-Ki-*ras* oncogene transformation of the human osteosarcoma TE-85 cell line. This new cell line was designated KRIB. When KRIB cells are intravenously or intraosseously injected into nude mice, they reproducibly form pulmonary metastases.

We had concerns about some of the manipulations of the host and tumour cells that might decrease the relevance of the models in terms of evaluating the efficacy of various therapies, so we developed our own experimental osteosarcoma model. SAOS-2 cells are available through the ATCC. They will not grow when injected intravenously, intratumourally or subcutaneously in nude mice. A population of SAOS-2 cells that were able to grow on 0.9% agarose were selected and injected intravenously into a nude mouse. A rare lung metastasis that developed more than 6 months later was isolated, expanded in tissue culture and reinjected (Radinsky *et al.*, 1994). This process was repeated a total of six times to produce SAOS-LM6 (Jia *et al.*, 1999b). The advantage of this model is that there is a natural selection of cells without manipulation of the host or tumour cells. The formation of micrometastases in 4–6 weeks and macroscopic disease by 8 weeks is reproducible. This model has been demonstrated to be useful in evaluating standard chemotherapeutic agents as well as new immunotherapies (Jia *et al.*, 1999b; Worth *et al.*, 2000).

Syngeneic Models

In syngeneic models (**Table 3**), tumour cells are injected into the same species/haplotype animals. The advantage of a syngeneic animal model is that immunocompetent animals can be used. This allows the interaction of the immune system on the new therapy to be assessed. Consequently, responses seen in these animal models may more closely mimic the responses in humans. Three murine syngeneic models for metastatic osteosarcoma have been described.

Table 2 Human–murine xenograft models for osteosarcoma

Cell line	Heterotropic/orthotopic	Metastatic potential	Manipulation of host	Reference
MNNG/HOS	Heterotropic (s.c.)	Rare	None	Chen *et al.* (1997)
Surgical specimens	Orthotopic? (flank muscle)	None	TBI/infant thymectomy	Meyers *et al.* (1990)
KRIB	Orthotopic (tibia)	Moderate (0–22 range)	v-Ki-*ras* oncogene transformation of cell line	Berlin *et al.* (1993)
SAOS-LM6	Heterotropic (i.v.)	High (> 200)	None	Jia *et al.* (1999b)

Table 3 Syngeneic murine models for osteosarcoma

	Heterotropic/orthotopic injection	Metastatic potential	Reference
Radiation-induced	Heterotropic (muscle)	Can approach 96%	Pollak *et al.* (1992)
Spontaneous	Heterotropic (subcutaneous)	Nearly 100%	Asai *et al.* (1998)
Spontaneous	Orthotopic (intraosseous)	High	Khana *et al.* (2001)

The murine osteosarcoma in the first model originated in a C3H-Sed mouse that had been irradiated (Pollak *et al.*, 1992). A fragment of this tumour was then implanted in the lateral gastrocnemius muscle. The tumour produces abundant neoblastic bone that invades the proximal skeletal muscle and metastasizes to the lung. The incidence of metastases is dependent upon when the original tumour is amputated. If the original tumour is amputated when it is 12 mm, 65% of the animals will develop pulmonary metastases. If the tumoured leg is amputated when the mass approaches 16 mm, 96% of the animals will develop pulmonary metastases (average number of metastases 16 ± 6). The advantage of this model is that it uses immunocompetent mice. At the time of diagnosis most patients have microscopic metastatic disease. It is unclear if this model behaves in the same manner with the early development of microscopic pulmonary metastases.

A second syngeneic mouse model uses a murine osteosarcoma that was first described by Dunn and Andevont (1963). This tumour arose spontaneously in the tail vertebra of a mouse. When injected into the femoral muscle, tumours will grow, but will not metastasize. Asai *et al.* (1998) took this cell line and cycled it through a mouse eight times to produce a cell line that is highly metastatic to the lung. This model is advantageous in that it reproducibly produces a large number of metastases. The disadvantage is that this is not an orthotopic model. The cells are implanted subcutaneously and not in bone. The authors conclude that this model is easier to use since subcutaneous tumours are easier to inject and measure as compared with intraosseous injections; however, it is not clear if therapies that are effective on subcutaneous tumours will have the same effect on intraosseous masses. Organ-specific growth factors may play a key role in the growth of tumour cells, thus tumour cells that grow in the lung may not grow in the skin and vice versa.

A recent report describes a new syngeneic, orthotopic model (Khana *et al.*, 2001). K7 and K12 are murine osteosarcoma cell lines. K7 cells were injected intraosseously into the tibia of a Balb/c mouse. A spontaneous metastasis arose in the lung, was isolated and surgically implanted into a paraosteal muscle flap. A highly metastatic pulmonary cell line was established from a pulmonary metastasis and was designated K7M2. This model has several advantages. It is syngeneic, orthotopic and results in spontaneous pulmonary metastases. Cell lines with a high metastatic and low metastatic potential can be compared. If differences can be identified between these cell lines, it is possible that new therapies could be designed to decrease the high metastatic potential of some tumour cells.

Spontaneous Canine Osteosarcoma

Similar to humans, large-breed dogs develop osteosarcoma that metastasizes to the lung. At the time of diagnosis nearly 90% of dogs have pulmonary micrometastases. This is based on the observation that dogs who have their primary tumoured limb amputated and receive no further therapy have a median survival of 3–4 months and die of pulmonary metastases. Dogs with osteosarcoma were instrumental in the preclinical of evaluation of an agent, L-MTP-PE, that activates macrophages to kill tumour cells (MacEwen *et al.*, 1989). Treatment of dogs with L-MTP-PE increased the survival time of these dogs from a median of 77 to 222 days. Based on these results, L-MTP-PE was introduced into clinical trials. A phase III multi-institutional randomized trial involving L-MTP-PE in patients with newly diagnosed osteosarcoma was completed recently and for the first time in more than 15 years there is an increase in the 5-year disease-free survival rate. The dog osteosarcoma model is a vary useful model for preclinical studies. The only disadvantage to this model is that although more than 8000 dogs are diagnosed with osteosarcoma per year, not all pet owners are willing to seek expensive therapy for dogs or to enter clinical trials.

Clinical Relevance of Experimental Tumour Behaviour

Each model system used to identify new therapeutic approach to osteosarcoma, be it the *in vitro* cell culture, a xenographic or syngeneic system, or the osteosarcoma that occurs spontaneously in the dog, has its unique set of advantages and disadvantages. By keeping the limitations in mind, we will be able to identify new therapies that could have a significant impact on survival rates of patients with osteosarcoma.

INTRODUCTION

Central nervous system (CNS) neoplasms must be approached differently from other neoplasms because of their location in the brain. While designing brain tumour therapy studies, experimenters must be cognisant of the sensitivity of CNS tissue to radiation, chemotherapy, cytokine therapy, and autoimmune reactions (experimental allergic encephalitis (EAE)), and experimental design must take into account special features of the brain such as its compartmentalization. The brain is in a compartment separated from the rest of the body by the blood–brain barrier (BBB) and this compartmentalization creates special challenges. One challenge is generating an immune response to a brain tumour when there are no lymphatics in the brain and very few immune system cells allowed into brain parenchyma. This chapter covers the methods used to work around these sensitivities and challenging features and describes in-depth the best models for brain tumour experimentation.

The chapter first presents a discussion of specific characteristics of CNS tumours, metabolism, morphology and cytokine secretion. Next, special considerations regarding establishment of human brain tumour cell lines, *in vitro* culture of CNS tumour cells, and *in vivo* models using human brain tumour cells are reviewed. Syngeneic animal tumour models are discussed, with a focus on characteristics of an ideal *in vivo* brain tumour model. The final section illustrates how results in animal models can lead to new therapeutic strategies utilized in the clinical setting. This chapter is designed to be a guide for the novice brain tumour investigator such that appropriate experimental models can be selected, implemented and interpreted in terms of clinical trial possibilities.

Characteristics of CNS Tumours

Primary CNS tumours can arise from any nervous system cell type, producing a spectrum of approximately 50 different tumour types. The most prevalent primary CNS tumours are those arising from neuroepithelial tissue, such as gliomas: astrocytoma, oligodendroglioma and ependymoma. The second most common tumours are those derived from cranial and spinal nerves, such as schwannoma and neurofibroma. Other sources of CNS tumour are the meninges, anterior pituitary and embryonal tissue (**Table 1**).

CNS tumours have a wide range of neoplastic expression patterns, involving characteristics such as anaplasia, growth rate, antigenic expression and genetic differentiation. The degree of anaplasia in CNS tumours ranges from mature cell types with specific antigenic expression patterns to cells with a lack of any normal cytological features. Growth patterns range from the fast-growing glioblastoma multiforme (GBM) to the slow-growing pilocytic astrocytoma that can take years to develop. Prevalent antigenic expression patterns in human brain tumours include synaptophysin, neurofilament proteins, glial fibrillary acidic protein (GFAP) and S100 (surface Ag). Common genetic changes are the loss of chromosome 10 (a high incidence in GBM, while uncommon in low-grade gliomas, suggesting its importance for tumour progression); epidermal growth factor receptor (EGFR) mutants; gains of chromosome 7; structural abnormalities of 9p, 19q and 22; loss of 1p, 9p, 10q, 17p, 19q and 22q (frequent in gliomas); loss of IFNα and -β genes (high-grade gliomas); overexpression of EGFR mutants, EGFR, PDGFR and MDM-2; p53 mutations; and p16 deletions. Loss of tumour-suppressor genes is fundamental for the development of many CNS tumours, especially the loss of *Rb*, *TP53*, *WT-1*, *WAF1*, *MTS1*, *NF1*, *NF2*, *DCC* and *MCC*. An example of how some of these chromosomal changes come together to cause malignancy is the transformation of glial cells to astrocytoma, anaplastic astrocytoma (AA) and finally GBM. This progression is caused by a specific series of chromosomal changes. The transformation to astrocytoma often involves the loss of 17p (p53 mutation), PDGF-α receptor overexpression and loss

Table 1 Primary brain tumours

Tumours derived from	Tumour type	Typical WHO Grade	Usual location
Neuroepithelial tissue	A. Pilocytic astrocytoma	I	Cerebellum, third ventricle and optic nerve
	Astrocytoma	II	Cerebral hemispheres, optic pathways, third ventricle, cerebellum and brainstem
	Anaplastic astrocytoma	III	Cerebral hemispheres
	Glioblastoma	IV	Cerebral hemispheres
	B. Oligodendroglioma	II	
	Anaplastic oligodendroglioma	III	
	C. Ependymoma	II	Floor of the fourth ventricle, central canal of the spinal cord, lateral or third ventricles and cerebellopontine angle
	D. Mixed oligoastrocytoma	II, III	
	E. Choroid plexus tumour	Papilloma: I Carcinoma: III	Choroid plexus
	Pineocytoma	II	
	Pineoblastoma	IV	
Embryonal tissue	Medulloblastoma	IV	Cerebellum or brainstem
	Neuroblastoma		
	Ependymoblastoma	I, II, III	
	Primitive neuroectodermal tumour	I, II, III	Supratentorial compartment
Cranial and spinal nerves	A. Schwannoma	I	Meatus acusticus internus or externus in the cerebello-pontine angle
	B. Neurofibroma	III, IV	
	C. Malignant peripheral nerve sheath tumour	III, IV	
	Malignant schwannoma	III, IV	
	Neurogenic sarcoma	III, IV	
	Anaplastic neurofibroma	III, IV	
Meninges	Meningioma	I	Dura
	Atypical meningioma	II	Dura
	Anaplastic meningioma	III	Dura and brain invasion
Sellar region	Pituitary adenoma	I	Sellar region
	Pituitary carcinoma	II	Brain invasion from sellar region, metastasis
	Craniopharyngioma	I	Sellar and suprasellar regions
Outside the CNS	Metastasis	IV	

of 22q. Progression to anaplastic astrocytoma involves the loss of 13q (Rb mutation), loss of 19q, loss of 9p (IFNα/β and p16^{INK4} mutation), and *CDK4* and *MDM2* gene amplification. Final progression to GBM involves *EGFR* gene amplification and rearrangement, and the loss of 10p and 10q.

CNS tumours have been shown to secrete cytokines to modulate the immune system. GBM tumours have been demonstrated to secrete TGF-β, IL-1α and -1β, IL-6, IL-10 and GM-CSF. Within a single tumour type, vast heterogeneity can be observed. For example, the malignant gliomas AA and GBM are each heterogeneous at morphological, biological, genetic and antigenic levels (Bigner *et al*., 1981). This heterogeneity is believed to be a consequence of the plasticity of neoplastic glial transformation.

No matter what the specific type or expression pattern, CNS tumours are expanding lesions that produce symptoms primarily by taking up space within the skull. As they grow through local diffuse infiltration or within distinct encapsulated areas of the brain, CNS tumours increase the mass of tissue residing within the rigid skull. CNS tumours

may also increase intracranial mass by blocking the flow of CSF, causing hydrocephaly. Increased mass leads to increased intracranial pressure, which causes compression and displacement of the brain and spinal cord. These intracranial changes may ultimately lead to herniation of the brainstem, followed by death. New brain tumour therapies should be tested thoroughly in experimental *in vivo* intracranial models to prove that the treatment targets the tumour without exacerbating intracranial pressure.

Tumour location has a large impact on symptoms and treatment possibilities. Tumours in the frontal lobe tend to cause personality changes; tumours in the left temporal lobe can lead to haemianopia and aphasia. Tumours in the cerebral hemispheres can often be resected; those in the brainstem often cannot. For these reasons, it is important to investigate therapeutic options through *in vivo* models that study each tumour type where it would be found in humans.

Although brain tumours have the capacity to divide rapidly, invade locally and metastasize within the CNS, it is very rare for a brain tumour to metastasize outside the CNS. It is not clear why brain tumours do not metastasize outside the CNS, but there are several fields of thought. Aggressive brain tumours, such as AA and GBM, may kill the patient before metastases can be detected. The fact that extraneural metastases have been related to previous surgery or radiation therapy supports this theory, as these patients have an increased length of survival, and thus an increased window for metastases to spread and develop. However, this correlation between surgery and extraneural metastases also supports the theory that brain tumour cells cannot cross the intact BBB. Surgery can give tumours direct access to extrameningeal tissues, bypassing the BBB. Researchers should keep this in mind when designing therapy that involves prolonged BBB disruption, as it is possible that this disruption may allow tumour cells to metastasize extraneurally. The BBB is a selective membrane, blocking the entrance of blood-borne molecules >180 Da and large, complex biological molecules such as cells and viruses from the brain. The theory of the BBB as a CNS tumour blockade is substantiated by the rare observation of brain tumour invasion of blood vessels, but weakened by the common occurrence of extra-CNS tumours metastasizing across the BBB into the CNS. Extra-CNS tumours may be able to bind the markers on the endothelial surface of brain tumour vasculature, whereas CNS tumours cannot bind the markers on the endothelial surface of non-brain target organ vasculature, which may be causing a one-way metastasis tide. This is supported by experiments performed in the 1960s where malignant gliomas were transplanted into subcutaneous tissue as an immunization procedure. The glioma cells grew but did not metastasize, which indicates that primary brain tumours have properties that make them fundamentally different from tumours originating elsewhere in the body and that the BBB is not the sole barrier to extra-CNS metastasis.

Virtually any malignant solid tumour in the body can spread to the CNS and involve the cerebrum, cerebellum, spinal cord, leptomeninges, dura or pituitary. The most common primary tumour sites are the lung and breast, followed by melanoma of the skin, the urinary tract, prostate, kidney, thyroid and gastrointestinal tract. Tumour metastasis to the CNS is present in approximately 20–40% of all cancer patients, and these metastases kill 10 times the number of patients dying from primary brain tumours. For this reason, experimental models for metastases to the brain are very important and are discussed in the animal *in vivo* models section.

Special Considerations for Researchers

The BBB is especially challenging for the clinician to overcome in the treatment of brain tumours. The intact BBB prevents the passage of ionized water-soluble drugs with a molecular mass >180 Da. Many of the currently available effective chemotherapeutic agents have a molecular mass between 200 and 1200 Da. The intact BBB also blocks the passage of large, complex biological molecules such as viruses and cells. Because it is so selective, the BBB must be bypassed or overcome to deliver therapy in a manner that causes no adverse effects to the neural tissue. Bypassing the BBB to generate an immune response is an important consideration in immunotherapy, as there is no lymphatic system to collect antigen and present it to the immune system. Because the BBB also blocks the entrance of many cells of the immune system to the brain, the immune response is often based solely on microglia cells, the specialized immune cells of the CNS. As a result, it is difficult to generate a strong immune response to CNS malignancies, including tumours. Immune cells can be activated outside the brain through *in vivo* or *in vitro* methods and then given access to the brain through analogous transplantation directly into the brain, or through infusion of the activated cells with concurrent breakdown of the BBB with certain drugs. Some of these techniques are described in the *in vivo* experimental models section.

Another special concern is the sensitivity of the CNS to inflammatory responses. Inflammatory responses cause swelling through the accumulation of inflammatory cells and fluid in the damaged site, and this swelling causes increased intracranial pressure and potentially herniation of the brain. The BBB normally protects the brain from harmful inflammation, but therapies that use cytokines, radiation or drugs can reduce the protective nature of the BBB. One particularly troublesome inflammatory process that can be induced through therapy is experimental allergic encephalomyelitis (EAE). The brain is normally protected from developing EAE because there is no route for antigens from ordinary brain parenchyma to be presented to the peripheral immune system. However, EAE can be induced through the use of whole tumour cell lysates in vaccines or therapy models because of the

normal and fetal CNS antigens expressed on glioma cell lines and brain tumour tissues. This has been shown experimentally in the ability of human GBM tissue to induce lethal EAE in nonhuman primates. Researchers must be aware of this potentially fatal complication and test their therapies thoroughly.

For work with animal models for CNS malignancies, the safety evaluation of a treatment or therapy for humans should include testing in two animal models. One of the animal models should be susceptible to EAE (e.g. Lewis rats) to permit more extensive evaluation of the safety of the experimental immunotherapeutic protocol, including the potentially detrimental autoimmune responses that could be stimulated by a cell-mediated immunotherapy protocol. Formally evaluating the risk of immunologically based therapies using this model should be considered in the preclinical testing of all such protocols. Additional animal models and their susceptibilities to EAE are discussed in the *in vivo* animal model section.

PRINCIPLES OF EXPERIMENTAL MODEL APPLICATIONS

Many experimental models for brain tumour research exist. First, human tumour cell models are discussed, including methods for establishing cell lines and for growing them in nude animals for *in vivo* studies. Second, animal tumour cell models are discussed, with a focus on the strengths and weaknesses of each model. Finally, the rapidly expanding field of transgenic and knockout animals and their applicability to brain tumour research is covered.

Human Brain Tumours

Human brain tumours can be studied *in vitro* by obtaining specimens from resections or biopsies or by using established cell lines. In addition, human CNS tumour xenografts are grown *in vivo* in laboratory animals.

Establishment of Cell Lines

Human glial tumour cells suitable for *in vitro* culture are often obtained from viable areas of gross tumour resections, but specimens may also be obtained through an ultrasonic aspirator, open or stereotactic biopsies or from CSF. Specific methods of growing explanted human CNS tumour cells have been described by Liwnicz *et al*. (1986), Onda *et al*. (1988) and Bjerkvig *et al*. (1990).

One major dilemma of primary explantation cell culture is determining whether the growing cells are malignant or have been overgrown by contaminating normal cellular elements. Our laboratory confirms the neoplastic genotype through formal karyotype analysis supplemented with DNA ploidy analysis, fluorescent *in situ* hybridization to determine loss of chromosome 10 and flow cytometry analysis using specific antibodies recognizing one of the EGFR mutations commonly found on human gliomas. Less specific techniques of selecting for neoplastic cells involve growing the newly explanted cells without CO_2, at cooler temperatures (34 °C), in nutrient-poor media, or in a spinner flask to select for cells capable of generating spheroids. One of the most reliable methods for proving that a population of cells is neoplastic is to implant them into an immunodeficient rodent and confirm their tumorigenicity by the assessment of progressive growth and serial transplantation. This method requires a large number of initial cells, sometimes $>5 \times 10^8$ cells, and the period until tumour growth may be as long as 6 months.

Previously Established Lines

A number of widely used human malignant glioma lines, such as U87MG, U105MG, U118MG, U138MG, U178MG, U251MG, U343MG, U373MG, U410MG and U1231MG, were derived by Ponten and Westermark at the University of Uppsala in Sweden. Many other gliomas are available from brain tumour research laboratories at academic sites such as Duke University. The medulloblastoma lines derived and characterized at Duke University and those derived by Tamura *et al*. (1989) demonstrate true medulloblastoma profiles with neuronal differentiation and positive staining for synaptophysin and neurofilament proteins, and not for GFAP. The Daoy medulloblastoma cell line described by Jacobsen *et al*. (1985) does demonstrate glioma-associated markers, in addition to being positive for synaptophysin. TE-671 was originally designated as a medulloblastoma, but has subsequently been shown to be a rhabdomyosarcoma.

Maintenance

Once a human CNS neoplastic cell line has been established, strict protocols must be established to prevent the development of artifacts. Some potential artifacts that can impact cell culture experiments significantly are (1) contamination with other cell lines carried within the same laboratory, (2) overgrowth with a competing cell type contained in the cell line, such as normal glial cells, endothelial cells, macrophages or cells of leptomeningeal origin, (3) contamination with *Mycoplasma*, a bacterial species that can alter cell growth drastically, and has been the cause of incorrect therapeutic responses, (4) tumour cell differentiation with alteration of certain biological properties including GFAP expression, (5) selection of subpopulations that have an *in vitro* growth advantage or (6) loss of tumorigenic capacity after serial passage *in vitro*, the mechanism of which is unknown. Testing for each of these potential artifacts must be done on a regular basis. *Mycoplasma* contamination is tested with high-performance liquid chromatographic analysis of cell

culture supernatants and is determined by the inability of conditioned media from *Mycoplasma*-free cell lines to convert deoxyadenosine to adenosine or thymidine to thymine. Changes in tumorigenicity may be detected through alterations in *in vitro* morphological and growth characteristics, which can be tested for through microscopic observation and growth curves. Changes in the predominant cell type of a cell line can be detected through karyotype and restriction fragment length polymorphism (RFLP) analysis, expression of GFAP, S100 and other surface antigens, presence of glucose-6-phosphate dehydrogenase isoenzymes and response to cyclic adenosine monophosphate and various standard chemotherapeutic agents. These combined tests create a specific profile for each cell line such that contamination or changes over time can be detected.

An alternative to standard cell culture techniques has been developed to reproduce more accurately the three-dimensional architectural pattern of human gliomas *in situ*. This technique uses multicellular spheroids prepared either directly from biopsies digested with collagenase and plated onto agar-coated flasks or from established cell lines. The production of extracellular matrix glycoproteins is promoted in this system. This technique is especially applicable in the testing of cytotoxic and cytostatic drugs.

In Vivo Models

Many human CNS tumour xenografts have been grown subcutaneously or intracranially and serially passaged in immunodeficient animals. These xenografts have primarily been GBM, in addition to some medulloblastomas, a few ependymomas and a myxopapillary ependymoma. Xenografts have also been grown in the intrathecal space of the rat, providing a model of neoplastic meningitis. The xenografts usually maintain the morphological features of the original tumour, including reactivity for GFAP and expression of tumour-associated antigens. The morphological features that characterize human GBMs, including necrosis, can be seen in these xenografts, although endothelial proliferation is less common. As in serial passage *in vitro*, serial passage *in vivo* may influence the subpopulation dynamics in the tumour, possibly creating a tumour that is histologically and biologically different from the initial tumour. As a result, it is important to confirm routinely that the tumours growing in the animals are the same as the original tumour, and not a differentiated tumour or a murine tumour induced by the presence of the xenografts.

Tumour cells can be given intracranially through stereotactic injection to specific sites in the brain. Tumour cells can also be injected into the carotid artery to set up intracranial growth in a less controlled manner, similar to the haematogenous route that tumour cell metastases take in humans to reach the brain. These intracranial models better simulate the clinical situation in the pattern of tumour growth and the barriers of the brain to therapy. However, the therapeutic efficacy may be evaluated solely on the basis of animal survival, which may not directly correlate with tumour growth. An alternative model is injection of tumour cells subcutaneously, for which evaluation of therapeutic efficacy is based on tumour size. The subcutaneous model can provide an assessment of tumour susceptibility to a specific therapy without the confounding variables that come with the intracranial model – BBB and therapeutic efficacy in the CNS. A common approach is to complete preliminary testing in the subcutaneous model before testing in an intracranial model.

Animal Models

Many transplantable animal brain tumour models are available, each with unique attributes that may be advantageous or disadvantageous for obtaining accurate and clinically relevant answers to specific experimental questions. Animal tumour cell lines can be used to study CNS malignancies *in vitro* and *in vivo*. The use of animal cell lines provides a more natural model for *in vivo* experiments, as the animals have functional immune systems and are receiving allogenic transplants apposed to the immunodeficient mice used in human xenotransplantation studies. The ideal animal glial tumour model is a tumour that (1) arises spontaneously or is derived from a tumour that arose spontaneously, (2) displays evidence of glial differentiation histologically and at a molecular level, (3) is biologically and genetically stable and (4) requires few tumour cells to initiate (a) predictable tumour growth *in vitro* and (b) reproducible and fatal growth intracerebrally and subcutaneously *in vivo* in syngeneic animals.

Spontaneous Brain Tumour Models

Spontaneous CNS tumours are not unique to humans, but they are more prevalent in humans than in lower species. Therefore, one of the main difficulties in the use of animal models is to overcome the relatively rare incidence of spontaneous tumours in most animals, even in older animals. The prevalence of spontaneous CNS tumours is reported to be as low as 0.01%. However, some spontaneous tumours have been isolated and established as cell lines. The most widely used spontaneous tumours that have been found in inbred rodent strains and established as cell lines include spontaneous gliomas (astrocytomas) from VM mice, neuroblastoma from A/J mice and melanoma from C57BL/6 mice. No spontaneous brain tumour models in rats have been established. The major limitation to the use of mouse models in the evaluation of immunotherapy protocols is the resistance to induction of EAE. Mice in general, and particularly mouse strains such as C57BL/6 and VM/Dk with the H-2^b MHC background, are notoriously resistant to the induction of EAE.

VM Gliomas

A number of transplantable cell lines that are uniformly tumorigenic in syngeneic VM mice, both intracranially and subcutaneously, that appear to be glial in origin to a number of observers, and that express glial markers such as GFAP and glutamine synthetase (Sampson *et al*., 1997) have subsequently been derived from VM gliomas. Two of these cell lines have been extensively characterized. The SMA-497 cell line has been extensively studied in chemotherapeutic assays both *in vitro* as multicellular tumour spheroids and *in vivo* in syngeneic VM mice. The SMA-560 murine astrocytoma cell line is not a cloned population; thus, it maintains representation of some of the heterogeneity of the original tumour and has recently been shown to secrete biologically active TGF-β, an immunosuppressant secreted by many human malignant gliomas (Sampson *et al*., 1997). Because these tumours arose spontaneously in an inbred mouse strain, are highly tumorigenic, are clearly of an astrocytic lineage and secrete an immunosuppressant commonly secreted by human gliomas, they serve as an excellent animal model of human gliomas, especially when immunotherapeutic protocols are being assessed.

4C8 Glioma

A more recently established glioma cell line is the 4C8 glioma. This cell line was derived from a spontaneous glioma-like tumour that arose in mice transgenically modified to express the neu oncogene (c-*neu*) under the transcriptional control of the myelin basic protein (MBP) gene promoter. 4C8 has been used to establish subcutaneous and intracranial tumours in syngeneic B6D2F1 mice.

C1300 Neuroblastoma

Another spontaneously arising tumour that may be a useful model for nervous system tumours is the C1300 neuroblastoma that arose in the abdominal cavity of an inbred A/J mouse. This cell line has a typical neuroblastic appearance and can be grown intraperitoneally or subcutaneously in syngeneic A/J mice.

B16 Melanoma

The B16 melanoma is syngeneic in C57BL/6 mice. Because of its spontaneous origin and wide use, the B16 melanoma is a practical model of secondary tumours that grow within the nervous system. B16 melanoma is also valuable as a primary CNS tumour model because it arises from the same cells: neural crest cells. Characteristics of its growth and therapy have been well established outside the CNS, making it an easy model with which to work.

Induced Brain Tumour Models

An alternative to spontaneous tumour models is induced animal tumours. Physical, viral or chemical agents can induce nervous system tumours in experimental animals. Although therapeutic ionizing radiation is accepted as the only neurocarcinogen in humans, viruses and chemicals have been successful at inducing nervous system tumours in various species of experimental animals. Although these models were initially directed at uncovering the aetiology of human brain tumours, the rapid progress that has been made in the last decade in understanding the molecular basis of human nervous system tumours directly may mean that these models will not fulfil their promise in this area. Many of them may remain useful, however, in evaluating novel approaches to brain tumour therapeutics.

Physical Agents

Ionizing and ultraviolet radiation, low-frequency electric and magnetic fields and hyperthermia have been considered potential physical neurocarcinogens. Ionizing radiation is the only established human neurocarcinogen, but radiation has been used only infrequently for the induction of nervous system tumours in animals. Rats have been susceptible to the induction of GBMs after the direct intracerebral implantation of ^{60}Co, transplacental intravenous administration of ^{32}P or total body irradiation. Total body irradiation was also successful in inducing tumours in Rhesus monkeys (*Macaca mulatta*) that possess all the histopathological features of human GBM. Unfortunately, none of these tumours have been established appropriately for use in an experimental transplantation model.

Viral Agents

The foundation for the discovery of proto-oncogenes and tumour-suppressor genes can be attributed to early studies in viral carcinogenesis. Vázquez-López (1936), using cell-free extracts of the Rous sarcoma to induce intracranial sarcomas in chickens, is generally credited with the first induction of an intracranial tumour by a virus. Intracranial injection of a number of different viruses has since been used to induce a large variety of nervous system tumours in lower animals and nonhuman primates. In addition to the large number of positive yields, the method has the advantage over chemically induced tumour models (discussed in the next section) of producing tumours within a relatively short time, often within a few weeks. Newborn animals show the greatest degree of susceptibility, the yield depending on the type of virus used, the exact age of the animal at the time of inoculation and the precise dose and concentration of the virus injected. A good deal of correlation exists between the type of virus used and the tumour type produced, although this is not absolute: AA and GBM have most often been obtained with the oncogenic RNA viruses such as the avian, murine and simian sarcoma viruses. Choroid plexus papillomas are induced by some of the simian and human types of papovaviruses, and medulloblastomas and pineocytomas by isolates of the human JC papovaviruses. Finally, neuroblastomas and

retinoblastomas have been reliably induced with the human adenovirus type 12.

Oncogenic RNA viruses have been the most serviceable in the development of useful animal models of cerebral tumours. A technique for reproducibly inducing glial tumours with a uniform mortality distribution in large numbers of rats was established by using the avian sarcoma virus (ASV). An important feature of these tumours is that syngeneic rats bearing ASV-induced tumours have exhibited a depression in their cell-mediated immune responses not unlike those found in humans with malignant glial tumours. A permanent cell line, S635 (clone 5), derived from an AA induced in a neonatal female F344 rat by intracerebral inoculation with concentrated Schmidt–Ruppin-D strain of this virus, has provided a useful rodent brain tumour model. Cells from this line cultured *in vitro* and tumours grown *in vivo* from this cell line have a consistent architecture composed of interlaced, elongated cells that express GFAP, even after more than 100 passages *in vitro*. This cell line, *in vitro,* has a population doubling time of 18.82 h and a colony formation efficiency of 90.8%. *In vivo*, these cells are highly tumorigenic, with as few as 100 cells being uniformly lethal within 1 month when injected intracerebrally into syngeneic rats.

Chemical Agents

The early establishment of an association between tobacco snuff use and oral cancers and between chimney sweeping and scrotal cancer laid the foundation for the study of chemicals as carcinogenic agents. Since that time, in an effort to establish models for testing brain tumour therapies, a number of different compounds that consistently induce nervous system tumours in experimental animals have been identified. The relative ease with which nervous system tumours could be selectively obtained in experimental animals after the administration of these agents, particularly polycyclic aromatic hydrocarbons (PAHs) and the *N*-nitroso compounds, resulted in a vigorous exploration of these animal models in various basic and applied aspects of neuro-oncology research. Many of these tumours have been subsequently passaged *in vitro* and *in vivo* and are now widely used to evaluate potential therapeutic agents.

Polycyclic Aromatic Hydrocarbons and Derivatives. PAHs and their derivatives have been used to induce gliomas, meningiomas and malignant schwannomas. PAHs may also be capable of transforming fetal mouse brain cells *in vitro*. Several chemicals from this large group of compounds have been shown to be neurocarcinogens, with 3- and 20-methylcholanthrene (MCA), benzo[*a*]pyrene and dimethylbenz[*a*]anthracene being the most effective and widely studied. Mice, rats and Syrian hamsters are generally the only animal species vulnerable to neuro-oncogenesis from use of these compounds, and tumour induction generally requires direct implantation of these compounds in the form of powder or pellets into the brain. Malignant tumours of the sciatic nerve in mice have also been produced by injecting PAHs locally.

Methylcholanthrene-induced murine tumours

The ependymoblastoma series. A series of murine gliomas were induced in the 1940s and 1950s by direct implantation of MCA pellets intracerebrally. The tumours derived by this technique, especially the Ep, EpA, GL261 and GL26, have become the most widely used models of murine primary intracranial glial neoplasms in the USA and are often referred to as the ependymoblastoma series because of their early histological classification. These tumours can all be grown subcutaneously and intracerebrally *in vivo*, and some have been established as cell lines *in vitro*. The histological picture of these tumours is similar to that of the rare childhood human ependymoblastoma, but these tumours really demonstrate no signs of ependymal differentiation and on closer examination consist only of undifferentiated cells of uncertain origin. Hence, if they model human gliomas at all, at best they represent a rare form of childhood glioma and not the more common malignant astrocytic tumours generally seen in humans.

Despite their extensive use, these tumours have been poorly characterized, and their derivation is not clearly documented. For example, induction of the Ep tumour is generally attributed to Zimmerman and Arnold (1941), who injected 20-MCA pellets intracranially in male C3H mice. Although a number of tumours of different histologies were obtained by using this technique, none were initially classified as ependymoblastoma. Apparently, one of the mixed gliomas induced in these experiments emerged with the histological appearance of ependymoblastoma after serial subcutaneous passage. Subsequent researchers, using the Ep cell line from Zimmerman and referencing this original paper (Zimmerman and Arnold, 1941), usually transplanted this tumour into C57BL/6 mice. C57BL/6 mice carry the H-2^b MHC haplotype and are therefore incompatible with the H-2^k MHC haplotype of C3H mice from which the tumour was originally derived. Even Zimmerman himself, when referring to this ependymoblastoma, references this original paper (Zimmerman and Arnold, 1941), which used C3H mice (H-2^k) exclusively, but states that the tumour has been propagated in C57BL/6 mice (H-2^b). The EpA tumour, a subline of the Ep tumour, suffers from the same problems. Although the details are unclear, the Glioma 261 cell line (GL261) also appears to have been induced in male C3H mice (H-2^k) by the implantation of 20-MCA pellets, yet many authors transplant this tumour into C57BL/6 mice (H-2^b). Similarly, the derivation of the Glioma 26 (GL26) tumour, also induced by Zimmerman and Arnold, cannot be deduced accurately from the published literature. However, reports of the presence of H-2^b MHC class I and II molecules on the cell lines of the ependymoblastoma series suggest that they may have indeed been derived from C57BL mice.

The failure to document stringently that the tumour lines used by a particular investigator are syngeneic with the inbred mouse strain used will allow potential histocompatibility differences to influence experimental results greatly. Overall, these findings suggest that extensive characterization of cell lines within the ependymoblastoma series is needed prior to any meaningful experimentation and that favourable responses to various therapeutic modalities using these cell lines must, therefore, always be interpreted with caution and preferably confirmed in a second experimental system. Finally, because all these tumours did not arise spontaneously but were induced artificially with chemicals, these tumours cannot, by virtue of their origin, accurately portray the intrinsic qualities of spontaneous human tumours.

L1210 Leukaemia. L1210 leukaemia was induced by the application of 0.2% MCA in diethyl ether cutaneously on an inbred female DBA mouse (subline 212) and may serve as a very useful model of tumours metastatic to the nervous system. After systemic injection, these leukaemic cells disseminate and infiltrate peripheral blood, lymph nodes, liver, spleen and brain. The tumour grows primarily along the leptomeninges as in humans with CNS leukaemia. L1210 leukaemia has been used to demonstrate the efficacy of a number of chemotherapeutic agents and has been extensively used to demonstrate the protective barrier that the intracranial compartment provides against many of these agents.

N-Nitroso Compounds and Other Alkylating Agents. Some alkylating agents, especially the nitrosourea derivatives, have a striking neurotropicity and are more powerful and more reliable inducers of experimental nervous system tumours than are PAHs. Although a large number of different alkylating agents have been employed for inducing nervous system neoplasms in experimental animals, *N*-methyl-*N*-nitrosourea (MNU) and especially *N*-ethyl-*N*-nitrosourea (ENU) remain the most widely used of these compounds, and they are particularly effective in rats. Importantly, nonhuman primates are also susceptible to the neurocarcinogenic action of these substances when exposed transplacentally. Mice, however, are relatively resistant to the neuro-oncogenic action of these compounds, so most murine brain tumour models have been derived from PAH-induced tumours. The relative activity of MNU or ENU in the rat is highly dependent on the age of the animal at the time of injection. MNU is the most active neuro-oncogenic substance in adult animals, whereas the higher alkyl homologues, including ENU, are significantly less effective in adult rats. In very young animals, on the other hand, the relative oncogenicity of MNU and ENU is curiously reversed, and a very high incidence of nervous system tumours is induced by a single subcutaneous or intracerebral injection of ENU in newborn animals. This marked susceptibility of younger animals to tumour induction with ENU provided a convenient transplacental approach to nervous system tumour induction. In this protocol, a single low-dose intravenous injection of ENU is given to gravid rats on the fifteenth or sixteenth day of gestation, which produces tumours in virtually 100% of the offspring, with a latency period of approximately 300 days. In addition to brain tumours, tumours of the trigeminal nerve, spinal cord and peripheral nervous system (PNS) can also be induced.

Nitrosourea administration usually results in multiple subependymal tumours that morphologically resemble mixed gliomas, usually with a mixture of oligodendroglia and astrocytes, which may involve the cerebrum, cerebellum or spinal cord. Typical oligodendrogliomas, which more frequently appear in the hemispheric subcortical white matter, and also typical astrocytomas are produced with these compounds, but these gliomas hardly ever show the typical histological features of GBMs. PNS tumours also frequently develop after administration of the *N*-nitroso compounds and are generally anaplastic schwannomas. The cranial nerve roots within the cerebellopontine angle and the spinal nerve roots are most frequently involved.

Most of the commonly used rat glioma cell lines have been induced by systemic or transplacental injection of nitrosoureas. The 9L gliosarcoma and the C6 glioma are the most commonly used cell lines derived by these techniques.

9L Gliosarcoma. The 9L gliosarcoma cell line was derived from a tumour originally induced in inbred male Fischer 344 (F344) rats by weekly intravenous injections of 5 mg/kg MNU. It has acquired an extensive sarcomatous component, however, after serial passage, and differs considerably from the original tumour, which had the histological appearance of an AA. These changes demonstrate the phenotypic and genetic instability associated with this cell line and sublines derived from it. Thus, this cell line should be obtained from the original source when possible, and the source of any sublines should always be identified. Favourable therapeutic outcomes with this tumour must always be viewed in the light of its genetic instability, which potentially could produce confounding immune responses against this tumour, even in theoretically syngeneic F344 rats.

C6 Glioma. The C6 glioma is a very frequently used experimental model of nervous system neoplasia. However, it is a completely inappropriate model whenever histoincompatibility may alter experimental results, which is almost always. The major limitation to using the C6 cell line is its uncertain genetic background. The reference usually cited for the induction of this cell line (Benda *et al.*, 1968) does not report the rat strain from which the tumour was derived. However, Figure 1 in that paper is identical with Figure 10 in a subsequent paper by the same authors (Benda *et al.*, 1971), which indicates that the C6 glioma was induced by weekly intravenous injections of 5 mg/kg MNU in random-bred male Wistar–Furth rats. Because this cell line was derived in

a randomly bred rat, no syngeneic host exists for this cell line. It has also been discovered recently that the C6 cell line carries an MHC haplotype different from the RT1.A^d MHC haplotype found on BDIX and BDX rats, a strain often used in experiments with the C6 cell line. Therefore, therapeutic responses determined with this cell line in immunocompetent rats must always be evaluated in the context of the allogeneic responses that may be stimulated against this line, even in inbred Wistar–Furth rats, which clearly differ genetically from the cell line itself. Thus, although the C6 cell line remains a good model for *in vitro* glioma studies, for *in vivo* studies, especially ones those where immunological responses may play an important role, results should always be confirmed in more appropriate model systems.

CNS-1 Glioma. A more recent addition to the wide variety of nitrosourea-induced rat glioma cell lines, the CNS-1 cell line, has one particular feature that may make it extremely useful. The CNS-1 cell line was induced in inbred Lewis rats by weekly injection of MNU. Because Lewis rats are highly susceptible to the induction of EAE, this cell line permits more extensive evaluation of the safety of experimental immunotherapeutic protocols, including the potentially detrimental autoimmune responses that could be stimulated by cell-mediated immunotherapy protocols. In light of the documented expression of normal and fetal CNS antigens on glioma cell lines and brain tumour tissues and the ability of human GBM tissue to induce lethal EAE in non-human primates, consideration should be given to evaluating formally the risk of immunologically based therapies using this model in the preclinical testing of all such protocols.

Transgenic and Knockout Models

The development of gene targeting with the ability to alter or modify genes has opened new doors for neuro-oncology researchers. Most of the original neuro-oncology experiments with transgenic animals were designed to study the role of different genes in brain tumorigenesis. Common genes targeted in this research include *p53*, *Rb* and *Nf1* (**Table 2**). The development of transgenic mice using tissue-specific promoters such as GFAP and MBP has also been extensively used to study neural tumour formation. The combination of transgene expression in knockout mice has been used in order to study the effects of multiple alterations on tumorigenesis, thereby mimicking the process of tumour formation more accurately. All of these experiments and their results are discussed below.

Knockout mice are created through homologous recombination to express only one copy of a gene (heterozygous gene deletion) or no copies of the gene (null; homozygous gene deletion). *Ptc*, *Rb*, *p53* and *Nf1* are four genes that have been examined in knockout mice for their effects on brain tumorigenesis. Homozygous inactivation of *Ptc* in mice is fatal during embryogenesis, whereas heterozygous inactivation of *Ptc* in mice leads to medulloblastoma development. Homozygous *Rb1* knockout mice are not viable and heterozygous *Rb1* knockout mice develop pituitary adenocarcinomas at an increased rate. Homozygous *p53* knockout mice have been shown to accelerate tumorigenesis, developing lymphomas, sarcomas and gliomas at a higher rate. These mice have a decrease in gamma radiation and doxorubicin-induced apoptosis, causing increased tumorigenesis. Conversely, Jacks *et al*. (1994) demonstrated homozygous *p53* knockout mice not to develop brain tumours, and heterozygous *p53* knockout mice to develop only rare ependymomas. Homozygous *Nf1* knockout mice are predisposed to tumour formation. Phaeochromocytoma is a tumour derived from the adrenal medulla (neural crest derived tissue) and is one of the predominate tumour types found in *Nf1* null mice.

Yin *et al*. (1997) used *Rb* knockout mice to study the ability of *Bax* to act as a tumour suppressor in the *p53*-mediated apoptosis. Through taking mice with *Rb* inactivation in brain epithelium and crossing them with *Bax*- and/or *p53*-deficient mice, mice were created that lacked *Rb* and *Bax* expression in brain epithelium. These mice developed tumours at a higher rate than *Rb* knockout mice alone, which indicates that *Bax* is required for a full *p53*-mediated response, and therefore that *Bax* acts as a tumour suppressor.

The same *Rb* knockout model was used by Liao *et al*. (1999) to study the role of *Atm* in *p53*-dependent apoptosis and tumour suppression. Mice with *Rb* inactivation in brain epithelium were crossed with *Atm*-deficient mice to create mice that lacked *Rb* and *Atm* expression in brain epithelium. In this study, *p53*-dependent apoptosis, transactivation and tumour suppression were unaffected by *Atm* deficiency, which indicates that signalling in the DNA damage pathway is distinct from that in the oncogene-induced pathway. It was further shown that *Atm* deficiency has no effect on tumorigenesis and tumour progression in this model.

Marino *et al*. (2000) induced medulloblastomas in *p53* null mice by inactivating *Rb* in the external granular layer cells of the cerebellum. Because *p53* homozygous knockout (null) mice do not develop brain tumours, this research indicates that the loss of *Rb* function is essential for medulloblastoma development.

Transgenic mouse models are typically made to express an additional gene ubiquitously under transcriptional control of a gene expressed only in the target tissue. The glial cell specific GFAP promoter and the MBP, expressed only in myelinating cells, have been used as anchor genes for the introduction of transgenes in the nervous system. Through this technique, ERBB2 and the SV 40 large T antigen have been introduced specifically into murine nervous systems. Transgenic ERBB2 mice develop oligodendrogliomas, and transgenic SV 40 large T antigen mice develop anaplastic astrocytomas.

Table 2 Transgenic and knockout mouse models

Gene	Expression	Tumour type	Reference
Ptc	Heterozygous (+/−) knockout	Medulloblastoma	Goodrich *et al.* (1997); Zurawel *et al.* (2000); Wetmore *et al.* (2000)
Rb1	Heterozygous (+/−) knockout	Pituitary carcinoma	Jacks *et al.* (1992)
Rb1 and *bax*	Rb1 (+/−) and Bax (−/−) knockout	Pituitary carcinoma	Yin *et al.* (1997)
Rb1 and *Atm*	Rb1 (+/−) and Atm (−/−) knockout	Pituitary carcinoma	Liao *et al.* (1999)
p53	Homozygous (−/−) knockout	None	Jacks *et al.* (1994)
	Heterozygous (+/−) knockout	Ependymoma	Jacks *et al.* (1994)
p53 and *Rb1*	TP53 (−/−) knockout and Rb1 (−/−) inactivation	Medulloblastoma	Marino *et al.* (2000)
Nf1	Homozygous (−/−) knockout	Phaeochromocytoma	Jacks *et al.* (1994)
EGFR, mutant	Glial cells	Glioma	Holland (2000)
v-src	GFAP-expressing cells	Astrocytoma, GBM	Theurillat *et al.* (1999)
erbB2	MBP-expressing cells	Oligodendroglioma	Hayes *et al.* (1992)
SV 40 large T antigen	GFAP-expressing cells	Anaplastic astrocytoma	Danks *et al.* (1995)
	Tyrosine hydroxylase promoter–enhancer	PNET	Suri *et al.* (1993)
	Tryptophan hydroxylase promoter	Pineal tumours	Son *et al.* (1996)
	MSV enhancer–natural promoter	PNET	Korf *et al.* (1990); Theuring *et al.* (1990); Gotz *et al.* (1992)
	LH β-subunit promoter	PNET; retinoblastoma	Windle *et al.* (1990a); Marcus *et al.* (1991)
	Interphotoreceptor retinoid-binding protein promoter	PNET	al-Ubaidi *et al.* (1992)
	PNMT promoter	Retinoblastoma	Baetge *et al.* (1988); Hammang *et al.* (1993)
	Schwann cell-specific P_0	Schwannoma	Messing *et al.* (1994)
	LVP or SV40 enhancer–promoter	Choroid plexus tumour	Chen and Van Dyke (1991)
	CF transmembrane conductance regulator–promoter	Malignant intraventricular ependymomas and choroid plexus carcinomas	Perraud *et al.* (1992)
	GnRH promoter	Neuroblastoma	Mellon *et al.* (1990); Radovick *et al.* (1991)
	Olfactory marker protein regulatory elements	Neuroblastoma	Largent *et al.* (1993)
	Glycoprotein hormone α-subunit promoter–enhancer	Gonadotrope anterior pituitary adenomas	Windle *et al.* (1990b)
SV40 early region	Metallothionein promoter	Choroid plexus carcinoma	Brinster *et al.* (1984); Palmiter *et al.* (1985)
JCV (T-ag)	SV 40 regulatory region	Choroid plexus papilloma	Ressetar *et al.* (1993)
JCV (Mad-1)	JCV early region promoter	Neuroblastoma	Small *et al.* (1986)
JCV (CY)	JCV early region promoter	Medulloblastoma, PNET	Krynska *et al.* (1999)
Adenovirus E1A and E1B	MMTV LTR	Neuroblastoma	Koike *et al.* (1990)
Polyomavirus large T antigen	Polyoma early region promoter	Pituitary adenoma	Helseth *et al.* (1995)

Table 2 (Continued)

Gene	Expression	Tumour type	Reference
Polyomavirus middle T antigen	Polyoma early region promoter	Pituitary adenoma	Bautch *et al.* (1987)
	Thymidine kinase promoter	Neuroblastoma	Aguzzi *et al.* (1990)
Papillomavirus 16 *E6*, *E7* and *ORF*	Human β-actin promoter	Ependymoma, pituitary carcinoma, choroid plexus carcinoma	Arbeit *et al.* (1993)
HTLV-1 TAT	HTLV-1 LTR	Peripheral nerve sheath tumours	Hinrichs *et al.* (1987)
MYC and *TAX*	HTLV-1 LTR	Brain tumours (not specified)	Benvenisty *et al.* (1992)

Table 3 Rodent brain tumour models[a]

Species	Cell lines	Syngeneic strain	Induction technique	Histological type	GFAP staining
Mouse	P560	VM/Dk	Spontaneous[b]	Anaplastic astrocytoma	++
Mouse	GL261	Unclear	MCA	Ependymoblastoma	No data
Mouse	GL26	Unclear	MCA	Ependymoblastoma	+
Mouse	Ep, EpA	Unclear	MCA	Ependymoblastoma	No data
Mouse	L1210	DBA	MCA	Leukaemia	N/A
Mouse	B16	C57BL/6	Spontaneous	Melanoma	N/A
Rat	S635-clone 5	Inbred CD Fischer 344	ASV (Schmidt–Ruppin)	Anaplastic astrocytoma	++
Rat	9L	Inbred CD Fischer 344	MNU	Gliosarcoma	−
Rat	RG-2	Inbred CD Fischer 344	ENU	Glioma	−[c]
Rat	CNS-1	Inbred Lewis	MNU	Glioma	+
Rat	C6	None (random-bred Wistar–Furth)	MNU	Glioma	+[d]

[a]Abbreviations: GFAP, glial fibrillary acidic protein; MNU, *N*-methyl-*N*-nitrosourea; ENU, *N*-ethyl-*N*-nitrosourea; MCA, 3- and 20-methylcholanthrene; N/A, not applicable.
[b]VM/Dk mice have a high incidence of spontaneous tumours. These lines were derived from spontaneous astrocytomas in this mouse strain.
[c]Some GFAP-positive cells have been noted in intracerebral xenografts, but these could be reactive cells only.
[d]Inducible by dbcAMP, norepinephrine and organ culture.

The GFAP-v-src transgenic mouse model developed by Weissenberger *et al*. (1997) was used to study the triggering of angiogenesis during tumour progression. GFAP-v-src mice develop low-grade astrocytomas early in their lives. These low-grade tumours develop into highly malignant, hypervascularized GBM. By studying VEGF levels at different tumour stages, Theurillat *et al*. (1999) found that expression of angiogenic signals is an early event during tumour progression and precedes hypervascularization. Because of the similarity in tumour progression between GFAP-v-src and human gliomas, these transgenic mice may be an excellent model for anti-angiogenic research.

Holland (2000) created transgenic EGFR mutant mice. These mice express a constitutively active, mutant form of EGFR in cells of glial lineage. The presence of the mutant EGFR induces glioma-like lesions, with characteristics of increased cell density, vascular proliferation and GFAP and nestin expression. These transgenic mice will allow for testing of target-specific therapies against EGFR mutants in a model that is very similar to glioma development in humans.

Summary

A number of transplantable animal brain tumour models are available (**Table 3**), each with unique attributes that may be advantageous or disadvantageous in finding accurate and clinically relevant answers to specific experimental questions. The primary use of experimental models is to predict therapeutic responses in human tumours. In this sense, because very few treatment modalities have shown efficacy against human primary brain tumours clinically, it is difficult to prove that one model is necessarily better than another. Nevertheless, it is probably prudent to avoid basing clinical decisions on information obtained from use of models that can be predicted to provide potentially misleading results, for example, those with inherent histoincompatibilities.

IN VIVO EXPERIMENTAL TECHNIQUES

In vivo experimental techniques include implanting tumours intracranially, use of a metastasis model,

techniques for overcoming the BBB, radiation and treatment through injection and infusion and treatment through viral transfection (gene therapy).

Implanting Tumours Intracranially

Intracranial injection requires the use of a stereotactic frame, such as the Kopf stereotactic frame (Kopf Instruments, Tujunga, CA, USA), and highly accurate syringes, such as Hamilton syringes. Cells for injection should be gently harvested, rinsed well in sterile Dulbecco's phosphate-buffered saline, counted and resuspended in 10% (v/v) methylcellulose in zinc option medium. The number of cells required can be determined by injecting increasing numbers of cells (30, 100, 300, 1000, etc.) until 100% of animals develop tumours. This mixture is loaded into a 250-μL Hamilton syringe for mice or a 500-μL syringe for larger rodents such as rats. The syringe is positioned in the stereotactic frame, the animals are anaesthetized and the needle is positioned at bregma. To implant tumour cells in the right caudate nucleus of mice, the needle is moved 2 mm to the right of bregma and 4 mm below the surface, and 5 μL of cells are given. These coordinates were determined by using *A Stereotaxic Atlas of the Albino Mouse Forebrain* (Slotnick and Leonard, 1975). Coordinates for rats can be determined with *A Stereotaxic Atlas of the Rat Brain* (Pelligrino *et al*., 1979) or *The Rat Brain: a Stereotaxic Atlas of the Forebrain and Lower Parts of the Brain Stem* (Konig and Klippel, 1974). Stereotactic atlases for pig, monkey (*Macaca mulatta*, *Macaca fuscata*, *Cebus apella*, *Pan satyrus*, *Saimiri sciureus*), cat, pigeon, golden hamster, chick (*Gallus domesticus*), dog and baboon are also available.

Metastasis Model

To emulate brain metastases in an animal model, researchers have directly injected tumour cells into the brain and also injected tumour cells intracarotid. The direct intracranial injection excludes the possibility of metastases in additional organs, keeping the model simple. The intracarotid method mimics the development of brain metastases through haematogenous spread. The intracarotid model produces metastases in different regions of the brain, according to where the tumour cells grow the best (meninges versus parenchyma).

Cells from brain metastases have a lower growth rate and have a lower metastatic potential than tumour cells from visceral metastases, which indicates that brain metastases originate from a unique subpopulation of cells within the primary neoplasm. Thus, the intracarotid injection of tumour cells may be a more accurate depiction of metastases to the brain because of the added selection step of tumour cells crossing the BBB to enter the brain parenchyma.

Overcoming the BBB

The BBB is a formidable shield against drug or antibody therapy given intravenously, as only very small molecules (<180 Da) can cross the barrier freely. One common method of overcoming the BBB is giving high doses of drug or antibody systemically, such that enough can cross the barrier to be efficacious against malignancy in the CNS. Unfortunately, systemic toxicity is often reached before an effective concentration is achieved in the CNS. This method is also expensive and wasteful because of the amount of drug or antibody needed. Breaking down the BBB immediately before giving the therapy gives greater access to the brain, and therefore decreases the dose, systemic toxicity and price of treatment. Mannitol is the most frequently used BBB disruption agent. Mannitol is a hypertonic sugar solution that is introduced to the internal carotid or vertebral artery circulation immediately before the administration of intra-arterial chemotherapy. In rats, mannitol can be infused cephalad at 25% in 37 °C water via a catheter in the external carotid artery, at a rate of 0.12 mL/s, by using a constant-flow pump. The treatment is then immediately given through the same catheter.

Direct delivery of drugs and antibody to the tumour through stereotactic injection may be a better route. Direct injection requires less drug or antibody and only the tumour and the tissue immediately surrounding the tumour are exposed to the treatment, which eliminates systemic toxicity. The number of times drugs or antibody can be delivered through this route is limited because of the invasiveness of the technique.

The BBB can also hamper the development of an immune response to tumours in the CNS, as there is restricted movement of regular immune system cells into the CNS, and the CNS immune cells (microglia) may have different processes of antigen gathering and recognition. Methods to overcome this difficulty have been explored, and one strategy involves surgically removing part or all of an intracranial tumour, homogenizing the tumour, pulsing antigen-presenting cells (APCs) with the homogenate and injecting the pulsed cells systemically. It has been shown that an efficacious cellular response to CNS tumours can be induced through these pulsed APCs (Heimberger *et al*., 2000a). This demonstrates that these CNS tumours are not incapable of generating an immune response, but that the tumours are shielded from generating a response by their location in the brain.

Radiation

In vivo experiments involving the effects of external radiation on intracranial tumours have been done in rat and mouse models. Radiation should be confined to the head to prevent radiation damage to the rest of the body. This can be done by anaesthetizing the animals and positioning them such that only their heads are exposed

during external beam radiation. Alternatively, for use with wide-field (whole-body) radiation, the animals can be anaesthetized and placed in restraining containers that restrict radiation to specific sites on the body, such as the brain, through shielding with 1 mm of Pb. Drug, cytokine or antibody treatment is often combined with radiation to test for synergy and to determine the appropriate schedule of dosing.

Treatment Through Injection and Infusion

Intracranial tumours can be treated through direct injection of drug, antibody or immune cells into the tumour. Rat and mouse experiments have been done where the use of a stereotactic frame allows for precise targeting of the tumour (Sampson *et al*., 2000). Small amounts of liquid (5–20 μL) can be injected at one time into the tumour. This method has two advantages over systemic treatment of brain tumours. First, it uses 1% of the amount of drug needed for systemic treatment. Second, the drug or antibody does not have to be altered such that it can pass through the BBB, which might possibly alter its efficacy against the tumour at the same time. The disadvantage is that direct injection is very invasive and cannot be done repeatedly.

Infusion has the same advantages as direct injection plus the ability to give larger doses, cover the tumour more extensively and treat over a longer period of time (Heimberger *et al*., 2000b). Infusion involves the surgical implantation of a tube into the centre of the brain tumour and attaching the tube to an infusion pump placed subcutaneously. Infusion of drug is a better method than simple injection, as infusion pushes the fluid through the tumour, giving greater penetration into the tumour and exposing tumour cells to more drug. Infusion pumps can be acquired commercially (ALZET Osmotic Pumps, DURECT, Cupertino, CA, USA) and used for up to 4-week intervals. A long infusion time should be used, unless the drug half-life at body temperature makes it necessary to use a shorter interval, as a longer infusion time will decrease the amount of pressure generated, lessening the amount of drug that is wasted as it is expelled from the brain along the tubing.

Treatment Through Viral Transfection

Gene therapy of brain tumours is a potential therapeutic modality. The four main approaches to gene therapy of brain tumours are (1) transfer of drug susceptibility with a suicide gene, (2) transduction with a toxic gene, (3) transduction with antisense cell-cycle genes and (4) adoptive immunotherapy. Gene therapy is accomplished through recombinant viral vectors that deliver genes specifically into dividing cells. Herpesvirus and adenovirus are two vectors commonly used, and the thymidine kinase gene is a common choice to transfer drug susceptibility. Thymidine kinase transduction makes tumour cells sensitive to the antiviral agent ganciclovir, a nontoxic prodrug. To deliver these viral vectors to the brain tumour, investigators typically use direct stereotactic inoculation into the tumour tissue. Other routes have been investigated, such as injecting the viral vectors intra-arterially after osmotic BBB disruption with mannitol.

The use of suicide genes in the therapy of brain tumours has many positive caveats. Because the brain consists mostly of nondividing cells, there is very little toxicity to nontumour cells. The 'bystander effect' extends the therapeutic effect of the viral vectors by extending cytotoxic effects to untransduced cells. Transfer of genes that repress growth through antiangiogenesis (interferon gamma) is another current field of research. *p53* gene replacement is strongly indicated as a therapeutic modality, and more efficacious modes of delivery are being explored.

Combination gene therapy is a promising concept for brain tumour treatment. By transferring more than one gene into a tumour, a heterogeneous mixture of tumour cells can be hit. This is important in brain tumour therapy because of the known heterogeneity of cells within a single glioma tumour (Bigner *et al*., 1981). The introduction of genes encoding multiple agents with different mechanisms of action through combination gene therapy may induce synergistic effects. Along that same line of thought, combining gene therapy with chemotherapy and radiation will most likely produce a superior response to one that is achievable through gene therapy alone.

INTERPRETATION OF EXPERIMENTAL RESULTS

A substantial amount of research has been done in the brain tumour field to date, and we have greatly advanced our understanding of brain tumour genetic and biological bases. However, little improvement has been made in the clinical outcome of brain tumour patients with highly malignant tumours. One reason for this discrepancy is that there are very few good models for glioma research. And, a general assumption is that unless the therapy works extremely well in a well-established, syngeneic animal model, it probably will not be efficacious against human brain tumours clinically. Another reason for the lag in improving clinical outcomes is that it is difficult to extrapolate positive results in animal models to positive results in human brain tumour patients. Human brain tumour patients are much more complex than any animal or *in vitro* brain tumour model, and it is therefore difficult to interpret experimental findings in animal models as they would apply to human patients.

An additional problem in extrapolating results from animal models to humans is that many enzymes and

proteins differ from species to species. Consequently, a therapy that works through alterations in cellular enzymes or proteins and is effective in mice may have little or no specificity for the same enzymes or proteins in humans, and thus little efficacy.

CONCLUSION

There are a number of brain tumour models currently available, encompassing a wide variety of *in vitro* and *in vivo* systems. Many chemotherapy and immunotherapy agents have been tested experimentally in these systems and subsequently approved for clinical use. The mainstays of current brain tumour therapy are surgical resection, radiation, and chemotherapy. However, more specific and efficacious therapies are now being introduced: gene therapy, tumour-specific antibodies given intrathecally or intratumourally, antiangiogenesis factors and dendritic cells being activated with tumour-specific lysate and reintroduced. These new therapies will be added to the regimen of surgery, radiation and chemotherapy and are expected to improve outcomes.

There are still major issues to be resolved in the clinical treatment of brain tumours, such as safe, effective delivery of genetic material in gene therapy, safe, effective delivery of immunotherapy and chemotherapy and the best method, timing, and combination of surgery with other treatment modalities. To resolve these issues, the interpretation of results in experimental animal models and the extrapolation to the treatment of humans clinically must be worked out further.

- Perspectives

BIOLOGICAL ORIGIN AND TUMOUR SPECIFICS

Carcinoma of the uterine endometrium is one of the most frequently diagnosed malignancies of the female reproductive tract and accounts for approximately 34 000 new cases reported each year in the United States (Miller *et al*., 1993). Although the incidence of endometrial cancer varies widely throughout the world, industrialized countries in Europe and North America report incidences 4–5 times higher than in developing countries of Asia, Africa and South America and also Japan; world-wide, approximately 150 000 cases are diagnosed each year, making endometrial neoplasia a leading cancer in women (Harras, 1996). Epidemiological and clinico-pathological evidence suggest that there are two forms of endometrial carcinoma, based on histopathological characteristics, hormone responsiveness, aggressiveness and differentiation of the lesion, and patient history, especially exposure to unopposed oestrogens (Deligdisch and Holinka, 1987; Kurman *et al*., 1994); most endometrial tumours can be categorized as either hormone-responsive and well differentiated (Type I), or hormone unresponsive and poorly differentiated (Type II), with the former neoplasms usually occurring in perimenopausal women and the latter usually occurring in older women (>60 years) (Kurman *et al*., 1994).

Oestrogens are known risk factors for Type I uterine carcinoma in humans, whereas Type II tumours are usually unrelated to oestrogen (Kurman *et al*., 1994). Clinical studies evaluating oestrogen replacement therapy (ERT) in postmenopausal women have been especially useful in establishing the association between treatment with unopposed oestrogens and Type I endometrial cancer (Persson *et al*., 1989). The role of unopposed oestrogen stimulation in endometrial carcinogenesis is so strong that most factors associated with increased oestrogen levels such as chronic anovulation or obesity increase the risk of uterine disease. In contrast, factors that lower the proliferative effects of oestrogen on the endometrium, such as the addition of progesterone or its derivatives (collectively called progestins) to hormone replacement therapies (HPT), lower the risk of endometrial cancer (Kurman *et al*., 1994).

Studies reporting a high incidence of both endometrial carcinoma and breast cancer among mothers, sisters and aunts of patients diagnosed with endometrial cancer suggest a genetic factor in the development of a small number of these lesions (Harras, 1996). Endometrial cancer and breast cancers share some other risk factors such as early age at menarche and late age at menopause. Unlike breast cancer, late age at first birth has not been found to be a risk for endometrial cancer. However, multiple births have been associated with decreased risk of endometrial cancer while women who have never had children, particularly those with a clinical history of infertility, are at greater risk of developing the disease. Reports of women with Stein–Leventhal syndrome, a rare condition characterized by polycystic ovaries, excessive oestrogen production and infertility, have noted a particularly high risk for endometrial carcinoma. Obesity, which is often accompanied by increased levels of endogenous oestrogens, is recognized as another risk factor; in spite of the evidence linking obesity to development of endometrial carcinoma, few studies have investigated the potential role of dietary factors in developing the disease (Levi *et al*., 1993). Surveying all of these reported risk factors suggests a common link between hormonal imbalances especially excess oestrogen production (Miller *et al*., 1993).

An increasing number of reports suggest that women treated with tamoxifen, a therapeutic compound with antioestrogenic (antagonist) activity in the breast but

oestrogenic (agonist) activity in the uterus, may have an increased risk of developing endometrial cancer (Magriples *et al*., 1993; van Leeuwen *et al*., 1994; Fisher *et al*., 1994; Friedl and Jordan, 1994; King, 1995). In fact, the World Health Organisation's International Agency for Research on Cancer (IARC) and the US National Toxicology Program (NTP) published their evaluation of the carcinogenic risks of tamoxifen, supporting the hypothesis that this pharmaceutical drug is associated with increased risk of endometrial cancer (IARC, 1996; NTP, 2000). Further experimental animal studies give additional support to tamoxifen's carcinogenic potential in the rodent uterus (Newbold *et al*., 1997). Although tamoxifen is reported to exert its effects by competing with oestrogen for binding to the oestrogen receptor (ER), thereby blocking the transcriptional activity of the receptor, the exact mechanisms by which it decreases breast cancer yet increases uterine cancer remain unclear. Its complex pharmacological behaviour suggests that tamoxifen's antagonistic or agonistic activities are dose, species, tissue and cell type dependent (Mahfoudi *et al*., 1995). Data continue to accumulate, however, to suggest that various drugs and environmental chemicals with hormonal activity may represent aetiological factors for human endometrial disease, including cancer.

PRINCIPLES OF MODEL APPLICATIONS

Given the documented role of oestrogens in the development of uterine disease and the increasing use of hormones to alleviate symptoms of menopause and other gynaecological problems, it is important to have appropriate *in vivo* experimental animal models to study the ontogeny and progression of uterine carcinoma and the mechanisms associated with this disease. Further, it becomes increasingly important to have an experimental animal model of uterine carcinoma since many environmental chemicals have been reported to possess oestrogenic activity and exposure, therefore, is possibly widespread. Since the carcinogenic potential of these environmental chemicals for the human uterus is unknown, this demands careful attention.

Although carcinogenic responses to hormones have been noted (e.g. liver, testis and pituitary tumours in mice treated with oestrogen), the power of experimental animal models can be greatly enhanced with the development and use of target organ-specific models. However, so far there are few experimental models for which oestrogens can be shown to induce uterine cancer. In fact, adult rodents given long-term treatment with the potent synthetic oestrogen, diethylstilboestrol (DES), did not show a significant increase in uterine tumours (Highman *et al*., 1980). In a long-term feeding study, oestrogenic compounds given to adult mice was not associated with increased incidence of uterine carcinogenesis; endometrial hyperplasia was seen, suggesting oestrogen stimulation, but uterine cancers were lower than 1% after lifetime exposures to high doses (Highman *et al*., 1980). However, rodents, i.e. mice or hamsters treated neonatally on days 1–5 with DES, show a high incidence of uterine cancers (Leavitt *et al*., 1981, 1982; Newbold and McLachlan, 1982; Newbold *et al*., 1990). As an example, **Figure 1** shows the prevalence of uterine tumours in mice following neonatal treatment with DES on days 1–5 (2 μg per pup per day). By 18 months of age, neonatal DES-exposed mice had a 90% incidence of uterine carcinoma (Newbold *et al*., 1990); this increased to >95% in animals older than 24 months. These DES-induced uterine tumours were oestrogen dependent; when DES-treated mice were ovariectomized before puberty, no uterine tumours developed (**Figure 1**). To demonstrate neoplasia, uterine tumours were transplanted and carried in nude mice. The transplanted tissue retained some differentiated uterine gland structure and function and, in addition, required oestrogen supplementation for maintenance (Newbold *et al*., 1990). Another verification of neoplasia was the fact the uterine tumour cells grew on soft agar, an assay commonly used to demonstrate neoplasia potential. Other compounds with oestrogenic activity, i.e. hexoestrol and tetrafluorodiethystilboestrol (TF-DES) also induced a high prevalence of uterine adenocarcinoma following developmental treatment with the compounds (Newbold *et al*., 1990); 17β-oestradiol induced uterine carcinoma but the prevalence of lesions was lower than that induced by DES (Newbold *et al*., 1990). Further, recent studies describe the induction

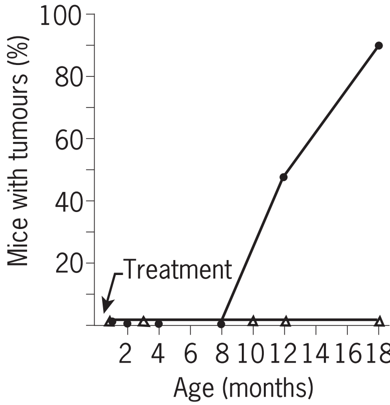

Figure 1 Incidence of uterine carcinoma in developmentally oestrogenized mice. Neonatal mice were treated with DES (2 μg per pup per day) on days 1–5 and killed at various ages. One group of mice was left intact (•) and the other group was prepubertally ovariectomized (△) on day 17. Ovariectomy before puberty blocks the development of uterine carcinoma later in life. In intact mice, the prevalence of tumours was 90% at 18 months. In animals older than 18 months, the lesion progressed to involve more of the uterine structure and the lesions became more undifferentiated. (From Newbold *et al*., 1990, *Cancer Research*, **50**, 7677–7681.)

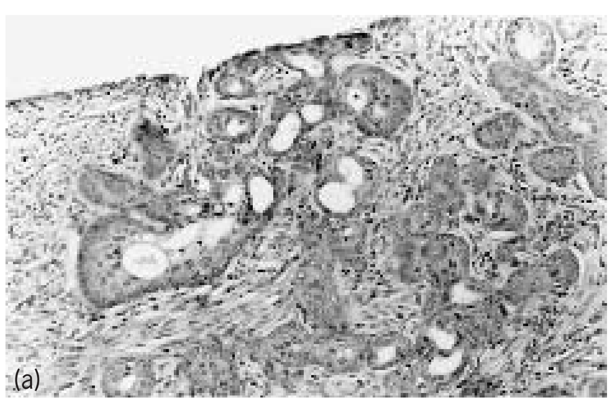
of uterine adenocarcinoma following neonatal treatment of mice with catechol oestrogens (Newbold and Liehr, 2000); mice treated with 17β-oestradiol and with 17α-ethinyloestradiol had a total uterine tumour incidence of 7% and 43% respectively. 2-Hydroxyoestradiol induced tumours in 12% of the mice but 4-hydroxyoestradiol was the most carcinogenic oestrogen, with a 66% incidence of uterine adenocarcinoma. The high tumour incidence with 4-hydroxyoestradiol supports the postulated role of this metabolite in inducing DNA damage which results in hormone-associated cancers (Newbold and Liehr, 2000).

These oestrogen-induced neoplasms in mice are histologically similar to those reported in humans (Newbold and McLachlan, 1982; Newbold *et al*., 1990; Harras, 1996; Newbold and Liehr, 2000). **Figure 2** shows a representative histological picture of the murine uterine carcinomas associated with neonatal treatment with DES. Cell lines have been derived from these uterine carcinomas (Hebert *et al*., 1992) and biochemical and molecular alterations studied (Endo *et al*., 1994; Risinger *et al*., 1994). Similarly, in the neonatal oestrogen-exposed hamster, uterine carcinoma occurs at a high frequency following developmental exposure to DES (Leavitt *et al*., 1981, 1982). Further studies in the hamster conclude that imbalances in the oestrogen-regulated uterine expression of c-*jun*, c-*fos*, c-*myc*, *bax*, *bcl-2* and *bcl-x* proto-oncogenes probably play a role in the molecular mechanisms by which neonatal DES treatment ultimately induces epithelial neoplasia in the rodent uterus (Zheng and Hendry, 1997). Thus, the oestrogen-treated neonatal rodent provides an excellent model for further studies on uterine carcinoma. (For additional endocrine models see chapter on *Mammary Tumour Induction in Animals as a Model for Human Breast Cancer*.)



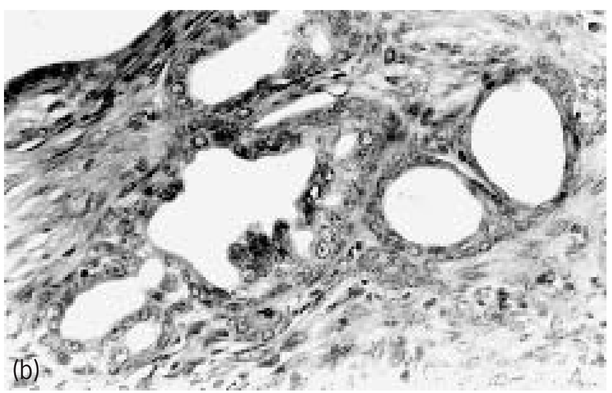


Figure 2 Uterine adenocarcinoma in a 18-month-old mouse treated neonatally on days 1–5 with DES (2 μg per pup per day). (a) Low-power magnification: areas of neoplastic cells form relatively well-defined glandular patterns. (b) High-power magnification: endometrial glands are crowded together with little intervening stroma. (From Newbold *et al*., 1990, *Cancer Research*, **50**, 7677–7681.)

POTENTIAL PROBLEMS OF RESEARCH MODELS

It is interesting that examination of numerous chemical carcinogenesis databases reveals few studies in which uterine tumours in rats or mice are associated with chemical treatment. However, the design of these studies aimed at identifying chemicals for carcinogenic potential starts exposures when animals are mature (approximately 5–8 weeks of age at the earliest). The timing of treatment may not be adequate to detect many uterine carcinogens if exposure of relatively undifferentiated cell types is important for carcinogenic transformation. This may be an important missing factor in terms of demonstrating organ-specific tumours, in particular, with the human uterus representing one of the most sensitive sites for oestrogen-associated neoplasia, and exposure models using undifferentiated cells should be considered. The undifferentiated uterine cells of the neonatal rodent have been demonstrated to be a sensitive model of oestrogen-induced carcinogenesis.

PERSPECTIVES

The newborn rodent is exposed to oestrogens in a period that is especially sensitive to neoplastic transformation; compared with mature tissues, it is relatively deficient in the ‘classical’ uterine epithelial oestrogen receptor (ERα) and mature ER–oestrogen mechanisms. These uterine epithelial cells, however, have the ability to respond to oestrogens by cell division whether through ERα in the stroma (Bigsby *et al*., 1990) or through various growth factor pathways (McLachlan *et al*., 1994). The primate endometrium following menses resembles the neonatal mouse uterine epithelium, i.e. low epithelial ER, ability to respond to oestrogens by cell division and similar growth factor pathways. In other words, the newly re-epithelialized human endometrium may functionally recapitulate the neonatal mouse uterine epithelium on a monthly basis.

Thus, whereas the adult mouse, rat or hamster uterus appears refractory to the carcinogenic potential of

oestrogenic chemicals, developing uterine tissues are highly susceptible to perturbation by oestrogens. Differentiation of the uterine epithelial target cell may render the tissue less sensitive. This suggests an important biological principle which can be tested. Rather than comparing animal models with humans according to age, whenever possible, similar biological stages should be compared (**Figure 3**). The newborn mouse uterine epithelium has low levels of ER, but will respond to oestrogens; it is also the biological period in which oestrogens can neoplastically transform the cell. Likewise, each month following menstruation, the subhuman primate uterus undergoes re-epithelialization; the new epithelium is deficient in ER yet responds to oestrogen (McClellan *et al*., 1986). Therefore, it is possibly susceptible to neoplastic transformation each month. Likewise, the human uterus undergoes the same cyclic re-epithelialization process and fluctuations in ER levels (Brenner and West, 1975; Katzenellenbogen, 1980; Lessey *et al*., 1988; Bern, 1992). Furthermore, the primate uterus at postmenopause is characterized by low levels of ER but a high susceptibility to perturbation by oestrogens (Kurman *et al*., 1994).

In summary, the newborn mouse is not only useful in determining the developmental toxicity of oestrogens (Bern, 1992), but additionally, it has the potential to predict the cellular risk (undifferentiated cellular phenotype) of the adult human uterus. It is feasible that the undifferentiated human endometrium, which has the potential to divide, proliferate and differentiate during each menstrual cycle, puts a woman at increased risk, whereas this risk is

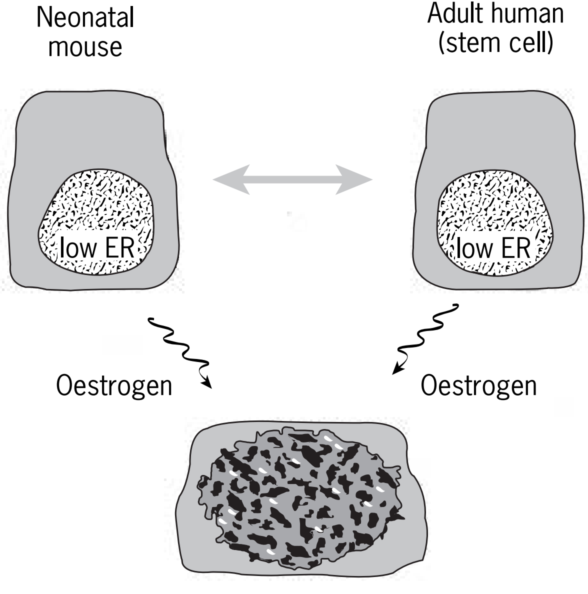

Figure 3 Schematic representation of hormonally responsive uterine epithelial cells from a neonatal mouse and an adult human comparing similar cellular phenotypes.

only apparent for the rodent in early development. Nevertheless, the neonatal treated rodent provides a new model to focus on cellular risks that are important in identifying potential carcinogens and additional studies designed to investigate the mechanism involved in these hormone-associated lesions. Further use of the animal model to investigate treatment and prevention strategies for endocrine-related cancer should follow.

Chapter 75

Plain Film Radiography

Anne M. Silas and J. Marc Pipas

Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire, USA

CONTENTS

- Introduction
- Musculoskeletal Neoplasms
- Abdominal Neoplasms
- Lung Neoplasms
- Complications of Cancer – Disease and Therapy
- Conclusion

INTRODUCTION

Initial imaging of the chest, abdomen and musculoskeletal systems has traditionally consisted of plain film radiology for the evaluation of suspected pathology. Plain radiographs are readily available, require relatively basic patient cooperation (i.e. a long breath hold, such as is often necessary for computed tomography (CT) or magnetic resonance imaging (MRI), is not necessary) and are fairly low in cost. On the other hand, the diagnostic yield for the detection and follow-up of cancer using plain film imaging techniques may be low. As a screening modality, plain films are often nonspecific. While the basic supposition of screening is the detection of early-stage disease in asymptomatic individuals, where the intent is to reduce mortality, plain radiographs often lack both sensitivity and specificity, and therefore must be relied on with caution. The aim of this chapter is to review the most common uses of general radiography with plain films in the initial evaluation and follow-up of cancer, and to present the particular areas of real utility and the limitations of this modality.

Chest radiography, in conjunction with sputum analyses, was used in the past to screen for lung cancer with little proven benefit. Traditional chest radiography has typically demonstrated larger parenchymal lesions, but lacked soft tissue contrast necessary to evaluate small or central lesions, or lymphadenopathy in the hilar regions or mediastinum. Evolving digital radiography techniques may increase plain film sensitivity for the detection of cancerous lesions.

Plain film examination of the abdomen is best used to exclude perforation or obstruction. As a screening modality in the setting of mild or nonspecific complaints, abdominal radiography has been shown to yield little diagnostic information. Cross-sectional imaging modalities such as CT and MRI show greater soft tissue resolution and provide more diagnostic detail when evaluating for soft tissue or solid organ abnormalities.

High spatial resolution of radiographs in addition to high contrast of bony detail is beneficial for the plain film evaluation of the bony skeleton. Suspicious findings involving aberration of cortical integrity and morphology can usually be seen accurately. While musculoskeletal plain film surveys are useful for the detection of internal lesion characteristics and matrices, soft tissue and neurovascular involvement cannot be distinguished with this modality. Surveys are considered useful for certain malignancies with a high incidence of bone involvement which may be asymptomatic (e.g. prostate or breast cancer or multiple myeloma). For the most part, musculoskeletal X-rays are most useful when obtained in conjunction with symptoms or signs, or with radionuclide studies.

Multiplanar modalities such as ultrasound, CT and MRI are capable of greater spatial and soft tissue resolution than plain film radiography. As such, these modalities yield more specific diagnostic information than plain films and are essential imaging techniques for initial diagnosis and follow-up of cancer.

This chapter will briefly discuss the role of plain film radiography in the diagnosis and follow-up of lung, abdominal and musculoskeletal neoplasms. There is a limited role in dealing with other neoplasms, such as those of the central nervous or haematopoietic systems, a role confined largely to specific situations which are beyond the scope of this chapter.

MUSCULOSKELETAL NEOPLASMS

Traditional X-ray evaluation has served as the initial imaging tool for the evaluation of bone lesions. X-rays are often the initial diagnostic test, and are focused on a specific symptomatic area. Radiographs provide information regarding the appearance of osseous structures, such as bone density, morphology and cortical integrity. Internal characteristics of benign and malignant lesions such as ossification or chondroid matrices, tumour margins and rate and aggressiveness of growth patterns seen on serial studies may also be assessed (Peabody *et al*., 1998). These radiographic features, along with clinical information such as patient age, provide the basis for formulating the initial differential diagnosis and diagnostic plan (Jaovisidha *et al*., 1998).

Plain film radiographs have to been used to follow and evaluate response to treatment and also to show side effects of treatment and disease such as osteopenia, soft tissue calcification and pathological fractures. Radiographs also complement newer imaging modalities such as MRI by contributing imaging data of the highest spatial resolution to help resolve cross-sectional data that may be nonspecific (Feldman, 2000). While digital radiography techniques have augmented the contrast resolution of the plain film examination, these still fall short of many advanced imaging features of other available modalities such as the multiplanar capability of MRI, MRI evaluation of bone marrow and CT detection of subtle matrix presence and involvement of cancellous bone.

Primary benign bone lesions are characterized at plain film examination by well-demarcated and intact tumour margins and precise zones of transition from involved to uninvolved segments.

Calcification of internal bony tumoural architecture is detectable at plain film examination. Elements that calcify may be of osteoid (bone) or chondroid (cartilage) origin and are referred to as osteoid or chondroid matrices when identified. These findings however, are nonspecific as these features are found in both benign and malignant lesions. Additional characteristics such as patient age and lesion multiplicity and location are invoked to aid in categorizing these findings.

Many benign bone lesions such as aneurysmal bone cysts, fibrous dysplasia and giant cell tumour are readily identifiable at plain film examination. Typical location, patient age and radiographic features provide sufficient diagnostic information. Following excision, these lesions may be followed radiographically for recurrence, characterized by a change in the cemented appearance of a curreted lesion or prosthesis, or by increased lysis of surrounding bone (Davies and Vanel, 1998). Soft tissue masses are late signs of recurrence and are not reliably identifiable on plain film examination. While MRI displays greater soft tissue contrast for the identification of soft tissue masses, cortical bone signal alterations secondary to treatment may not be distinguishable from those due to recurrence. That is, the increased specificity of tissue delineation inherent in MRI may be lost in the postoperative state, when normal healing may not be distinguishable from recurrent tumour. In this situation, changes in the appearance over time on plain X-rays may be definitive.

The absence of well-defined lesion margins and a wider transition zones, as well as serial film demonstration of rapid growth, suggesting more aggressive lesions, should increase the concern for malignancy.

Malignant processes such as multiple myeloma have radiographic features of generalized osteopenia and expansile, lytic bony lesions, as well as pathological fractures (Blake *et al*., 1999) (**Figure 1**). The skeletal survey has traditionally been considered the initial diagnostic imaging modality for patients with proven or suspected myeloma, since these lesions are usually not detected at scintigraphy. This is because radionuclide bone scans demonstrate increased uptake of the tracer in areas of

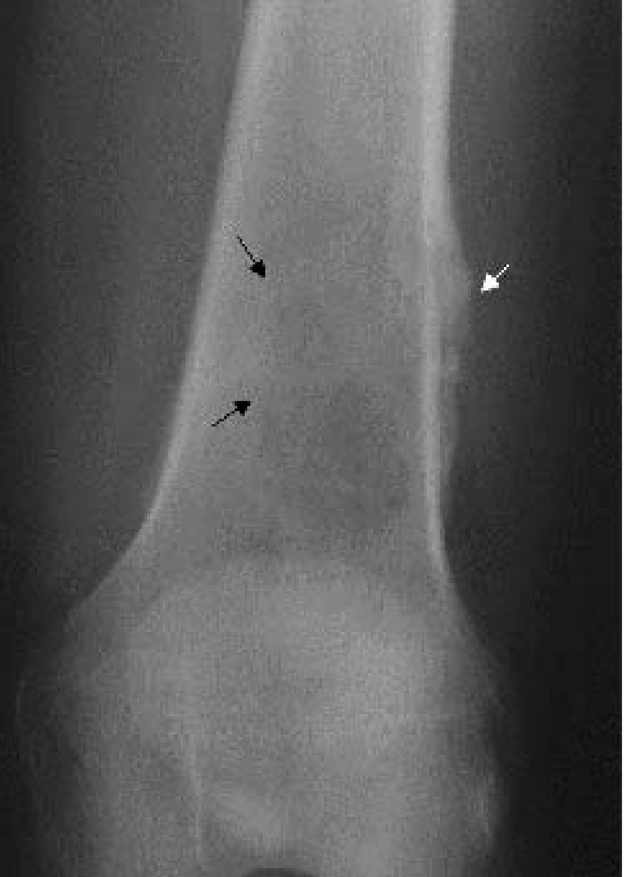

Figure 1 Metastatic bone lesion. 75-year-old female with painful distal femur. Plain film radiograph of distal femur shows permeative, lytic lesion (black arrows) with cortical periosteal reaction (white arrow) seen in distal femur.

bone turnover – that is, destruction and repair. In multiple myeloma, there is typically focal destruction without repair, and therefore the bone scan may be negative in the presence of widespread bony involvement. A significant percentage of bone density must be lost, however, for these lesions to be visible on plain films.

Other primary malignant bone lesions such as chondrosarcoma and osteosarcoma are characterized radiographically by periosteal new bone formation, lifting of the cortex and cortical destruction and chondroid or osteoid matrix. Subtle internal matrices are often better appreciated with CT scanning (Nathan *et al*., 1999). Treatment of malignant sarcomas often incorporates surgical resection and chemo- and radiation therapy. Resection usually involves most of the involved bone and as such recurrence is found in surrounding soft tissues, at the site of resection or at the junction of an implanted prosthesis (Davies and Vanel, 1998). Displaced cement or altered prosthesis position, in comparison with baseline X-rays, may be indicative of underlying recurrence. MRI has been considered the best imaging modality for the evaluation of musculoskeletal neoplasms since soft tissue detail, neurovascular involvement and joint extension can be demonstrated in multiplanar fashion. Again, however, the specificity of MRI may be lost in the postoperative situation.

Soft tissue and neurovascular infiltration, haematoma, local extension and distant metastases and local host response to chemotherapy cannot be reliably identified by plain film radiography (Lindner *et al*., 1998).

Distant metastases and multiplicity of disease may be identified with advanced imaging techniques including radionuclide scintigraphy, CT and MRI. Patterns of bony lysis or sclerosis tend to replicate themselves when imaged by plain film skeletal survey and may be used to identify skeletal metastases, be they due to synchronous or metachronous disease. Whereas radiographs are used for baseline screening for pathological fractures and pulmonary metastases, chest CT is more sensitive for the detection of small, multiple lung nodules. Additional sites of metastatic involvement including the brain and soft tissues of the abdomen and retroperitoneum are not well assessed at plain film radiography and require cross-sectional evaluation (Bearcroft and Davies, 1999). Scintigraphy plays a role in the identification of skeletal metastases but is insensitive to the presence of very small lesions, and to lesions with very rapid bone destruction.

ABDOMINAL NEOPLASMS

Plain film examination of the abdomen has largely been replaced by CT and ultrasound for screening and detection of neoplasms. Plain film screening for cancer, in the patient with mild or nonspecific symptoms, yields little diagnostic information. Use in specific situations, such as bowel perforation or obstruction, has been shown to be very useful (William, 2000).

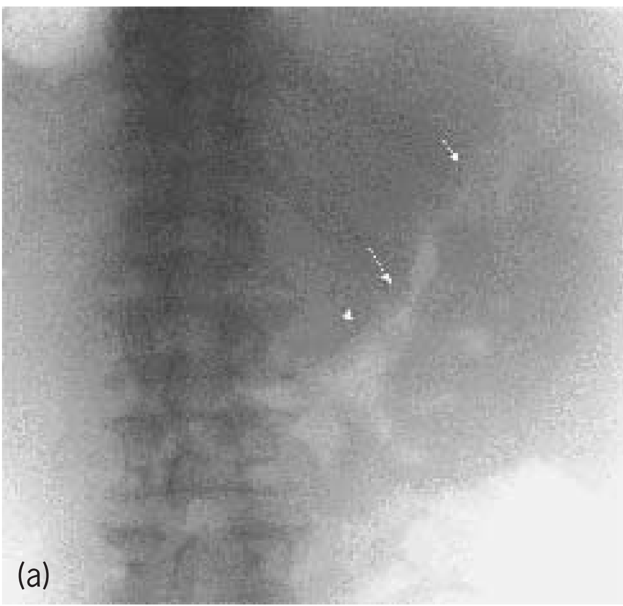
Some basic principles of X-ray attenuation are helpful in clarifying the reasons for this. Intra-abdominal soft tissue contrast is created by the differential attenuation of X-rays by fat, water and air. Retroperitoneal spaces are defined by fat surrounding structures such as the kidneys and retroperitoneal portions of small and large bowel loops. The psoas muscle is a readily identifiable retroperitoneal landmark, since this muscle is bordered by fat. Inferior edges of intraperitoneal structures such as the liver and spleen are also bordered by fat making these visible on X-rays. Indirectly, the organ edges may be infered by their mass effect on adjacent air-filled loops of bowel. Enlargement of these solid organs effaces these fat planes and displaces bowel loops. Intraperitoneal soft tissue masses or ascites (i.e. processes behaving like water density projected against water-density liver or spleen on plain films) also obscures soft tissue planes (Messmer, 2000).

Lymphomas, classified as Hodgkin disease (HD) or extranodal non-Hodgkin lymphoma (NHL), are soft tissue neoplasms involving either lymph nodes, spleen or extranodal sites. Plain film radiography is generally of little use; diagnosis and follow-up require imaging using a modality with greater soft tissue contrast resolution, such as ultrasound or CT scanning (Bragg, 1987) (**Figure 2**).

Hollow viscera such as small and large bowel and stomach contain variable amounts of gas, detectable at radiography. Normal bowel gas acts as contrast material on abdominal plain films. Gas may be seen within ulcerating soft tissue masses or outlining foci of bowel wall thickening associated with neoplastic masses (**Figure 3**). Secondary signs of carcinoma such as bowel obstruction or perforation are usually evident at plain film examination. Liquid barium contrast (administered by mouth or per rectum) is used with insufflated gas to perform double-contrast radiographic examinations of the upper and lower gastrointestinal tract (Bradford *et al*., 2000). These radiographic techniques may be used for duodenal and colonic cancer detection. Staging of neoplastic processes involves the use of additional imaging modalities such as MRI, CT scan and endosonography (Thoeni, 1997).

Dense calcifications are readily apparent on plain films, although intra-abdominal calcifications related to cancer are rare. Typically calcified solid masses include uterine leiomyomas and lymph nodes. Dystrophic and psammomatous calcifications may be seen with fibrolamellar hepatocellular carcinomas, renal cell carcinomas, ovarian cystadenocarcinomas and metastases (Baker and Cho, 2000).

Abdominal plain films, then, are most useful in acute situations, such as when there is a question of bowel perforation or obstruction. They are very useful in combination with barium to define abnormalities in the bowel, but they have little role for routine evaluation or for screening.



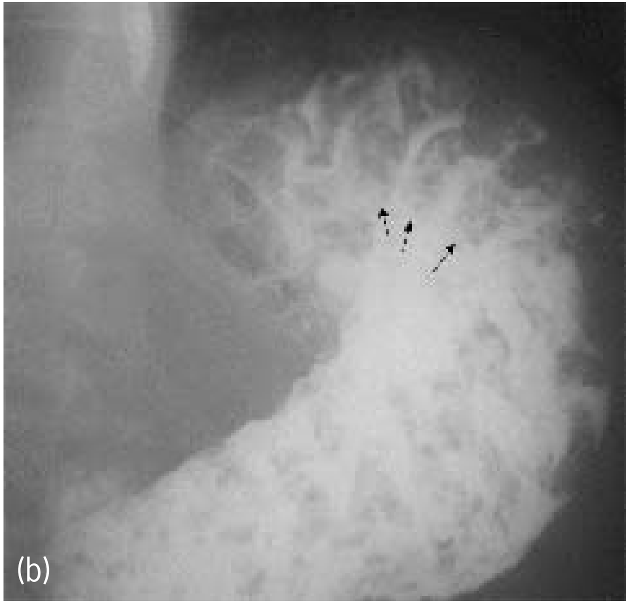


Figure 2 Gastric lymphoma. 36-year-old male with early satiety. (a) Plain film of the abdomen shows upper abdominal soft tissue mass in expected region of stomach with narrowed, lobulated, air-filled luminal contour (white arrows) suggesting gastric wall mass. (b) Double contrast upper gastrointestinal barium examination confirms thickened gastric folds with irregular mucosal contours (black arrows).

LUNG NEOPLASMS

Lung cancer is the leading cause of cancer deaths among men and women in the United States (Miettinen, 2000). Although considerable debate exists in the current literature regarding the role of chest X-ray screening for lung cancer, improved prognosis is clearly associated with detection (by whatever means) of early-stage, potentially curable lesions in high-risk populations (Caro *et al*., 2000; Gavelli and Giampalma, 2000).

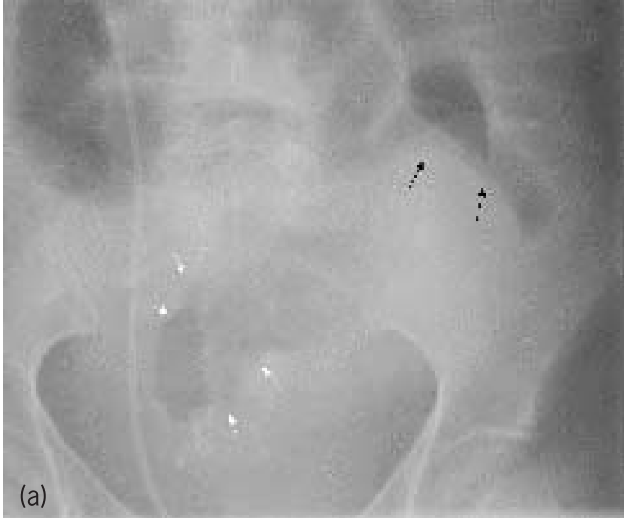
Chest radiography has traditionally served as the first-line imaging modality for lung cancer screening. Plain film radiography of the chest is widely available and of relatively low cost, compared with CT, for the purposes of lung cancer screening and has been recommended as a screening modality for high-risk populations (Dominioni *et al*., 2000) (**Figure 4**). While traditional chest X-rays have been described as having poor diagnostic value for the detection of small lung cancers (Yang *et al*., 2001), various factors continue to influence detection. The most common lung cancer cell type is now adenocarcinoma, which has been described as more slowly growing compared to squamous cell carcinoma, thereby widening the window of beneficial detection (Austin *et al*., 2001). Solid lung tumours, those not maintaining air-filled alveolar spaces, are better seen on chest radiographs (Yang *et al*., 2001). Technological advances in computer-aided conventional and digital chest examinations may improve the diagnostic potential of chest radiography, increasing the yield of nonmetastatic disease (Reeves and Kostis, 2000). The usual chest X-rays are analogue in format. Digital chest radiographs may have somewhat reduced inherent resolution, but the ability to post-process, to re-examine the image with magnification and with alteration of the relative densities, may add substantially to the sensitivity and utility of plain chest X-rays.

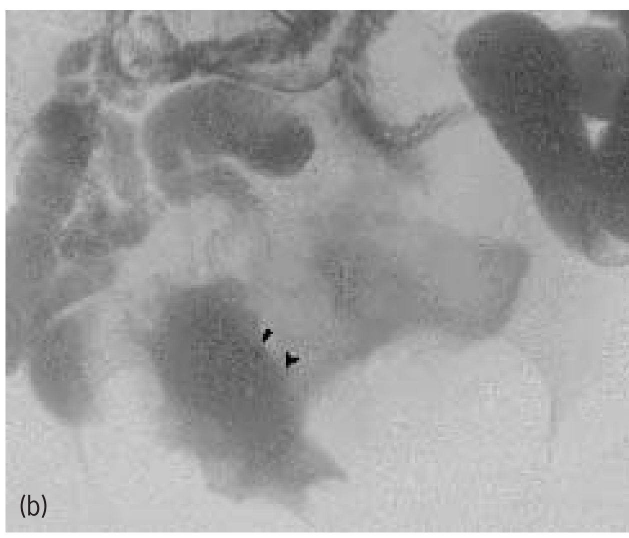
Recent technical advances in the use of low-dose chest CT have proved superior for early-stage lung cancer detection. A recent review of lung cancer detection and screening trials shows that chest CT is more sensitive for detecting small lung nodules that may be cancerous and that CT detects more lung cancers than plain film radiography (Miettinen *et al*., 2001). These findings imply that screening chest CT will detect more cases of resectable early-stage lung cancer, although effects on reducing mortality secondary to the disease are still unknown (Boiselle *et al*., 2000; Patz *et al*., 2000).

Low-dose screening CT will also detect small indeterminate nodules, the majority of which will be benign. The workup of these nodules, however, will not be insignificant in terms of cost and time. The efficiency, then, of low-dose chest CT for lung cancer screening requires further evaluation (MacMahon and Vyborny, 1994).

COMPLICATIONS OF CANCER – DISEASE AND THERAPY

Deleterious effects of cancer chemotherapy and steroid therapy include osteoporosis and osteonecrosis. Proposed mechanisms for these side effects include decreased





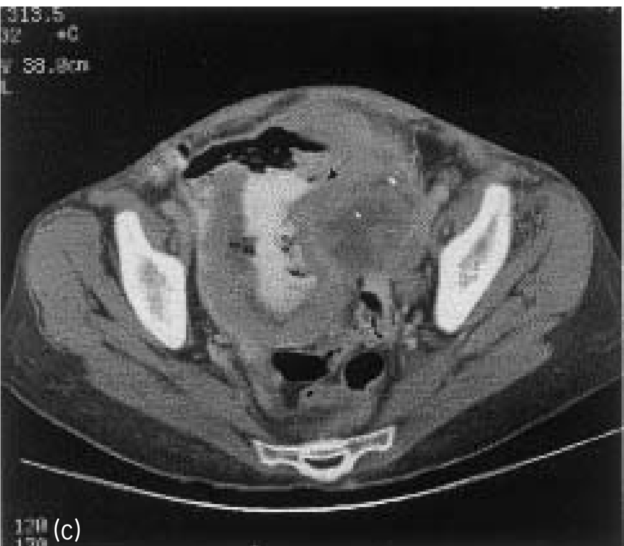


Figure 3 Metastatic melanoma. 53-year-old female with known melanoma and abdominal pain. (a) Abdominal radiograph shows distended, air-filled loops of bowel in abdomen that are displaced upward by pelvic soft tissue mass (black arrows) containing unusual air pattern (white arrows). (b) Double-contrast barium examination of the small bowel shows unusual collection of barium (arrowheads) conforming to configuration of unusual air pattern seen on plain film (a). (c) CT scan confirms luminal contrast filling ulcerated pelvic soft tissue mass (black arrow).

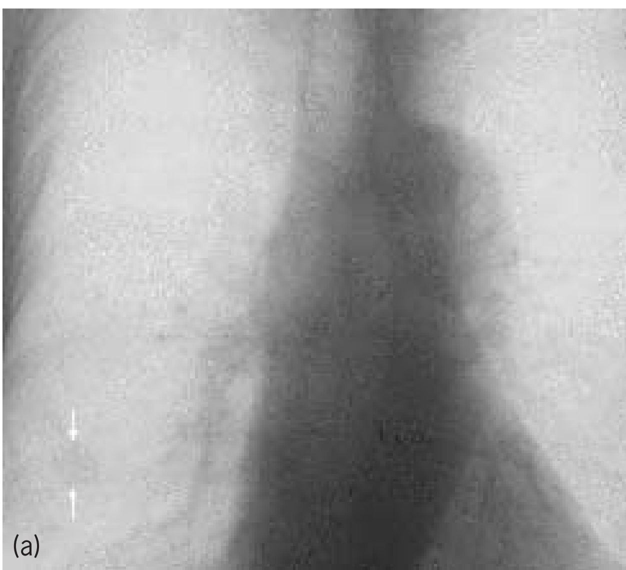
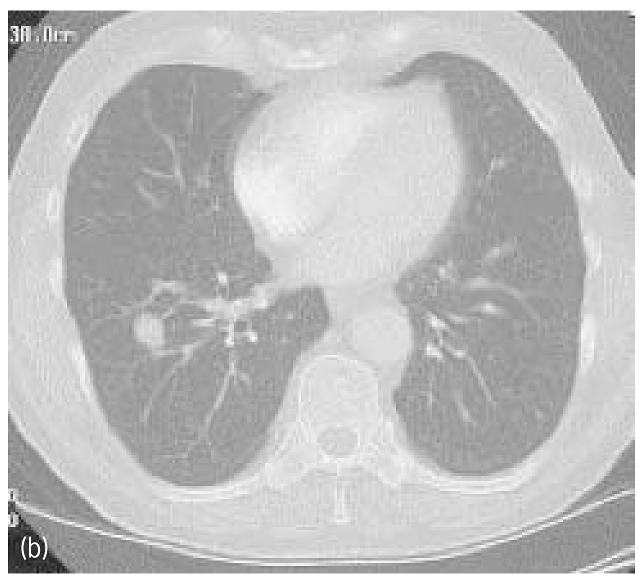
bone formation characterized by deficient osteoblasts and osteoclasts, and also focal bone segment death characterized by cell death in cortical bone (Weinstein *et al*., 1998). The role of radiographs for surveillance of these deleterious side effects is controversial as radiographic diagnosis of osteoporosis is subject to wide interpreter variability. Furthermore, the positive predictive value of plain film detection of bony erosions for the purpose of predicting clinically significant joint disease has recently been reported as 40% (Falbo *et al*., 1999).

Osteoporosis may result from cancer treatment drugs, such as methotrexate, as well as the tumour itself. Osteoporosis is a process affecting the microarchitecture of bony tissue, causing loss of bone mass which can lead to fractures. These fractures, and diminished bone density, may be seen on plain films, although subtle or incomplete fractures and processes involving bone marrow are more sensitively imaged with MRI. The role of plain film radiographic evaluation may lie in identifying those patients at risk of the effects of osteoporosis and who may benefit from the institution of prophylaxis or treatment. An example is the use of orthopaedic procedures to prevent pathological fracture due to a metastatic deposit, or the institution of pharmacotherapy to treat severe systemic osteoporosis.

Methotrexate is one chemotherapeutic agent that has been recognized as associated with osteoporosis (Pfeilschifter and Fiel, 2000). Methotrexate osteopathy is probably secondary to the combined processes of increased bone resorption and inhibited bone formation. Other agents associated with osteoporosis include cyclophosphamide, doxorubicin and corticosteroids. While bone densitometry is considered the study of choice for the evaluation of osteopenia, plain film evaluation is performed as a first-line imaging modality. While significant loss of bone mass is required before radiographic evidence of loss of density is evident, plain films, particularly if prior films are available for comparison, are useful for screening purposes, and





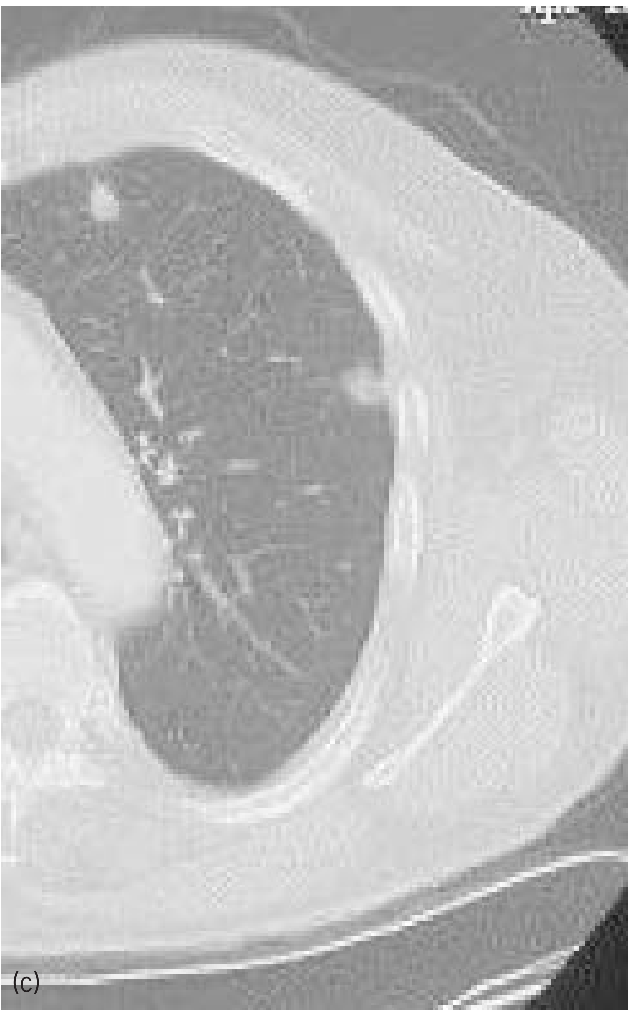


Figure 4 Metastatic rectal cancer. 75-year-old male with resected rectal cancer. (a) Follow-up chest X-ray shows new right lung nodule (white arrows). (b) CT scan shows right lung nodule seen at plain film examination of chest. (c) CT scan of left chest shows additional nodules.

also demonstrate specific abnormalities associated with osteoporosis, such as vertebral body wedge compression fractures and late signs of femoral osteonecrosis.

Hypertrophic pulmonary osteoarthropathy (HPO) may be secondary to an underlying process such as lung cancer. Typical findings of HPO on plain film examination include periostitis involving diaphyseal regions of long bones, becoming thicker and more extensive with time, as well as soft tissue ossification (Viola *et al*., 2000). Lung cancer may be detected secondarily following the identification of HPO on plain films. Radiographic follow-up for resolution of bone changes following resection of lung cancer is controversial. Failure of bone abnormalities to resolve postresection was previously thought to favour poor prognosis, although a recent report showed that in two patients, the absence of reversal of periosteal changes did not correlate with poor long-term outcome (Orts *et al*., 2000).

CONCLUSION

Plain film radiography is an imaging modality that is widely available, low in cost, has essentially no associated morbidity unless used excessively and frequently serves as the first-line imaging modality in the workup of many disease processes.

Bone radiographs identify features of bony disease that may be unique to the diagnosis in question, and are useful for evaluation of musculoskeletal neoplasms both initially

as the sole modality, for follow-up of lesions and in conjunction with additional modalities such as CT and radionuclide scanning and MRI.

The use of chest X-rays for the detection of lung cancer is controversial as the effect of dedicated screening programmes on long-term survival is still unknown. Extensive studies to evaluate this question, that is, whether early detection actually alters survival overall, or whether it merely discloses very slow-growing lesions that would have little impact on long-term outcome, are currently under way. Recent studies have suggested that the use of CT scanning for the identification of lung cancer, in particular small and multifocal lung lesions, is beneficial. Whether or not screening of high-risk patients with CT will reduce mortality secondary to lung cancer, compared with screening with chest radiographs or with no routine radiographic screening, has not yet been conclusively shown.

Finally, while plain film examination of the abdomen yields information regarding bowel obstruction and perforation, and also bowel wall thickening and displacement of bowel loops, this imaging modality lacks the contrast resolution necessary to distinguish soft tissue detail in the abdomen and pelvis. Abdominal radiographs, then, are mainly of use in patients with particular symptoms or signs. They play no role in the evaluation or follow-up of patients with known or suspected malignancies.

Plain X-rays, then, play a major role for evaluation of malignancies in certain organ systems. They have the advantages of ready availability in most facilities around the world, relatively low cost, little if any associated morbidity if obtained properly and high utility in specific situations. They have significant limitations, but have the added advantage that these limitations are well delineated and widely recognized. Plain radiography, as initially developed by Roentgen in 1895, remains a central tool in the diagnosis and treatment of malignancies.

- Basic CT Features and Techniques
- Clinical Applications
- Future Directions

INTRODUCTION

Computed tomography (CT) has widespread oncological applications. CT produces transverse sections that provide a three-dimensional display of the distribution of X-ray attenuation within the body. Its basic principle is that the internal structure of an object can be reconstructed from multiple projections of the object. Highly collimated X-rays are focused on pre-selected transverse sections of a patient. The data acquired from the multiple detectors subsequently undergo computer analysis, reconstructing the precise attenuation information into an image for display on a monitor. CT can detect minute differences in tissue X-ray attenuation and provides highly accurate quantitative information about the X-ray attenuation properties of the imaged tissues. All CT scanners have an X-ray generator, scanning gantry, computer system, operator and physician's viewing consoles and a hard copy camera (**Figure 1**) (Ter-Pogossian, 1977). The scanning gantry supports the high-heat-capacity X-ray tube, collimators, detector array with its associated electronics and scanning drive motor. Recent advances in both scanner hardware, with faster image acquisition, and in software applications, with multiple viewing options and interactive capabilities, have produced new and exciting CT applications.

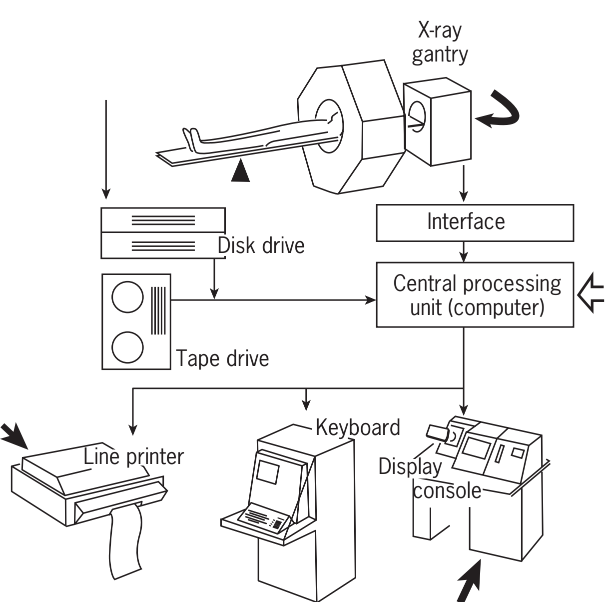

Figure 1 Basic components of a CT scanner. The scanning equipment consists of the CT table (arrowhead) and the X-ray gantry which consists of the X-ray tube, generator, collimators and detectors (curved arrow). These are interfaced with the main computer (central processing unit (CPU)) (open arrow), which in turn interfaces with the viewing elements which may include: technologists' and radiologists' display consoles (broad arrow), tape and disk drives (long arrow) and printer (short arrow). (From Ter-Pogossian, 1977, *Seminars in Roentgenology*, **12**, 13–25.)

BASIC CT FEATURES AND TECHNIQUES

Data Acquisition

In conventional radiography, a large proportion of available information is lost in attempting to display it from a three-dimensional patient on to a two-dimensional film as all of the structures are superimposed on top of each other. Individual structures can be distinguished only if they differ significantly in density from one another, thus enabling them to stand out clearly against the tissues in front and behind them. With standard CT, single sections of a patient are imaged sequentially. This is accomplished by obtaining a series of angular projections or views of the section and reconstructing a two-dimensional image from this series of one-dimensional projections. The X-ray beam

is confined to a selected section of the patient (the width of which is determined by the prepatient collimators close to the X-ray tube). This improves image detail by eliminating the superimposition of unwanted structures. Post-patient collimators located close to the X-ray detectors limit scatter radiation which is also a cause of image degradation in conventional radiography. The detectors measure the intensity of the X-ray beam exiting the patient and their signals are used by the central processing unit (CPU) to calculate 'profiles' of the X-ray attenuation by the tissues traversed that section (Ter-Pogossian, 1977).

Image Reconstruction

The information obtained by the detectors is first stored in quantitative form. The scanned transverse section of the patient is subdivided into a series of small individual blocks called 'voxels.' Each voxel is assigned a value proportional to the degree that it attenuated the X-ray beam. The linear attenuation coefficient (μ) is used to quantitate the attenuation. It is determined by the following equation:

$$N = N_0 e^{\mu - x} \quad [1]$$

where N_0 is the number of initial photons, N the number of transmitted photons and x the slice thickness. Thousands of these equations, derived from linear transmission readings taken from different directions (projections), must be solved to determine the linear attenuation coefficients of all the voxels.

The linear attenuation coefficients then undergo another calculation, which permits the computer to present the information as a picture with a large grey scale. The reconstructed CT image is a two-dimensional array of quantized grey-scale values or picture elements (pixels). The pixel values or CT numbers are expressed as the ratio of attenuation coefficients between a given material and water, and are directly related to the linear attenuation coefficients at corresponding positions within the slice:

$$\begin{aligned}&\text{pixel value (Hounsefield units)}\\&= 1000\,(\mu - \mu^{\text{water}})/\mu^{\text{water}}\end{aligned} \quad [2]$$

where (μ is the average linear attenuation coefficient of the voxel represented by the pixel and μ^{water} is the linear attenuation coefficient of water (both are evaluated for the effective energy of the beam exiting the patient) (Barnes *et al*., 1979). Thus, water has a CT number of zero, and a region with a CT number of 100 Hounsefield units (HU) has a linear attenuation coefficient that is 10% greater than that of water. CT images usually have 12 bits per pixel, and they are employed to represent numbers ranging from −1000 to 3095 HU, or 4096 grey scale values. Air has a CT number of −1000 HU, fat ranges from −50 to −350 HU, soft tissue structures from 10 to 80 HU and bone from 400 to 3000 HU.

In order to display this wide range of CT numbers on a monitor with generally 256 shades of grey, a CT number ('window level') is selected which is the estimated average of the tissue of interest. The computer is then instructed to assign one shade of grey to each of the 128 CT numbers below and each of the 128 CT numbers above the window level ('window width'). Both the window level and width can be adjusted in accordance to the structure being evaluated. Multiple window levels and window widths are employed to maximize the information that can be obtained from a single CT examination (**Figure 2**).

CT Scanner Evolution

Godfrey N. Hounsefield of EMI Ltd in England introduced the first clinical CT scanner in 1971 (Hounsefield, 1973). Thereafter, there have been four generations or models of the standard two-dimensional CT scanner. Their scanner designs differed in the movement of the X-ray source and both the number and the movement (or lack of, as in the case of the fourth-generation CT) of the X-ray detectors. Developments in both CT hardware and software have been, to a great extent, toward faster scanning. Patient motion, either voluntary (inability to cooperate or understand instructions) or involuntary (due to respiration, cardiovascular pulsations or peristalsis) can result in data misregistration which may cause omission of lesions.

Spiral, helical or continuous-volume CT scanners, with their attendant hardware and software developments, were introduced clinically in 1989 (Kalendar *et al*., 1990; Brink *et al*., 1994). The source–detector assembly is supported by multiple parallel slip-rings rather than electrical cables which permit its continuous rotation. This has decreased interscan delays to less than 5 s and has made volume-acquisition CT scanning possible. Scanning involves simultaneous patient movement at a constant rate through the gantry during continuous rotation of the source–detector assembly such that continuous data acquisition is achieved throughout a volume of interest. The terms spiral or helical CT are derived from the fact that during the scanning process, the X-ray focus describes a spiral or helical path around the patient (**Figure 3**) (Kalendar *et al*., 1990). Scan times for an entire study range from less than 10 s to as long as 30 s, with a data set often obtained within a single breath-hold. Direct reconstruction of images from data obtained over any 360° segment of a spiral CT acquisition will result in motion artifacts due to patient transport. The spiral data set first undergoes a mathematical smoothing process (interpolation) which can be calculated from any arbitrary table position within the scanned volume, followed by conventional image reconstruction. A data volume is generated that may be viewed as transaxial planar images or with multiplanar and 3D methods.

Volumes of interest are scanned continuously, providing seamless or overlapping sets of images. This is of

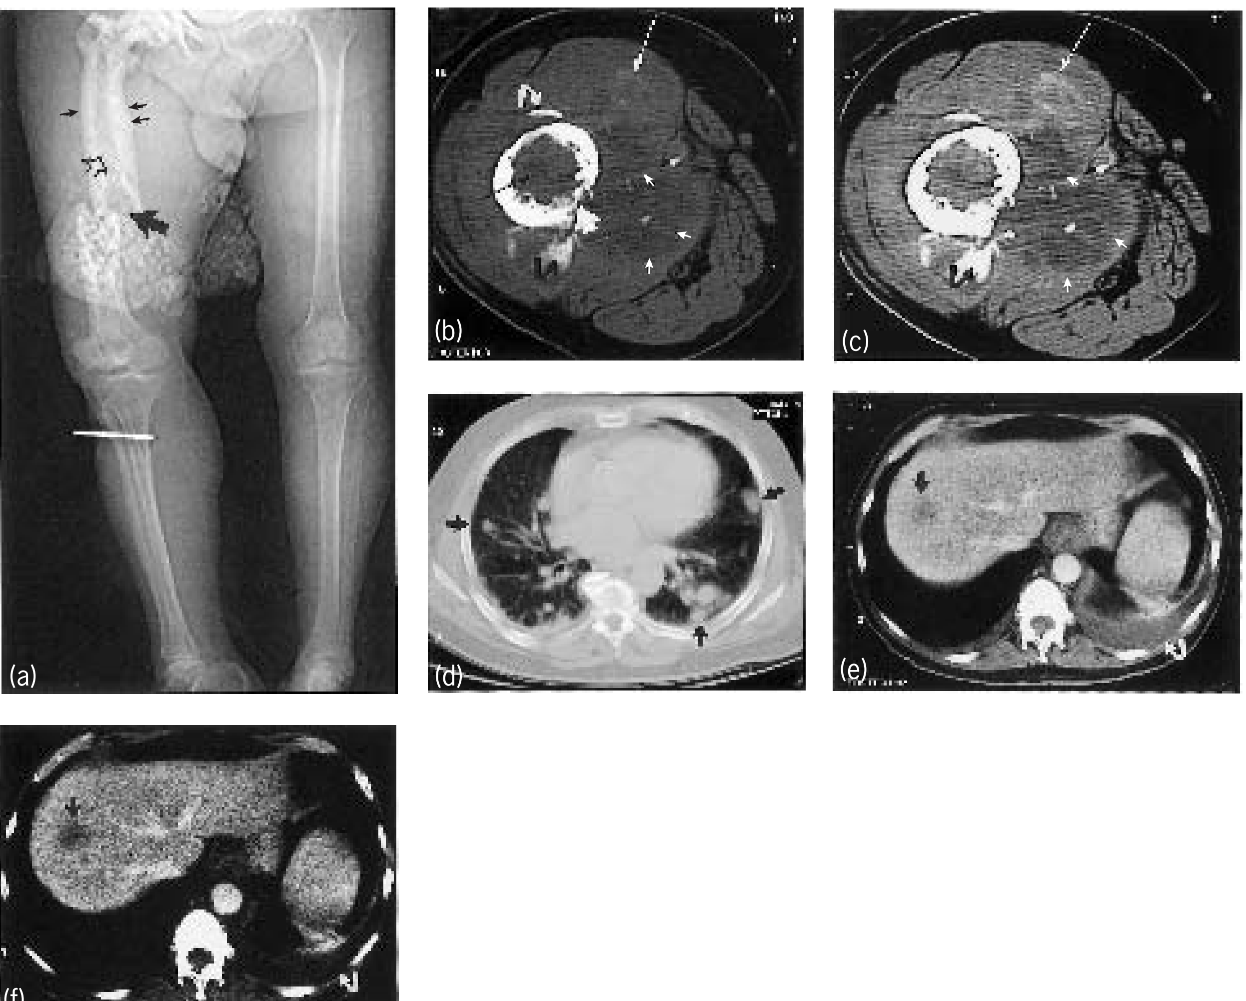

Figure 2 Window settings on CT. Malignant degeneration of a benign lesion. (a) A CT scout image of the legs reveals a pathological fracture of the midiaphysis of the femur. The bone is abnormally enlarged with marked cortical thickening (small arrows) and thickened trabeculae (open arrow) compatible with Paget's disease of bone. A luscency is present at the level of the fracture (large arrow). The scout image is analogous to a conventional radiograph, which is routinely acquired when a patient is first placed on the CT table. It serves to ensure appropriate patient positioning to include the entire area under investigation. It is the reference from which to assign the most superior and inferior locations of the upcoming scan, to select the appropriate field of view (FOV), slice thickness and interslice skip in order to ensure adequate area coverage and sufficient radiographic detail. (b) An axial CT image through the level of the fracture in bone windows confirms the presence of a central lytic lesion (long black arrow) with an associated fracture (large white arrow). Bony fragments (curved arrow) and ill-defined luscent areas (small arrows) representing oedema are present in the adjacent soft tissues. The high attenuation area in this noncontrast CT is compatible with acute blood (long white arrow). (c) Same image as (b) with soft tissue window setting. The fine detail of the bony fragment (curved black arrow) is obscured. The soft tissue changes however, are better appreciated. The luscent areas (small arrows) are more obvious and better defined as is the haemorrhagic area (long arrow). A CT-guided percutaneous biopsy revealed an osteosarcoma. (d) Thoracic CT axial image with lung window setting reveals multiple, bilateral lung nodules compatible with metastatic disease (arrows). Lung window settings optimize visualization of the lung parenchyma at the expense of the skeletal (b) and soft tissue (c) areas. (e) Axial image caudal to (d) at the level of the lower chest and upper abdomen with soft tissue windows reveals a low attenuation hepatic lesion (straight arrow) compatible with a metastasis and a left pleural effusion (curved arrow). (f) Same image as (e) utilizing liver window settings which enhance the conspicuity of the hepatic metastasis (straight arrow). The left pleural effusion is barely visible (curved arrow).

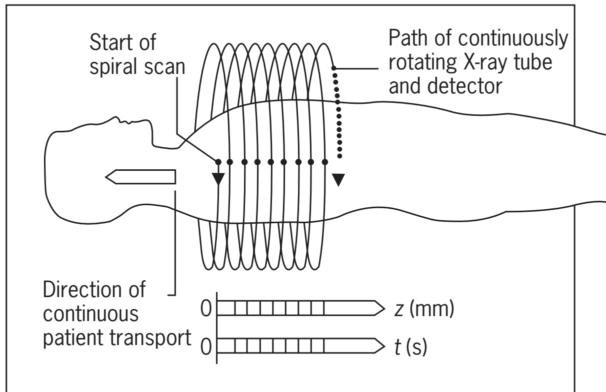

Figure 3 Helical CT scanning. Continuous patient transport and rotating X-ray tube and detectors result in volumetric data acquisition. (From Kalendar *et al.*, 1990, *Radiology*, **176**, 181–183.)

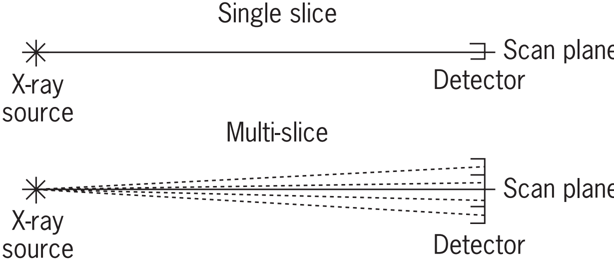

Figure 4 Single-slice vs multi-slice imaging. In single-slice imaging, there is a single X-ray source and single detector. In multi-slice imaging, there are multiple detectors. Thus with multi-slice imaging on a single revolution, multiple slices are generated at once permitting significantly greater speed or resolution. (From Fox *et al.*, 1998, *Neuroimaging Clinics of North America*, **8**, 497–513.)

major importance in scanning anatomical regions, which are subject to patient motion, in which data misregistration from section to section may cause omission of structures or lesions and degradation in the quality of multiplanar and 3D displays. It is also clinically useful in contrast media studies in which complete organs or a large volume need to be measured during different phases of enhancement.

Multidetector-row helical CT is the latest innovation in scanning. Instead of a single row of detectors, multiple rows are used. These rotate simultaneously so that multiple axial images can be obtained at once. In helical mode, four (or more) interweaving helices are created. The ability to acquire multiple images simultaneously can be used for increased speed to limit the effects of cardiac pulsation and peristalsis and to permit a greater area to be covered on one breathold limiting or eliminating misregistration due to breathing. Alternatively, by focusing on a limited region, much higher resolution is possible, particularly for 3D and virtual imaging (**Figure 4**) (Hu *et al.*, 2000).

CLINICAL APPLICATIONS

Lesion Detection

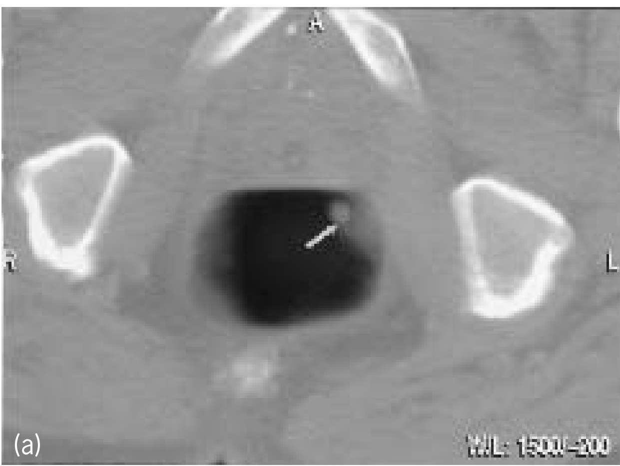
Asymptomatic Patients: Screening

Advances in CT scanner technology have enabled helical CT to be used as a cancer screening modality. Since entire body regions can now be scanned seamlessly and rapidly, often within a single breath-hold, CT examinations are more feasible for a broad range of patients and diseases. An increase in patient throughput due to the increased speed of new scanners permits the performance of a large volume of studies. These factors are crucial to any successful screening programme.

Lung and colon cancers are currently the first and second most common causes of cancer-related deaths in the United States (Landis *et al.*, 1998). The goal of screening in either case is detection and intervention at an early, potentially curable stage. Radiation dose is always a consideration, particularly in long-term screening programmes which require serial examinations every 1–2 years. Fortunately, substantial dose reduction is possible in both cases owing to the high inherent contrast between air-containing organs (the lung and the air-distended colon) and the soft tissue nodules or polyps. Although studies have investigated the accuracy of low-dose CT in the detection of pulmonary nodules (Itoh *et al.*, 2000) and to lesser extent colonic polyps, the controversy concerning technique continues.

Colon cancer is the second leading cause of cancer-related deaths per year in industrialized nations. Most large bowel malignancies arise from pre-existing adenomas; this is substantiated by a decreased rate of cancer occurrence after colonoscopic polypectomy (Winawer *et al.*, 1993). Polyps 1.0 cm in diameter or larger are associated with a higher risk of future malignant change. In individuals older than 50 years, the prevalence of polyps and cancers increases. Therefore, screening is recommended for average-risk individuals in this age group. Screening asymptomatic persons for colorectal cancer is increasingly recognized to result in a 25–50% reduction in cancer mortality. The aim of screening is to detect and remove precancerous polyps and so prevent the development of invasive carcinoma (Winawer *et al.*, 1993). Endoscopy is currently the investigation of choice for the screening, diagnosis, and treatment of colorectal polyps. It is expensive, however, and can have serious complications.

Helical endoluminal CT colonography has shown promise in screening for intraluminal colonic abnormalities such as tumours and polyps. The preparation is identical with that of conventional colonoscopy. The patient is



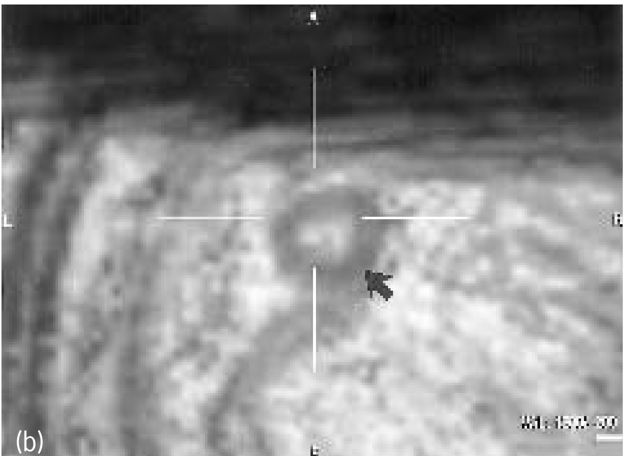


Figure 5 CT or virtual colography (colonography or colonoscopy). (a) Axial CT image at the level of the distended distal sigmoid colon demonstrates a polyp (arrow). (b) Single image from virtual colonoscopic study demonstrates the polyp (black arrow, epicentre of crosshairs).

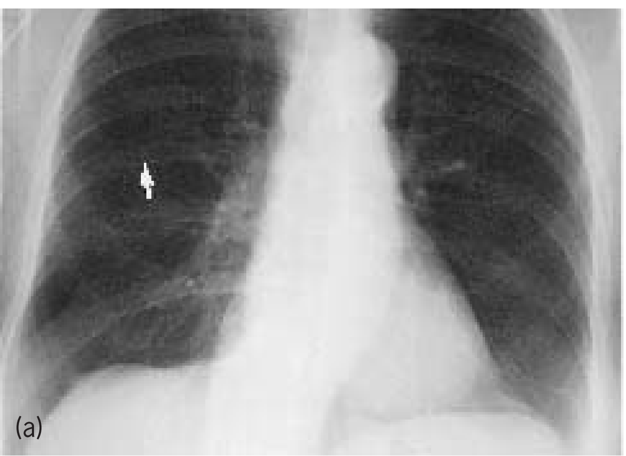
placed on the CT table and the colon is gently distended by puffs of air to tolerance. Utilizing the subsequent scout image, the entire colon is localized and two breath-hold scans, one supine and the other prone, are obtained. The total examination time is less than 15 min. The acquired data are then viewed as a combination of magnified multiplanar reformatted images and three-dimensional volume-rendered or shaded surface endoluminal images, permitting ante- and retrograde navigation through the colonic lumen (Morrin *et al*., 1999). Preliminary results indicate that the sensitivity for detection of polyps larger than 1 cm is 100%, with a sensitivity of 71–90% for 5–9-mm polyps (**Figure 5**) (Morrin *et al*., 1999).

In addition, CT colonography has demonstrated utility in visualizing the more proximal portions of the colon in cases where conventional colonoscopies which have been incomplete – 5–15% of cases either for technical reasons (Macari *et al*., 1999; Morrin *et al*., 1999) or secondary to an obstructing lesion (Fenlon *et al*., 1999). This is significant because 40% of polyps occur proximal to the splenic flexure. Furthermore, synchronous adenomas are more common in the proximal colon of patients with left-sided polyps. Thirty-one percent of a group of asymptomatic individuals with benign distal adenomas at screening flexible sigmoidoscopy were found to have proximal synchronous neoplasms (Read *et al*., 1997). The CT colography is performed at the same sitting, with the instillation of only a small amount of additional air.

Lung cancer is the leading cause of cancer-related deaths in the United States. The cure rate for lung cancer is 12% with only a slightly higher 5-year survival rate. When stage I cancer is resected, the 5-year survival can be as high as 70% (Henschke *et al*., 1999). Earlier screening programmes utilizing chest X-rays failed to demonstrate any improvement in mortality. In Japan, since the introduction of a national screening programme, survival rates have increased from 33.7% prior to screening to 58.4% (Koike *et al*., 1999). These results were attributed to the relative increased rate of detection of stage I cases – particularly IA peripheral, and also roentgenographically occult lesions. One thousand patients have been enrolled in the Early Lung Cancer Action Project (ELCAP) since its formation in 1992. They are symptom-free individuals, aged 60 years or older, with no history of cancer, who have at least a 10 pack-year history of cigarette smoking and who are medically fit to undergo thoracic surgery (Henschke *et al*., 1999). The protocol consists of a chest X-ray and a low-dose helical CT scan. If a non-calcified nodule is detected, a standard-dose chest CT with high-resolution scanning of the nodule is performed (**Figure 6**). A nodule is classified as benign if its margins are smooth, it measures less than 20 mm and it contains benign calcifications, which were undetected on the low-dose scan. If these criteria are not met, further recommendations are made based upon nodule size (follow-up high-resolution scans if the nodule is 5 mm or less in size, or biopsy if it is 6 mm or larger). The initial results indicate that for low-dose CT, non-calcified nodules were detected three times as commonly as on chest radiography, malignant tumours four times as commonly and stage I tumours six times as commonly. The high frequency of detection of stage I tumours is a strong indication that the cure rate of CT-detected disease is much higher than the current overall cure rate of 12% in the United States (Henschke *et al*., 1999).

Helical CT and software advances now permit three-dimensional volumetric measurements of small pulmonary nodules. These measurements appear to be more accurate than standard two-dimensional measurements in assessing nodule growth and in calculating their doubling times which has been a reasonable, noninvasive technique for prediction of malignancy (Yankelevitz *et al*., 2000).



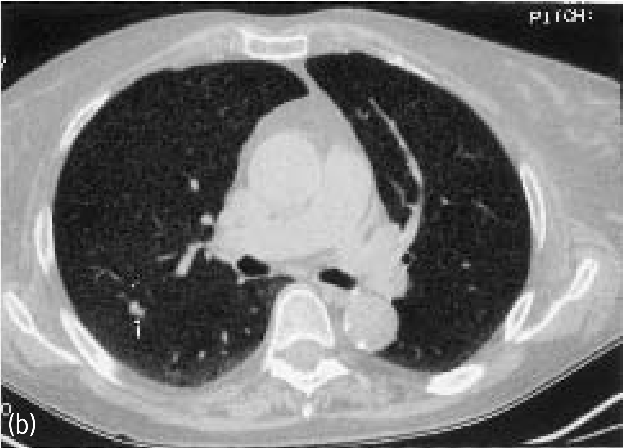


Figure 6 Solitary pulmonary nodule in an asymptomatic smoker. (a) Frontal chest radiograph reveals a tiny, barely perceptible parenchymal nodule (large arrow). (b) A high-resolution axial CT scan confirms the presence of a non-calcified, somewhat lobular parenchymal nodule (small arrow) which was resected and revealed a stage 1 bronchoalveolar cell carcinoma.

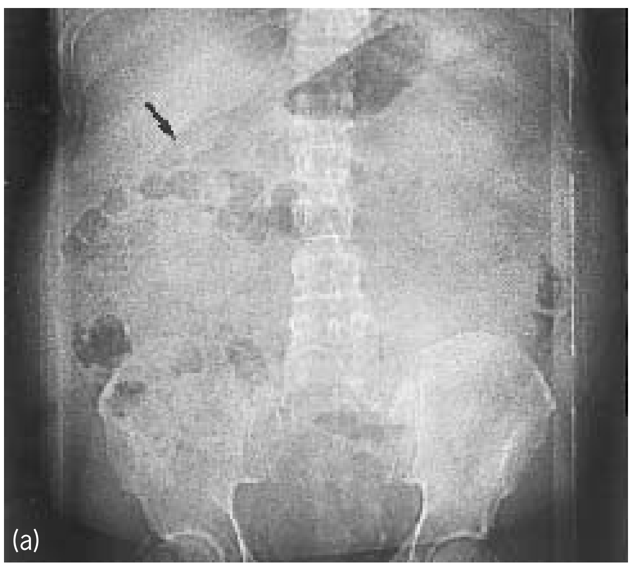

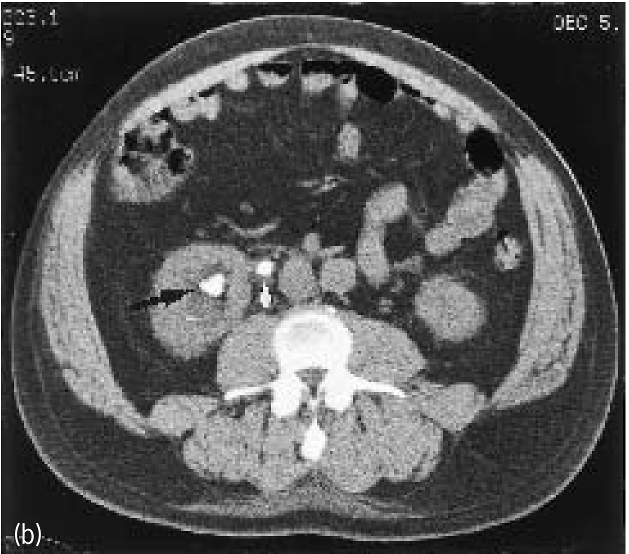

Figure 7 Nephrolithiasis on noncontrast CT, the flank pain protocol. (a) CT scout image of a patient with right flank pain fails to demonstrate any radiopacities in the region of the urinary tract (arrow). (b) Axial slice from a noncontrast CT demonstrates two calculi, one in the renal pelvis (black arrow) and the other in the proximal ureter (white arrow). Noncontrast CT is useful in patients with paraneoplastic syndrome and in cases of suspicious nephrolithiasis to identify ureterolithiasis as the cause of abdominal pain. All stones are opaque on CT except for the rare Indinivir stone in human immunodeficiency virus (HIV) patients receiving this drug.

Symptomatic Patients: Initial Radiographic Workup

CT is widely employed in the diagnostic workup of clinical abnormalities and may, in fact be the examination initially indicated. Abnormalities may be discovered by history such as acute flank pain (**Figure 7**), physical examination as in the case of acute neurological changes suspicious of an intracranial bleed (**Figure 8**) or on laboratory testing. Haematuria detected on routine urine analysis in individuals (particularly males) older than 55 years necessitates evaluation of both the upper and lower urinary tracts. Conventional intravenous pyelography (IVP) has been the standard imaging examination. CT/IVP is a technique consisting of a conventional IVP generally without linear tomography, followed within 2 h by CT scanning of the kidneys and any area of concern on the IVP (Warshauer *et al.*, 1988). This technique provides clarification of IVP findings such as renal

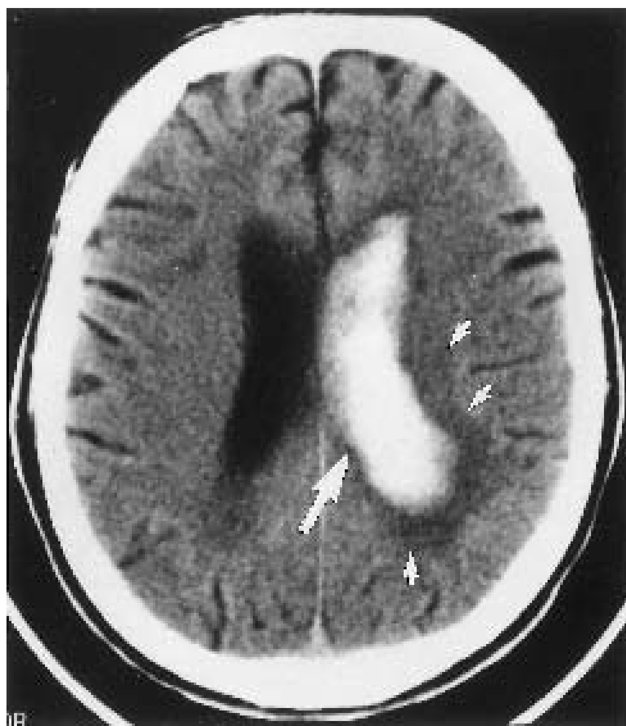

Figure 8 Noncontrast cranial CT. Axial image reveals high attenuation (bright) acute blood within the enlarged left lateral ventricle (large arrow). The adjacent low attenuation (dark) areas are secondary to the accompanying brain oedema (small arrows). The findings were secondary to an acute haemorrhage of a previously undiagnosed brain metastasis in a patient with known primary lung cancer.

malposition, abnormalities in the renal contour, or collecting system (**Figure 9**). It has greater sensitivity for renal lesion detection and specificity in distinguishing simple renal cysts (which require no further workup) from suspected renal neoplasms (**Table 1**) (Bosniak *et al*., 1986).

Occasionally, a CT examination which is indicated in the initial workup of one clinically suspected illness reveals instead a different aetiology, as in the cases of two patients who presented with a palpable right lower quadrant mass (**Figure 10**). A CT scan is frequently requested to investigate further newly discovered radiographic abnormalities (**Figure 11**). Finally, CT has a role in the investigation of an unknown primary malignancy in a patient presenting with radiographic findings indicative of a metastatic lesion (**Figure 12**).

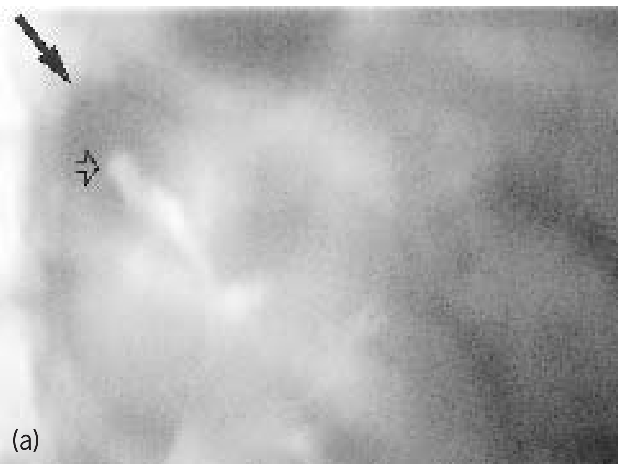
Lesion Characterization

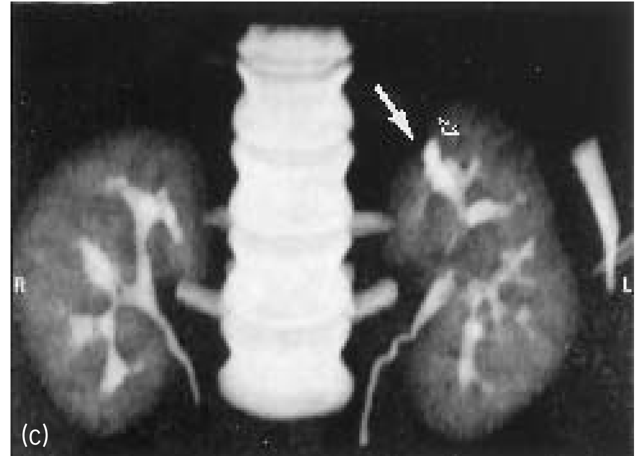
Computed tomography not only possesses increased sensitivity for overall lesion detection over conventional radiography, but in some cases also improved specificity. Noncontrast CT, owing to its sensitivity in discriminating tissues of differing X-ray attenuations, may be sufficient to characterize a lesion measuring at least 1 cm as benign, thus obviating the need for further workup. Detection of fat in a pulmonary mass is pathognomonic for a hamartoma, and in the kidney, an angiomyolipoma. The presence of a smooth-walled completely or centrally calcified pulmonary nodule is diagnostic of a benign granuloma. A round, thin-walled lesion composed of homogeneous fluid (up to 20 HU) is indicative of a benign cyst (see **Figure 21e**). These may occur anywhere within the body and are often discovered incidentally.

Dedicated CT examinations are performed to optimize detection and characterization of masses within the kidney (**Tables 1** and **2**) (Bosniak, 1986, 1997; Aronson *et al*., 1991; Birnbaum *et al*., 1996; Szolar *et al*., 1997; Yuh and Cohan, 1999), lung (**Table 3**) (Yamashita *et al*., 1995; Zhang and Kono, 1997; Swensen *et al*., 2000), adrenal (**Table 4**) (Korobkin *et al*., 1996, 1998; Outwater *et al*., 1996; Boland *et al*., 1997, 1998; Macari *et al*., 1998) and liver (**Table 5**) (Weg *et al*., 1998; Inaba *et al*., 2000; Hollett *et al*., 1995; Baron *et al*., 1996; Miller *et al*., 1998; Chen *et al*., 1999; Murakami *et al*., 2001). Helical CT scanning is used to reduce data misregistration and partial volume averaging with the use of single-breath hold thin-section volumetric acquisitions through an entire organ (liver, kidney) or lesion (pulmonary nodule) prior to and during multiple predetermined phases of intravenous contrast enhancement. The generated data are free of motion artifact and permit comparison of identical levels on scans obtained before and after contrast administration. Partial volume averaging occurs when portions of two adjacent structures are in the same voxel creating an incorrect CT number. This is minimized because a section through the centre of a lesion is assured with helical CT when overlapping sections are reconstructed.

Accurate CT differentiation of a renal neoplasm from a simple (**Table 1**) or a mildly complicated renal cyst (**Table 2**) requires thorough lesion analysis on both pre- and postcontrast scans (Bosniak, 1986, 1997; Aronson *et al*., 1991; Birnbaum *et al*., 1996; Szolar *et al*., 1997; Yuh and Cohan, 1999). Because renal masses do not contain functioning nephrons, enhancement, when present, is generally indicative of neovascularity and malignancy. Enhancement of solid renal masses may be more pronounced on the corticomedullary (vascular) phase which usually occurs between 25 and 80 s after initiation of contrast injection. However, almost all masses have decreased attenuation (and so are more conspicuous) relative to normal renal parenchyma during the other two phases. The nephographic phase usually begins 85–120 s after the onset of injection when contrast filters through the glomeruli and enters the loop of Henle and the collecting ducts. The excretory phase begins when the contrast is first excreted into the calyces, approximately 3–5 min after the onset of injection (**Figure 13**) (Yuh and Cohan, 1999).

A similar protocol is used to distinguish a benign from a malignant solitary pulmonary nodule based upon their





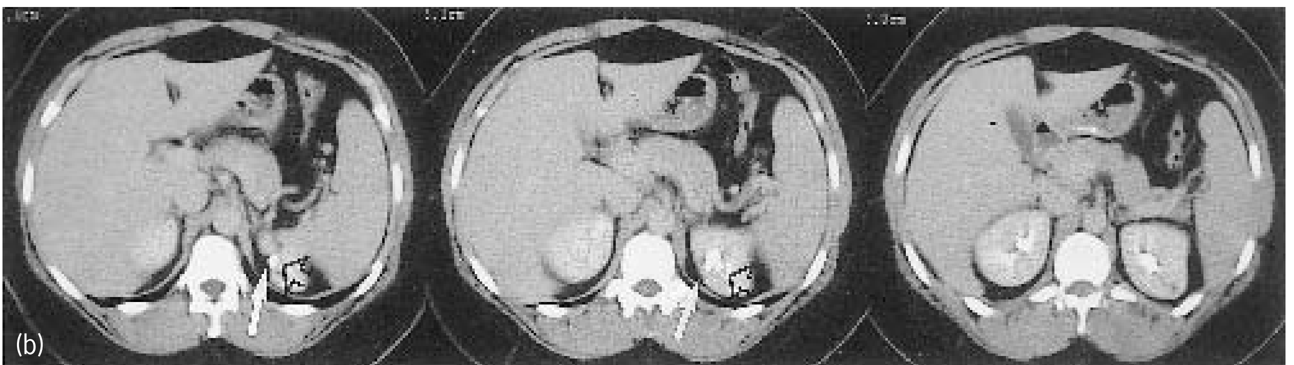


Figure 9 IVP compared with volume-rendered 3D image from the CT scan. (a) Cortical thinning representing a scar in the upper pole of the left kidney (solid arrow) and calyceal blunting (open arrow) typical of reflux nephropathy are seen on this linear coronal nephrotomogram from the conventional IVP. (b) Serial axial CT images also demonstrate scarring in the medial aspect of the upper kidney (solid arrows) but lack the same detail of the collecting system (open arrows). (c) A volume-rendered coronal 3D image displays the same information and detail regarding the renal parenchyma (solid arrow) and collecting system (open arrow) as seen on the IVP. Currently either an IVP combined with a CT or a CT with reconstruction is recommended to evaluate patients with haematuria, or other renal problems, which may affect either the collecting system or the parenchyma rather than the IVP alone.

Table 1 CT characterization of renal cysts vs tumours

Cysts	Malignant tumours
Near water density (0–20 HU)	Greater than water density (regions)
No or thin wall calcification	Coarse wall calcification
Do not enhance	May enhance in regions

differences in vascularity (Yamashita *et al*., 1995; Zhang and Kono, 1997; Swensen *et al*., 2000). To be eligible for this examination a nodule must measure 5 mm or more in diameter, be solid, relatively spherical, homogeneous, without calcification or fat on nonenhanced, thin-section CT images. Helical scanning is performed through the lesion pre and at 1, 2, 3 and 4 min after the onset of contrast injection (**Figure 14; see colour plate section for parts (h) and (i)**). Using enhancement greater than 15 HU as a marker for malignancy, the most recent multicentre study reported 98% sensitivity, 58% specificity and 77% accuracy (Swensen *et al*., 2000).

The initial diagnostic CT scan can provide additional pertinent information for a patient's subsequent workup and treatment plan, including clinical tumour staging (both local extent and the presence or absence of distant metastases) and determination of the best site and modality for histological tissue sampling. It also serves as a baseline examination for comparison with subsequent studies.

Tumour Staging

CT scanning is the established modality for staging virtually all tumours. CT is routinely employed for the preoperative staging of non-small cell lung cancer

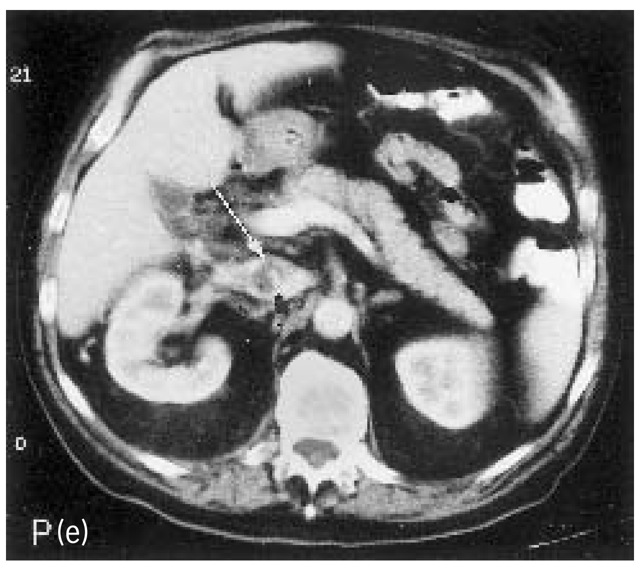

Figure 10 Abdominal CT scans performed for palpable right lower quadrant masses. (a) The caecum is poorly coated by the oral contrast (curved arrow) owing to the presence of a soft tissue mass (short arrow). This proved to be a caecal carcinoma. The acute clinical presentation resulted from perforation as evidenced by the presence of extraluminal air (long arrow). (b) An adjacent axial image in the same CT scan reveals extraluminal fluid (open arrow). Note the abnormal local lymphadenopathy (tiny arrows). (c) An axial CT image in another patient reveals a large mass (large arrow), with central fluid-appearing areas compatible with necrosis (small arrows) extending into the caecum (curved arrows) accounting for the palpable abnormality. (d) A scan cranial to (c) reveals that the mass (solid arrows) originates in the right kidney and is a pathologically proven renal cell carcinoma. The right renal vein (open arrows) is enlarged and contains solid material compatible with thrombus extending into the inferior vena cava (curved arrow). (e) Another axial image cranial to (d) demonstrates enhancing (tumour) thrombus (arrowhead) within the inferior vena cava (IVC) (long arrow). This information is vital for surgical planning. If thrombus is detected at the level of and distal to the intrahepatic IVC, a cardiac surgeon may be required during the surgery to excise tumour from the right atrium.

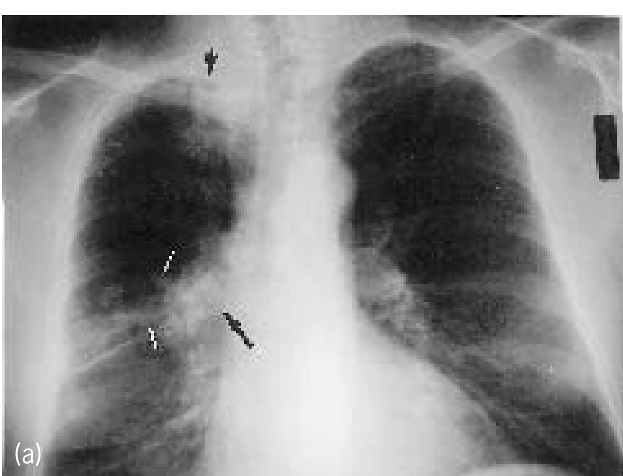

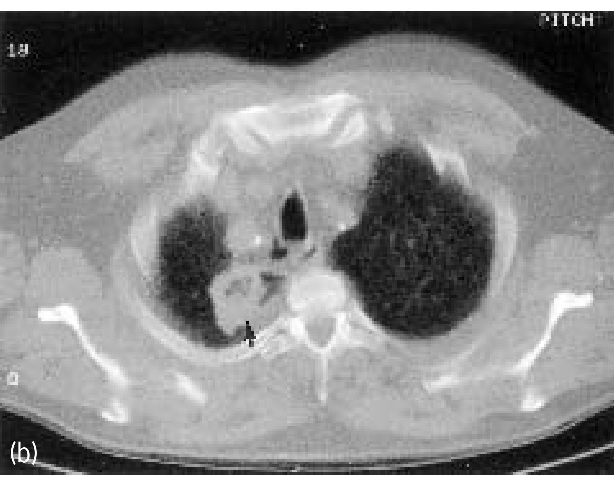

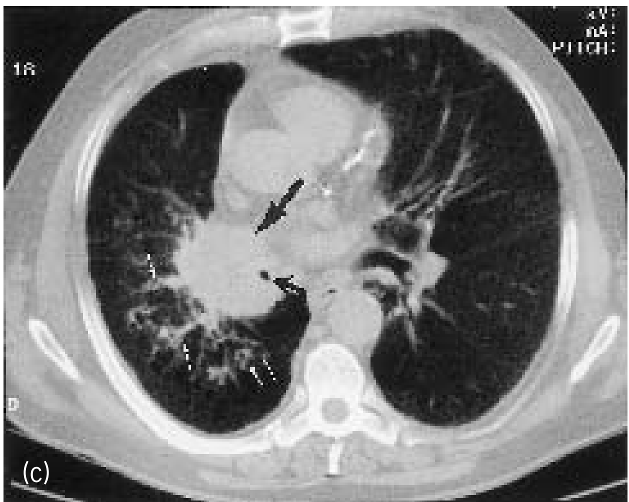

Figure 11 CT scan ordered for abnormal or suspicious radiographic findings. (a) A chest radiograph performed as part of the preoperative workup for coronary artery bypass graft surgery reveals a right apical (possibly cavitary) opacity (short black arrow), and an enlarged, dense right hilum (long black arrow) with adjacent thickened interstitial markings (white arrows). (b) A non-contrast CT image confirms the presence of the apical cavitary mass (black arrow). (c) Axial image at the level of the hila. A right hilar mass (long black arrow) encircles and narrows the bronchus intermedius (curved arrow). CT better demonstrates abnormally thickened perihilar interstitial markings compatible with lymphangitic tumour spread (white arrows). Pathology revealed a primary squamous cell lung carcinoma.

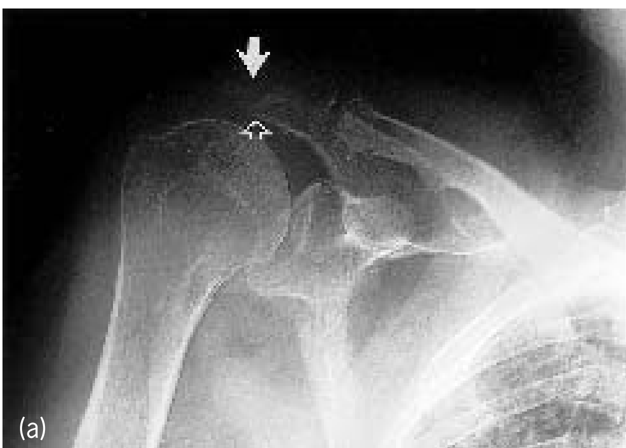

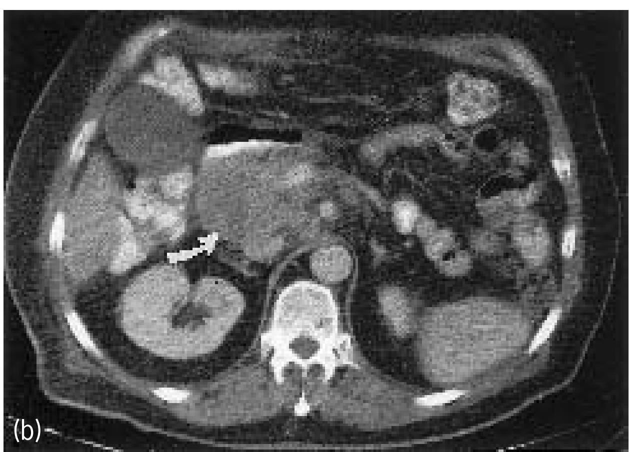

Figure 12 Clinical presentation of a metastatic lesion in the absence of a known primary. (a) A shoulder radiograph ordered because of pain in the absence of trauma demonstrates destruction of the distal acromion (open arrow) with bony fragments in the adjacent soft tissues (closed arrow). Biopsy revealed metastatic adenocarcinoma. (b) Abdominal CT identifies the primary neoplasm, a mass in the pancreatic head (curved arrow).

(NSCLC) (Patz *et al*., 1999). It provides information regarding the lung mass(es) including size and location (lobe, relationship to bronchi), the presence and location of suspicious lymphadenopathy and mediastinal, pleural, chest wall (**Figure 15a**) and local spinal involvement (**Figure 15b**).

Chest CT examinations routinely include the adrenal glands since up to 10% of NSCLC patients will have an adrenal mass as the only site of extrathoracic disease at initial presentation (Macari *et al*., 1998). Differentiation of an adrenal adenoma from a nonadenoma is necessary in order to prevent curative surgery in the presence of extrathoracic metastasis (**Table 4**) (Korobkin *et al*., 1996, 1998; Outwater *et al*., 1996; Boland *et al*., 1997, 1998; Macari *et al*., 1998). Scanning through the adrenal glands helps to ensure complete coverage of the lungs even in the presence of respiratory variability and/or hyperinflation secondary to emphysema. In the latter case, CT demonstration of extensive emphysematous lung destruction may suggest clinical inoperability secondary to an insufficient pulmonary reserve despite tumour resectability. As with pancreatic carcinoma, surgical resection provides the best chance for survival in patients with NSCLC and so extensive surgical procedures (rather than the standard lobectomy and mediastinal node dissection) may be considered. Preoperative CT scanning can not only suggest resectability, it can also influence the nature of surgical procedure itself. Pneumonectomy is indicated if the mass involves a main bronchus, chest wall involvement may require resection of multiple ribs and in some centres a solitary adrenal metastasis is resected at the time of the thoracic resection.

Preoperative identification of haematogenous or distant metastases is clinically useful even when resection of a primary tumour is indicated regardless of its stage. The role of CT in preoperative staging of colon cancer has been controversial with overall accuracies reported in the range 48–77% (Horton *et al*., 2000). These results are due in part, to the inability of CT to demonstrate microscopic tumour extension and to distinguish normal-sized lymph nodes with tumour from those without tumour (Zerhouni *et al*., 1996; Boiselle *et al*., 1998). These limitations are common to all CT oncological imaging and have contributed to the use of complementary imaging modalities such as magnetic resonance imaging (MRI) and positive emission tomography (PET) in addition to CT (Zerhouni *et al*., 1996; Abdel-Nabi *et al*., 1998; Boiselle *et al*., 1998). Indications for preoperative CT in colon cancer include suspected haematogenous or distal nodal metastases, suspected invasion into adjacent organs or abscess formation, atypical

Table 2 Bosniak classification of renal cystic masses

Category I
Simple, uncomplicated benign cyst
Category II
Minimally complicated cyst that is benign with
one or more of the following:
one or more thin septae
thin areas of calcification in the cyst wall or septation
fluid within the cyst has a higher attenuation than clear fluid
Category III
Complicated cyst with some findings seen in
malignant lesions including:
septal wall irregularity, thickness >1 mm, or associated solid elements at its attachment
multiple locules
more extensive areas of calcification, which are thick and/or irregular
inhomogeneous cyst fluid
Category IV
Cystic carcinoma
irregular margins
nonuniform wall thickening
solid component
enhancing nodularity

Table 3 CT characterization of a pulmonary nodule

	Benign	**Malignant**
Noncontrast		
Contour	Smooth, well defined	Irregular, spiculated
Composition		
Calcifications (if present)	Central, smooth margins	Peripheral, irregular margins
Fat	May be present	Absent
Periphery opacities	Adjacent lung parenchyma	Variable hazy
	Appears normal	Secondary to desmoplastic reaction
	Pleural tags absent	May be present
Postcontrast		
Enhancement	<15 HU	>20 HU
	(between 16 and 20 HU enhancement is indeterminate)	

Table 4 Phases of hepatic CT in malignancy

Phases	Time after onset of injection	Abnormalities best seen
Precontrast		Calcifications
Postcontrast		
Arterial	20–25 s	Hepatoma Hypervascular metastases
Late arterial	40 s	Hepatoma (some best seen here)
Portal venous	70 s	Most metastases
Equilibrium	8–12 min	Cholangiocarcinoma (delayed enhancement)
Delayed	4–6 h	Any mass (hepatic parenchyma accumulates iodine)

Table 5 CT characterization of adrenal masses

	Adenoma	Malignancy
Precontrast		
Size	<4 cm in diameter	Primary tumours usually >5 cm
Composition	<10 HU (MR is indicated when 10–20 HU)	>20 HU
Postcontrast	Rapid washout <37 HU at 30 min	Delayed washout >40 HU at 30 min

symptoms or unusual histology. The liver is the most common site for distant metastases. Their preoperative identification may be of importance as a solitary metastasis may be resected concurrently with the primary tumour. Dynamic contrast-enhanced CT and non-enhanced MRI both have 85% accuracy in diagnosing hepatic metastases (Zerhouni *et al*., 1996). Multidetector scanning (Weg *et al*., 1998) and CT arterial portography with or without CT hepatic arteriography have improved detection, with accuracies of 89–94% (Inaba *et al*., 2000).

A dedicated CT liver protocol is helpful in characterizing hepatic masses (Miller *et al*., 1988; Hollett *et al*., 1995; Baron *et al*., 1996; Chen *et al*., 1999; Murakami *et al*., 2001). Most hepatic metastases including those secondary to colon cancer are hypoattenuating masses best seen during the portal venous phase of enhancement as opposed to other liver lesions (**Figure 16**) (**Table 5**). Malignancies with a greater hepatic arterial blood supply and arterioportal shunting are hyperintense on the arterial phase (Chen *et al*., 1999). These include hepatomas (**Figure 17**) and hypervascular metastases secondary to carcinoid, pancreatic islet cell tumour, melanoma, thyroid carcinoma, phaeochromocytoma and breast and renal carcinoma (Miller *et al*., 1988; Hollett *et al*., 1995; Baron *et al*., 1996; Chen *et al*., 1999; Murakami *et al*., 2001).

Tissue Sampling

Histological confirmation of malignancy can often be made by a CT-guided transcutaneous needle biopsy (TCNB), obviating the need for an open biopsy. The initial diagnostic CT scan, by demonstrating suspicious primary or metastatic lesions, can assist in the selection of the most appropriate site and method for tissue sampling. In the case of a suspected lung cancer, which is central and communicates with a bronchus, sputum cytology or bronchoscopy with or without transbronchial biopsy may be appropriate. If the mass is peripheral, transthoracic needle biopsy (TTNA) may be performed under fluoroscopy if it is of sufficient size. If it is too small or surrounded by numerous bullae, CT guidance is preferable as it can reliably depict the mass and demonstrate the optimal trajectory, traversing the least amount of lung parenchyma and avoiding surrounding bullae if possible. Overall sensitivities of 82–100% and specificities of 94–100% have been reported for TTNA for carcinoma. The most common complication is a 5–57% risk of pneumothorax, 1.6–17% of which require a chest tube (Wescott *et al*., 1997; Dennie *et al*., 2001). CT fluoroscopy is currently available (Daly *et al*., 1999). Its utilization may reduce complications by providing continuous real-time monitoring, thus decreasing the total procedure time and the actual time during which a biopsy needle is in the lung. Aside from the histological confirmation of malignancy, differentiation between non-small-cell (NSCLC) and small-cell lung cancers is critical owing to their differences in treatment options. Small-cell cancers are generally effectively treated with chemotherapy alone, thus obviating surgical considerations.

CT-guided TCNB of a suspicious metastasis, even if the primary neoplasm is large and accessible, provides

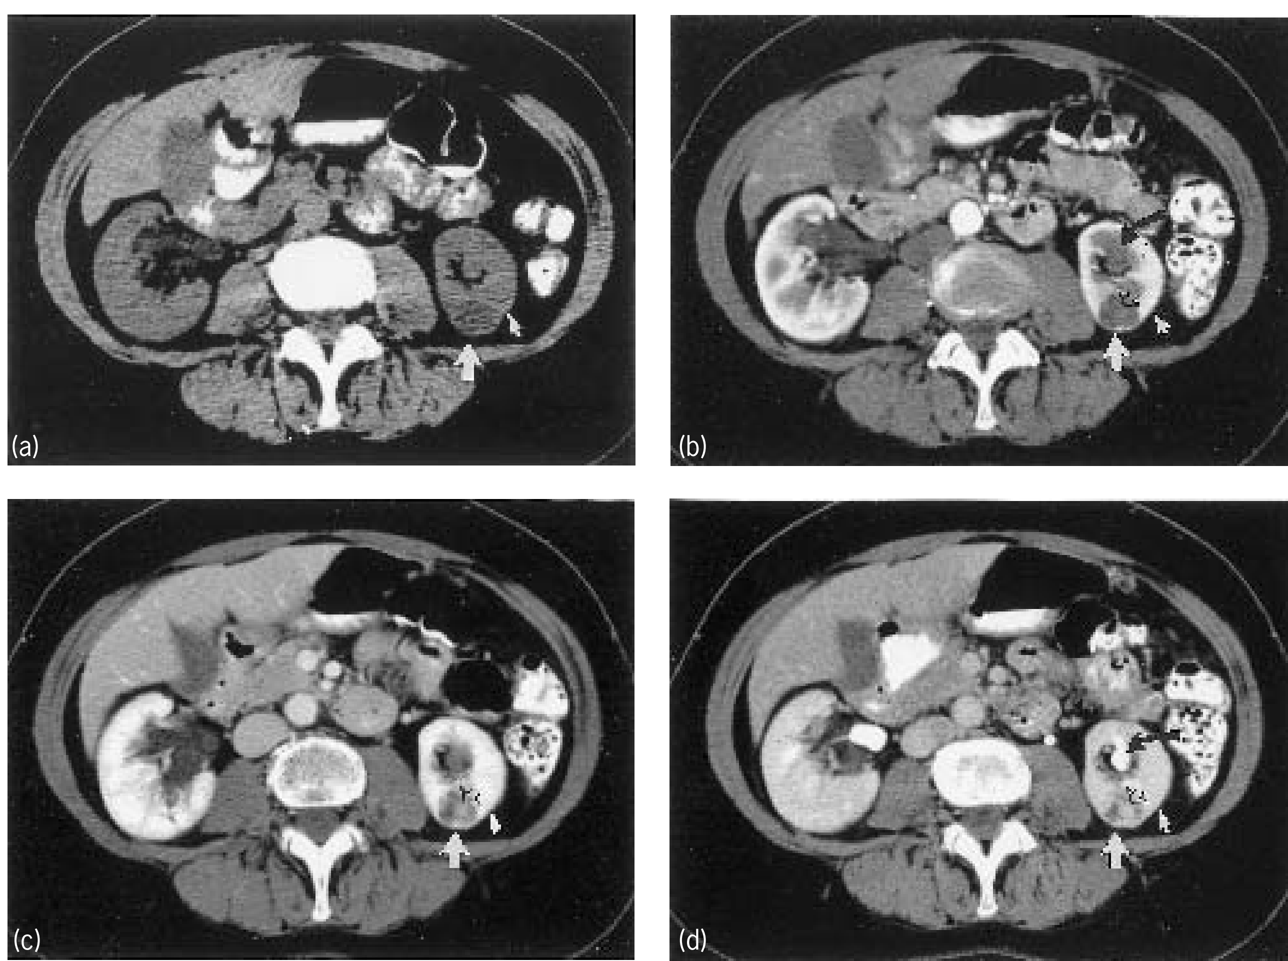

Figure 13 Multiphase imaging of a patient with left renal cell carcinoma. (a) Noncontrast CT though the kidneys demonstrates a mass in the posterior aspect of the left kidney (large arrow) which is hypodense relative to the normal renal parenchyma (small arrow). The noncontrast CT series is used to obtain baseline Hounsefield units (HU), density measurements, and to identify the presence of calcium, which may be obscured after injection of intravenous contrast medium. (b) Corticomedullary (vascular) phase imaging. The lesion is seen as a hypodense mass (large solid arrow) compared with the renal parenchyma (small solid arrow). Note the minimal enhancement within it (open arrow). The contrast has not reached the urine-collecting system which appears of lower attenuation (curved arrow). (c) Peak nephrographic phase imaging. Image at the same level performed just before the excretion of contrast medium shows loss of corticomedullary definition, which was present on the previous image and a more homogeneous parenchyma (small solid arrow). The lesion is well defined (large solid arrow), but exhibits greater enhancement (open arrow). (d) Excretory phase imaging. A delayed image done at the time of excretion of the contrast into the collecting system (curved arrow) shows a less intense nephrogram (small solid arrow) than that seen just prior to excretion but there is more intense tumoral enhancement (open arrow). Maximum tumoural enhancement can be seen at any phase, but is most typically seen on delayed images. Since maximum enhancement can be seen on any phase, multiphase imaging is a great aid in defining and enhancing borderline cases. In addition, different phases are needed to optimize the imaging of multiple organs. For example, the early phases (arterial and portal venous) are best to identify hepatic metastases, while the delayed (nephrographic and excretory) phases are superior for identification of renal lesions and of enhancement in them.

staging information. Determination of mediastinal nodal involvement is crucial for staging NSCLC which is required for appropriate prognostic assessment and therapeutic determination (Mountain, 1997; Mountain and Dresler, 1997). CT diagnosis of mediastinal disease is based upon nodal size. Utilizing 1 cm as the upper limit of normal for the short-axis dimension of a node, CT has been reported to have 62% sensitivity and

64% specificity in assessing lymph node metastases (McLoud *et al*., 1992). Its low sensitivity is secondary to the high frequency of microscopic metastases within normal-sized nodes, and its low specificity is due to the frequent occurrence of enlarged, hyperplastic nodes (Patz *et al*., 1999). Nevertheless, CT identification and localization of enlarged nodes can assist in the selection of the appropriate invasive procedure (mediastinoscopy, mediastinotomy, thoracoscopy and transbronchial biopsy) for staging.

Lymph nodes in the aortopulmonary window are generally not accessible with cervical mediastinoscopy and thus necessitate either parasternal or anterior mediastinotomy for biopsy (Boiselle *et al*., 1998). TTNA of an enlarged mediastinal node, if possible, expedites treatment initiation by eliminating the performance of one of the other biopsy procedures. Biopsy of a probable intra-abdominal or skeletal metastasis with CT-guided TCNB has the additional benefit of eliminating the risk of pneumothorax associated with TTNA. CT guidance has a role even in the biopsy of a superficial mass by demonstrating its internal architecture. The site for tissue sampling can be optimized away from areas of low yield such as necrosis, periosteal reaction or callus formation in a pathological fracture. Adjacent major vessels or nerves can also be avoided. CT-guided TCNB has a role in surveillance by confirming disease recurrence (**Figures 18** and **19**). This enables expeditious institution of appropriate therapy (Som *et al*., 1999).

Percutaneous CT sampling of other primary malignancies is equally safe and efficacious. Biopsy of abdominal primaries yields an approximately 95% positive result when malignancy is present with virtually

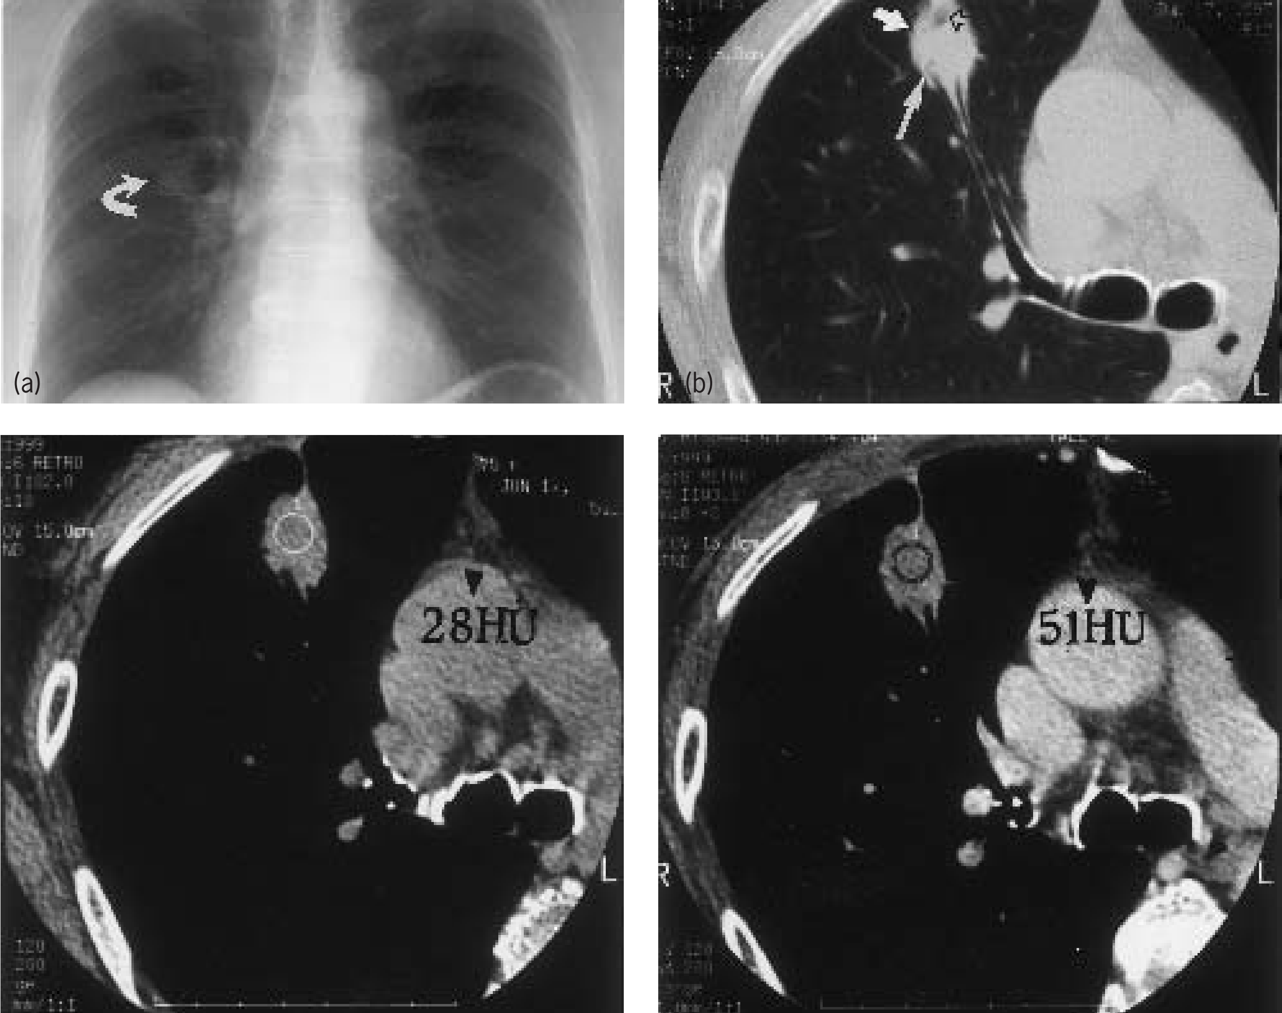

Figure 14 (Continued)

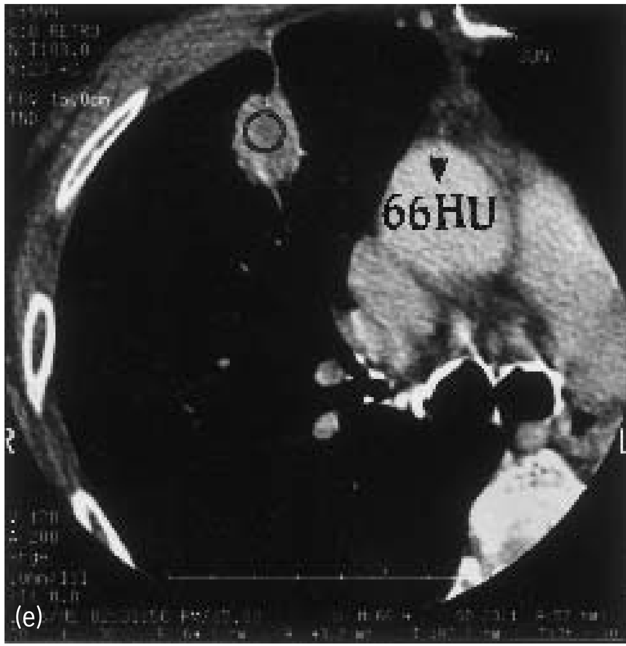

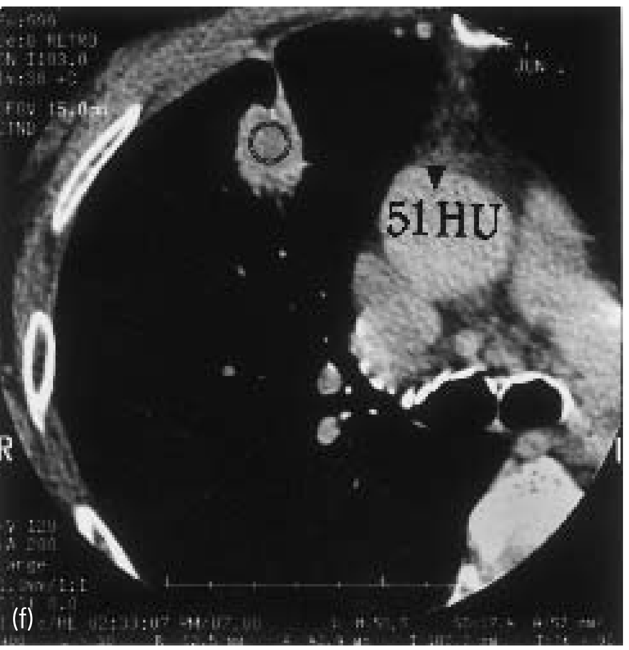

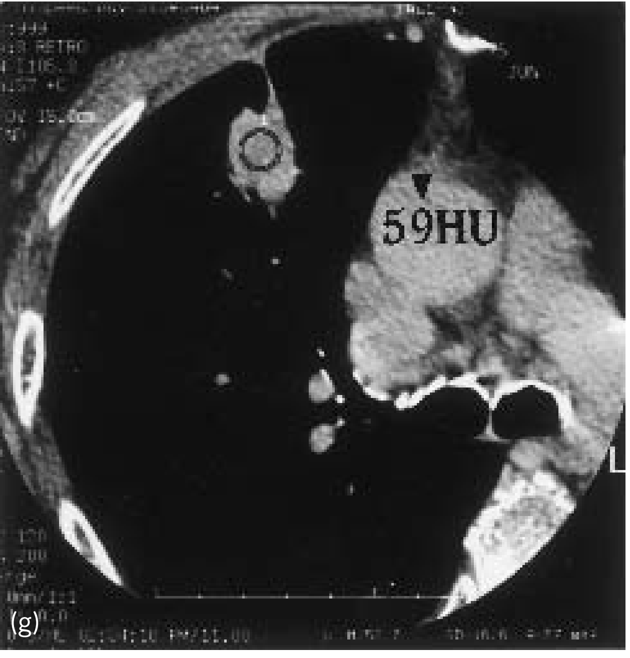

Figure 14 Imaging workup of a solitary pulmonary nodule, a biopsy-proven lung cancer. (a) A frontal chest radiograph reveals a solitary noncalcified nodule in the right lung (curved arrow). (b) A high-resolution CT scan provides further morphological detail. The nodule is fairly homogeneous, without calcifications, but with a focal luscency (open arrow) and an air bronchogram (long arrow). Its margins are irregular (short arrow). (c)–(g) CT evaluation of nodule enhancement. The white circles demarcate the region of interest used for measuring the nodule's density: at baseline (c) prior to the injection of intravenous contrast, medium and at 1 min (d), 2 min (e), 3 min (f) and 4 min (g) after the onset of the injection. The measurements in Hounsefield units (HU) are noted (arrowheads). Abnormal enhancement of 31 HU is present at 4 min, indicative of a malignant lesion. See colour plate section for parts (h) and (i).

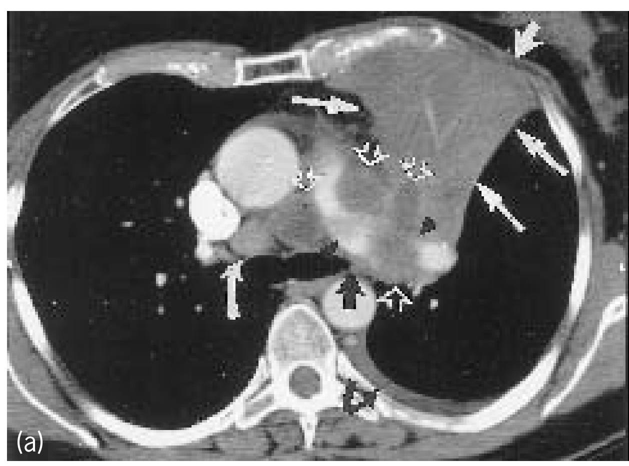
no false-positive results and rare complications such as bleeding (Sundaram *et al.*, 1982). As with lung biopsies, the studies can be done on an outpatient basis. In addition to initial evaluation of neoplastic processes, percutaneous CT biopsies can be used to confirm recurrent disease, permitting optimal treatment.

Surgical Planning

CT plays a major role in surgical planning. In pancreatic carcinoma, which has a poor prognosis with a survival rate of 20% in the first and less than 5% in the fifth year, surgical resection offers the only chance for cure with a 20% 5-year survival. Only 20% of patients will have disease deemed surgically resectable at the time of diagnosis (O'Malley *et al.*, 1999). The ability to identify these patients accurately is essential, as there is a 20–30% surgical morbidity (Sheridan *et al.*, 1999). The role of CT scanning is for tumour detection and preoperative assessment of disease extent. Although its accuracy for tumour detection approaches 100%, determination of resectability is more problematic. Up to 25–50% of patients considered preoperatively to



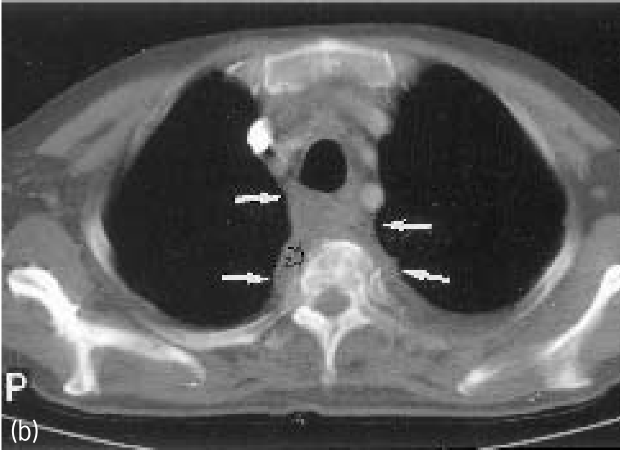


Figure 15 Evaluation of lung tumours for resectability. (a) Initial contrast-enhanced chest CT in a patient with newly diagnosed non-small cell carcinoma of the lung. The left main bronchus terminates abruptly at the level of the upper lobe bronchus (black arrow) by extensive necrotic (low attenuation) central (left hilar and mediastinal) masses (open arrows), with resultant left upper lobe collapse (long arrows). There is encasement of the left main pulmonary artery (arrowheads) as well as contralateral lymphadenopathy (curved white arrow). More peripherally, there is chest wall extension (broad arrow) and a small pleural effusion (curved black arrow). (b) Axial image from a thoracic CT of another patient with lung cancer reveals a mediastinal mass (solid arrows) with destruction of a contiguous vertebral body (open arrow).

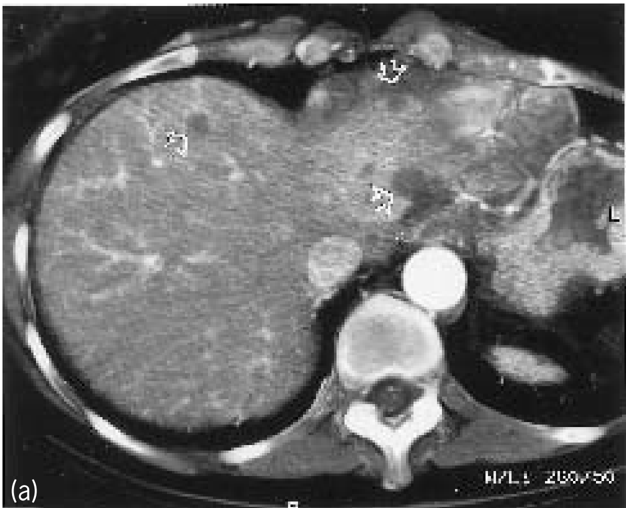

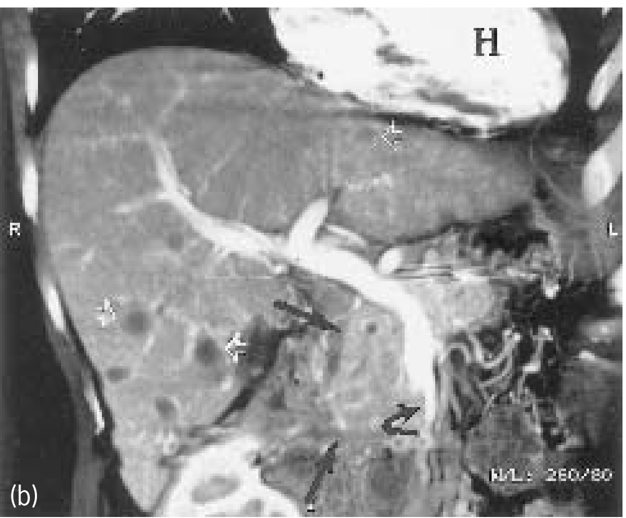

Figure 16 Hepatic metastases from pancreatic carcinoma. (a) Representative axial image through the liver demonstrates low-density hepatic metastases (open arrows). This is performed in the portal venous phase when most hepatic metastases are best appreciated as being less dense than normal parenchyma. (b) 2D coronal reconstruction image demonstrates multiple hepatic metastases (open arrows) as well as the pancreatic mass (straight black arrows). Note the involvement of the superior mesenteric vein (curved arrow) in the region of the mass. H = heart.

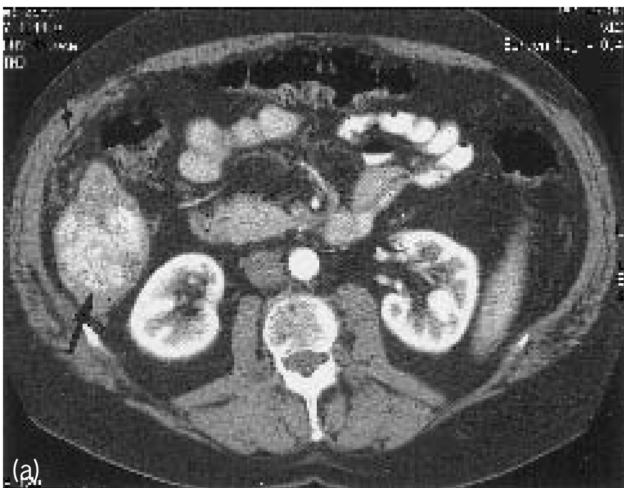
have resectable disease on CT were unresectable at surgery (O'Malley *et al*., 1999). Criteria include spread of disease outside the pancreas (usually the liver or peritoneum), contiguous invasion of adjacent organs including the stomach or colon and involvement of major peripancreatic vessels – arterial encasement or venous occlusion (**Figure 20**). A dedicated pancreatic mass CT is performed utilizing thin-section dynamic multiphasic



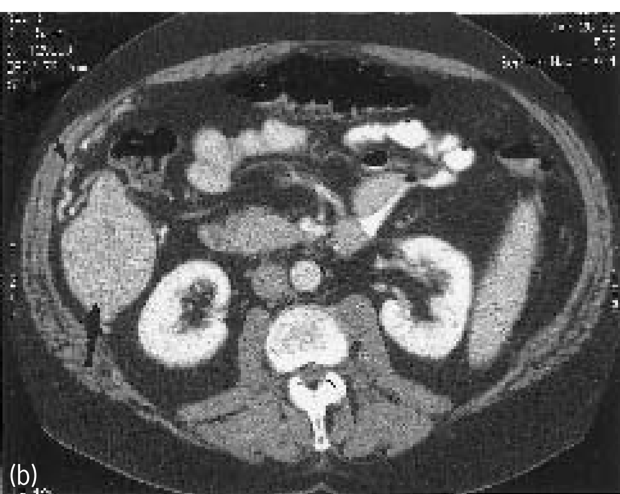


Figure 17 Multiphase imaging for the identification of a hepatoma. (a) Axial scan done through the right lobe of the liver during early imaging (arterial phase) demonstrates a hypervascular mass (large arrow) which enhances brightly on this phase. Maximum enhancement in the arterial phase is typical of hepatoma and certain other hypervascular tumours. In contrast, most hepatic tumours are best identified on the portal venous phase. Note the unenhanced collateral vessels in this cirrhotic patient (small arrow). (b) Same patient, scanning during the standard portal venous phase. The hypervascular tumour is not well appreciated (large arrow). Early scanning is necessary in patients with a suspicion of hypervascular tumours such as hepatoma. Most standard liver primary/secondary tumours are best seen on the portal venous phase. The collateral vessels have enhanced (small arrow).

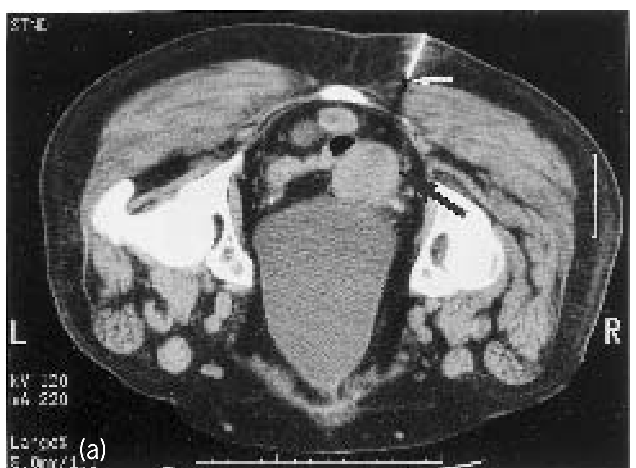

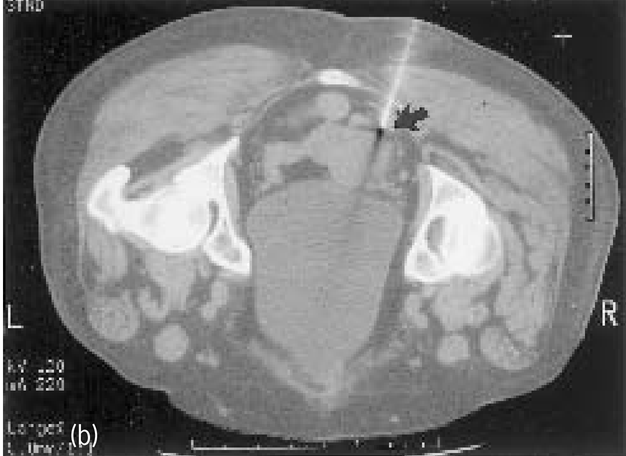

Figure 18 CT-guided biopsies. (a) CT-guided biopsy in the diagnosis of recurrent tumour. Patient with previous cervical carcinoma, who presented with a right pelvic mass (black arrow). On the initial image, the opaque needle is seen extending through the subcutaneous tissues. A black artifact extends from the needle tip (white arrow). (b) The needle has been advanced to the surface of the mass (arrow) permitting needle aspiration cytology or biopsy. This is a highly reliable technique with 95% sensitivity in patients having primary/secondary neoplastic disease. It is an out-patient procedure with extremely infrequent complications.

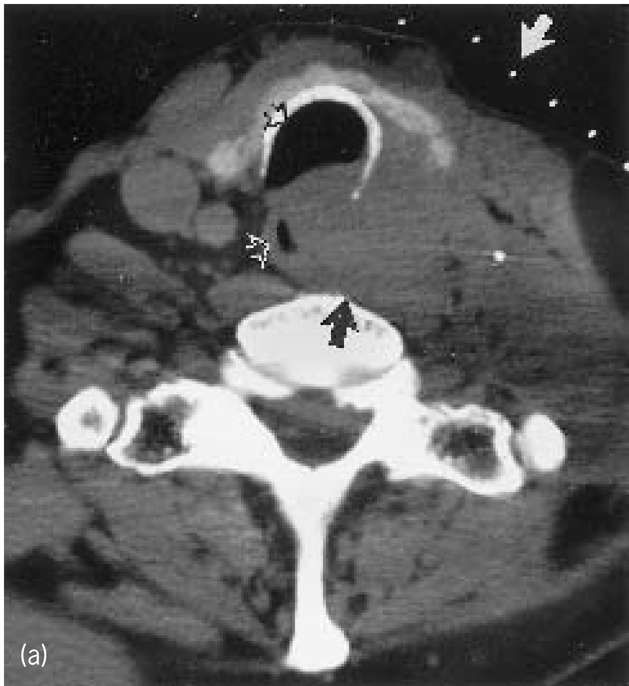
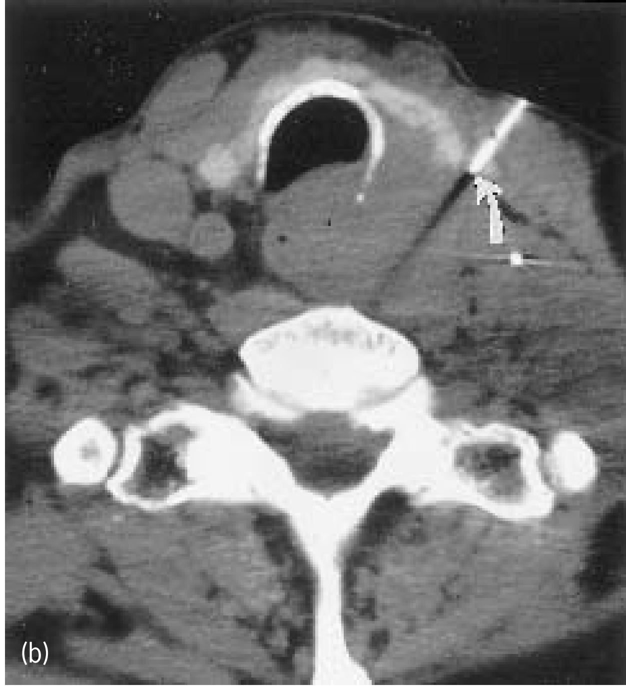
helical scanning (**Figure 21a**) (Nishiharu *et al.*, 1999; O'Malley *et al.*, 1999; Sheridan *et al.*, 1999). The acquired data set subsequently undergoes image analysis and interactive volume rendering. With multi-planar re-formation (MPR), reconstructed axial images are stacked to create a volume of imaging data from which two-dimensional images are generated (Ibukkuro *et al.*, 1995). A reference plane (coronal or sagittal) can then be selected for viewing (**Figure 21b and c**) and subsequent manipulation (tilted or rotated) (**Figure 21d and e**). CT angiography with MPR can display a vessel in a format similar to conventional angiography





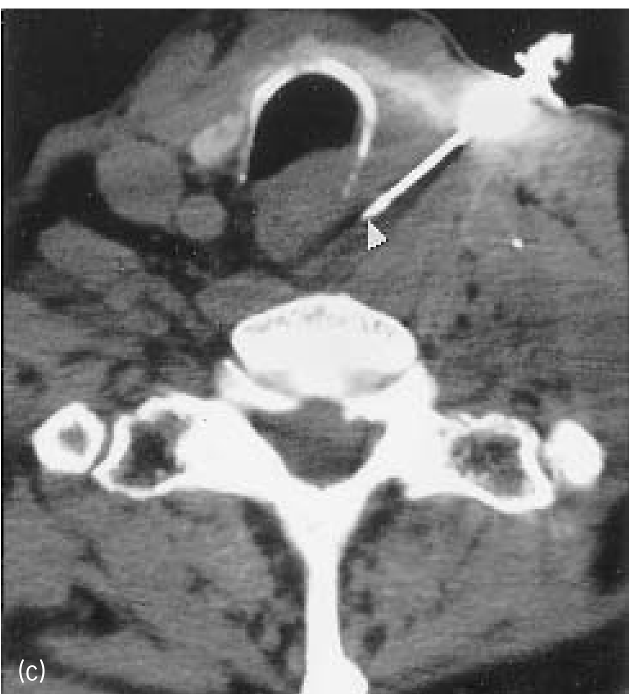


Figure 19 (a) CT-guided biopsy in the diagnosis of recurrent tumour in another patient. Patient with previous squamous cell carcinoma of the neck presented with a large soft tissue mass (black closed arrow) in the area of prior resection. It extends into the trachea (black open arrow) and abuts the oesophagus (open white arrow). Once a biopsy location is selected, a row of needles is placed on the skin. The appropriate entry site is selected relative to the corresponding needles (white closed arrow). (b) The biopsy needle is seen extending through the subcutaneous tissues. A black artifact extends from the needle tip (curved arrow). (c) The needle has been advanced into the mass with the tip successfully positioned (arrowhead) permitting needle aspiration cytology or biopsy. This is a highly reliable technique with 95% sensitivity in patients having primary/secondary neoplastic disease.

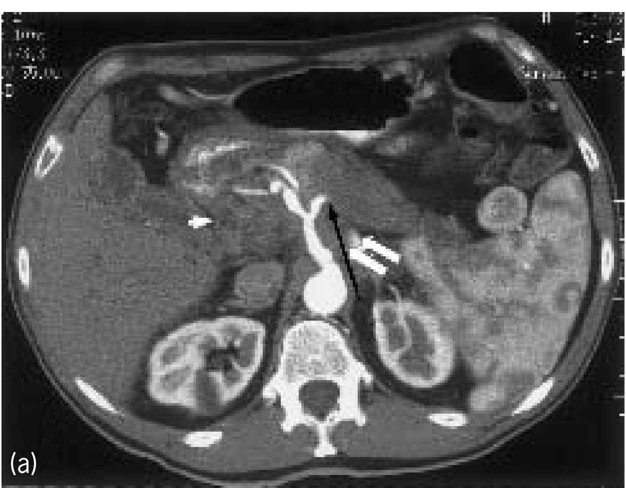
that is easier to understand than an axial CT image (**Figure 21f and g**). Furthermore, 2D and 3D (**Figure 21h–i**) vascular imaging techniques have the additional advantage over conventional angiography that they are capable of displaying a structure or mass surrounding a blood vessel in addition to a lesion inside the vessel. This is particularly helpful in pancreatic cancer imaging since many of the important anatomical landmarks lie in different planes (Novick and Fishman, 1998). Multiphase thin-section helical CT with 2D and 3D re-formation can assist in all stages of surgical planning for potentially resectable cases (**Figure 22**), or provide follow-up of a palliative procedure in others (**Figure 23**).



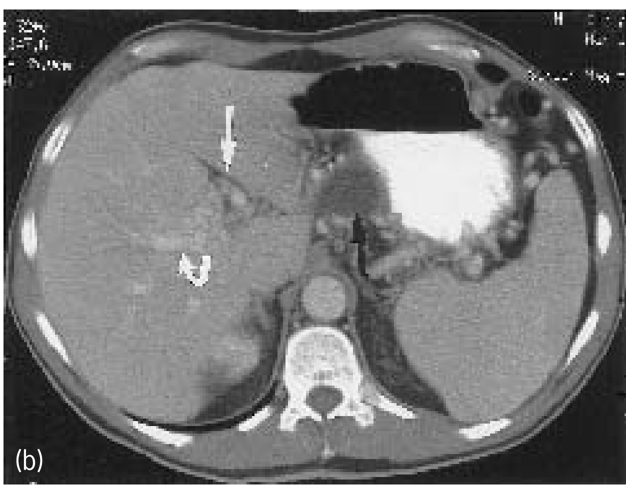


Figure 20 Local invasion. Pancreatic carcinoma with involvement of the hepatic artery, and obstruction of the portal vein with cavernous transformation. (a) Arterial phase imaging at the level of a pancreatic tumour (short white arrows) demonstrates the encasement of the splenic artery (long black arrow) and the failure to identify the portal vein. (b) A scan on a later phase through the liver demonstrates reconstitution of the right portal vein (curved arrow) and cavernous transformation of the main portal vein (white straight arrow). Note the necrotic adenopathy in the lesser sac (black arrow). CT produces exquisite detail of vessels and readily identifies local involvement of the structures.

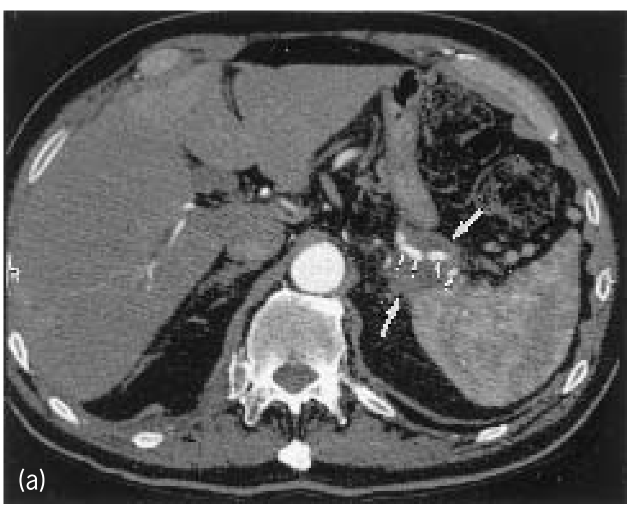

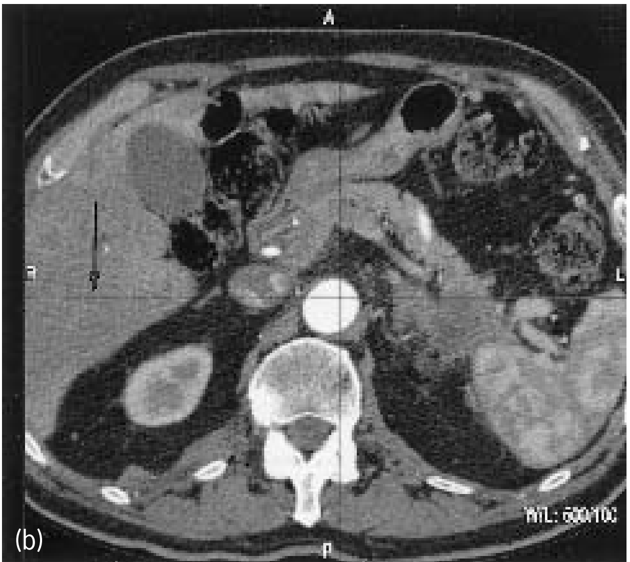

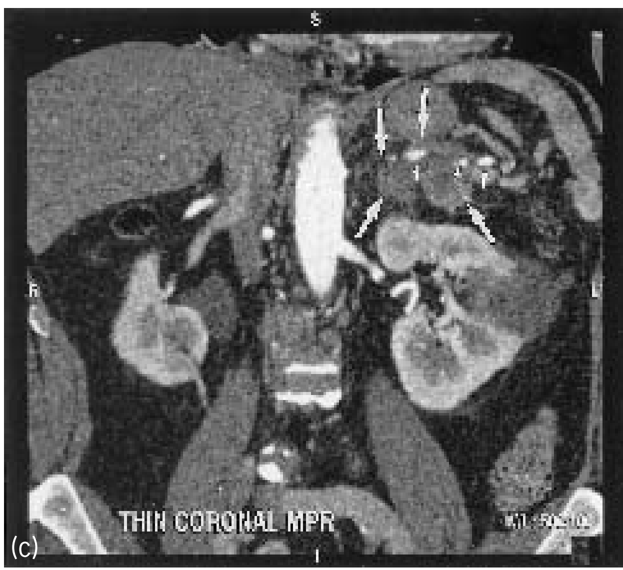

Figure 21 (*continued*)

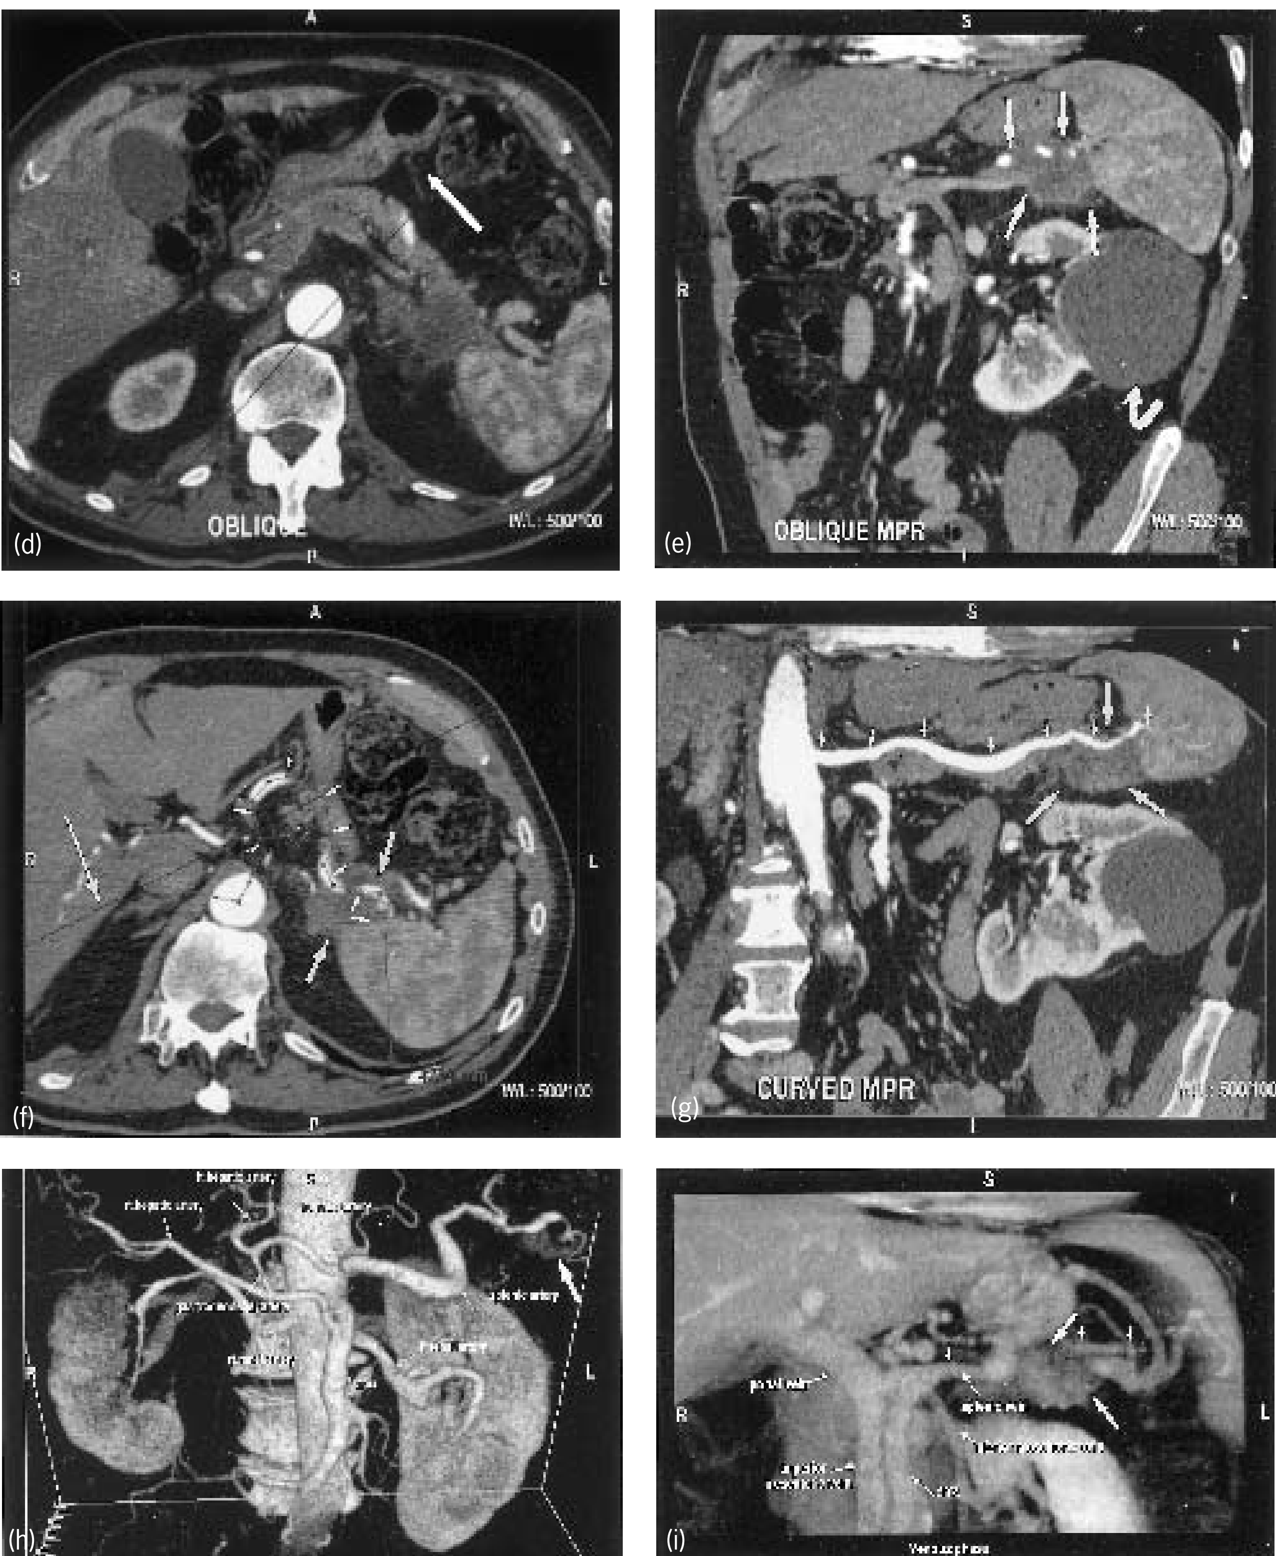

Figure 21 Utility of two-dimensional multiplanar re-formation (MPR) and three-dimensional helical CT angiography (CTA) in staging and surgical planning. (a) A thin section axial image in the arterial phase demonstrates a pancreatic tail mass (large arrows) involving the distal splenic artery (small arrows). (b),(c) A more caudal axial scan. Crosshairs have been placed for selection of the coronal reformation plane (long arrow in (b)). Coronal MPR image (c) demonstrates the distal splenic artery (small arrows) and its relationship to the mass (large arrows). (d),(e) Axial image (d) demonstrating selection of an oblique plane (long arrow) to produce an oblique MPR (e) with a more elongated presentation of the

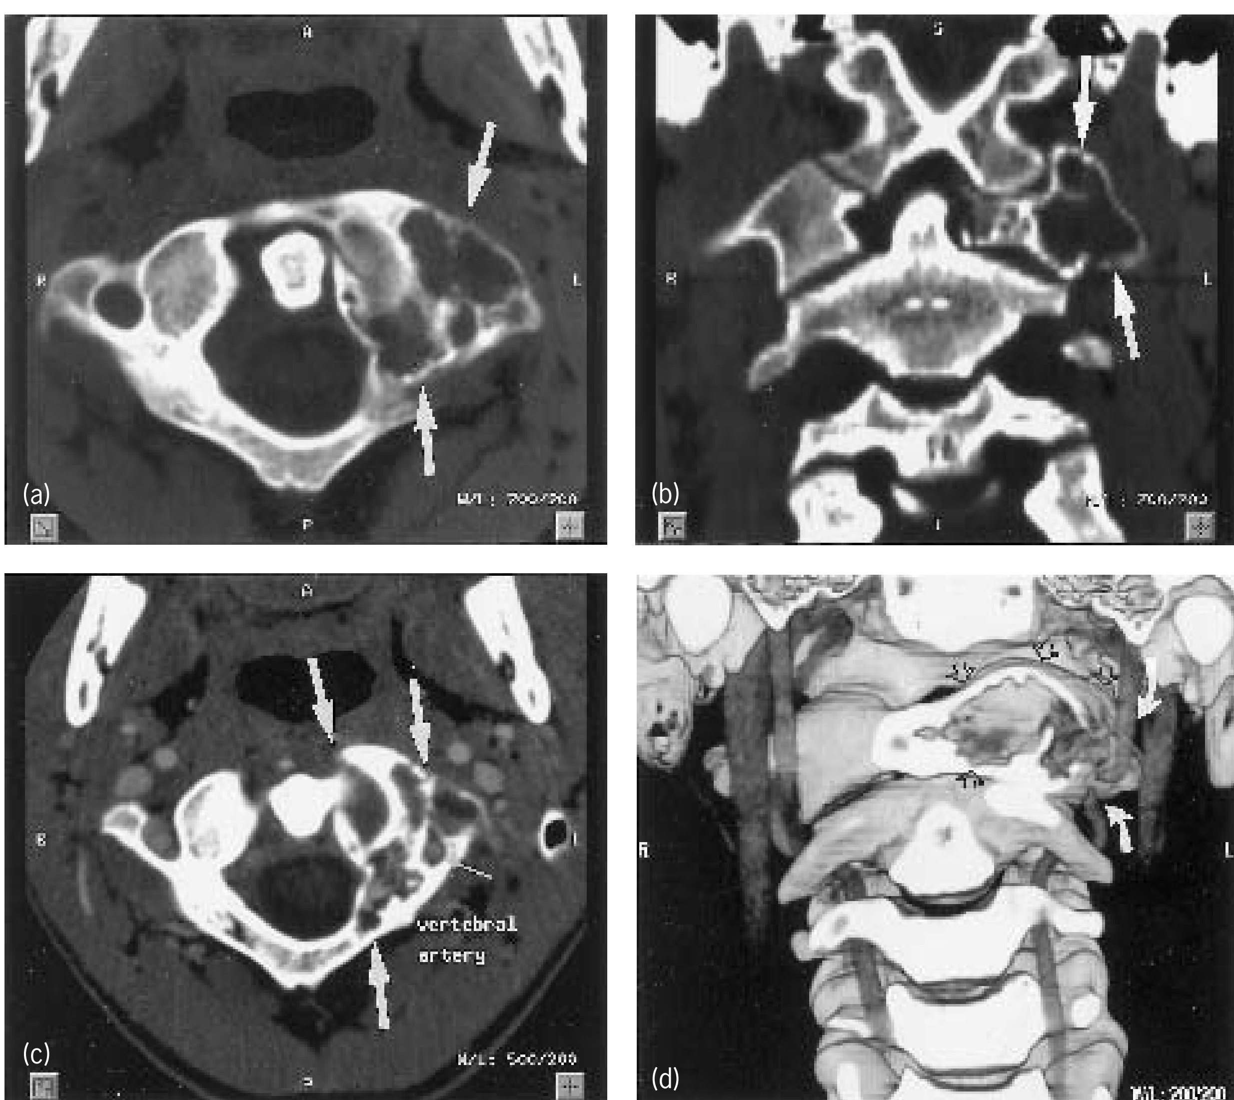

Figure 22 CT angiography with 3D reconstruction in a 17-year-old diagnosed with a vertebral osteosarcoma and referred for a CTA prior to a presurgical embolization of the left vertebral artery. (a),(b) Axial (a) and coronal (b) images demonstrate a lytic mass (arrows) in the C1 vertebral body representing the known osteosarcoma. (c) Axial image following injection of intravenous contrast reveals the location of the vertebral artery (yellow arrow) relative to the mass (white arrows). (d) Coronal 3D shaded surface area reconstruction exquisitely demonstrates the course of the vertebral artery (curved arrows) and its relationship relative to the tumour (open arrows).

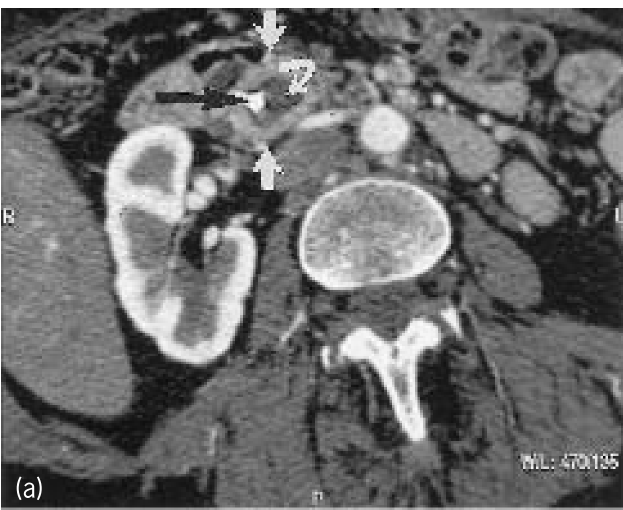
Figure 21 (*caption continued*)
mass (straight arrows). Note the large left renal cyst (curved arrow). (f),(g) Curved re-formation. A line is drawn by the operator (long white arrow) on the axial scan (f) along the projected course of the splenic artery (small arrows) including its portion through the mass (large arrows identify mass). The result is a curved MPR (g) which displays the entire artery (small arrows) as well as the pancreatic tail mass (large arrows). (h) 3D volume-rendered coronal model of the arterial anatomy with shaded surface display (SSD). Pancreatic tail mass (large arrow). (i) Coronal 3D display image showing the venous anatomy. There is occlusion of the splenic vein in the area of the pancreatic mass (large arrows) with distal reconstitution (small arrows). These images provide better delineation of a neoplasm itself as well as the status of adjacent structures. Surgical planes can be virtually created to further assist in surgical planning. The arterial anatomy described in (h) is in actuality figure (i) and the venous anatomy described under (i) is actually (h).



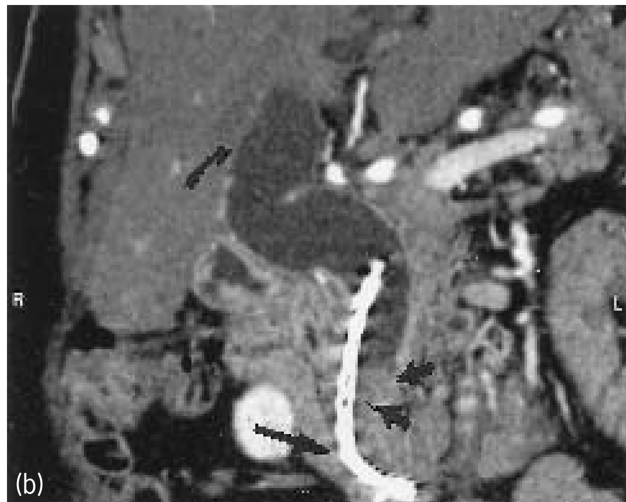


Figure 23 Cholangiocarcinoma in the distal common bile duct. (a) Axial scan through the thick-walled distal common bile duct (white arrows) in a patient with a stent (black arrow). The duct is distended with low-density bile (curved arrow). (b) Standard two-dimensional reconstruction shows the stent going through the dilated common bile duct (curved arrow) into the duodenum (long arrow). The tumour is well appreciated as an abrupt obstructing mass (short arrows).

Nephron-sparing surgery is the surgical treatment of choice for patients with renal cell carcinoma who have a solitary kidney, contralateral renal impairment or bilateral tumours. Its success rate is similar to that of radical nephrectomy in patients with a single tumour under 4 cm in size and with a normally functioning contralateral kidney. It is more technically challenging than radical nephrectomy and is benefitted by the diagnostic information and preoperative planning information provided by triphasic helical CT scanning and 3D volume rendering (Coll *et al*., 2000). Volume rendering techniques incorporate the entire CT data set into a 3D image (Calhoun *et al*., 1999). Preoperative information includes renal position relative to the lower rib cage, spine and iliac crest, tumour location and depth of extension into the kidney, relationship of the tumour to the collecting system and renal arterial and venous anatomy, including the segmental arterial supply to the tumour (**Figure 24**).

Therapy

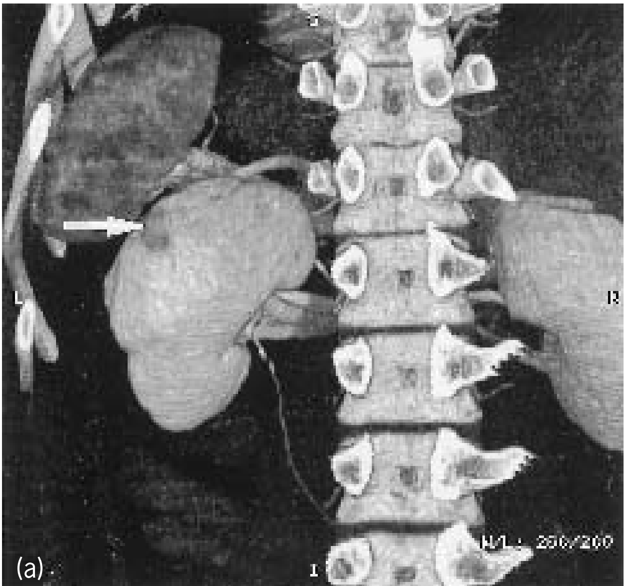
Local Nonsurgical Treatment of Disease

The art of radiation therapy entails the administration of a precise dose of ionizing radiation to a designated tissue volume. Treatments are often limited by the tolerance of surrounding normal tissue (Mohan *et al*., 1998). The role of CT includes depicting anatomical structures for better delineation of the tumour volume and healthy critical organs, allowing planning in a three-dimensional setting, permitting accurate placement of beams and field-shaping devices and allowing more accurate prediction of dose at various sites. CT-guided conformal radiation therapy permits accurate and consistent tumour localization immediately prior to treatment while sparing adjacent normal tissues. This permits the administration of higher radiation doses to tumours such as prostate, with reported improvements in local tumour control (55–94%) and reduction of complications in normal tissues from 10 to 20% (Zelefsky *et al*., 1988). Percutaneous ablation of both primary and metastatic tumours is currently being performed. Accurate preprocedural tumour localization, and immediate and long-term follow-up of its efficacy, are accomplished utilizing CT.

Surgical resection and orthotopic liver transplantation currently offer the best hope for survival for patients with hepatocellular carcinoma (HCC). The disease in unresectable in 80% of patients at the time of initial diagnosis (Okuda *et al*., 1985). Interventional procedures including local ethanol injection are currently being performed in patients who are unresectable or whose clinical status renders them inoperable (Livarhi *et al*., 1986). CT provides imaging guidance for the injection, immediate confirmation of the success of the procedure and long-term follow-up (**Figure 25**).

Palliation

CT may confirm the necessity and success of various palliative procedures. The placement of stents may be endobronchial when there is proximal bronchial obstruction sufficient to cause significant respiratory compromise, endovascular as in the case of superior vena cava obstruction or endoluminal in the presence of biliary obstruction (**Figure 23**).



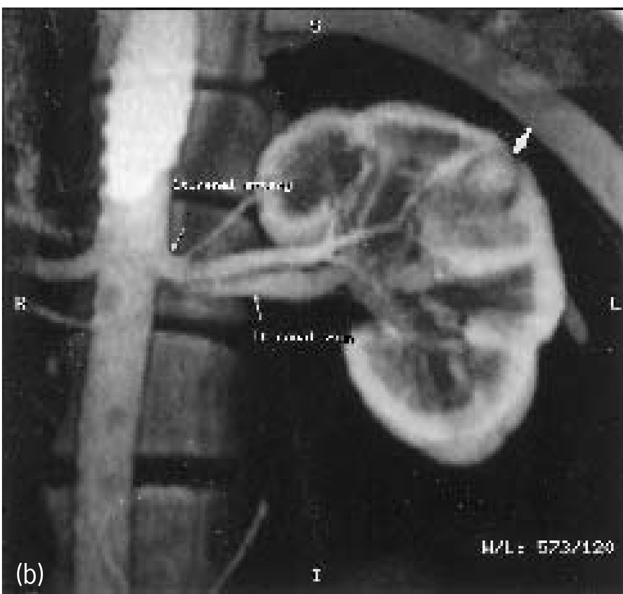


Figure 24 Renal-cell carcinoma. Role of 3D imaging in surgical planning for partial nephrectomy. (a) 3D reconstruction when viewed from behind demonstrates a 1-cm tumour on the surface of the left kidney (arrow). (b) Imaging during the arterial phase demonstrates the small tumour (arrow) and clearly defines the planes that can be used for a surgical approach. In addition, a single left renal artery and single left renal vein are identified and labelled. It is extremely important in doing partial nephrectomies to know the vascular anatomy. (c) 3D axial image viewed from above, which is a view commonly used in surgery, demonstrates the tumour (short arrow). The left renal artery (long arrow) is seen coming off the aorta with an anterior branch and the left renal vein (curved arrow) is readily seen anterior to it (the anterior is inferior and posterior is superior in the view). Identification of exact tumour location and vascular anatomy is crucial to the surgeon in planning a nephron-sparing, partial nephrectomy. The 'CT angiogram' obviates the need for a standard angiogram, which is a more invasive study.

Follow-up

Surveillance

Routine surveillance of oncological patients is frequently conducted utilizing CT. They are performed at appropriate intervals to monitor treatment efficacy (**Figure 26**). CT surveillance provides an opportunity for early detection and biopsy of a suspected lesion (**Figures 18** and **19**), which in turn can result in prompt institution of appropriate therapy. Local and potential distant sites of recurrence are scanned. CT findings indicative of unresponsiveness includes lack of tumour regression, local increase in size and/or number of lesions or adenopathy and the development of distant metastases (**Figure 27**).

The importance of CT in determining local recurrence is exemplified in patients who have undergone radiation for supraglottic or glottic carcinoma. Accurate interpretation of CT examinations in patients who undergo radiation requires that the expected changes due to treatment not be misinterpreted as residual or recurrent tumour. A baseline CT showing complete resolution at the primary site and symmetric–appearing laryngeal and hypopharyngeal tissues (i.e. expected radiation therapy-related changes) is predictive of permanent local control. However, if less than 50% estimated volume

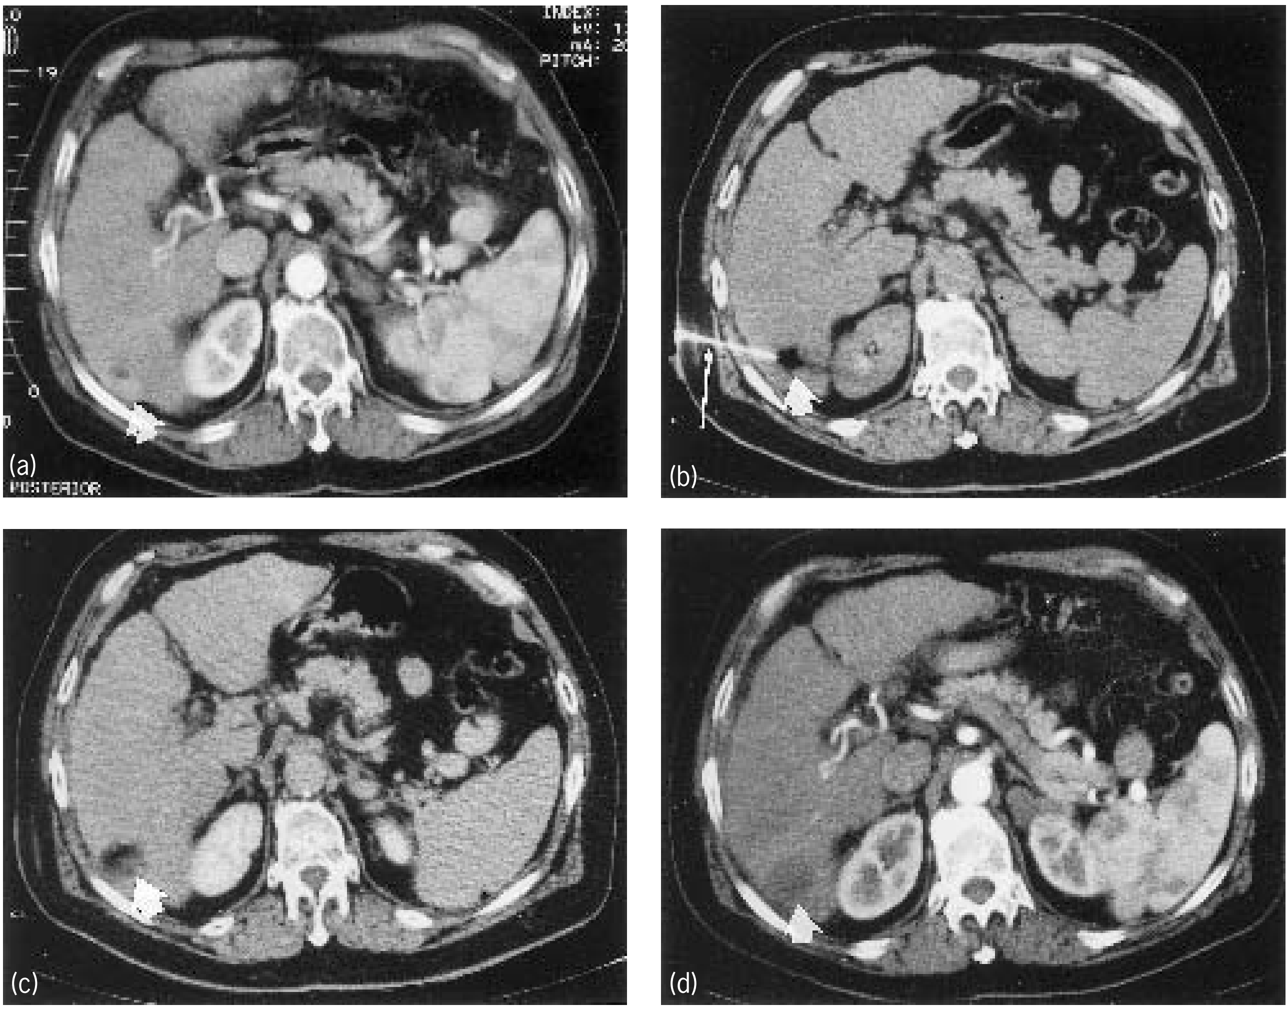

Figure 25 Ethanol ablation of a hepatoma utilizing CT. (a) Arterial phase CT reveals an enhancing mass in the posterior segment of the right hepatic lobe (arrow). Biopsy-confirmed hepatoma. (b) Axial scan performed during the CT-guided percutaneous ethanol injection procedure. Following confirmation of accurate needle placement (long arrow), ethanol is injected resulting in a defect (short arrow) in the mass. (c) Image obtained at completion of the procedure reveals an area of mixed attenuation in the mass (arrow). (d) Followup study. Arterial phase scan at the same level as the preprocedure CT (a) demonstrates the absence of early enhancement. Instead, only a relatively low attenuation area is seen (arrow). This disappearance of the hypervascularity denotes a successful ablation procedure.

reduction or a focal mass with a diameter $\geq$1 cm is found, immediate further investigation is warranted, as the likelihood of local failure is high (Hermans *et al*., 2000).

Even in situations where the earliest evidence of recurrence is local, the possibility of distant metastases must be considered and appropriate scans obtained. Recurrent cervical carcinoma typically occurs in the pelvis with masses or lymphadenopathy (**Figure 19**). However, with the introduction of intensive pelvic radiation therapy, there has been an increase in atypical manifestations of recurrence, including distant solid organ metastases (Fulcher *et al*., 1999). In addition, follow-up CT scans may provide early detection and diagnosis of a second primary cancer (Munden *et al*., 1997; Quint *et al*., 2000).

Disease progression may be clinically silent and detected on routine surveillance studies, or it may present with clinical findings requiring investigation. Dyspnea is a relatively common symptom in oncological patients. A high-resolution CT scan of the chest performed for dyspnea in a patient with breast cancer may reveal pulmonary lymphangitic carcinomatosis – haematogenous spread of tumour into the lungs, penetrating vessel walls and the surrounding interstitium and lymphatics (**Figure 28**) (Johkoh *et al*., 1992). Patients may present with an abnormal physical examination, such as a superficial mass (**Figure 29**), superior vena cava syndrome (**Figure 30**), or an acute change in mental status (**Figure 8**).

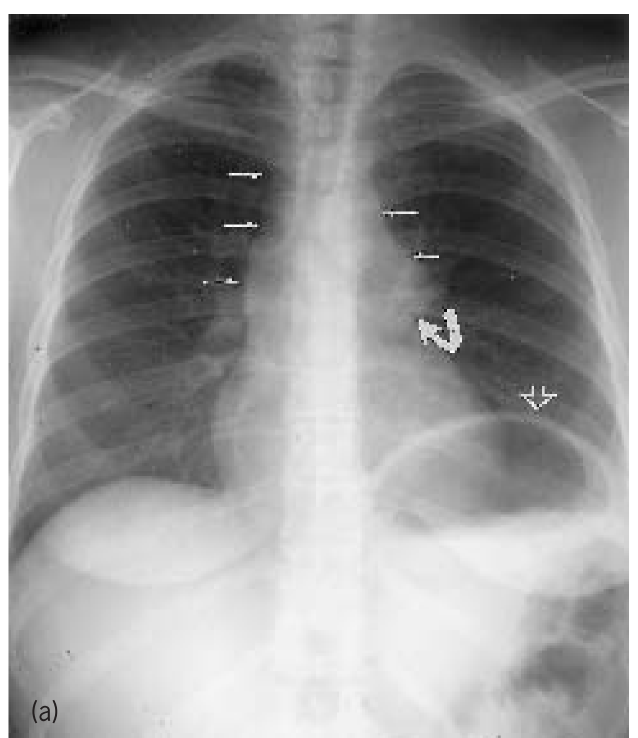

Figure 26 CT in staging non-Hodgkin lymphoma. (a) A chest radiograph in a patient with non-Hodgkin lymphoma demonstrates widening of the mediastinum (straight arrows), hilar enlargement (curved arrow) and elevation of the left diaphragm (open arrow). Pretreatment (b) and posttreatment (c) intravenous contrast-enhanced thoracic CT examinations. Initial scan at the level of the superior vena cava (SVC) (curved arrow) reveals extensive bilateral mediastinal lymphadenopathy (straight arrows). While the vessels including the aorta (long arrow) and brachiocephalic vein (open arrow) are encased they are not occluded, a feature which distinguishes lymphomas from most carcinomas of similar size. Posttreatment axial image (c) at a similar level reveals treatment response with marked diminution of the mediastinal mass (straight arrow). A central venous catheter is present in the SVC through which chemotherapy had been administered (curved arrow). (d), (e) Pretreatment (d) and posttreatment (e) axial images at the level of carina (black arrows). Prior to therapy (d) the extensive mediastinal lymphadenopathy (straight white arrows) encompasses the phrenic nerve accounting for the left diaphragmatic elevation. Chest wall extension (curved arrow) is present, a feature associated with non-Hodgkin rather than Hodgkin lymphoma. Following therapy, (e) calcifications (open arrow) are present in the residual adenopathy (white arrows). The chest wall involvement has regressed (curved arrow).

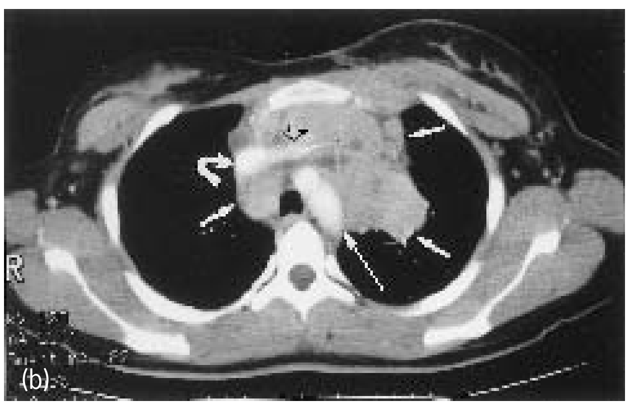

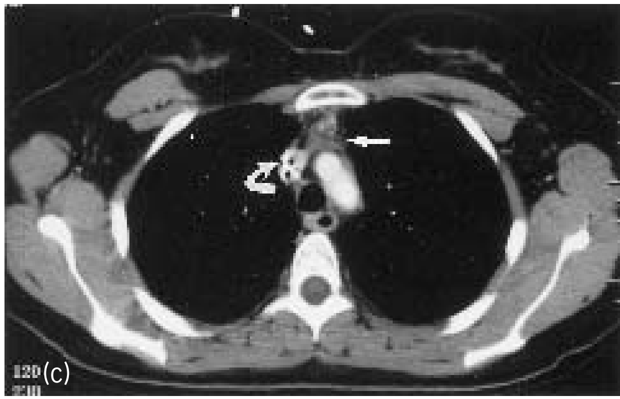

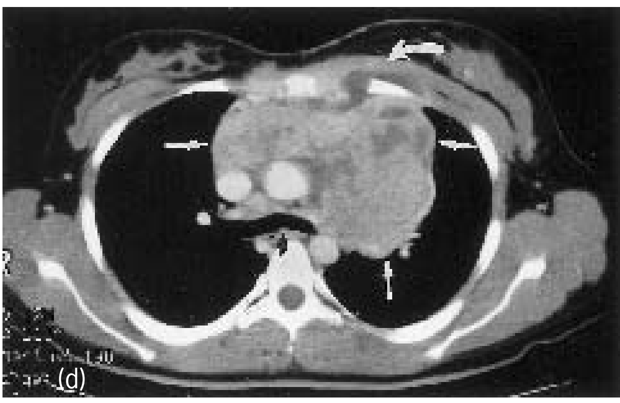

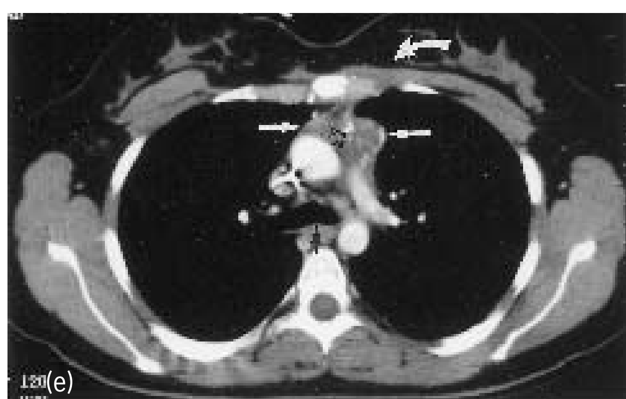

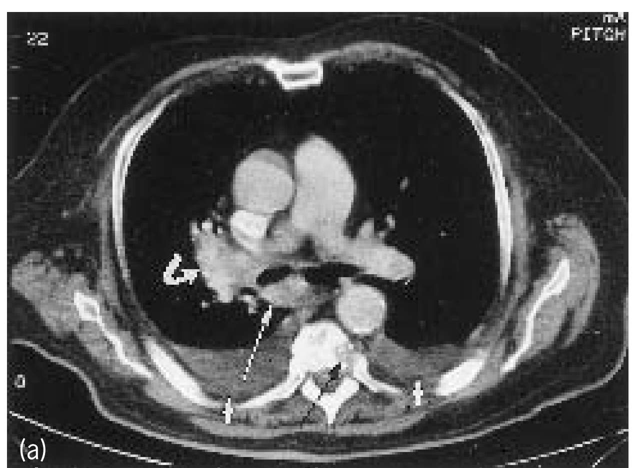

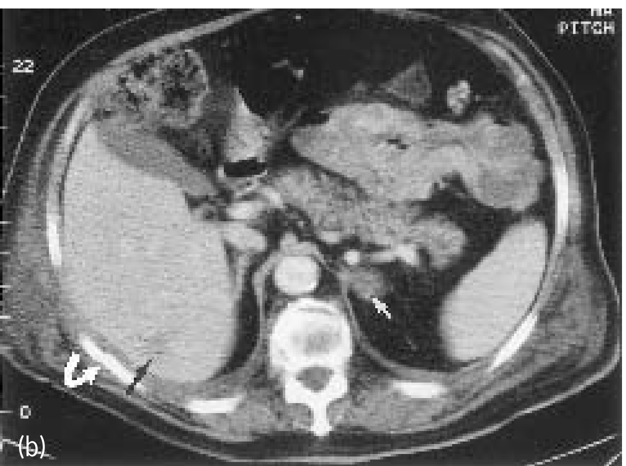

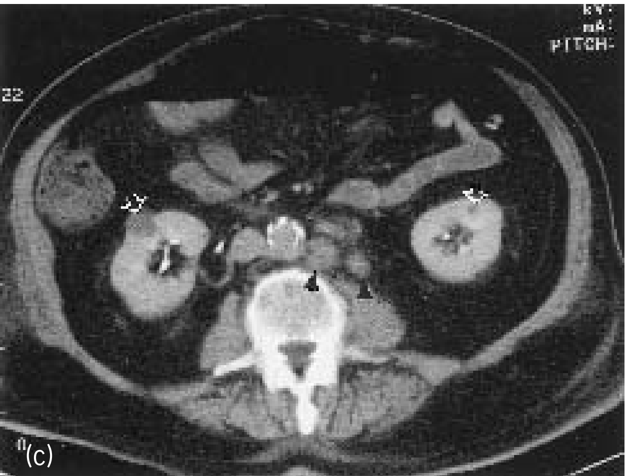

Figure 27 Unresponsive small-cell lung cancer. Multiple sites of neoplastic involvement are revealed during a contrast-enhanced thoracic and abdominal CT. (a) Axial image of the chest demonstrates adenopathy in the right hilum (curved arrow) and mediastinum (long white arrow). Bilateral pleural effusions (short arrows) and vertebral body destruction (long black arrow) are also present. (b) Axial image of the upper abdomen reveals a hepatic metastasis (black arrow), a left adrenal mass (white arrow) and a pathological right rib fracture (curved arrow). (c) Image caudal to (b) demonstrates bilateral renal masses (open arrows) and left para-aortic adenopathy (arrowheads).

Complications

The oncological treatments themselves have risks of complications. Postsurgical complications are often worked up with CT. Acute complications such as anastomotic leakage or abscess formation may appear as extraluminal collections on CT. Intestinal obstruction is usually a more chronic complication, especially in patients with a history of surgery for abdominal malignancy. CT is valuable for determining the presence or absence and the level and cause of bowel obstruction (Ha *et al*., 1998). The obstruction may be benign, secondary to adhesions or related to neoplastic disease. Recurrent tumour or peritoneal carcinomatosis causes malignant obstruction. CT findings not only confirm the diagnosis of intestinal obstruction but also are useful in management. The long-term survival rate in the presence of a malignant obstruction is poor, and the incidence of strangulated obstruction is rare, so early surgical intervention is not generally performed. On the other hand, up to one quarter of the patients have a benign cause, a resectable or easily bypassed local recurrence or a potentially curable new primary, making them candidates for early surgery should conservative management fail.

Complications secondary to nonsurgical treatment modalities are also amenable to CT scanning. CT is more sensitive and demonstrates radiation-induced lung parenchymal changes earlier than chest radiography (Park *et al*., 2000). When pulmonary areas of increased opacity are seen following radiation, the differential diagnosis includes radiation pneumonitis, local recurrence, lymphangitic tumour spread and infectious pneumonitis. The appearance of radiation pneumonitis is unique as it is generally confined to the radiation portals. CT is useful as it can depict not only the nature of the opacities (diffuse haziness and areas of consolidation in the acute, and fibrotic changes in the chronic phases), but also localize them. High-resolution chest CT is valuable in demonstrating findings suggestive of pulmonary toxicity secondary to chemotherapeutic agents in the appropriate clinical setting. In cases where the findings are nonspecific, HRCT is helpful in directing a biopsy to more abnormal areas thus increasing the yield of diagnostic material. CT may also assist in the workup of other more generalized complications such as infection and pulmonary emboli, the latter with and without deep venous thrombosis (Loud *et al*., 2000; Qanadli *et al*., 2000).

FUTURE DIRECTIONS

Advances in CT technology continue. Some involve the CT scanner itself such as the development of portable machines which can be placed in hospital elevators and moved to different patient care areas, or scanners with rotational capabilities to assist in conformal radiotherapy delivery. Faster scanners and improvements in software promise to further expand the imaging capabilities of CT. Multislice imaging utilizing a greater number of detectors will result in increased scanning speed, the creation of more scanning options and improved utilization of administered contrast.

Software advances are continuing to expand the imaging capabilities of CT. New virtual imaging techniques

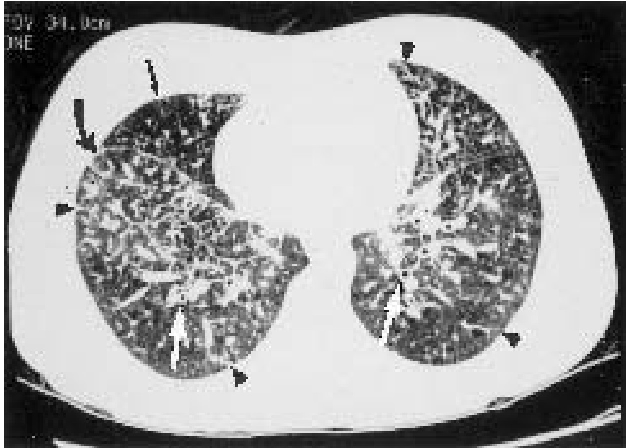

Figure 28 High-resolution CT (HRCT) of the lungs. A patient with known breast cancer developed dyspnea with no clinical evidence of infection. An axial image reveals bilateral patchy interstitial abnormalities including: thickening of peribronchial (white arrows), interlobular (arrowheads) and interlobar (curved arrow) interstitium. Note the normal appearing interlobular septa in the uninvolved right middle lobe (straight arrow). The HRCT technique employs increased milliamperage or kilovolt peak X-rays, thin collimation and an edge-enhanced reconstruction algorithm in order to display the pulmonary interstitium optimally.

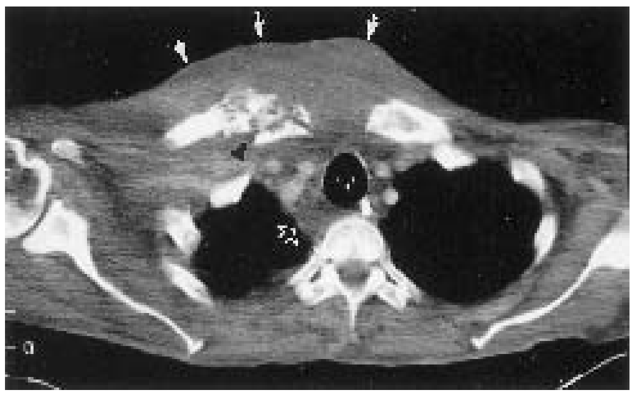

Figure 29 Thoracic CT image of a patient with a history of non-Hodgkin lymphoma who presented with a large visible and palpable mass which is shown to be dramatic chest wall extension (closed arrows) of the mediastinal adenopathy (open arrow), with destruction of the medial right clavicle (arrowhead).

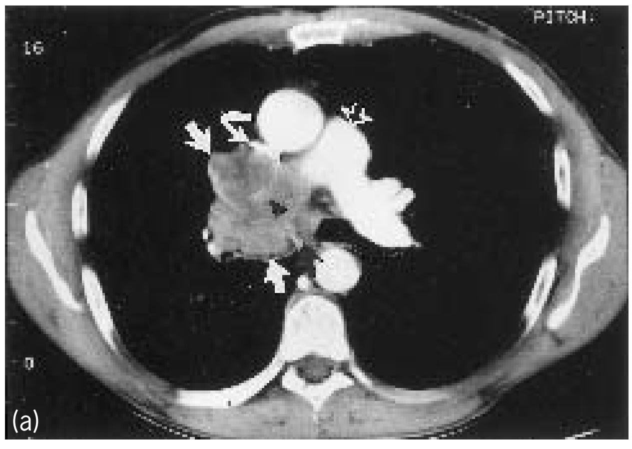

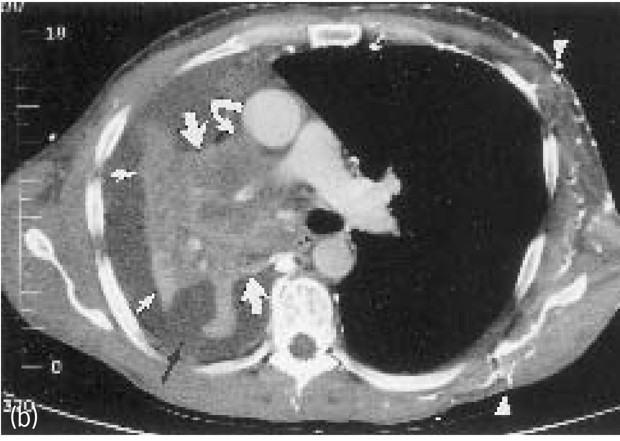

Figure 30 Progression of disease (lung cancer). (a) Axial CT scan of a patient with biopsy-proven adenosquamous carcinoma of the lung at the level of the main pulmonary artery (open arrow) reveals a large, heterogeneous mass (arrows). The barely visible right pulmonary artery (arrowhead) and absence of an air-filled right mainstem bronchus (black arrow) indicate their involvement. The SVC is compressed but patent (curved arrow). (b) Follow-up scan obtained 1 month later when the patient presented with SVC syndrome-engorgement of the veins of the upper chest, neck and face. Axial image at the same level reveals disease progression. The margins of the actual mass (large white arrows) are obscured owing to the development of right lung collapse (small white arrows). A contrast-filled SVC is no longer visualized owing to interval tumour growth (curved arrow). Numerous contrast-enhanced collateral vessels are now visualized throughout the left chest wall (arrowheads). Note the presence of a new pleural effusion (black arrow).

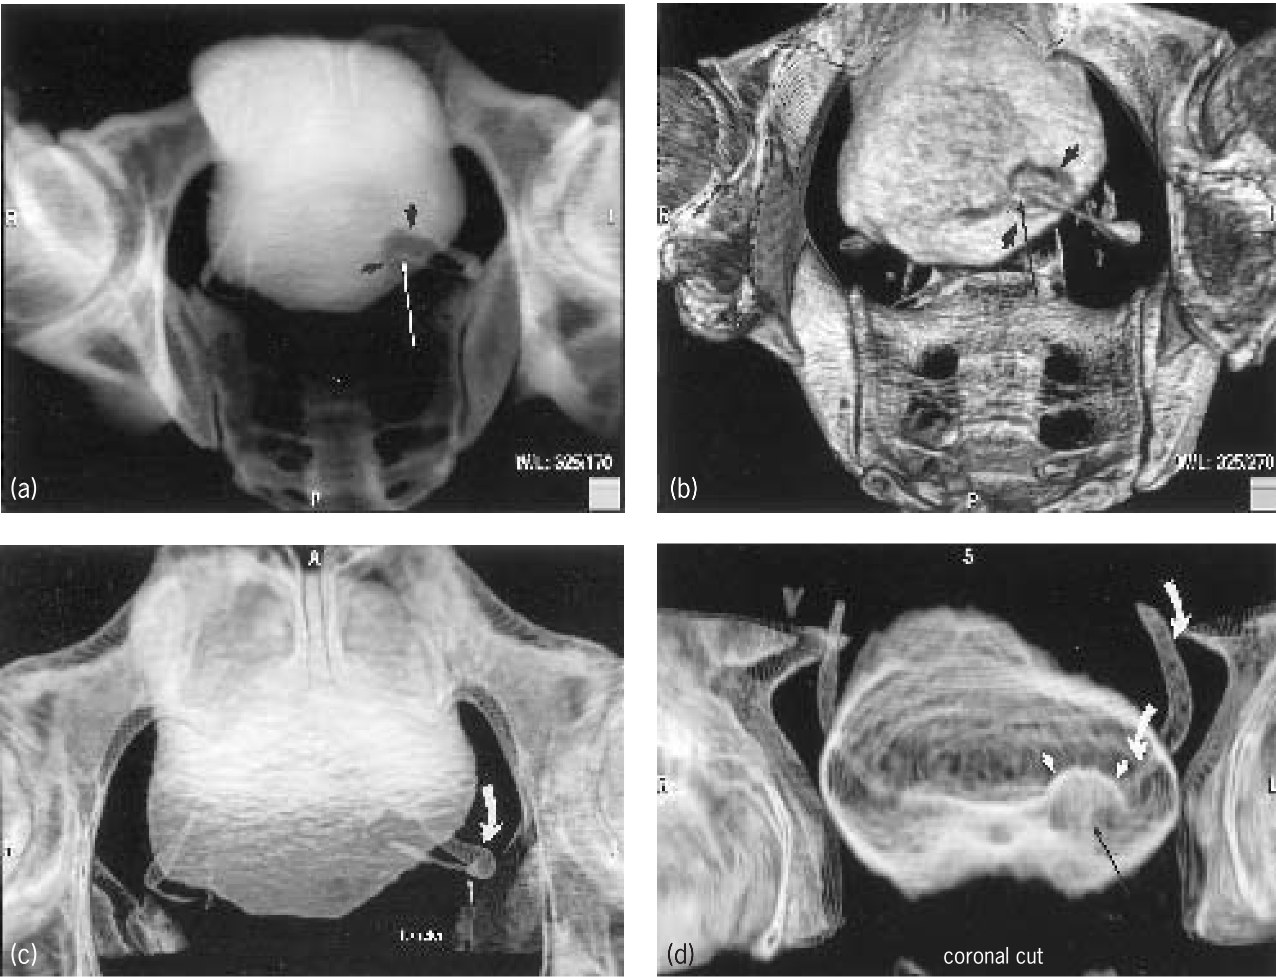

Figure 31 Bladder tumour with 'virtual' imaging. These volume rendered 3D models were reconstructed from axial CT images acquired as part of a CT/IVP examination in which a vesical abnormality was detected. Different techniques were employed to alter their transparencies. (a) 3D reconstruction in the axial plane as viewed from above demonstrates a tumour in the left hemitrigone (short arrows) where the ureter enters the bladder without obstruction to the ureter (long arrow). (b) The 3D reconstruction utilizing a shaded surface display further accentuates the tumour margins (short arrows). The distal ureter (long arrow) and its relationship to the tumour are again displayed. (c) The same 3D reconstruction rendered with a 'transparency technique' permits evaluation of the inner lumen of the left ureter (curved arrow). (d) 3D reconstruction in the coronal plane with further transparency application demonstrates not only the inner lumen of the distal left ureter (curved arrow), but also of the bladder. Note the mass in the hemitrigone (short arrows) and the distal ureter within it (long arrow). Postprocessing data manipulation can permit added information to be extracted from the image and can also be a great aid in guiding the surgeon to the correct approach.

are being evaluated. Three-dimensional helical CT of the tracheobronchial tree (Zeiberg *et al.*, 1996) and virtual bronchoscopy (Ferretti *et al.*, 2000) show promise in evaluating the central airway. Multiplanar CT pancreatography and distal cholangiography appear promising (Prassopoulos *et al.*, 1998; Raptopoulos *et al.*, 1998). Initial studies suggest that virtual cystoscopy maybe helpful in detection of bladder tumours larger than 5 mm (**Figure 31**) (Song *et al.*, 2001). Computer-assisted detection of lesions is also being developed (Summers *et al.*, 1998).

CT scans are being further integrated with complementary imaging modalities such as ultrasound (US) and magnetic resonance imaging (MRI). The correlation of a tumour's appearance and location on CT with its physiology (such as increased glucose uptake in a metabolically active lesion) as demonstrated by positron emission tomography (PET) has tremendous implications for oncological imaging.

- General Principles of Ultrasound as Applied to Cancer Imaging
- Doppler Ultrasound
- Ultrasound Contrast Agents
- Specific Clinical Applications of Ultrasound for Cancer Diagnosis
- New Advances in Ultrasound Technology
- Conclusion

INTRODUCTION

Ultrasound is a widely available cross-sectional imaging technique that is used for both diagnosis of cancer and image-directed therapy. This chapter will discuss general principles of ultrasound imaging, including Doppler blood flow analysis and how these techniques are applied for cancer detection. Potential applications of intraoperative ultrasound and new ultrasound techniques such as laparoscopic ultrasound and contrast imaging will also be addressed. Ultrasound-directed biopsy and therapy are discussed elsewhere.

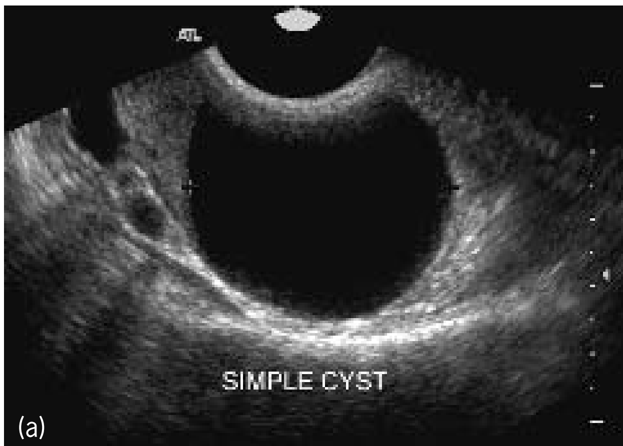
GENERAL PRINCIPLES OF ULTRASOUND AS APPLIED TO CANCER IMAGING

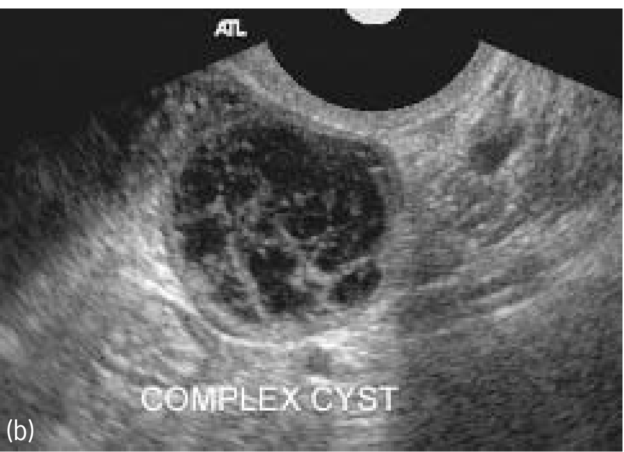
Ultrasound imaging is based on the transmission of high-frequency sound through tissue by using a hand-held transducer that both transmits and receives sound. The varying attenuation of sound by different tissue interfaces is used to generate an image. As sound travels through tissue, echoes are generated when some sound is reflected back to the transducer at each tissue interface. The distance of the interface or object is determined by the elapsed time between transmitted and received echo signals. The terms used to describe findings on ultrasound images relate to acoustic properties such as echogenicity, reflection and acoustic transmission.

In order to detect malignancies it is necessary to have sufficient soft tissue contrast to differentiate normal tissue from malignant masses and adequate spatial resolution to detect small masses or normal anatomical structures. Ultrasound has excellent soft tissue contrast and is the best imaging modality for differentiation of cystic, fluid containing masses from solid lesions (**Figure 1**). Fluid-containing masses have no internal echoes, and since sound is not attenuated by fluid, there is acoustic enhancement posterior to fluid-containing structures. Solid masses have internal echoes on ultrasound and are readily differentiated from fluid-containing cystic lesions. Ultrasound soft tissue contrast is used to characterize the internal architecture of lesions as a means of differentiating benign from malignant disease.

Soft tissue contrast provided by ultrasound has been improved further by the new technique of harmonic imaging. Harmonics are weak ultrasound signals that are produced when the incoming signal wavelength is altered by varying speed of sound transmission within tissue. The harmonic frequencies produced within tissue are multiples of the original signal frequency. Since harmonics are generated within the tissues there is less image background noise from scatter. Harmonic imaging, now routinely available, improves the depiction of fluid-containing structures, and better defines internal architecture of masses. In cancer patients, the information from harmonic ultrasound is particularly useful for the detection of small hepatic masses or for the identification of hepatocellular carcinomas that have similar echogenicity to normal liver (Hann *et al.*, 1999). Harmonic ultrasound is reported to provide additional information for liver imaging compared with standard ultrasound in approximately 30% of cancer patients because improved soft tissue contrast allows identification of smaller and more subtle lesions.

Ultrasound has excellent spatial resolution, in the range of 1 mm with standard transducers. New high-frequency transducers have sub-millimetre resolution. Normal anatomy such as extrahepatic bile ducts or small structures such as mural nodules within masses are readily resolved by sonography. The spatial resolution of ultrasound is





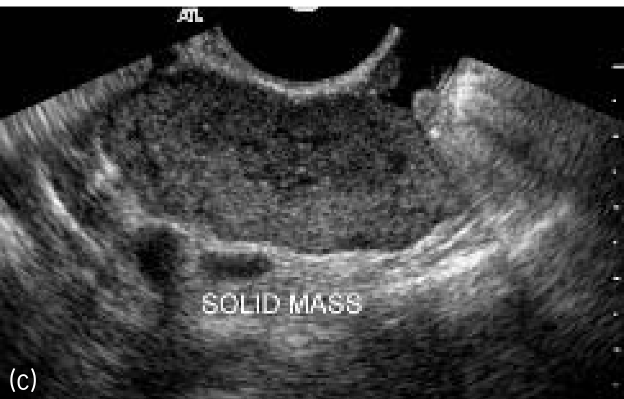


Figure 1 Ovarian masses in three different patients illustrate the use of ultrasound to differentiate between fluid and solid masses. (a) Simple benign cyst has no internal echoes (black area) and has a thin, smooth, white echogenic wall. (b) Complex ovarian mass has fluid (black areas) and solid components (white areas) due to multiple septations within the mass. With increasing complexity, there is increased likelihood of malignancy. (c) Solid ovarian carcinoma has internal echoes throughout the lesion.

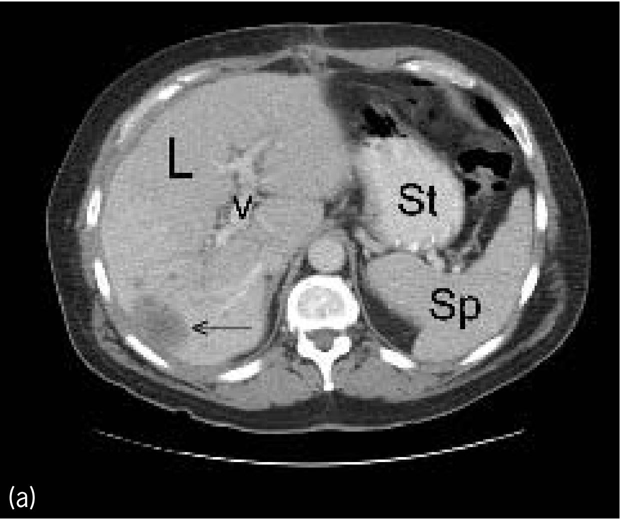
directly related to transducer frequency. Higher frequency transducers have better resolution, but tissue penetration is limited because high-frequency signals are attenuated faster. In general, the highest frequency transducer that provides adequate image depth is chosen for examinations. For examination of superficial structures such as breast, thyroid and scrotum, high-frequency transducers in the range 7.5–15 MHz are used, but for abdominal imaging lower frequency transducers in the range 3–6 MHz are required for greater sound penetration to image deep organs.

Compared with computed tomography, ultrasound has comparable spatial resolution and better contrast resolution. There are other important differences in the two imaging techniques. Ultrasound images are generated manually and the quality of the study is directly related to the experience of the ultrasonographer. Ultrasound is therefore more operator dependent than computed tomography or magnetic resonance imaging. Another difference between ultrasound and computed tomography relates to the image field of view. Computed tomography provides a cross-sectional view of an entire anatomical region, but ultrasound images show cross-sectional anatomy in limited projections determined by acoustic windows that avoid artifact-producing bone and air. Because the acoustic properties of bone and air are so markedly different from soft tissue, at bone and air interfaces most of the transmitted sound is reflected back to the transducer and structures deep to bone and air are obscured by an acoustic shadow. For this reason, ultrasound images are generated in such a way as to avoid regions of bone- or gas-containing structures such as lung or gastrointestinal tract (**Figure 2**). Superficial organs such as thyroid, scrotum and breast are readily accessed by ultrasound. In the abdomen, liver, gallbladder, bile ducts, spleen and kidneys are well visualized sonographically, but the retroperitoneum may be obscured by bowel gas. To overcome potential artifacts from bowel gas, pelvic sonography is performed by displacing bowel from the pelvis with a filled urinary bladder or by direct transvaginal ultrasound that places the transducer close to the ovaries and uterus without interposed bowel.

Although ultrasound may give a limited field of view, it does provide multiplanar imaging similar to computerized tomography and magnetic resonance imaging. Ultrasound has an advantage in that the images are obtained in real time so there is no motion degradation and subtle changes during respiration or the cardiac cycle may be used to aid diagnosis. For example, ultrasound real-time imaging can identify changes in blood vessel calibre during respiration to differentiate between compression by tumour or direct tumour invasion of a vessel.



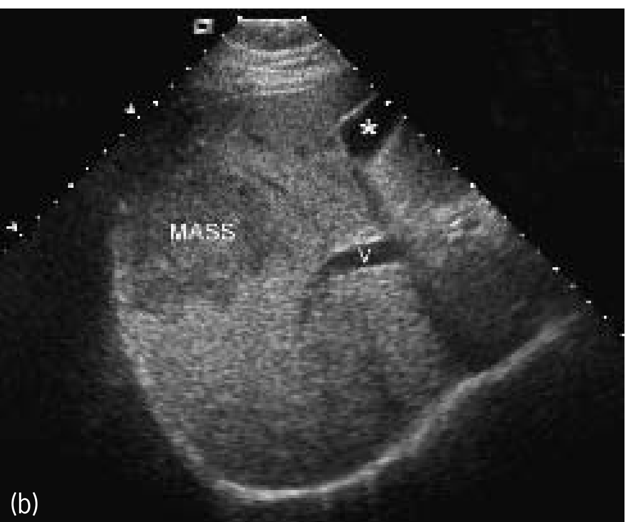


Figure 2 Comparison of computed tomography and ultrasound images in a patient with hepatic metastasis. (a) Computed tomographic axial image reveals the entire liver including the posterior metastasis (arrow). The stomach and spleen are also shown. (b) Ultrasound transverse image reveals the internal architecture of the metastasis (MASS, arrow heads). A portion of the portal vein (V) and gallbladder (asterisk) are included in the image, but since ultrasound is limited by air, the field of view is smaller than for computed tomography.

An encased blood vessel remains constricted, but a compressed vessel lumen changes during quiet respiration. Also, observations may be made regarding tissue compliance. Soft masses may be deformed by variations in applied pressure by the examiner at the skin surface but firm tumours remain rigid.

DOPPLER ULTRASOUND

Doppler imaging is unique to ultrasound and provides information regarding changes in blood flow during the cardiac cycle, direction of blood flow and patency of vessels. Assessment of blood flow characteristics is useful since tumours require angiogenesis for growth and since malignant tumours locally encase or obstruct blood vessels. The Doppler information can be displayed in three ways. Duplex Doppler samples flow within a vessel and displays velocity of flow over time (both mean and peak) as well as direction of flow relative to the position of the transducer. Some tumours such as hepatocellular carcinomas are characterized by high peak systolic velocity flow, a useful sign for diagnosis. This technique also readily identifies flow reversal within a vessel, as seen in the portal vein when portal venous hypertension is present. Power Doppler reveals amplitude of blood flow, but not flow direction. It is sensitive for slower flow and is the best technique for displaying the distribution of blood vessels within a mass. These Doppler techniques may be obtained individually or displayed simultaneously and often a combination of Doppler techniques is used. (**Figure 3; see colour plate section**).

Blood vessels in malignant tumours often lack a normal branching pattern and have a tortuous angulated course with areas of displacement by mass effect from tumour nodules (Tschammler *et al*., 1998). Tumour vessels lack muscular layers, so the Doppler waveform is often altered with low-resistance, high-diastolic flow that may be detected on duplex Doppler imaging. Doppler information is particularly useful for determining tumour involvement of vessels and can detect both intraluminal thrombi and occlusion. The pattern of vascular involvement by tumours may determine therapy. For example, liver tumours, regardless of size, that involve hepatic veins and portal veins may not be amenable to curative surgical resection, whereas large hepatic tumours without vascular involvement may be successfully resected.

ULTRASOUND CONTRAST AGENTS

Ultrasound intravenous contrast agents have recently been developed to improve the detection and characterization of tumour perfusion. These agents are highly reflective microbubbles that are encapsulated within a shell for stability. The microbubbles are less than 10 μm in diameter so that they can clear the pulmonary capillaries and remain in circulation. Contrast enhancement is produced by the interaction of the microbubbles and the ultrasound frequency. When micro bubbles are struck by an ultrasound signal, they alternately expand and contract, emitting harmonic frequencies that are multiples of the original transmitted ultrasound frequency. The ultrasound machine can selectively receive these harmonic

signals to show the distribution of arteries and veins. In addition, as the contrast agent recirculates through tissue capillaries, parenchymal enhancement also occurs (**Figure 4; see colour plate section**).

Ultrasound contrast agents have several potential applications for cancer diagnosis and treatment. For example, malignant liver tumours that are primarily supplied by the hepatic artery, such as hepatocellular carcinoma and vascular metastases, show hypervascularity with rapid arterial enhancement (Kim *et al.*, 1998). This pattern of enhancement differs from that of benign haemangiomas that exhibit gradual enhancement, filling from peripheral to central regions. During the parenchymal phase of contrast enhancement, hepatic tumours appear more conspicuous as dark masses against the contrast enhanced normal liver (Wilson *et al.*, 2000) (**Figure 5**). Improved detection of renal, breast and prostate tumours by contrast-enhanced ultrasound has also been reported. Some ultrasound contrast agents have a different mode of action: as reticuloendothelial agents, they are picked up by normal liver cells, but not by tumours.

Ultrasound contrast agents may also be used to monitor the response of tumours to treatment. Hepatic tumours are often treated with radiofrequency probes or alcohol injections that are placed directly into the mass. Both methods coagulate the tumour and destroy tumour vascularity. Ultrasound contrast agents are reported to be highly sensitive for the detection of any residual vascularity and are thus useful to assess adequacy of treatment (Koito *et al.*, 2000).

SPECIFIC CLINICAL APPLICATIONS OF ULTRASOUND FOR CANCER DIAGNOSIS

Ultrasound is generally the initial imaging study for cancer detection since it is readily available and relatively inexpensive. Ultrasound may detect abnormalities, but differentiation of benign from malignant disease often is not possible without biopsy. However, masses in the abdomen or pelvis as well as superficial structures are easily accessed by ultrasound-guided biopsy that can provide a definitive tissue diagnosis. Because ultrasound field of view is limited by bone and air, ultrasound is not suited for cancer staging that requires accurate visualization of all anatomical regions. Computed tomography is the preferred imaging technique for tumour staging.

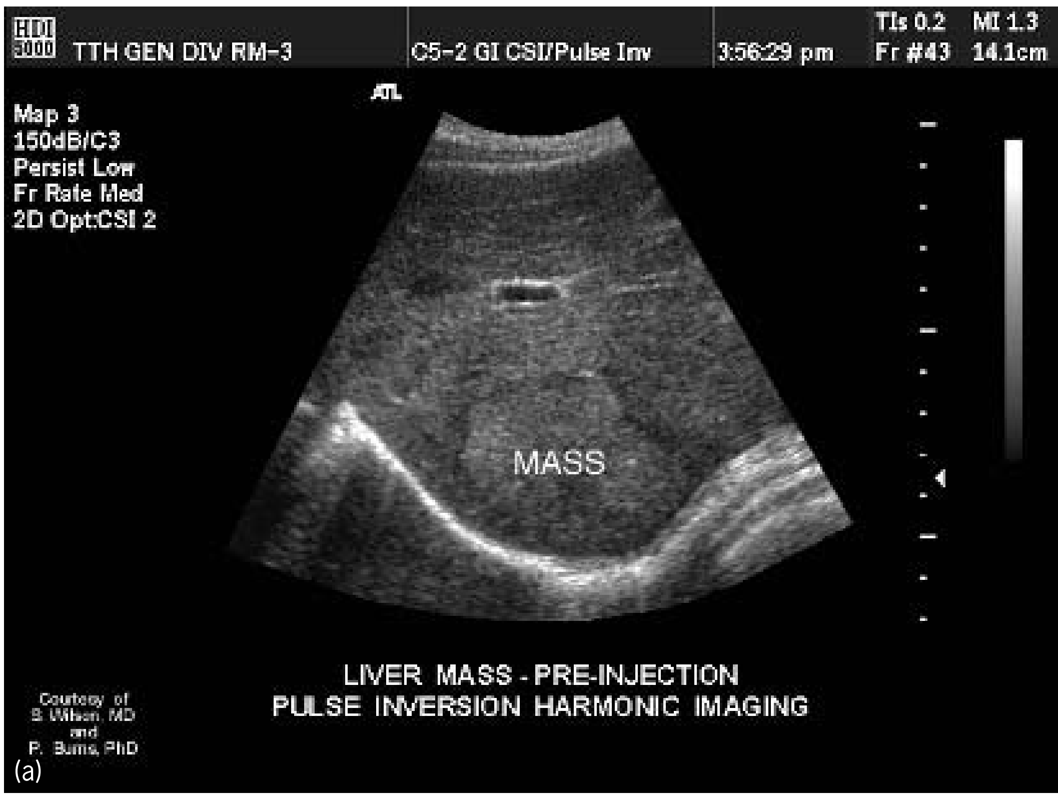
Breast

Breast cancer screening is performed by mammography but when a mass is evident by mammography or physical examination, ultrasound evaluation may provide additional useful information by differentiating benign cysts from solid masses. It is essential that the ultrasound examination be interpreted with mammographic correlation to ensure that ultrasound findings anatomically correspond in location to mammographic abnormalities. Benign simple cysts have anechoic interiors, sharp margins, a thin wall and posterior enhancement. Breast cancers are solid hypoechoic masses that appear dark compared with normal breast tissue on ultrasound images. Malignant infiltrating ductal carcinomas are often irregular in contour, taller than wide, and may have posterior acoustic shadowing because of the fibrous response associated with breast cancer growth (Stavros *et al.*, 1995). Microcalcifications, commonly present in ductal carcinomas, are best evaluated mammographically, but also may be seen on ultrasound images performed with very high-frequency transducers. Infiltrating lobular carcinoma characteristically has irregular ill-defined margins on ultrasound with distortion of adjacent breast parenchyma. In contrast to the pattern seen in carcinomas, benign fibroadenomas are smooth in contour, have an oblong shape, and may have a thin echogenic halo. The shape and border of a mass are the most useful predictors of malignancy for solid masses, but there is considerable overlap in ultrasound appearance. Noninvasive identification of vascular changes and estimates of blood vessel density by Doppler ultrasound are also being explored for breast cancer detection since blood vessels comprise a significant portion of tumour volume and tumours have both altered flow states and vascular distribution.

For breast masses that are indeterminate for malignancy by mammography or ultrasound, biopsy is required for definitive diagnosis. Percutaneous image-guided core biopsy of the breast has become standard as a minimally invasive, cost-effective alternative to surgical biopsy for histological diagnosis. Ultrasound guidance for breast core biopsy using a 14-gauge needle has been shown to have 100% correlation with surgical biopsy in a study of 181 lesions (Parker *et al.*, 1993). Ultrasound guidance for core biopsy of breast masses is advantageous because the procedure is done in real time and precise location of the needle can be determined throughout the procedure.

Thyroid

Ultrasound is superior to physical examination for the detection of thyroid nodules and localization of palpable neck masses. The majority of thyroid nodules are benign and there is considerable overlap of appearances between benign and malignant thyroid nodules, but nodules with irregular margins, microcalcifications and thick irregular peripheral haloes on ultrasound images are suspicious for malignancy (Tessler and Tublin, 1999) (**Figure 6**). Papillary, medullary and Hurthle cell thyroid cancers



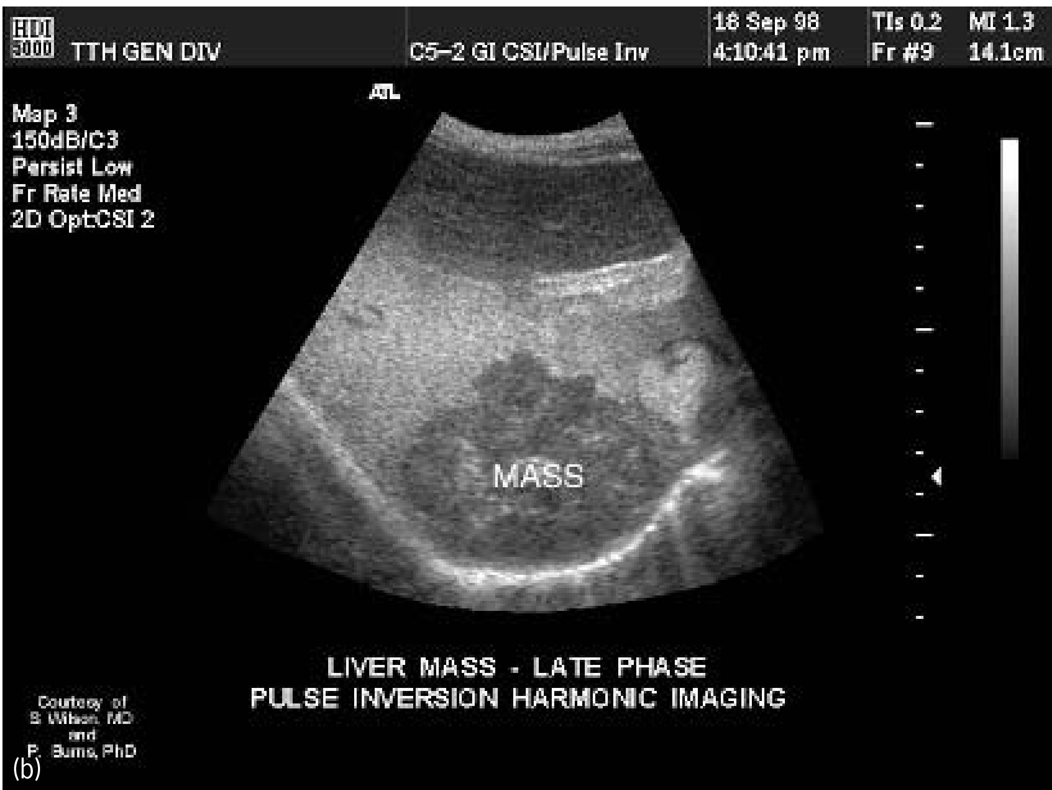


Figure 5 Images of the liver pre- and postadministration of ultrasound contrast show improved visualization of liver mass after contrast administration. Images courtesy of ATL Ultrasound, a Philips Medical Systems Company (Advanced Technology Ultrasound, Bothell, WA, USA). (a) Transverse view of the liver shows a mass posteriorly. (b) Following administration of intravenous microbubble contrast, the contour of the mass is better delineated.

frequently metastasize to cervical nodes. Metastatic nodes are typically enlarged, round in shape and have inhomogeneous texture, calcifications and distorted internal vascularity.

Thyroid nodules and cervical lymph nodes are easily biopsied under sonographic guidance for cytological diagnosis. Fine-needle biopsy, rather than large-bore core biopsy, is used because the gland is small, hypervascular and adjacent to major blood vessels. Ultrasound guidance for thyroid biopsy improves accuracy of diagnosis and reduces insufficient samples compared with standard fine-needle aspiration biopsy.

In patients with thyroid carcinoma previously treated by total thyroidectomy and radioablation, radioiodine uptake and serum thyroglobulin assays have been routinely used to monitor for recurrence. Ultrasound is being used increasingly in this setting since 20% of tumours are not iodine avid and antibodies to thyroglobulin may give spurious results. In the post-thyroidectomy cancer patient, ultrasound may detect residual or recurrent disease in the neck, and masses in the thyroid bed or abnormal cervical lymph nodes may be biopsied under ultrasound guidance for cytopathological diagnosis (**Figure 7; see colour plate section**). For the subgroup of thyroid cancer patients who have been treated by subtotal thyroidectomy, radioiodine and thyroglobulin cannot be used since there is residual thyroid tissue. For these patients, ultrasound is superior to physical examination, the only other means of monitoring for recurrent disease.

Scrotum

Ultrasound has sensitivity approaching 100% for detection of intratesticular masses and it is the gold standard for the diagnosis of testicular cancer (Benson *et al*., 1989). Ultrasound has 98% accuracy for distinguishing between intra- and extratesticular scrotal masses. This distinction is essential since any intratesticular solid mass is suspicious for testicular carcinoma whereas masses arising in the epididymis are commonly benign. All solid intratesticular masses are considered potentially malignant and are treated surgically by inguinal orchiectomy. Percutaneous biopsy is not performed for intratesticular masses because it increases the risk of tumour spread.

The majority of primary testicular cancers appear as hypoechoic masses on ultrasound. Germ-cell tumours are most common, representing approximately 90–95% of all testicular neoplasms, and the majority of tumours have mixed cell type. There are a few ultrasound features that may be used to distinguish between histological subtypes, but correlation with age at presentation and serum tumour markers is also helpful. Seminomas are the most common single cell type and usually are hypoechoic, homogeneous

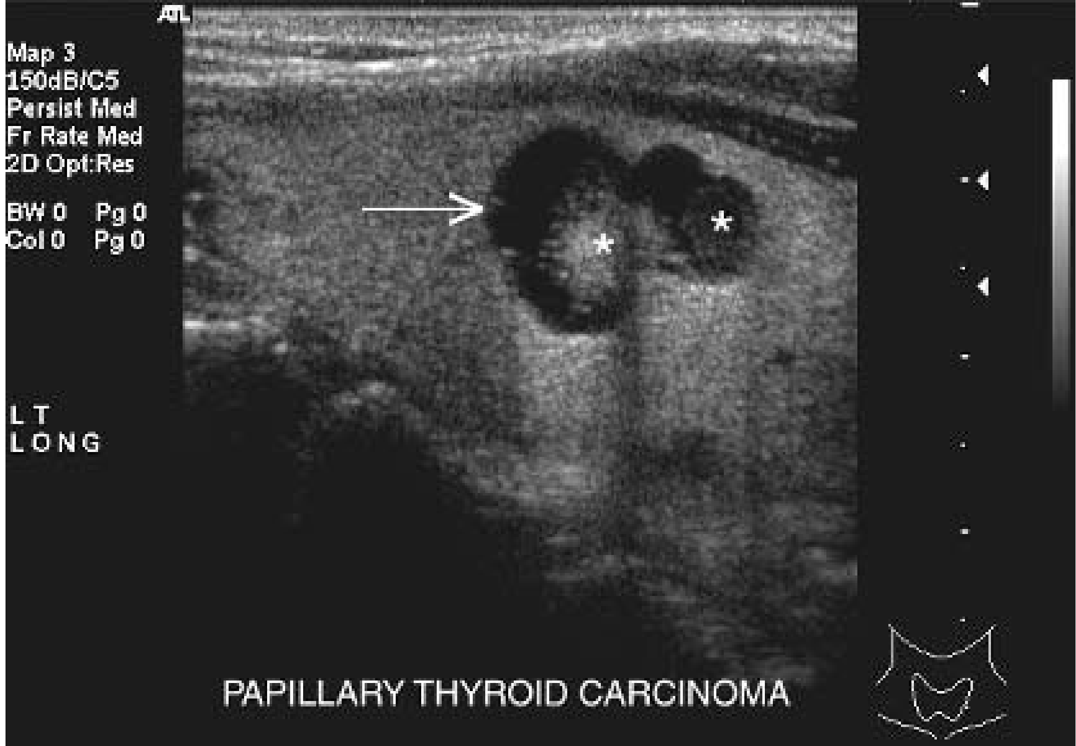

Figure 6 Longitudinal ultrasound image of a papillary thyroid carcinoma (arrow) shows that it contains fluid (dark areas) and solid papillary projections (asterisks).

and smoothly marginated on ultrasound images. Embryonal cell tumours, teratomas and choriocarcinomas are more often inhomogeneous, and may contain cystic areas or calcification evident on ultrasound. Doppler ultrasound provides little additional information for characterization of testicular tumours because tumour hypervascularity is proportional to increased tumour size rather than histopathology.

Multiple masses or bilateral intratesticular masses on ultrasound most frequently represent metastases from leukaemia, lymphoma, lung, genitourinary tumours or melanoma. Leukaemia and lymphoma are infiltrative and appear as an enlarged hypoechoic heterogeneous testicle on ultrasound. The testicle is a sanctuary site for leukaemic cells during chemotherapy and relapse in the testicle detected by ultrasound is relatively common.

Scrotal ultrasound is also valuable in men who present with mediastinal, retroperitoneal or supraclavicular lymphadenopathy to identify a primary occult testicular tumour. Testicular tumours may metastasize widely despite their small size, and the primary tumour may regress with only a residual echogenic shadowing focus seen on ultrasound to indicate the site of the 'burned-out' primary that becomes calcified (**Figure 8**).

Uterus

Ultrasound imaging of the female pelvis may be performed transabdominally with a filled urinary bladder or transvaginally by a high-frequency ultrasound probe placed in the vagina. The transvaginal technique provides optimum resolution because the probe is close to the uterus and ovaries, and a higher frequency transducer can be used.

Uterine cancer is usually diagnosed by endometrial biopsy performed for the clinical symptom of postmenopausal bleeding, but it may also be detected by demonstration of thickened endometrium exceeding 5 mm on transvaginal ultrasound of a postmenopausal woman (Dubinsky *et al.*, 1997). Endometrial cancers may be heterogeneous in echogenicity and hypervascular on Doppler imaging, but these signs are less reliable than endometrial thickness measurements for diagnosis of endometrial cancer. Depth of myometrial invasion in endometrial cancer is poorly assessed by ultrasound and magnetic resonance imaging is considered superior for that determination.

Saline infusion sonohysterography may be used also to evaluate endometrial abnormalities (Laifer-Narin *et al.*, 1999). Saline infusion hysterography is performed by instillation of sterile saline into the uterine cavity followed immediately by imaging with transvaginal ultrasound. The fluid outlines the contour of the endometrium and aids diagnosis of diffuse endometrial thickening and focal masses. Such information may guide subsequent intervention. Diffuse endometrial thickening may be biopsied by blind endometrial biopsy in the gynaecologist's office. Focal endometrial masses require dilation, curettage and

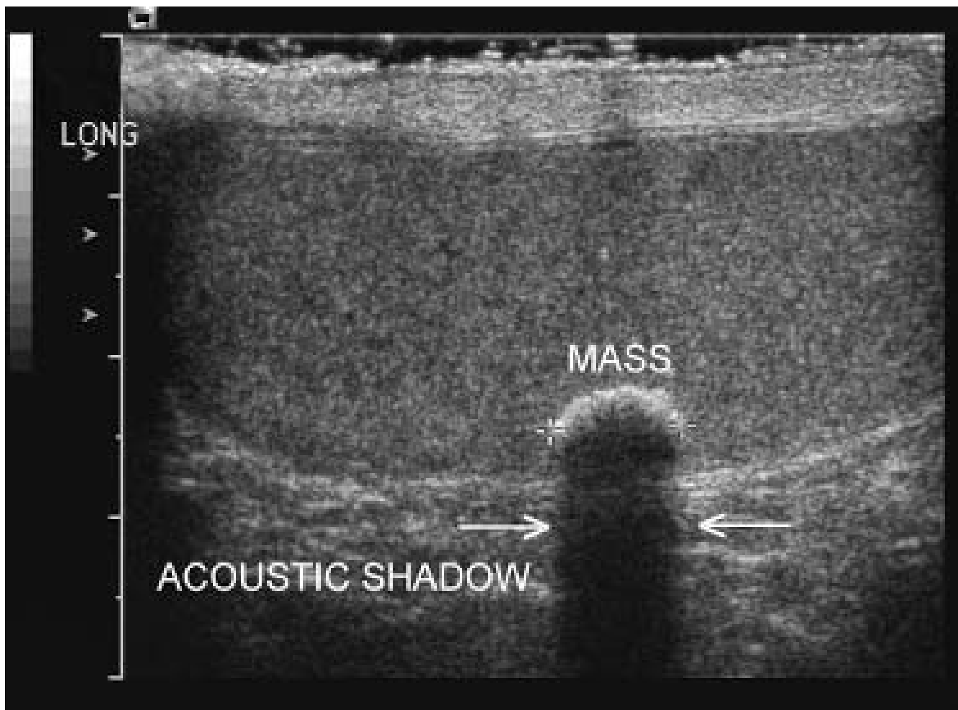

Figure 8 Longitudinal scrotal ultrasound image reveals a primary intratesticular germ-cell tumour that is calcified with resultant posterior acoustic shadowing.

hysteroscopy for removal. Saline infusion sonohysterography is particularly useful for the assessment of endometrial abnormalities in breast cancer patients treated with tamoxifen (**Figure 9**) Tamoxifen has a weak oestrogenic effect that results in endometrial abnormalities including endometrial carcinoma, hyperplasia and polyps. On saline infusion sonohysterography, polyps are shown as masses that often contain cystic spaces and project into the endometrial cavity. In contrast, endometrial carcinoma and hyperplasia cause focal or diffuse endometrial thickening.

Ovary

Ultrasound diagnosis of ovarian cancer is based on ovarian volume, morphology and blood flow. Ultrasound provides excellent visualization of the ovary in all three dimensions and is the best imaging method for evaluating ovarian internal architecture. Normal ovarian volume in premenopausal women ranges up to 18–20 cm^3. After menopause ovarian volume ranges up to 8 cm^3, but the ovaries continue to decrease in size with advancing age. An enlarged ovary for age and increasing ovarian volume on serial ultrasound examinations are findings suspicious for ovarian carcinoma.

Ovarian carcinomas and benign ovarian masses are often cystic on ultrasound, but the morphology of the ovary may differentiate between benign and malignant disease. Benign ovarian cysts have smooth, thin walls, no internal echoes and enhancement of the ultrasound signal posterior to the cyst. Cysts with thin septations or uniform low level echoes throughout are also probably benign. Solid ovarian masses and cysts with thick irregular walls, nodular septations and solid components are suspicious for malignancy by ultrasound criteria (**Figure 10**). Metastases to ovaries are often bilateral and may be either cystic or solid depending on the primary carcinoma. Breast, pancreas and gastric metastases to the ovary are typically solid whereas secondary tumours from mucin-secreting primaries from colon or stomach are more likely cystic. In premenopausal women physiological cysts that occur as part of the menstrual cycle may mimic the ultrasound appearance of ovarian neoplasms, but physiological cysts are transient. Premenopausal women with suspicious ovarian masses should always have follow-up sonograms in 6 weeks or after the next menses, to exclude physiological cysts and decrease false-positive ultrasound diagnoses.

Assessment of tumour angiogenesis by Doppler flow is another method for diagnosis of ovarian cancer by ultrasound. Ovarian tumours may have an increased number of blood vessels that can be shown by power Doppler imaging and the distribution of vascularity in ovarian cancers may be more central in location than in benign ovarian masses, which often show peripheral distribution of blood flow. Tumour vessels lack a muscular layer and are characterized by low-impedence, low-resistance blood flow that may be measured with the duplex Doppler technique. Vascular impedence is measured by ratios such as resistive index and pulsatility index that compare flow in diastole relative to systole. When diastolic flow is increased as with tumour vascularity, the ratios are low. Unfortunately, many benign conditions, including the physiological corpus luteum of the normal

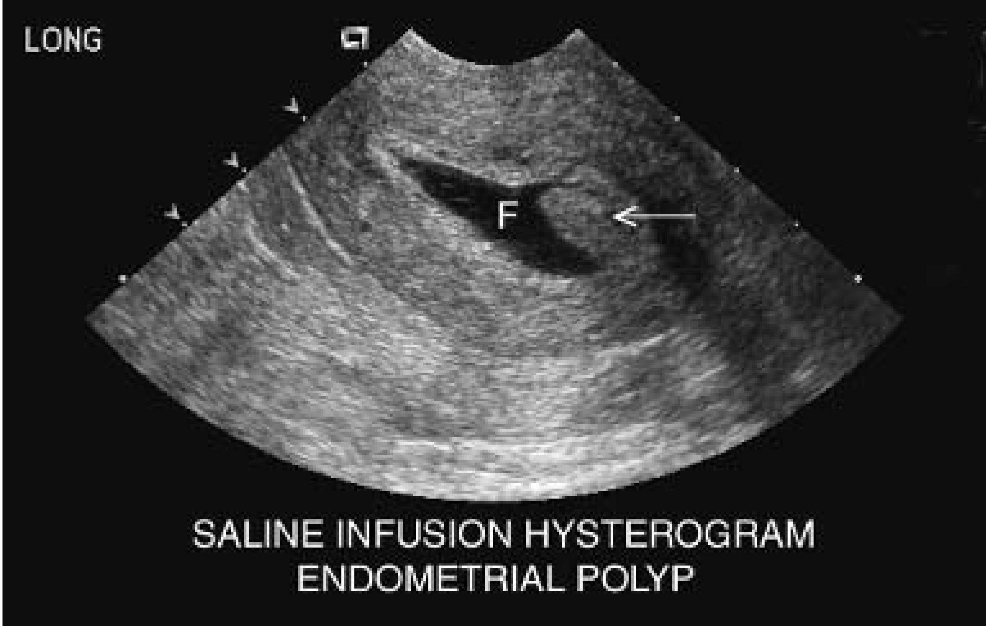

Figure 9 Longitudinal image of the uterus from a saline infusion sonohysterogram in a tamoxifen-treated breast cancer patient shows fluid (F) filling the endometrial cavity and an endometrial polyp (arrow) in the fundus.

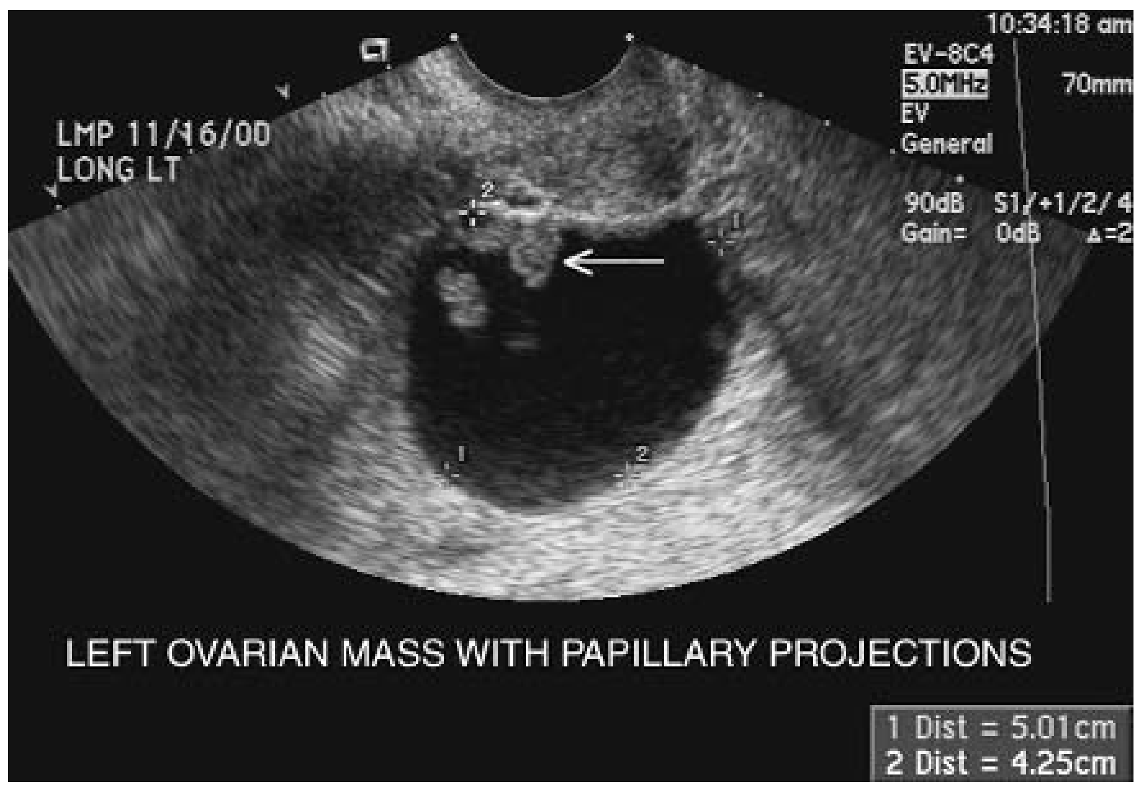

Figure 10 Transverse ultrasound image of an ovarian carcinoma reveals suspicious solid mural nodules (arrow) projecting from the wall of the cyst.

menstrual cycle, have similar flow patterns. Despite initial optimism, Doppler indices lack sufficient specificity to serve as independent predictors of malignancy, particularly in premenopausal women.

The best results for ultrasound diagnosis of ovarian cancer are obtained by the combination of Doppler and ovarian morphology as shown in a meta-analysis of 5159 patients studied with current ultrasound technique (Kinkel *et al*., 2000). Using this approach, ultrasound has approximately 93% sensitivity and 93% specificity for diagnosis of ovarian cancer. The best predictors of malignancy are considered the presence of solid components within an ovarian mass, central flow on Doppler, ascites and septations within a mass (Brown *et al*., 1998). Results of ultrasound are improved further by correlation with serum tumour markers, such as CA-125 that is elevated in women with advanced ovarian cancer and in 50% of women with stage 1 ovarian cancer.

There has been interest in using ultrasound to screen women for ovarian cancer since ultrasound has such high diagnostic accuracy for detection and characterization of ovarian masses. However, there is a difference between using a test for diagnosis in the clinical setting versus screening of asymptomatic women. For diagnostic ultrasound women are symptomatic or have suspected pelvic pathology and the prevalence of disease is relatively high. A positive test result is therefore more likely to identify ovarian cancer correctly since it is more common within the group. In contrast, the majority of asymptomatic women in a screened population are normal and the prevalence of ovarian cancer is low even in women with a family history of ovarian cancer. Since ovarian cancer is infrequent in a screened group, a positive test result is less reliable owing to more false-positive diagnoses because the proportion of women with ovarian cancer is so low. Current recommendations are that available evidence does not support ultrasound screening for ovarian cancer in pre- or postmenopausal women with or without a family history of ovarian cancer.

Liver and Bile Ducts

Ultrasound is used to detect primary and metastatic hepatobiliary tumours and to provide guidance for diagnostic biopsy. Ultrasound also has a role for preoperative and intraoperative planning to determine if tumours are amenable to surgical resection. Often management of patients with hepatobiliary tumours requires the use of multiple imaging modalities. The choice of cross-sectional imaging technique may vary by availability, cost and experience. In Europe and the UK ultrasound is more widely used for imaging of hepatic malignancies; in the United States computed tomography is preferred.

Hepatic tumours appear as focal masses that have different echogenicity than adjacent normal liver. Lesion

detection is determined by the relative difference in echogenicity rather than size of the tumour. Small tumours, approximately 1 cm in diameter, are detectable by ultrasound if there is sufficient contrast between the tumour and normal liver, but if the tumour has echogenicity similar to liver, it may be difficult to visualize even if it is relatively large. Conspicuity of a liver mass may be different on ultrasound as compared with computed tomography or magnetic resonance imaging because ultrasound is based on the acoustic properties of tissue rather than tissue attenuation in a radiation beam or magnetic field. Harmonic ultrasound has been shown to improve the ultrasound detection of hepatic masses through better soft tissue contrast. In a study comparing harmonic imaging of liver tumours with standard ultrasound, eight of 48 patients had lesions evident only on harmonic ultrasound (Hann *et al*., 1999). Harmonic ultrasound is now used routinely as the primary ultrasound technique for detection of hepatic lesions.

Hepatocellular carcinoma is the most common primary hepatic tumour and has an especially high incidence in Asia and Africa. These tumours may be focal, infiltrative or multiple and the ultrasound appearance is variable. Small hepatocellular carcinomas <5 cm in diameter are usually less echogenic than the adjacent liver and may have a thin peripheral halo. Larger tumours are ill-defined and heterogeneous owing to areas of fibrosis and necrosis. Doppler ultrasound may detect increased vascularity within these hypervascular tumours that have arteriovenous shunts and high velocity arterial flow with frequency shifts exceeding 4.5 kHz (**Figure 11; see colour plate section**). One study found that 32 of 46 hepatocellular carcinomas, four of 86 metastases and none of 66 benign hepatic lesions had frequency shifts of 4.5 kHz or greater (Reinhold *et al*., 1995). Doppler evaluation may also suggest the diagnosis of hepatocellular carcinoma by identification of portal vein thrombosis that occurs in 40% of hepatocellular carcinomas and hepatic vein thrombosis, present in approximately 15% of hepatocellular carcinomas.

Metastases to liver are multiple and echogenicity is variable. Echogenic metastases are often of gastrointestinal origin or are from vascular tumours such as carcinoid, pancreatic islet cell, choriocarcinoma or renal cell carcinoma. A hypoechoic halo at the peripheral margin of a liver mass is highly suggestive of colorectal metastasis to liver, but may also be seen with hepatocellular carcinomas. This target or bull's eye appearance is due to distended sinusoidal spaces and new tumour vessel formation (Kruskal *et al*., 2000) (**Figure 12**). Appearance of metastases may provide clues for site of origin. For example, calcified metastases are seen from mucin-secreting tumours of the colon or medullary carcinoma of the thyroid, and cystic, fluid-containing metastases often arise from ovary or colon carcinoma, sarcoma or melanoma. Lymphoma, lung, melanoma and pancreas metastases are frequently hypoechoic on ultrasound. Chemotherapy may alter the

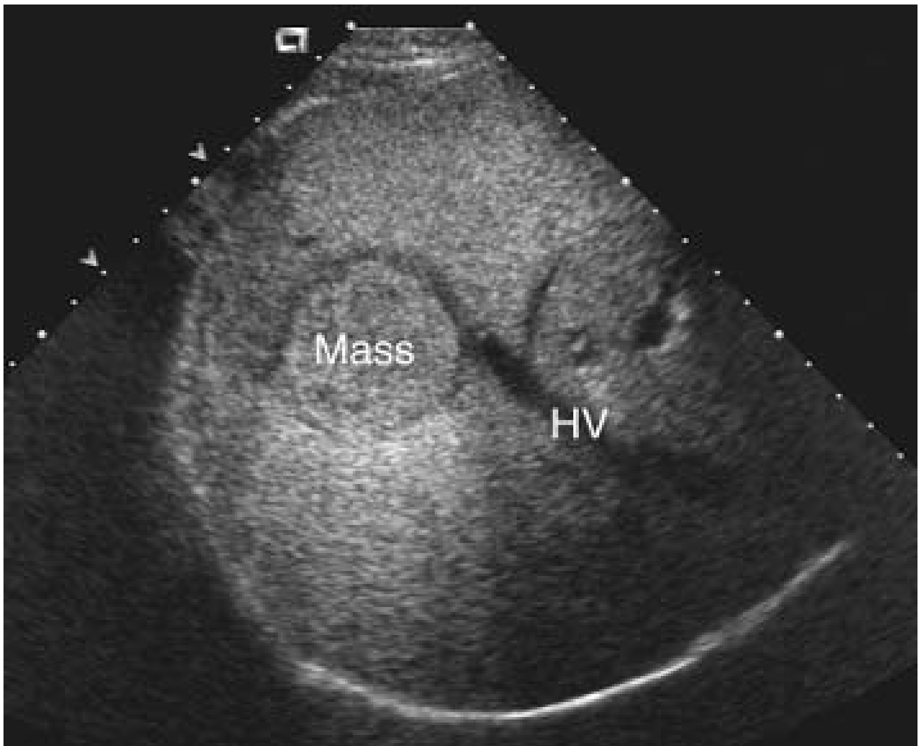

Figure 12 Transverse ultrasound image of the liver reveals a mass with surrounding hypoechoic (dark) halo that is characteristic of colorectal metastasis. HV = hepatic vein.

appearance of metastases and the background echogenicity of the liver. Breast carcinoma metastases to liver are often mixed in echogenicity prior to treatment, but may appear echogenic postchemotherapy. Chemotherapy-associated fatty change in the liver produces heterogeneous texture with patchy areas of increased echogenicity. This ultrasound appearance due to metabolic change in the liver may make metastases less evident or less well defined on ultrasound images. For this reason, computed tomography is preferred to monitor the response of hepatic metastases to chemotherapy.

Ultrasound is useful for the preoperative assessment of patients with primary and secondary hepatic malignancies that are being considered for curative resection. For the 25% of patients with colorectal metastases limited to the liver, surgical resection offers improved survival in the range 20–30% compared with chemotherapy. Hepatic resections are performed along planes between anatomical hepatic segments each of which has portal venous inflow, hepatic venous outflow and bilary drainage. Using the segmental approach to hepatic resection it is possible to remove up to approximately 70% of the liver because the remaining disease-free liver has intact vascular supply and biliary drainage and the liver hypertrophies in volume postoperatively. For preoperative planning, computed tomography or ultrasound is used to determine the distribution of tumour within the liver and to ensure that the remaining liver has normal vascularity. Tumours confined to a localized area of the liver are potentially resectable but scattered tumours throughout multiple segments are not amenable to surgical resection. Surgery is also contraindicated if tumours involve one side of the liver and the portal or hepatic vein on the opposite side, since blood flow must be preserved in the remaining liver. Doppler and grey scale ultrasound are used in combination to evaluate the hepatic vasculature preoperatively. Encased veins have irregular contour and narrowed calibre. When the portal or hepatic veins are thrombosed, the vessel may appear expanded or have an intraluminal filling defect. Demonstration of arterial flow within an occluded expanded portal vein or hepatic vein is diagnostic of tumour growth into the vessel as may be seen with hepatocellular carcinoma.

Biliary tumours are managed by curative surgical resection or by placement of stents or biliary drainage catheters to relieve bile duct obstruction. Ultrasound is reliable for determining the level of bile duct obstruction and to image the tumour mass directly. As with hepatic tumours, the distribution of bile duct involvement within the hepatic segments determines whether surgical resection is feasible. Cholangiocarcinomas appear as nodular bile duct masses, irregular scirrhous tumours that stricture the bile ducts or intraluminal papillary masses that expand the duct. The scirrhous and nodular tumours are locally invasive and often encase or occlude adjacent hepatic blood vessels. It is preferable to image bile duct tumours prior to placement of biliary drainage catheters because the catheter allows reflux of intestinal air into the biliary tree and the pneumobilia causes artifacts that may obscure the bile duct tumour.

Intraoperative ultrasound provides higher resolution for imaging hepatic and biliary tumours. Intraoperative ultrasound is performed with the transducer placed directly on the hepatic surface. Because the liver is closer to the transducer, it is possible to scan with higher frequency, higher resolution probes. Intraoperative ultrasound is reported to detect 25–35% additional liver lesions in patients who have been evaluated preoperatively by computed tomography, ultrasound or magnetic resonance imaging (Kane *et al*., 1994). In a study of patients with hepatic cancer, Kane *et al*. reported that intraoperative ultrasound altered surgical management in 51% of patients. The relative contribution of intraoperative ultrasound for the detection of additional liver masses may decrease as thin-slice, high-resolution, multidetector computed tomography scanners are more widely available.

Kidney

It is now recommended that computed tomography be used for the initial evaluation of patients with microhaematuria in whom renal or bladder tumours are suspected clinically. This change in the imaging algorithm for exclusion of renal masses has altered the role of ultrasound. Renal ultrasound in the cancer patient is primarily used to characterize renal masses detected by computed tomography and to exclude hydronephrosis in patients with renal failure or abdominal masses.

The excellent cyst–solid differentiation of ultrasound makes it ideal for the evaluation of renal masses that are indeterminate by computed tomography. Even small renal cysts less than 1 cm in diameter may be resolved by ultrasound. Renal cysts with thin walls and no internal septations are benign; any solid renal mass is considered suspicious for renal cell carcinoma. Cystic masses with thick nodular septations or calcifications also may be malignant. If internal vascularity is present within a renal mass on Doppler imaging, the likelihood of malignancy is increased. It is easier to identify a renal cyst than a solid renal mass on ultrasound because there is a great deal of contrast between the fluid-containing cyst and the adjacent normal renal parenchyma. Small solid renal masses are more difficult to visualize by ultrasound but variations in echogenicity, Doppler blood flow patterns and abnormalities in contour of the kidney are all used to improve detection (Forman *et al*., 1993; Jinzaki *et al*., 1998).

Transitional cell tumours are evident on ultrasound as solid masses that are less echogenic than the fatty tissue in the renal hilum. These tumours may cause hydronephrosis or locally obstruct renal calyces. The dilated fluid-filled urinary collecting system aids identification of masses in the renal pelvis or bladder. For tumours of the prostate ultrasound is no longer used for screening. Endorectal

prostate ultrasound is performed routinely, however, for guiding systematic biopsies from various quadrants of the gland in order to establish a definitive diagnosis in men with elevated serum prostate-specific antigen.

NEW ADVANCES IN ULTRASOUND TECHNOLOGY

With advances in computer technology, manufacturers are now able to produce smaller ultrasound units and miniaturized transducers. These changes allow for the potential expansion of the role of ultrasound for imaging diagnosis. Smaller, less expensive ultrasound machines may be used by general physicians as an extension of physical examination. However, since the quality of the ultrasound examination is so operator dependent, practitioners or oncologists using ultrasound would need sufficient ultrasound training in order to standardize quality of care. Portable ultrasound units could also be used in the operating room or at the bedside for the evaluation of critically ill patients.

Miniature transducers allow for intraluminal imaging of blood vessels or the gastrointestional tract. Small transducers may be mounted on tips of catheters for angiographic imaging or attached to endoscopes for staging of gastrointestinal and biliary tumours. Similarly, miniature ultrasound probes may be used for ultrasound imaging during minimally invasive surgical procedures such as laparoscopy for tumour staging (Liu *et al*., 1995).

Three-dimensional ultrasound is also being evaluated in the clinical setting for the estimation of tumour volume, for assessment of tumour vascularity and for lesion characterization. Ultrasound three-dimensional techniques are not as developed as computed tomography and magnetic resonance imaging multiplanar imaging, but they do show potential for readily accessible volumetric data regarding size of tumours. Preliminary studies have shown that three-dimensional techniques for transvaginal ultrasound of the ovaries may improve differentiation of benign from malignant ovarian tumours (Kurjak *et al*., 2000).

Ultrasound contrast agents have been shown to improve the visualization of blood vessels and tumour angiogenesis. Currently ultrasound contrast agents are used to assess tumour viability postradiofrequency ablation (Koito *et al*., 2000). Ultrasound contrast agents may be useful also to monitor response to treatment of antiangiogenesis agents as these become more available. Another theoretical application for ultrasound contrast microbubbles is for targeted delivery of chemotherapeutic agents or gene therapy. Intravenously administered microbubbles burst when exposed to an ultrasound pulse. If the ultrasound signal was given in a selected region and the microbubbles contained therapeutic agents, this could serve as a method for selective drug delivery. This method would be particularly useful for tumours that have local regional spread, rather than systemic metastases.

CONCLUSION

Ultrasound is used for initial diagnosis of malignancy and image-guided biopsy, but not for tumour staging. It is an inexpensive, readily available imaging technique, but ultrasound requires an experienced operator for optimal results. Doppler imaging is unique to ultrasound and provides information regarding tumour vascular distribution and flow dynamics. The excellent spatial resolution and soft tissue contrast provided by ultrasound are the major advantages of this imaging technique.

INTRODUCTION

Magnetic resonance imaging (MRI) plays an important role in the diagnostic evaluation of patients with known or suspected cancer. Compared with other imaging studies, MRI provides intrinsically higher soft-tissue contrast resolution and is therefore an attractive alternative to computed tomography (CT), especially when the use of iodinated contrast material is contraindicated. In addition, because MRI is devoid of ionizing radiation, it can be safely used in children, young adults and pregnant women. Recent developments have extended its role to functional imaging, which holds the promise of providing biochemical information at a molecular level. The purpose of this chapter is to provide an overview of the role of MRI in diagnostic imaging of the oncological patient.

Clinical MRI is based on the distribution of hydrogen atoms in the body. T_1 and T_2 relaxation times reflect intrinsic magnetic properties of protons in hydrogen atoms. These processes can be measured to obtain high-resolution T_1-weighted and T_2-weighted images of the body. In general, on T_1-weighted images, both water and tumours appear darker (lower signal intensity) than surrounding normal tissue (**Figures 1** and **2**) and on T_2-weighted images, both water and tumours appear brighter (higher signal intensity) than surrounding normal tissue. Common contraindications to the use of MRI include the presence of pacemakers, cochlear implants and metallic aneurysm clips of uncertain manufacture. Claustrophobia, and also the inability to lie still for 30–45 min, are also not uncommon problems. Additionally, medically unstable patients may not be able to enter the magnet safely,

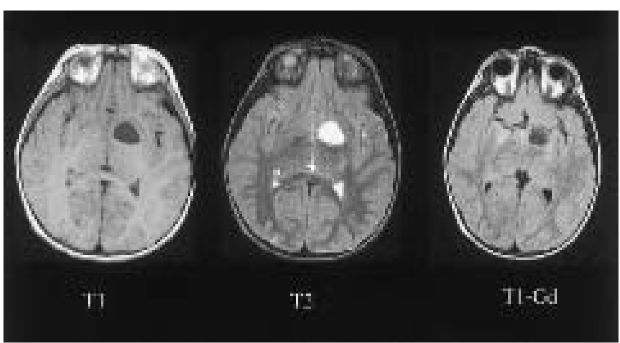

Figure 1 Low-grade glioma: well-defined T_1 low signal intensity and T_2 high signal intensity lesion located in the left basal ganglia without surrounding oedema. Minimal peripheral enhancement is seen on the postcontrast T_1 image.

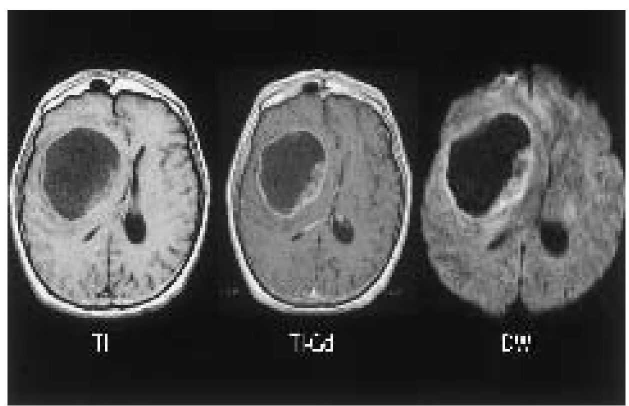

Figure 2 High-grade glioma: large necrotic mass in the right cerebral hemisphere with associated surrounding white matter oedema and mass effect on the ipsilaterlal ventricle. Heterogeneous peripheral nodular enhancement is present on post-Gd T_1-weighted image (middle). Diffusion-weighted MR (DWI) confirms a fluid necrotic centre.

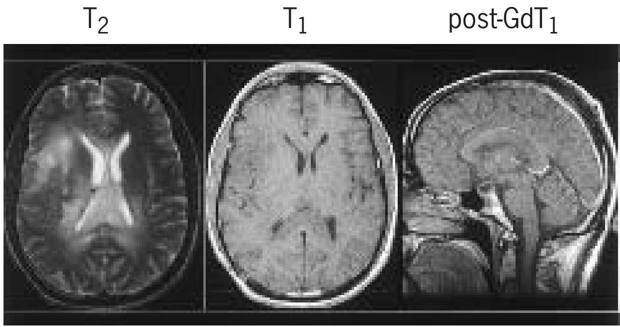

Figure 3 Glioma versus lymphoma versus demylinating disease: diffuse swelling on the distal body and splenium of corpus callosum, and right cerebral hemisphere, T_2 hyperintensity signal from white matter oedema. Lack of enhancement was observed on postcontrast T_1 image, more suggestive of demyelination.

because some monitoring and treatment devices are incompatible with the magnetic field produced by MRI systems.

BRAIN AND SPINE

MRI, because of its higher sensitivity than CT scanning in tumour detection, is typically the initial imaging modality of choice for CNS evaluation. When the presence of calcification or acute intra parenchymal haemorrhage is in question, however, CT scanning may still be required. Contrast-enhanced MRI is superior to contrast-enhanced CT in the detection of metastases. MRI is also not subject to beam hardening artifacts, which can limit CT's sensitivity in detecting leptomeningeal carcinomatosis, or small parenchymal metastases in the posterior fossa or near the calvarium (Hansberger and Dillon, 1988).

The primary role of the radiologist in oncological imaging of the central nervous system (CNS) is in the detection of tumours (**Figure 3**), MRI is well suited for this role, as it has intrinsically high sensitivity in the detection of primary or metastatic disease in brain, meninges or spinal canal. Intravenous administration of Gd–DTPA further improves the detection of intraparenchymal, leptomeningeal and dural-based metastases, and may also sometimes help in differentiating viable from necrotic tumour (Yuh *et al.*, 1992). Some authors advocate the use of double-or even triple-dose gadolinium to improve further the sensitivity of MR in lesion detection. Screening for drop metastases in the spinal canal, in cases of intraventricular or posterior fossa tumours, is best performed with MRI.

The secondary role of the radiologist in oncological imaging of the CNS is in the accurate anatomical localization of tumours, as the differential diagnosis, presurgical mapping and further work-up are highly dependent on precise lesion localization. Such localization is best achieved with MRI (Brant-Zawadzki *et al.*, 1984). Currently, since the introduction of blood oxygen level dependent (BOLD) functional MRI, the relationship between tumour location and the location of other critical structures, such as the motor and language centres of the brain, can now be accurately mapped (Buchbinder and Cosgrove, 1998).

It is difficult to predict brain tumour grade accurately using conventional MRI techniques alone. The presence or absence of enhancement, signal heterogeneity or frank necrosis only weakly correlate with neoplasm grade. Although the presence of calcifications and/or well-defined margins suggests low tumour grade, these findings are unreliable; similarly, the presence of haemorrhage or oedema and mass effect does not reliably correlate with high tumour grade (Arrington *et al.*, 1998). Moreover, the distinction between recurrent tumour and radiation-induced necrosis, using conventional MRI sequences only, is similarly problematic. Newer, dynamic contrast enhanced and spin-labelled functional MR perfusion imaging techniques, however, which assess the microvascularity of tumours (blood volume and blood flow) as markers of tumour grade, have shown great promise in the more sensitive determination of both brain tumour grade and recurrent tumour detection (Lev and Rosen, 1999). The sensitivity and specificity of perfusion MRI in this regard clearly exceeds that of nuclear medicine techniques such as FDG-PET (positron emission tomography) scanning. Functional MR spectroscopy has also been shown to play a beneficial role in the management of suspected brain tumours (Adamson *et al.*, 1998) (**Figure 4**). Image-guided neurosurgery and intraoperative MRI are additional recent developments that can assist neurosurgeons in both planning their surgical approach, and in the complete removal of brain tumours.

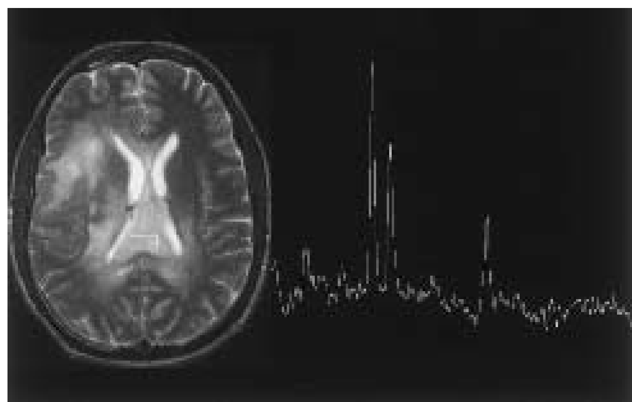

Figure 4 MR spectroscopy: spectral waveform of the signal abnormality in the distal body/splenium of corpus callosum shows reduced NAA peak favouring a diagnosis of tumour rather than demyelination. The lack of enhancement suggests gliomatosus cerebri.

Follow-up

Tumour progression is evaluated by noting the overall size, signal characteristics, pattern of contrast enhancement and associated evidence of spread of disease. The development of a new contrast-enhancing lesion or an area of T_2 hyperintense signal within post-treatment, irradiated tumour beds may represent dedifferentiation within the original tumour signifying a higher grade, tumour recurrence, radiation necrosis or post-surgical change (Dillon and Nelson, 1998). The differentiation of tumour recurrence from benign gliosis is facilitated with the use of MR spectroscopy by noting the ratios of the spectral peaks of metabolites such as creatine, choline and (*N*-acetylaspartate) (NAA) within the imaging voxel. As noted above, perfusion MRI techniques are probably more effective than PET in assessing brain tumour responses to novel therapies, and offer high resolution and convenient coregistration with conventional MRI, as well as time- and cost-effectiveness.

MRI remains the modality of choice for evaluating the spinal cord and the thecal sac (**Figures 5** and **6**).

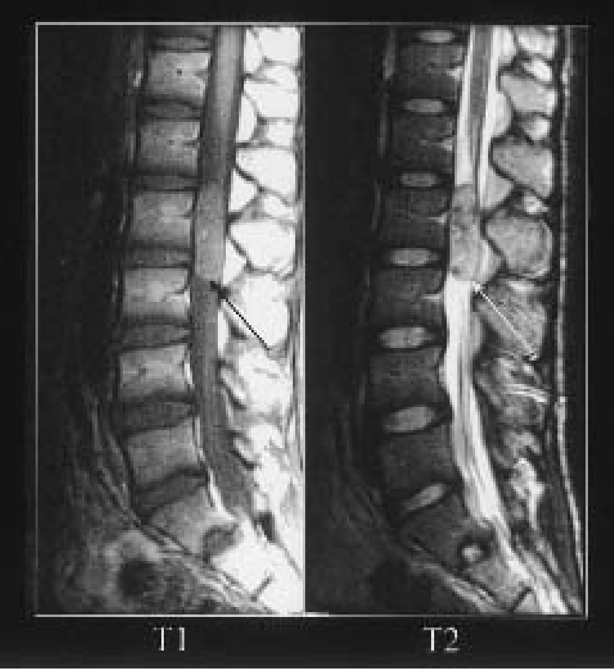

Figure 5 Ependymoma of the filum terminale: T_1 and T_2-weighted images show a well-defined intraspinal mass (arrow) arising from the filum terminale.

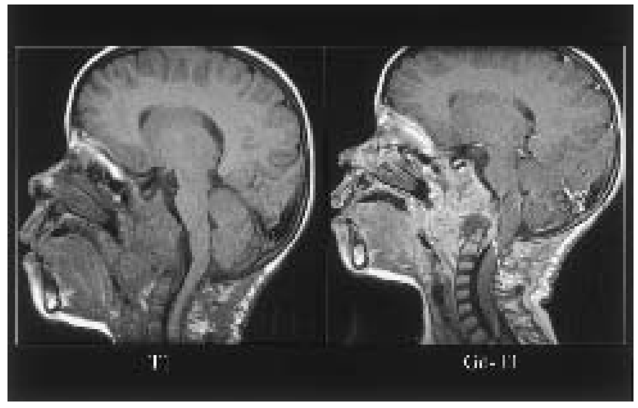

Figure 6 Clivus chordoma: pre- and postcontrast T_1-weighted image showing a large, enhancing and locally aggressive clival tumour, extending into the nasopharynx as well as intracranially (arrow).

HEAD AND NECK

Most mucosal tumours of the head and neck are detected clinically, by direct endoscopic visualization. The role of the radiologist in head and neck oncological imaging is therefore, not primarily, to detect or diagnose mucosal disease (predominantly squamous cell carcinoma), but, rather, to grade and stage tumours in anticipation of surgery and radiotherapy, and to determine submucosal or deep spread of primary or recurrent disease in 'blind spots' (such as the subglottic larynx) not amenable to direct visualization (Lev *et al*., 1998). The multiplanar capability of MRI allows complex anatomy and pathology of the skull base and neck to be well demonstrated, e.g. demonstration of perineural tumour extension into the skull basal foramina and fossa. The superior soft tissue resolution and tissue contrast of MRI allow tumour and involved lymph nodes to be differentiated from inflamed mucosa, retained secretions, fibrosis and normal structures, particularly skeletal muscle and blood vessels (Tabor and Curtin, 1989). Advantages of CT imaging of the head and neck include increased sensitivity for the detection of calcification, bony destruction and subtle bony erosion or skull base foraminal expansion.

Head and neck tumours typically demonstrate intermediate signal intensity, equal to or slightly greater than that of skeletal muscle on T_1-weighted MR imaging, and intermediate to high signal intensity on T_2-weighted MR imaging (the so-called 'evil grey' appearance). A very hyperintense signal on T_2-weighted imaging is more commonly due to soft tissue or mucosal inflammation or oedema, and is less suspicious of the presence of tumour. Gadolinium-enhanced T_1- or STIR- (short tau inversion recovery) weighted images are helpful in assessing intracranial extension and meningeal involvement of skull base tumours (**Figure 6**). Although in some series MRI has demonstrated a sensitivity as high as 100%, a specificity as high as 80% and an accuracy of almost 90% in the evaluation of head and neck tumours (Kabala *et al.*, 1992), it is critical to note again that direct visual inspection of the mucosal surfaces of the oro-, naso- and hypopharynx is essential in the work-up of head and neck neoplasms; potentially large mucosal tumours can easily be overlooked using conventional CT or MR imaging alone (**Figures 7 and 8**).

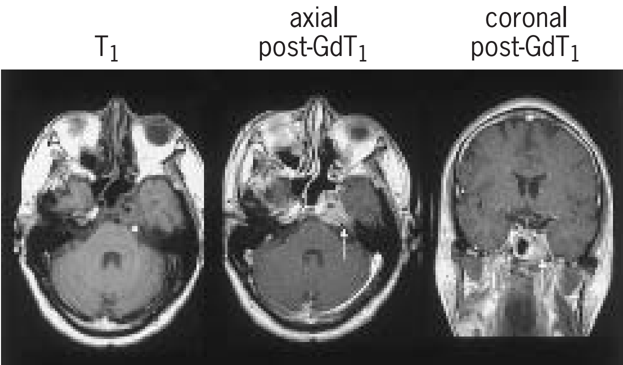

Figure 7 Skull base metastases: pre- and postcontrast T_1-weighted MR images in a patient with primary lung cancer, showing an ill-defined enhancing soft tissue mass centred in the left cavernous sinus and encasing the ipsilateral carotid artery (arrows).

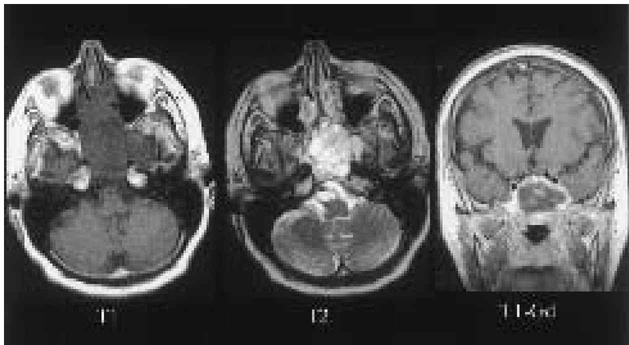

Figure 8 Sphenoid sinus cancer: a large soft tissue mass causing expansion of the sphenoid sinus with contiguous intra cranial extension.

The detection of metastatic lymph node involvement is based on size, shape and internal signal criteria (**Figure 9**). The criteria currently in use are imperfect, and represent a trade-off between sensitivity and specificity for neoplasm detection. According to one set of commonly used criteria, lymph nodes with a clinically relevant probability of metastatic involvement are considered to be those with (1) a maximum diameter of >1 cm, in the lower neck, (2) a maximum diameter of >1 cm and spherical, in the upper neck if the patient is in a high risk group, (3) a maximum diameter of >1.5 cm, in the upper neck if the patient is not in high risk group, or (4) any evidence of central necrosis (regions of increased signal intensity on T_2-weighted MR images, regions with relative lack of gadolinium enhancement or regions of focal low attenuation on CT imaging; central necrosis must always be distinguished from a 'fatty' hilum – a normal finding) (Som, 1987).

As in the central nervous system, the distinction between recurrent head and neck tumour and post-treatment change can be difficult. Early postradiation therapy changes (less than 4 months) may appear similar to inflammation, i.e. hypointense on T_1-weighted and hyperintense on T_2-weighted MR images. Beyond 6 months, with progressive fibrosis, the signal intensity changes tend to be hypointense on T_1-weighted and hypo- or isointense on T_2-weighted imaging. Criteria that suggest tumour recurrence include increased signal intensity on T_2-weighted sequences more than 6 months after radiation treatment, bulky mass beyond the original primary site and obliteration of tissue planes. These findings can often be better detected on postcontrast, fat-suppressed STIR-weighted MR images, although precise anatomical localization is typically best delineated on conventional nonenhanced T_1-weighted MR images. Preliminary results with both MR spectroscopy and MR perfusion imaging in the evaluation of native and post-treatment head and neck tumours have been encouraging.

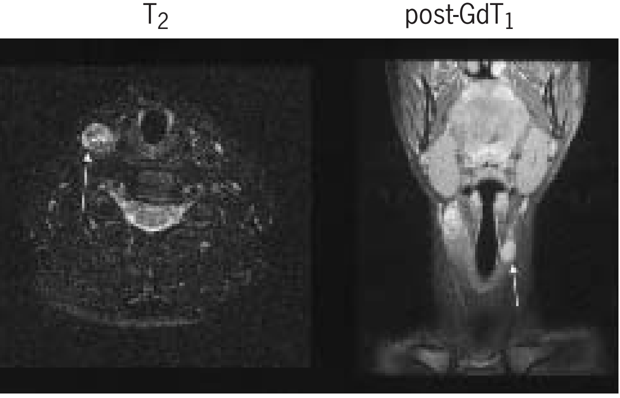

Figure 9 Recurrent thyroid cancer and lymph node metastases: T_2-weighted bright signal mass in the right neck consistent with recurrent tumour. Postcontrast T_1-weighted coronal image shows enhancing enlarged contralateral lymph node (arrow), consistent with metastasis.

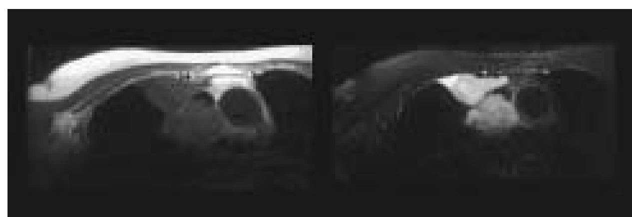

Figure 10 Primary lung carcinoma, T_1-weighted (left) and T_2-weighted (right) image of the chest are shown above which demonstrates tumour invasion into the superior vena cava.

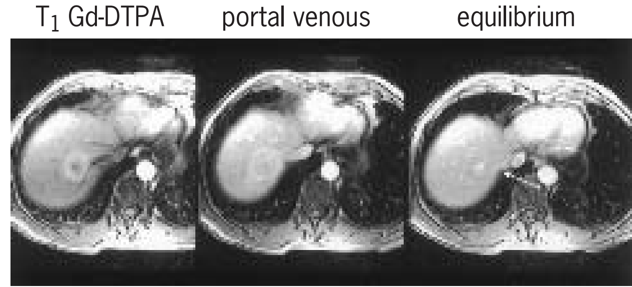

Figure 11 Liver metastases: sequential postcontrast T_1-weighted MR images show characteristic peripheral rim enhancement in the early phase images with subsequent peripheral washout of contrast on the delayed phase image (arrow).

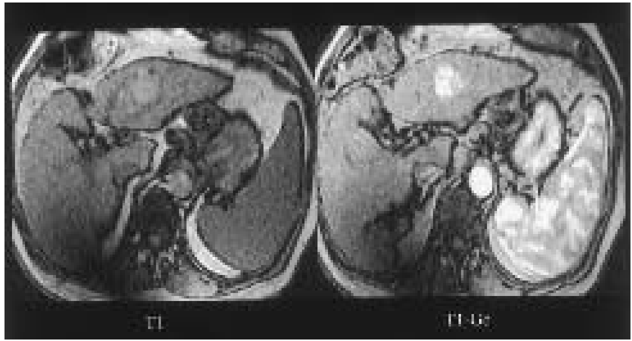

Figure 12 Hepatocellular carcinoma: pre- and post-contrast T_1-weighted axial images demonstrate cirrhotic, nodular liver with presence of a well-defined mass in the left lobe which enhances strongly in arterial phase.

CHEST

CT is the primary cross-sectional imaging modality for the evaluation of the lungs because of its superior spatial resolution, which permits better visualization of lung parenchyma and bronchial structures than does MRI. CT also helps detect calcification, which can be a useful finding in differentiating benign from malignant tumours.

MRI is a problem-solving modality in staging of the lung cancer. The multiplanar imaging capability of MRI is very useful in evaluating the extent of chest neoplasm and its relationship to the organs. Anatomical areas with a more vertical orientation – such as lung apices, thoracocervical junction, aortopulmonic window, subcarinal region and peridiaphragmatic areas – are better imaged with MRI. In patients with contraindication to iodinated CT contrast media, MRI can noninvasively assess the presence of vascular invasion. In Pancoast tumours, MRI can be utilized to determine brachial plexus involvement, chest wall invasion, spinal canal invasion and direct mediastinal invasion (White *et al*., 1993). MRI is useful in determining the involvement of pericardium, cardiac chambers and great vessels (**Figure 10**). Extension into the bronchus and trachea can be seen on MRI but CT is a better modality for such delineation.

LIVER

The liver is a common site for primary and secondary tumours. Owing to the high prevalence of benign primary hepatic tumours, the goals of liver imaging in patients with cancer are tumour detection and lesion characterization.

Liver evaluation is commonly undertaken in patients in whom, because of tumour type, symptoms of serum markers, liver metastases are suspected (**Figure 11**). The cornerstone of liver imaging is contrast-enhanced CT because it permits the rapid evaluation of the entire abdomen. Thus, live MRI is typically used when iodinated contrast media cannot be administered (e.g. prior contrast reaction; renal insufficiency). In addition, since liver lesion detection with CT or ultrasonography is compromised in patients with fatty infiltration, MRI serves an effective supplementary test. An important indication for liver MRI is the preoperative work-up of patients with resectable liver tumours (Ferrucci, 1994). More recently, MRI with liver specific contrast agents has been found to be highly effective in delineating and in staging tumour in the liver as well as in localizing tumours in various hepatic segments. MRI is also useful in patients with cirrhosis for detecting hepatomas and differentiating them from regenerating nodules and dysplastic nodules (**Figure 12**). However, owing to the high cost of MRI and limited access, ultrasonography is preferred as a screening test, leaving MRI for problem-solving equivocal sonographic studies. The role of MRI with liver-specific contrast is increasing in screening for malignant hepatic lesions, both primary and secondary.

Liver MRI is most commonly used for classifying indeterminate hepatic masses seen at CT or ultrasonography. For example, malignant liver masses can be readily differentiated from haemangiomas, cysts, focal nodular hyperplasia, dysplastic nodules and focal fatty infiltration. Signal intensity of the spleen is taken as an internal reference standard to characterize liver tumours. Typically most of the benign liver tumours are brighter

than spleen on T_2-weighted images, whereas malignant tumours have signal intensities similar to or less than those of the spleen (Wittenberg *et al*., 1988). Gadolinium–DTPA, essentially a blood pool agent, is commonly utilized to characterize tumours further by studying their perfusion pattern (Van Beers *et al*., 1997).

PANCREAS AND BILIARY TREE

Although MRI is highly effective in imaging the pancreas and biliary tree, the use of MRI in imaging these organs in the oncological population is limited. Usually, pancreatic MRI is used when administration of contrast media is contraindicated for CT. MRI may be equivalent to CT for the evaluation of the pancreas to rule out or confirm possible masses and/or stage pancreatic tumours with respect to vascular encasement and hepatic metastases (Fernando-del Castillo and Warshaw, 1990) (**Figure 13**). However in patients with suspected small functioning islet cell tumours, pancreatic MRI is superior to CT and should be the preferred initial test. Similarly, in patients with cystic pancreatic masses and a clinical suspicion of intrapapillary mucinous tumours (IPMT), MRI can be used to differentiate a focal from a diffuse process. This is undertaken with MR cholangiopancreatography (MRCP), which can also be used to noninvasively evaluate biliary obstruction (stone vs tumour) (Guibaud *et al*., 1995) (**Figure 14**). The tumour appears as a low-signal intensity mass lesion against the high signal intensity of the normal pancreas on fat-suppressed T_1-weighted spin-echo images. The tumour exhibits variable signal intensity on T_2-weighted images. Pancreatic tumours enhance less than normal pancreatic tissue and are therefore better appreciated on Gd-enhanced T_1-weighted images (Mergo *et al*., 1997). Preliminary results with MnDPDP (Teslascan, Nycomed Amersham, NJ) as a hepatobiliary contrast agent have reported a better contrast-to-noise ratio between the tumour and normal pancreas on T_1-weighted spin-echo and gradient-echo images, thereby increasing the lesion conspicuity.

Figure 13 Pancreatic cancer: pancreatic head mass best demonstrated on post-MnDPDP T_1-fat saturated image (arrow).

RENAL–ADRENAL

CT is the preferred test for evaluating the kidneys and adrenal glands. The indication for MRI is limited to patients unable to undergo a contrast-enhanced CT examination owing to prior contrast reaction or renal insufficiency. In addition, young adults with Von Hippel–Lindau syndrome who need serial scanning for monitoring the kidneys for development of malignancies are evaluated with MRI because MRI does not use ionizing radiation. Renal cell cancers appear hypointense on both T_1-weighted and T_2-weighted images. The latter is due to the high water content of the kidneys, making them hyperintense on T_2-weighted images (Semelka *et al*., 1993). The enhancement characteristics of renal masses are analagous to that of contrast-enhanced CT, with increased enhancement due to increased vascularity. The tumour thrombus enhances on Gd-enhanced images. MRI is useful to show the extent of tumour thrombus in the IVC which has implications for the surgical approach (**Figure 15**).

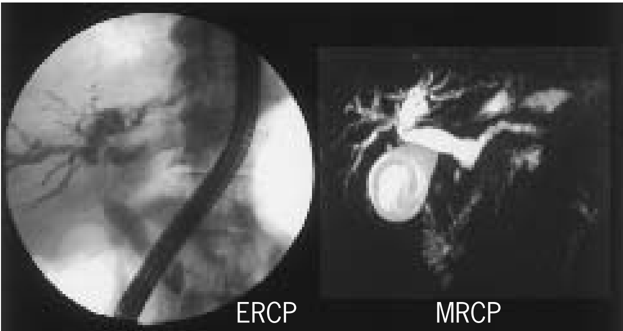

Figure 14 Cholangiocarcinoma: excellent ERCP and MRCP correlation of the level of CBD obstruction by a malignant CBD structure.

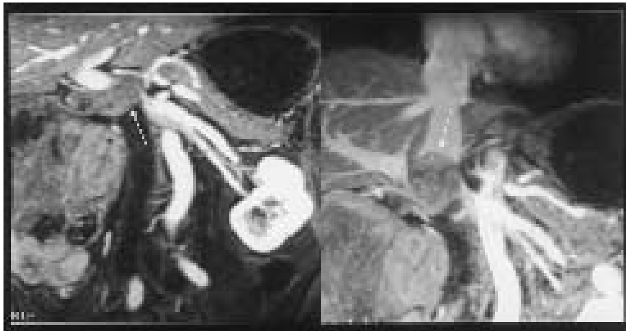

Figure 15 Renal cell carcinoma: MRI with Gd-enhanced MR angiography showing right renal tumour with contiguous invasion into the right renal vein (arrow) and the IVC (arrow).

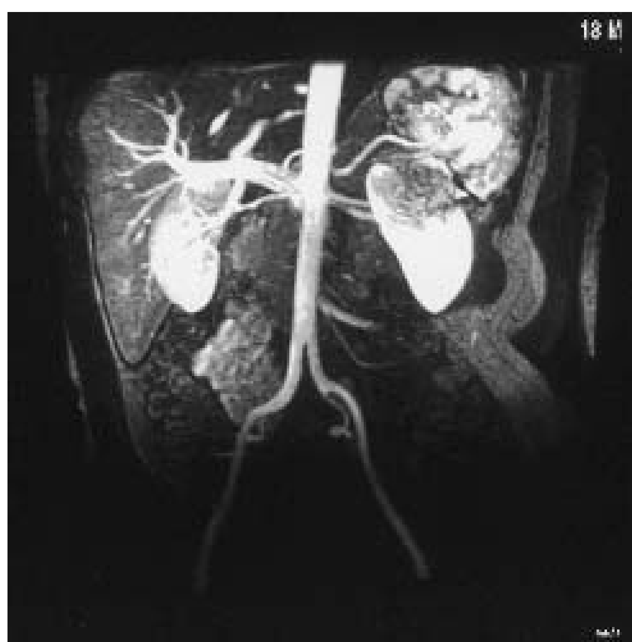

Figure 16 Renal cell carcinoma: Gd-enhanced MR angiography showing renal vessels free of the large, exophytic left upper pole renal cell carcinoma.

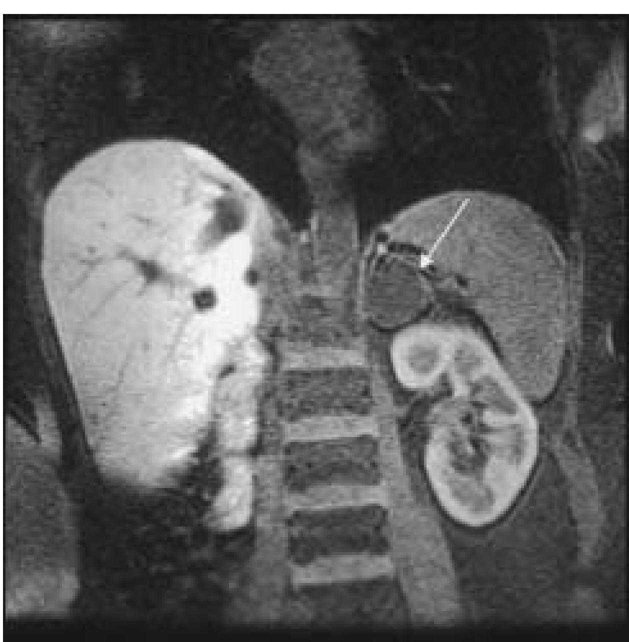

Figure 18 Adrenal metastases: post-MnDPDP enhanced T_1-weighted coronal MR image shows (arrow) a left suprarenal tumour with lack of any contrast uptake. Note the bright signal of the liver due to enhancement from MnDPDP uptake.

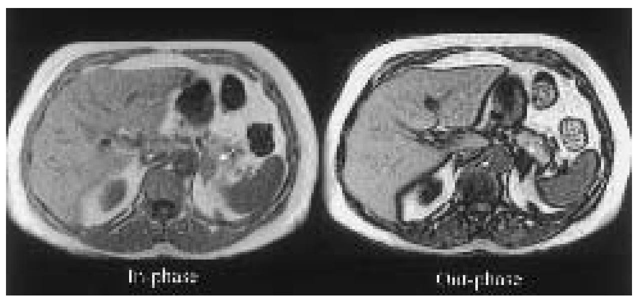

Figure 17 Adrenal adenoma: in-phase and out-of-phase T_1-weighted images. Note the drop in the signal intensity of adenoma on out-phase image.

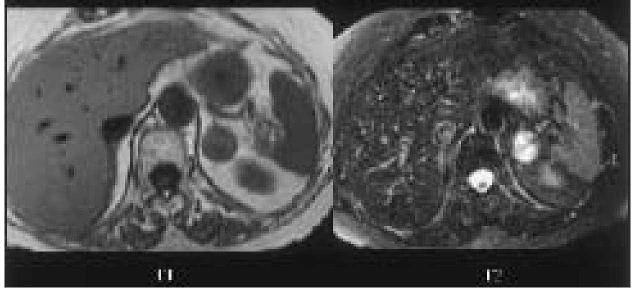

Figure 19 Adrenal phaeochromocytoma: left suprarenal tumour seen with low signal intensity on T_1-weighted image and very bright signal on T_2-weighted image.

MR imaging may be used to define whether a suprarenal mass is adrenal or renal, and to characterize a non-functioning adrenal adenoma (**Figures 16** and **17**). MRI is felt to be superior to CT for characterizing phaeochromocytomas. Adrenal adenomas resemble metastases in their signal intensities, with low signal on T_1-weighted and high signal on T_2-weighted images, but unlike metastases, adenomas may lose signal on the out-of-phase MR images in comparison with their signal on the in-phase images (Outwater *et al.*, 1996) (**Figures 17** and **18**). Phaeochromocytomas are characterized by their extreme hyperintensity on T_2-weighted images (**Figure 19**). Adrenal cortical carcinomas have no unique features that can be used to distinguish them from metastases.

COLON–RECTUM

Advances in the treatment of rectal carcinoma have increased the importance of accurate preoperative staging. Knowledge of the depth of tumour spread through and beyond the bowel wall influences the selection of patients who will benefit from preoperative adjuvant therapy (Drew *et al.*, 1999). CT is the primary modality to assess the lymph node and distant metastases. Endorectal coil MRI can be used as a focused study to evaluate the tumour extent within the muscle layers to differentiate the T_2 and T3 lesions and detect involvement of anal sphincter of levator ani muscle by rectal cancer (**Figure 20**). On T_1-weighted spin-echo images, rectosigmoid tumours appear as wall

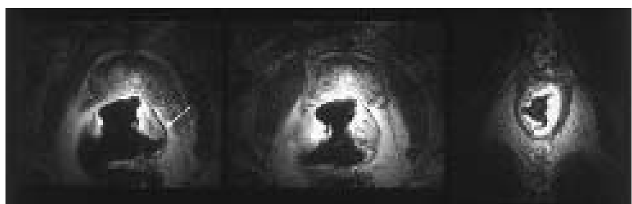

Figure 20 Rectal cancer: endorectal coil MRI shows a polypoid intraluminal tumour limited to the rectal wall as the peripheral dark stripe of serosa is intact (arrow).

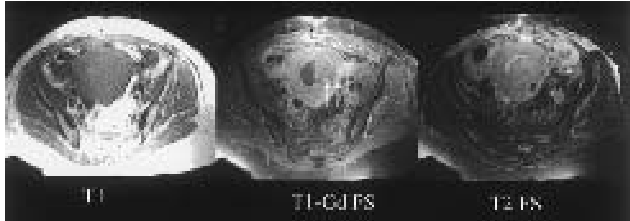

Figure 21 Endometrial cancer: polypoid intraluminal mass filling the endometrial canal is evident on T_1-weighted (left) and T_2-weighted (right) images. Contrast-enhanced T_1-weighted image (middle) shows true depth of myometrial invasion by the tumour (arrow).

thickening with a signal intensity similar to or slightly higher than that of skeletal muscle. Extension of the tumour beyond the bowel wall into perirectal fat (T3) can be well delineated on these T_1-weighted images, as the infiltrating tumour is of intermediate signal against the high signal of perirectal fat. The findings which suggest that a lesion is a T3 include extension of tumour beyond the contour of the interface between muscle and fat, with a rounded or nodular advancing margin. Gadolinium-enhanced T_1-weighted images improve definition of the tumour margins (de Lange *et al*., 1990). Coronal plane MRI is useful to establish the involvement of levator ani muscle and anal sphincter. Involvement of adjacent organs can be identified on axial and coronal MRI. Diagnosis of recurrent tumour is limited by inability to differentiate tumour, oedema, inflammation and fibrosis within 1 year, of radiation therapy. Tumour recurrence is suggested by a combination of high signal intensity on T_2-weighted images, round margins and the presence of >40% contrast enhancement.

CERVIX

MRI is the investigation of choice for local staging of the cervical cancer. The accuracy of MRI is superior to that of CT in assessing tumour size, defining parametrial and vaginal invasion and detecting regional lymph node involvement. Typically on T_2-weighted images the tumours appear brighter than the dark cervical stroma. Local spread into the surrounding fat is best appreciated on post-gadolinium fat saturated T_1-weighted images (Bragg and Hricak, 1993). Additionally, contrast administration is useful in distinguishing biopsy changes from residual tumour and in the evaluation of bladder and rectal invasion.

UTERUS

The overall prognosis in endometrial cancer depends on histological grade of the tumour, depth of myometrial invasion and lymph nodal involvement. When the tumour is confined to the uterus, determination of myometrial involvement is very important, as deep myometrial invasion is associated with a 40% incidence of lymph nodal involvement. This is better demonstrated on MRI than on CT. The indications for MRI in endometrial cancer include abnormal but nondiagnostic endocervical curettage, suspected advanced disease and patients at a poor risk for surgical staging.

Contrast-enhanced MR plays a major role in differentiating tumour margins from normal nonenhancing endometrium (Bragg and Hricak, 1993) (**Figure 21**). This also helps to determine tumour necrosis and volume of viable tumour. The staging accuracy of MRI in the assessment of patients with endometrial cancer has been reported to be in the range 83–92%. Lymph node involvement is judged on size criteria, and any node larger than 1 cm in the pelvis is considered abnormal unless proved otherwise. A staging classification has been developed based on MRI criteria. Breach in the integrity of the junctional zone places the tumour in category 1B. Extension into the cervix is best appreciated on sagittal T_1-weighted images. A high signal intensity on T_2-weighted images outside the uterus suggests extra-uterine spread (Hricak *et al*., 1987).

OVARIES AND ADNEXA

Ultrasound remains the initial imaging modality of choice for initial assessment of ovarian masses, and CT for subsequent tumour staging. The results of MRI are similar to those of CT in the characterization and staging of the ovarian tumours, although the multiplanar ability may be advantageous. Use of contrast agents (Gd–DTPA) increases the detection accuracy of MRI up to 92%, in the separation of benign from malignant tumours (Thurnher *et al*., 1990).

The MRI features suggesting ovarian malignancy include a cystic-appearing lesion with a wall thickness exceeding 3 mm, wall nodularity or the finding of a solid mass. Extension of the ovarian tumour is suggested by

indirect findings such as presence of ascites, nodular tumour implants on the peritoneal surface and/or loculated fluid collections. Post-Gd T_1-weighted fat-saturated imaging is considered to be the most sensitive imaging technique in detecting small peritoneal implants. Direct extension into adjacent organs can also be determined with MRI.

BREAST

The role of MRI in breast carcinoma is still evolving. At present it is a problem-solving modality and has no role as a screening modality. Current indications include invasive cancer in a breast with dense parenchyma, which is sub-optimally evaluated with film screen mammogram. It also provides information regarding vascularity, chest wall invasion (**Figure 22**) as noted, and MRI is devoid of ionizing radiation. The disadvantages include inability to detect microcalcification of early cancer, low specificity and high cost. Fat-suppressed contrast-enhanced MR imaging with special breast coils provides better images but still the tail of breast is difficult to image (Stelling, 1995). False-negative results of MR are due to carcinomas with minimal vascularity, partial volume averaging of small ($\leq$5 mm) lesions, smooth margins and motion artifacts. Some of the benign breast lesions may mimic carcinomas, by virtue of contrast enhancement. These include fibroadenoma, fibrocystic change and changes due to inflammation, recent surgery or recent radiotherapy. It is not possible to detect or exclude involvement of the nipple with Paget disease by contrast-enhanced MR as the nipple–areola complex normally shows brisk enhancement (Heywang *et al*., 1989). The future applications of MR in breast imaging include MR-guided biopsy and MR-directed therapy.

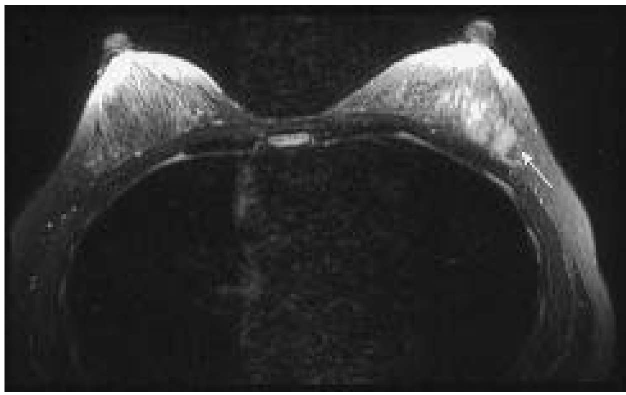

Figure 22 Breast cancer: Gd-enhanced fat saturated T_1 image shows a lobulated, poorly defined tumour suggestive of invasive cancer (arrow) seen in the left breast.

URINARY BLADDER

Treatment and prognosis of carcinoma of the urinary bladder depend on the depth of tumour infiltration into the bladder wall and the extent of the metastases. MRI and clinical staging complement each other in staging urinary bladder cancer. While clinical examination is sufficient in staging superficial bladder tumours, MRI is utilized in staging more invasive neoplasms (Fisher *et al*., 1985). MRI is superior to CT for staging of bladder cancer because of its multiplanar ability, which allows better imaging of trigone, prostate and seminal vesicles. The differentiation of T3a (muscular invasion) and T3b (invasion of perivesical fat) is better on MR than on CT, especially in tumours at the bladder dome or base. The reported accuracy of MRI for staging bladder cancers varies from 73 to 96% (Bryan *et al*., 1987). On T_1-weighted images the urine has a low signal, the bladder wall intermediate and the perivesical fat a high signal, thereby providing high inherent contrast. T_1-weighted images are good for detecting the perivesical infiltration of the tumour. On T_2 images the urine has a high signal, muscle a low signal and perivesical fat a high signal. The tumour has an intermediate signal on both T_1- and T_2-weighted images. Intraluminal tumours and bladder wall infiltration is better demonstrated on T_2-weighted images. After contrast administration, tumour, mucosa and lamina propria show earlier and greater enhancement compared with muscle layer and thereby visualization of small tumours ($\leq$7 mm) is improved. Delayed images after

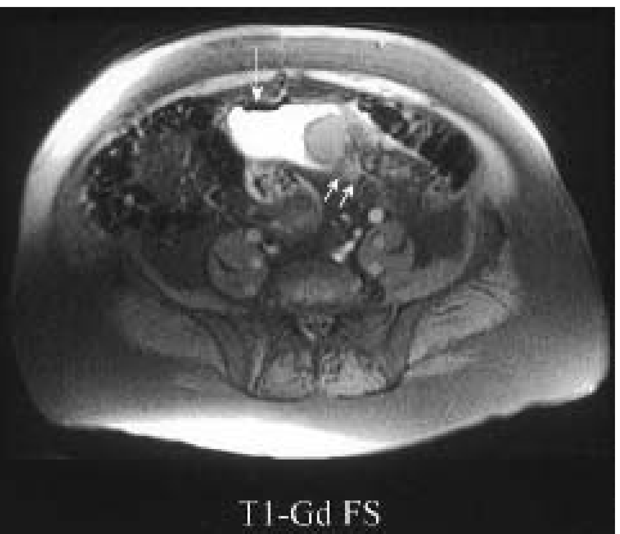

Figure 23 Bladder cancer: postcontrast T_1-weighted fat-saturated image demonstrates a lobulated intraluminal bladder mass along with contiguous extravesicular extension (small arrows) into the sigmoid colon. Presence of air in the bladder (large arrow) is indicative of colovesicle fistula.

contrast administration show the intraluminal tumour well against the high signal of excreted Gd in the bladder (**Figure 23**).

It is important to differentiate postsurgical fibrosis or granulation tissue from tumour recurrence. MR examination is usually performed 3 months after the procedure and T_2-weighted images show a high signal if it is tumour recurrence or a low signal if it is fibrosis.

PROSTATE

The primary role of MRI in imaging prostate cancer is to stage the disease, not for the detection of the disease. Currently, MRI is considered the imaging modality of choice to assess the extra-capsular spread of tumour (Bezzi *et al*., 1988). MR imaging of the prostate is best achieved with an endorectal coil as it provides higher resolution images than a body coil. Supplementary imaging with a body coil is required to image the abdomen and pelvis to detect lymphadenopathy. The T_1-weighted images are helpful in imaging the periprostatic fat, periprostatic veins, neurovascular bundles and lymph nodes. T_2-weighted images demonstrate the internal architecture of the prostate and seminal vesicles to better advantage.

Prostatic carcinoma appears in the peripheral zone as a low-signal area in the background of a normal high-signal peripheral zone on T_2-weighted images. The presence of seminal vesicle invasion is suggested by thickening of the tubules; other findings include a low signal mass, loss of normal seminal vesicle angle and low signal unilaterally or bilaterally (**Figure 24**). Coronal or sagittal images are the best for evaluating the seminal vesicles. The accuracy of MRI in the detection of transcapsular spread is 90% (Schnall *et al*., 1991). Direct invasion of the bladder and rectum can also be accurately detected on MRI. The involvement of lymph nodes is suggested by size criteria. Multiple clusters of nodes and size >1 cm are considered indicative of involvement. The accuracy of MR in detecting lymph nodes is equal to that of CT.

Figure 24 Prostate cancer: endorectal coil coronal (left) and axial T_2-weighted (right) MR image shows an ill-defined low signal intensity tumour in the superior aspect of the peripheral zone of the prostate (white arrow) with contiguous extension into the seminal vesicles (black arrow).

MR spectroscopy appears useful for noninvasive discrimination between benign prostatic hyperplasia and prostatic carcinoma. The ratio of citrate to choline peak areas and that of creatine to myo-inositol are currently considered the most useful to discriminate between advanced prostatic carcinoma (both ratios >1.0) and advanced benign prostatic hypertrophy cases (both ratios >1.0) (Garcia-Segura *et al*., 1999).

TESTIS

Ultrasonography represents the primary imaging modality to image the scrotum, because of its low cost and the effectiveness of imaging and accuracy achieved with high-frequency transducers. MRI is a supplemental imaging technique for tumour detection because of its multiplanar ability and excellent soft tissue contrast. In general, the tumours are isointense on T_1- and hypointense on T_2-weighted images relative to normal testicular tissue. MRI is useful in cases where the ultrasound is technically inadequate or the sonographic findings are ambiguous (Schnall, 1993).

MUSCULOSKELETAL

Soft-tissue Tumours

MRI is an excellent modality to evaluate soft tissue tumours. The primary role of MRI is to evaluate local extent and tumour stage. Tumour characterization is a secondary role as MRI is limited in its ability to differentiate benign lesions from malignant tumours, for which there are no absolute criteria. Benign tumours are usually small and well encapsulated with smooth margination, and exhibit signal homogeneity. Malignant tumours tend to be large (>3 cm) (Berquist, 1993), with irregular margination and invasion of adjacent organs and have heterogeneous signal intensity. Involvement of surrounding fat is well seen on T_1-weighted images whereas muscular invasion is better assessed on T_2-weighted images (**Figure 25**). Contrast-enhanced MRI is useful to delineate viable tumour and neurovascular bundle invasion and to differentiate oedema from tumour tissue. Involvement of adjacent bone is identified as an altered signal in the bone marrow. At times MRI may fail to identify subtle cortical involvement and periosteal reaction.

MRI features of some of the tumours are pathognomonic: a lipoma, for example, demonstrates a homogeneous bright signal on T_1-weighted images. However, it is not always possible to differentiate a benign lipoma from a low-grade liposarcoma. Other tumours can be difficult to characterize. Calcification within tumours can be missed on MRI and this may require correlation with plain X-ray or CT examination.

Bone Tumours

MRI plays an important role in the evaluation of malignant bone tumours, especially with the advent of limb-sparing surgery. The primary role of MRI is to stage the disease with regard to its local extent. MRI should be utilized in conjunction with plain radiography for characterizing bone tumours as the latter is a better predictor of histological diagnosis and more efficient in the differentiation of benign from malignant lesions.

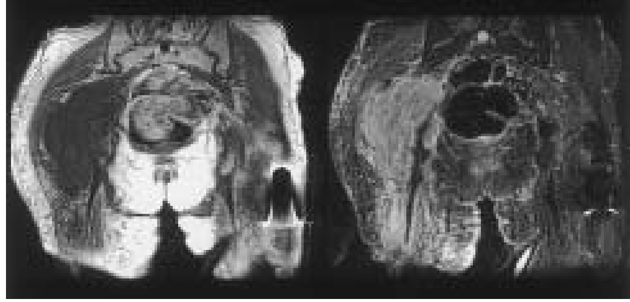

Figure 25 T_1 (left) and T_2 (right) weighted coronal MR images of a soft tissue sarcoma in the right gluteal compartment. Note the bright signal of the tumour in comparison to the surrounding musculature.

Figure 26 Bone sarcoma: contrast-enhanced T_1-weighted coronal image with fat suppression shows tumour involving distal right femur with associated pathological fracture and presence of a skip lesion in the proximal shaft (arrow).

The role of contrast agents is controversial, and currently routine use is not indicated. For selected tumours, such as osteosarcoma, gadolinium enhancement offers the potential for determining the efficacy of chemotherapy, by evaluating tumour necrosis prior and subsequent to chemotherapy. In certain situations, especially sarcomas close to joints, the use of gadolinium enhancement may help to clarify whether tumour resection should be intra- or extra-articular (Sundaram, 1997). Further, some reports demonstrate differentiation of tumour from oedema on postcontrast studies, and others have suggested that peak enhancement plotted against time may be useful to differentiate benign from malignant tumours.

Sagittal or coronal T_1 images are the most useful for evaluating the longitudinal extent of marrow involvement and possible invasion of contiguous joints. It is important to image from joint to joint to exclude skip lesions (**Figure 26**). T_2-weighted images show soft tissue involvement as a hyperintense signal against the intermediate signal of muscle. Cortical destruction and subtle tissue invasion is best appreciated on T_2-weighted axial images. When fat surrounds the bone, T_1-weighted images may also show such extension. Tumour calcification cannot be

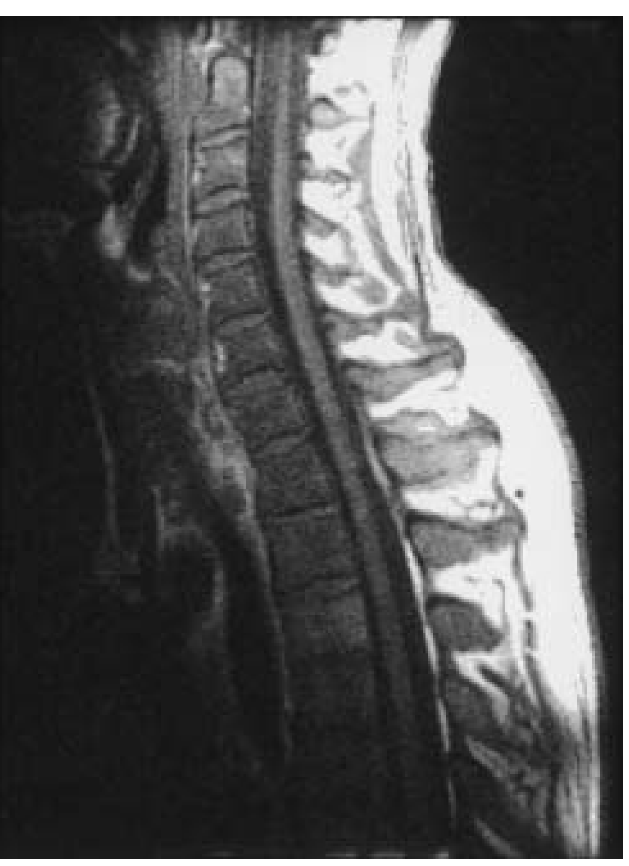

Figure 27 Spinal metastases from prostate carcinoma: diffuse alteration in the cervical and thoracic vertebral marrow signal on T_1-weighted sagittal image due to metastatic deposit.

identified unless it is gross. Involvement of neurovascular bundle should always be noted if present, as it precludes limb-sparing surgery. This also is best identified on axial T_2-weighted images. Tumour involvement is determined either by frank encasement of the neurovascular bundle or by loss of fat planes adjacent to it. MR angiography gives a preoperative map of the vessels and the tumour vascularity in certain cases. MRI plays an important role in follow-up of patients receiving radiotherapy or chemotherapy. The treatment response is assessed by evaluating for change in tumour volume and development of tumoural necrosis. This is best identified as central non-enhancing areas within the enhancing tumour on contrast-enhanced T_1-weighted images (Berquist, 1993).

The primary screening modality for bone metastases is planar bone scintigraphy. In the evaluation of spinal metastasis, however, MRI has sensitivity equal to or greater than that of scintigraphy, and it is possible to screen the entire spine on a single T_1-weighted sagittal sequence (**Figure 27**). It is also possible to ascertain the presence of impending vertebral collapse with MRI or the level of maximal spinal cord compression prior to performing decompression surgery. MRI can also be employed as a problem-solving modality when the scintigraphic findings are equivocal.

LYMPH NODE IMAGING

Lymph node imaging is commonly performed for staging lymphoma or metastatic disease. MRI and CT perform equally well in detecting lymph nodes. CT is preferred for a survey study, when more than one region must be evaluated as in staging lymphoma. MRI is reserved for a focused examination (e.g., for evaluation of pelvic nodes in prostatic or cervical malignancies) or in problem-solving situations. Size criteria are commonly utilized: usually lymph nodes >10 mm are considered pathological, except for axillary, groin and jugulo-digastric nodes, which can be as large as 15–20 mm in normal patients. The presence of bright signals and heterogeneity in the lymph node on T_2-weighted images are indicators of metastatic disease.

Recent clinical trials conducted with the reticuloendothelial system specific, iron oxide containing contrast agents have shown the ability to differentiate a benign from a malignant lymph node. This is because tumourous lymph nodes lack reticuloendothelial cells thereby reduced or heterogenous contrast uptake, in comparison with the normal homogeneous contrast uptake by normal or benign nodes.

INTRODUCTION TO NUCLEAR IMAGING

Nuclear medicine involves the imaging of radioactive isotopes which are attached to tracer substances (hence radiotracers). These radiotracers are incorporated into physiological processes within the body depending on the type of tracer. In this way, nuclear medicine is a 'functional' as opposed to 'anatomical' imaging technique in contrast to many radiological methods such as plain films, computed tomography (CT), ultrasound and magnetic resonance imaging (MRI). The most commonly used isotope is ^{99m}Tc, but a wide variety of other isotopes are used, and many of these can be attached to multiple tracers depending on the imaging requirements (see **Table 1**). Radiotracers are usually administered to the patient intravenously, but on occasion the oral (e.g. ^{131}I capsules for thyroid imaging), inhaled (e.g. nebulized [^{99m}Tc]DPTA for lung ventilation studies), intrathecal (e.g. [^{111}In]DPTA for cerebrospinal leak studies) or intracavitary (e.g. ^{32}P for treatment of peritoneal malignancies) routes are used.

Imaging is performed on a gamma camera, which incorporates a large scintillation crystal that converts the gamma rays produced by the isotopes into electrical signals. The remainder of the camera apparatus changes these electrical signals into a visual display of the distribution of the radiotracer along with various analyses of the energy spectrum of the gamma rays, which improve image quality by reducing scatter and other artifacts. Further details of gamma camera technology are beyond the scope of this chapter. Much nuclear imaging is planar, i.e. producing two-dimensional images from three-dimensional data, but multiplanar images can also be produced using single photon emission computed tomography (SPECT). These images are produced through the gamma camera rotating around the patient and result in a volume of information which can be sliced in any plane (e.g. sagittal, coronal and transaxial images can all be produced). This markedly improves the detection of smaller abnormalities, especially those located centrally within the body, as well as improving the localization of these abnormalities. It does increase imaging time considerably, and is difficult to perform in certain studies when the count rate is very low (e.g. ^{131}I). Conventional gamma cameras are optimized to image gamma rays with energies of 140 keV – that of ^{99m}Tc – but acceptable images are obtained over a wide range of energies. Positron emission tomography (PET) cameras use a unique imaging system and are described separately later in this chapter.

Nuclear medicine has occupied an important position in the evaluation of patients with suspected or known malignancy since its inception in the 1960s (in fact, ^{131}I was first used in the 1930s). With the advent of PET there has been a resurgence of interest in nuclear techniques and it is likely that PET scans will become as routine a part of the management of oncology patients as CT has. The principle uses of nuclear medicine are for the initial diagnosis of patients (differentiating benign from malignant masses) and for staging and for treatment follow-up. It is used both in isolation and in combination with other imaging techniques. This chapter is divided by scan type rather than disease type due to the considerable overlap of the latter.

Table 1 Commonly used isotopes and tracers in nuclear oncological imaging (isotopes in italics are used for positron emission tomography)

Isotope	Energy (keV)	Half-life	Tracer	Oncological indications
^{99m}Tc	140	6 h	MDP	Bone scanning
			MIBI	Parathyroid, brain and soft-tissue tumours, e.g. breast
			Nofetumomab Merpentan	Small-cell lung cancer
			Arcitumomab	Colorectal cancer

BONE SCANNING

Skeletal scintigraphy for the detection of bony metastatic disease is probably the most widely used nuclear medicine procedure in oncology patients.

Basic Principle

In the majority of cases of skeletal metastases, there is a derangement in bone turnover that occurs before a detectable change in the macroscopic anatomy. Up to 50% of bone mass must be lost before changes are seen on plain X-ray films. Bone scanning is performed with isotope labelled phosphate compounds that are accumulated in the skeleton in relation to bone turnover. Most metastases will institute a focal increase in bone turnover due to the tumour-related destruction. Bone scanning is among the most sensitive modalities available for the detection of skeletal lesions.

Indications

The majority of bone scans are performed in patients with known cancer for staging or for follow-up of known or suspected bone lesions. The most common malignancies examined are prostate and breast cancer – two diseases that readily metastasize to bone. In some instances, studies are performed for the evaluation of a focal complaint, such as pain, to determine if malignancy may be the cause. Scans may also be ordered to evaluate primary malignancies of the bone. Because osteosarcoma is a bone-forming tumour, bone scans may also be requested to detect soft tissue metastases in this disease entity.

Procedure

The most commonly used pharmaceutical for bone scanning is methylene diphosphonate (MDP) although several other similar compounds are available. Technetium-99m (^{99m}Tc) is an isotope that is virtually ideal for nuclear scintigraphy and is used as the label for all of these compounds. The agent is administered intravenously in a dose of 25 mCi for adults (200 μCi kg^{-1} for children). Over a period of time, about half of the radiolabelled phosphate adsorbs on bone and calcium while much of the remainder is excreted through the kidneys. Peak target to background (bone to soft tissue) ratio occurs about 3 h after the injection and it is at this time that images are acquired. Most often, scans of the entire skeleton are obtained. Sometimes the study is supplemented by tomographic imaging (SPECT). SPECT may increase the sensitivity for lesion detection in certain areas and also improves the ability to locate the lesion in three dimensions.

Image Interpretation

Multiple foci of increased activity located predominantly in the axial skeleton with little involvement of the distal extremities is the classic appearance of skeletal metastases (**Figures 1** and **2**). The more numerous the lesions, the more highly predictive is the scan. It is possible, of course, for a patient to present with a solitary metastatic lesion. Studies have shown that 10–30% of solitary bone lesions in patients with cancer represent metastases.

Metastases need not be focal but may involve more expansive areas of bone and even lead to diffuse involvement. The 'superscan' occurs with diffusely increased bone turnover (seen with not only metastases but with other skeletal pathology such as hyperparathyroidism) to the extent that there is little remaining MDP to be excreted through the kidneys leading to absence of bladder activity.

Bone scanning is commonly used to follow the course of patients being treated for malignancy. It must be kept in mind that these scans image the bone reaction to the destructive tumour. Shortly after the onset of therapy, it is possible that bone lesions may become more intense owing to the increase in repair. This simulates progression of disease and has been termed the 'flare' phenomenon. A series of scans is necessary for the true evaluation of the course of disease.

Value and Pitfalls

The strength of bone scans is their extremely high sensitivity. It is not unusual for a bone scan to depict metastatic lesions that cannot be detected by plain X-rays. A negative bone scan is a highly accurate means for excluding disease (McNeil, 1984).

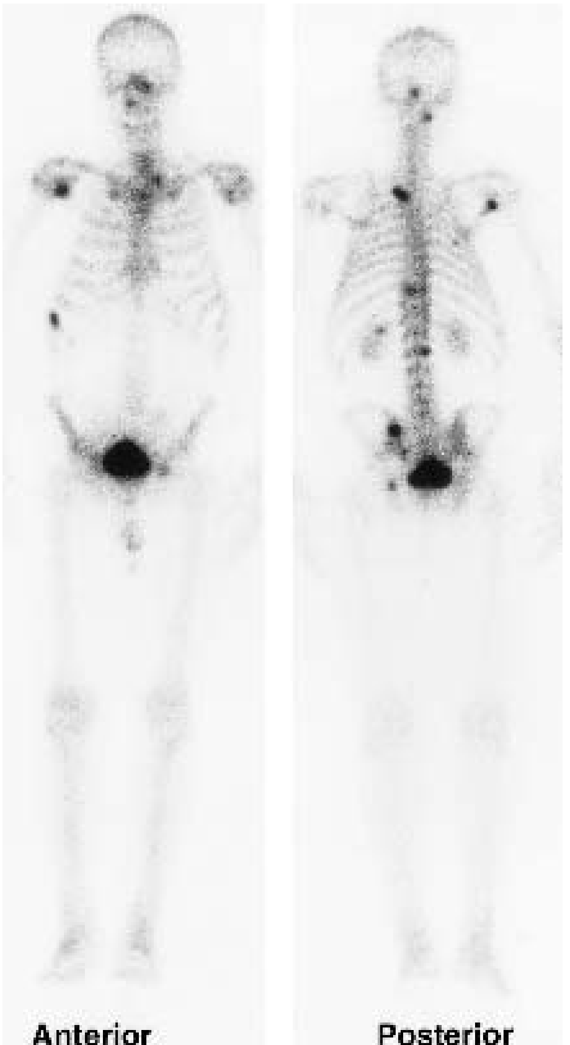

Figure 1 Whole-body bone scan of a 72-year-old male with prostate cancer showing widespread bony metastases.

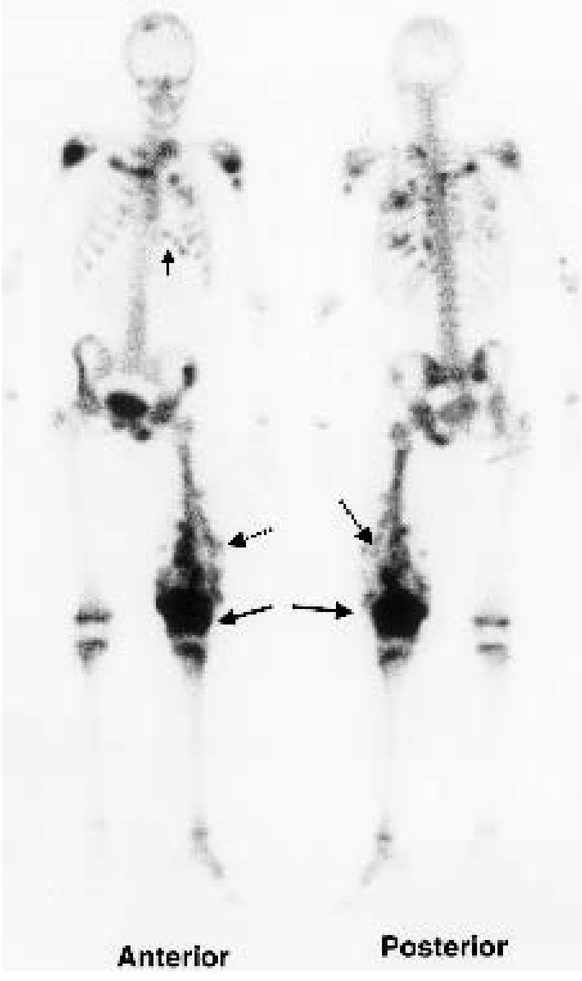

Figure 2 Whole-body bone scan of an 18-year-old boy with primary osteosarcoma of the distal left femur (solid arrow) with multiple bony metastases as well as metastases to his lung (small arrow) and soft tissues of the left thigh (dashed arrow).

As might be expected, the high sensitivity necessitates a less than optimal specificity. Since a wide spectrum of pathology can cause a resultant derangement of bone turnover, lesions that can have the appearance of metastatic disease may be caused by other processes. Probably the most common benign cause of focally increased ^{99m}Tc uptake is degenerative joint disease, a very common problem in the cancer patient age group. When lesions are isolated to the regions of joint spaces (particularly the spine), it is important that the study be interpreted with care. Correlative images such as plain film X-rays, or computed tomography (CT) are frequently used to aid bone scan interpretation. These are used to confirm the presence of a benign aetiology for increased bone turnover such as osteoarthritis, as a negative anatomical study does not exclude bone metastases. Another not uncommon cause of increased focal activity is previous trauma, especially rib fractures. Foci of increased activity at the costo-chondral junction or in a colinear distribution in adjacent ribs is highly suggestive of a traumatic aetiology.

False-negative studies can also occur with bone scans. Highly osteolytic metastases may not have enough of an osteoblastic (bone-forming) response to allow detection by bone scanning. The most common primary tumour to do this is multiple myeloma, wherein it has been estimated that as many as 50% of lesions may not be detectable. For this reason, plain film radiography rather than bone scanning is the modality of choice for staging myeloma patients. Renal cell carcinoma and thyroid cancer also have significantly high false-negative rates.

IODINE SCANNING

Basic Principle

Iodine is taken up by normal and, to a varying extent, neoplastic thyroid tissue as well as by several other organs such as the salivary glands. Radioactive iodine accumulates exactly as nonradioactive iodine does, and hence will show the distribution of iodine-avid tissue in the body. Neoplastic thyroid tissue takes up significantly less iodine than normal tissue, and hence appears as a 'cold' area on a radioiodine scan. A similar appearance is seen on a [^{99m}Tc]pertechnetate scan, which acts as an iodine analogue. Following total thyroidectomy, the neoplastic tissue can be stimulated to accumulate iodine by increasing the TSH (thyroid-stimulating hormone) levels as described below. Thyroid scanning can be performed using several isotopes – [^{99m}Tc]pertechnetate, ^{123}I and ^{131}I. The first two radiotracers are usually restricted to the evaluation of thyroid nodules. The image quality of [^{99m}Tc]pertechnetate and ^{123}I is considerably better than that of ^{131}I owing to the lower energies of the gamma emissions, and the radiation dose to the patient is much less (with the pertechnetate scans having the lowest radiation dose). In patients with known thyroid malignancies the isotope of choice is ^{131}I, which is used both for diagnosis and therapy.

Indications in Oncology

In the evaluation of a patient with a palpable thyroid nodule, either ^{99m}Tc pertechnetate or ^{123}I is used to assess for activity of the nodule. Nodules which are 'warm' or 'hot' (i.e. accumulate the tracer) on pertechnetate or iodine scans are very unlikely to be malignant, whereas those which are 'cold' (i.e. do not accumulate tracer) have a significantly higher likelihood of being malignant – about 10–20% of such nodules (see **Figure 3**). In the post-thyroidectomy patient ^{131}I scanning is used to assess the extent of the thyroid remnant as well as metastatic spread. ^{131}I therapy in much higher doses is then given to ablate the thyroid remnant as well as metastases, if present (Harbert, 1996).

Procedure

For the assessment of a suspicious thyroid nodule, either 300 μCi of ^{123}I is administered orally or 5 mCi of [^{99m}Tc]pertechnetate intravenously, with imaging 24 h or 20 min later, respectively.

Whole-body ^{131}I Scanning

Whole-body ^{131}I scans are only performed after patients have undergone a total thyroidectomy, as otherwise the intense uptake by the patient's normal thyroid tissue will prevent visualization of potential thyroid metastases. Following an optional preablation scan, a therapeutic dose of ^{131}I is administered. The dose given depends on the clinical and radiographic staging of the tumour but is usually in the range 100–250 mCi. The patient has to be admitted and monitored until the patient's radiation emissions are within an acceptable range. In some instances an outpatient dose of >30 mCi may suffice. Seven to ten days following this dose the whole body scan is usually repeated: the larger dose of radioiodine may show the presence of smaller or less iodine-avid metastases. Six to twelve months after thyroid remnant ablation, the diagnostic whole-body ^{131}I scan is repeated to evaluate the success of the ablation as well as for staging. Scans may then be repeated at 6–12-month intervals depending on the clinician preference and the tumour staging as well as the results of other monitoring studies such as the serum thyroglobulin level (e.g. an increase in serum thyroglobulin may stimulate a repeat study). An example of a whole body thyroid scan is shown in **Figure 4**.

To obtain sufficient uptake of ^{131}I into thyroid metastases, a high circulating level of thyroid-stimulating hormone (TSH) is required. As all patients are on exogenous T4 or T3 therapy following total thyroid ablation therapy,

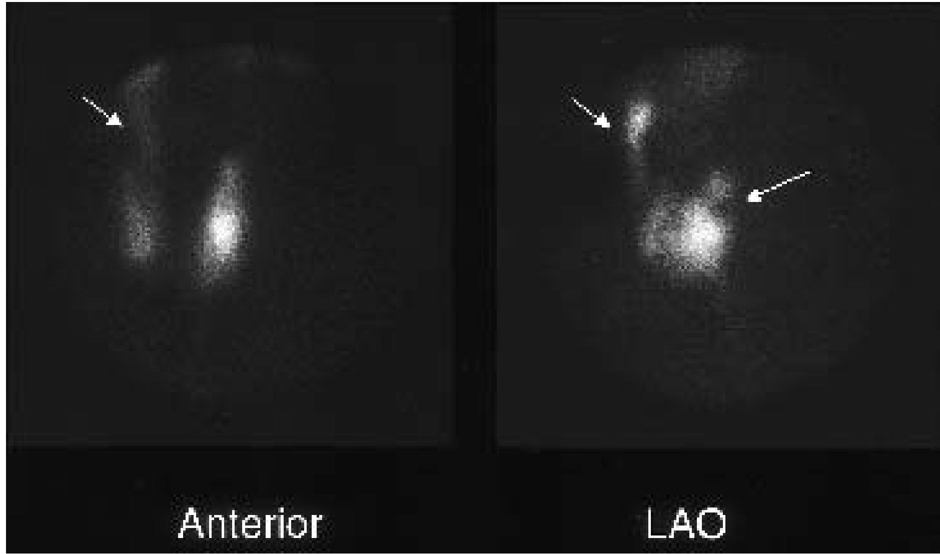

Figure 3 [^{99m}Tc]pertechnetate scan of the thyroid in a 43-year-old woman with a palpable nodule in the left lobe of the thyroid. A cold defect (arrow) is only seen clearly on the left anterior oblique (LAO) view corresponding to the palpable area. Biopsy indicated papillary carcinoma. The dashed arrow indicates a normal pyramidal lobe.

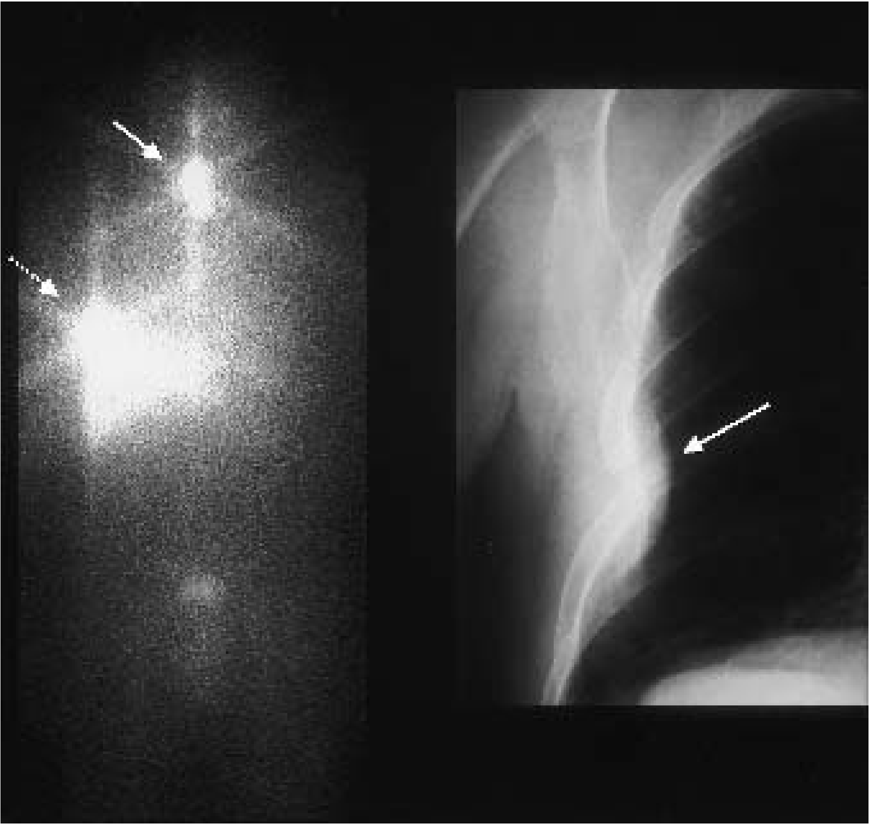

Figure 4 ^{131}I whole-body scan in a 50-year-old male with known follicular carcinoma of the thyroid, 2 years s/p total thyroidectomy and ^{131}I ablation therapy. A focus of intense activity in the neck (solid arrow) represents cervical nodal recurrence. An additional focus in the right lateral thorax (dashed arrow) was due to a rib metastasis, confirmed on the plain film (second image).

their TSH is suppressed. Until recently, therefore, all patients undergoing whole-body ^{131}I scanning for malignancy had withdrawal of T4 for 4–6 weeks or T3 for 2–3 weeks prior to the study, aiming for a TSH level of 30 IU L^{-1} or higher. The US Food and Drug Administration (FDA) has recently approved the administration of recombinant TSH (rTSH) to stimulate ^{131}I uptake in this group of patients. This does not require the withdrawal of thyroid hormone – which is unpleasant and greatly disliked by the patients – with rTSH being given intramuscularly on two consecutive days starting 2 days prior to the ^{131}I administration. The initial trials seem to suggest a slightly reduced sensitivity of this method compared with the withdrawal method, but others feel that in combination with thyroglobulin measurements it has adequate sensitivity (Schlumberger *et al*., 1999).

Image Interpretation

An initial scan following thyroidectomy will show the extent of any thyroid remnant (even after the most meticulous surgical thyroidectomy there is a small amount of normal thyroid tissue remaining) as well as other areas of nonthyroid iodine accumulation. Since iodine is also taken up by several other physiological processes, uptake is seen within the salivary glands, colon, nasal mucosa, urine, sweat and liver (the latter when circulating thyroid hormone is present). No normal uptake above background tissue should be seen outside the thyroid bed in the neck, in the lungs or in the bones, all common sites of metastases. Follow-up scans have several purposes: to demonstrate the success of ablation therapy, to indicate unsuspected metastases, to show the extent of metastases suspected on the basis of increasing thyroglobulin levels (see **Figure 4**), and to indicate the iodine avidity of the metastases for planned radioiodine therapy.

Value and Pitfalls

Most reasonably well-differentiated thyroid malignancies (papillary and follicular) and metastases accumulate radioiodine, but the presence of a large thyroid remnant will reduce sensitivity. Very anaplastic tumours may not accumulate iodine and medullary cell carcinoma is also not iodine avid. In anaplastic tumours thallium or ^{18}FDG PET may be used as alternative imaging methods (see below). Octreotide (see Peptides) as well as pentavalent DMSA (in Europe) have been used to image medullary cell tumours. Contamination of the study by sweat, saliva or nasal secretions is a common cause of a false-positive study. Inflammatory arthritis has also been reported to produce local ^{131}I accumulation. Gut activity has the potential to mask intraabdominal metastases, but these are rare outside the liver.

THALLIUM-201 SCANNING

Basic Principles

^{201}Tl is an isotope with a relatively long half-life of 74 h and low energy emissions (approximately 80 keV). Both of these properties impair the quality of gamma camera images obtained with this isotope. It is taken up into cells via the Na^+/K^+ pump, acting as an analogue of potassium. Because cell viability is vital to the integrity of this pump, thallium will only accumulate in viable cells. It has been extensively used in the past as a marker of myocardial perfusion and viability and, because it also accumulates in increasing amounts in neoplastic tissue relative to normal tissue, it is also used as a nonspecific tumour marker. In this way, it is very similar to the use of sestamibi, which is described below, but operates through a different mechanism. The poorer image quality and higher radiation dose of thallium also limit its usefulness.

Indications

Thallium has been used to image a wide variety of tumours, but most data are available for brain tumours and musculoskeletal tumours.

Brain Tumours

Thallium has been used in two major areas within neuro-oncology – differentiating recurrent tumour from radiation necrosis, and differentiating cerebral lymphoma from toxoplasmosis in AIDS patients. It has also been used as a noninvasive way of grading cerebral gliomas and predicting survival. In this manner it has been used as a ‘poor man’s FDG PET scan’ (see below). With anatomical imaging methods such as CT and MRI, radiation necrosis and tumour recurrence can appear very similar – both as enhancing lesions within the radiation field, frequently surrounding the surgical biopsy site. This is because contrast enhancement (whether with iodine- or gadolinium-based agents) is purely an indicator of blood–brain barrier breakdown, which occurs in both conditions. As thallium is a marker of cell viability, it will be taken up by the recurrent tumours but not by necrotic tissue from radiation necrosis (Slizofski *et al*., 1994). It also accumulates roughly proportionally to the degree of anaplasia of the tumour, but is not specific for tumour types (Black *et al*., 1989; Slizofski *et al*., 1994). The intensity of thallium uptake has been shown to correlate with glioma grading and inversely with prognosis in several studies (Black *et al*., 1989; Kosuda *et al*., 1994). In AIDS patients, both cerebral lymphoma and toxoplasmosis are common (and indeed may co-exist). Differentiating between the two may again be difficult on CT or MRI, but lymphoma is thallium avid, where toxoplasmosis and progressive multifocal leucoencephalopathy are not. A number of studies have

shown high sensitivities (92–100%) and reasonable specificities (80–94%) (Kessler *et al.*, 1998) for differentiating malignancy from infection or inflammation in AIDS patients, potentially reducing the number of cerebral biopsies required. [^{99m}Tc]MIBI has also been used with similar results to assess intracerebral neoplasms. Some difficulty can occur from high physiological uptake by the choroid plexus with [^{99m}Tc]MIBI.

Procedure for Brain Tumour Imaging

No patient preparation is necessary. A 2–3-mCi dose of ^{201}Tl chloride is administered intravenously and imaging commences 30–60 min later with SPECT imaging performed.

Image Interpretation

The images should always be interpreted alongside the results of a current anatomical study (CT or MRI) if available. Images are assessed for the presence of focal areas of increased thallium uptake (see **Figure 5**). The specificity of the study can be improved by obtaining a ratio of the count rate obtained in the abnormal area to a normal area (e.g. contralateral hemisphere in the brain). Cut-off ratios of 1.5–2 have been used to differentiate malignancy from benign processes, with the ratio being roughly proportional to the grade of malignancy. This ratio has also been shown to be inversely proportional to prognosis.

Value and Pitfalls of Thallium Brain Scanning

Thallium scanning provides a valuable way of identifying tumour recurrence, identifying potential areas of higher grade tumour for localizing biopsies and evaluating the response to therapy. It has been shown to be more accurate than CT for assessing recurrence. Low-grade tumours may not accumulate thallium and thus result in a false-negative study, as may very small tumours owing to the inherently poor resolution.

Studies have shown that tumours smaller than 1–1.6 cm have a high rate of false-negative thallium scans. These studies will not differentiate between lymphoma and other intracerebral malignancies such as metastatic disease or gliomas. The results in paediatric brain tumours have been mixed, with some studies showing a reduced sensitivity, although maintaining high specificities.

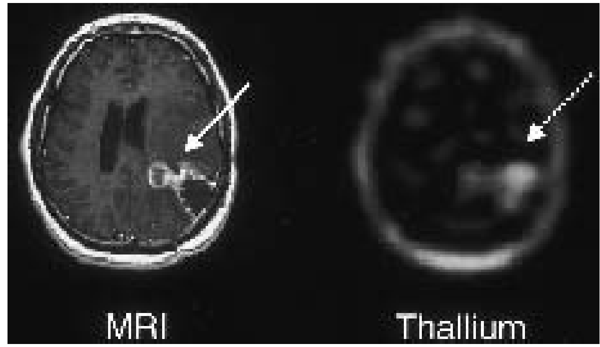

Figure 5 Brain MRI (gadolinium-enhanced T1 axial image) and thallium scan in a 34-year-old man with glioblastoma multiforme previously treated with surgery and radiotherapy. Postradiotherapy rim enhancement was seen at the surgical site (solid arrow). The thallium SPECT scan revealed markedly increased radiotracer accumulation at the same site (dashed arrow) confirming tumour recurrence rather than radiation necrosis. The patient died 4 months later and tumour recurrence was confirmed at autopsy.

Musculoskeletal Tumours

Through its properties as a nonspecific tumour agent, thallium has been used as a noninvasive way to differentiate benign from malignant bone and soft tissue sarcomas and to assess for metastases and recurrence (Sato *et al.*, 1998). While it does have a role to play in these areas in certain patients, e.g. it has been used to evaluate for metastases in osteosarcoma and Kaposi sarcoma with some success, its greatest potential is in assessing response to therapy. Studies in both osteosarcoma and soft tissue sarcomas have shown that changes in thallium uptake in response to preoperative chemotherapy are highly predictive of tumour necrosis percentages at surgery, which in itself is an important prognostic factor. Here, thallium is acting again as a viability marker, and a mid-course thallium scan is predictive of the final postchemotherapy response (Sumiya *et al.*, 1998). A less than 20% decrease in the thallium index (tumour-to-contralateral normal bone/soft tissue uptake) indicates a minimal response to chemotherapy. This is much more helpful than [^{99m}Tc]MDP bone scans in the same situation.

Procedure for Musculoskeletal Tumour Imaging

No patient preparation is necessary. A 2–3-mCi dose of ^{201}Tl chloride is administered intravenously and imaging commences 30–60 min later. SPECT imaging is optional, but patients benefit from SPECT imaging of the local tumour site.

Image Interpretation

In a similar way to brain tumours, the activity in the tumour can be compared with the contralateral limb or body region. This semiquantitative information is vital for assessing treatment response, and may be of some help in differentiating benign from malignant lesions, although there are limitations as indicated below.

Pitfalls of Thallium Musculoskeletal Imaging

Unfortunately, the significant incidence of both false-positive and -negative studies when attempting to use

thallium to differentiate benign from malignant musculoskeletal processes limits its use in this regard. Thallium accumulation has been reported in histiocytosis X, giant cell tumours, stress fractures and myositis ossificans. Lack of uptake has been reported in liposarcomas and myxoid tumours.

Other Potential Indications

Thallium has been investigated in several other soft tissue tumours including Kaposi sarcoma (where it is useful in combination with gallium scanning in distinguishing between intrathoracic lymphoma, Kaposi sarcoma and infection) and thyroid cancer. It is less sensitive than ^{131}I in detecting thyroid metastases in well-differentiated thyroid cancer, but has a potential role in the ^{131}I-negative, thyroglobulin-positive patient (i.e. less well differentiated thyroid malignancies). In medullary cell carcinoma of the thyroid, both pentavalent ^{99m}Tc–DMSA and octreotide appear more sensitive.

GALLIUM SCANNING

Basic Principles

Gallium-67 citrate is an agent that has been used for bone scanning and the detection of areas of inflammation or infection, but its greatest role has come in the field of oncology. Many tumours are known to accumulate gallium but it has been used most commonly in cases of lymphoma.

The exact reason for the concentration of gallium in various tumours is not clearly defined. Gallium is an analogue of iron and is bound in the plasma to transferrin and lactoferrin. It has been suggested that gallium binds to intratumoural ferritin stores.

Indications

Most lymphomas do accumulate gallium, to a greater extent in Hodgkin disease than in non-Hodgkin lymphoma (Turner *et al*., 1978). In these instances, gallium scans can play two roles: detection of sites of disease for staging purposes and follow-up after therapy. Since gallium scans have poor anatomical resolution, interpretation of scans is aided by a correlative study such as CT.

It is possible for gallium scans to detect sites of disease not seen by CT. This is especially true in the abdomen, where the presence of bowel can be limiting, as well as in the spleen. A baseline gallium scan is also helpful in ascertaining that the tumour in a patient who will be followed is initially gallium avid. The greatest value of gallium comes in its role in the follow-up of disease. Soft-tissue masses detected by CT may remain after treatment even when all active disease has been eradicated. Gallium is more highly specific: only active lymphoma itself will accumulate the radiotracer.

Procedure

It is now standard technique to use a higher dose of gallium for the detection of tumour than was previously used in cases of infection. This is called the ‘high-dose’ gallium scan and involves the intravenous administration of 10 mCi of ^{67}Ga citrate. Gallium has a physical half-life that is longer than that of technetium (78 h) and imaging is carried out over a period of several days. Initial images are typically acquired about 2–4 days after the administration of the dose. Since normal bowel excretion can complicate the interpretation of the images of the abdomen, delayed images are often obtained. Bowel contents will change in position and fade whereas tumour will retain its configuration and if it changes at all will probably show an increase in the target-to-background ratio. Many sites also perform tomographic (SPECT) imaging of the chest, abdomen and pelvis. The use of laxatives to clear colonic activity is somewhat controversial. It has been suggested that laxatives may inflame the colon and cause a resultant increase in bowel activity.

Image Interpretation

The normal distribution of gallium differs somewhat from patient to patient but, in general, activity will normally be seen in the liver, skeleton (and bone marrow), spleen, salivary glands, lacrimal glands and breast tissue in females. As mentioned above, gallium is excreted in the bowel giving rise to variable intestinal activity. Gallium is excreted through the kidneys during the first 24 h; renal and bladder activity is minimal by 72 h.

In patients with lymphoma an abnormal study is manifested by increased radiotracer activity at sites of adenopathy. It is common to see disease in the mediastinum, hilar, neck, retroperitoneum and pelvis (see **Figure 6**). Lymphoma may also involve other sites, including the spleen, bones and kidneys.

Pitfalls

Diffuse uptake within the lungs themselves may be due to lymphoma but gallium also accumulates in areas of inflammation. Diffuse uptake, therefore, may also be due to pulmonary toxicity from prior chemotherapy or to a superimposed pneumonia in an immunocompromised patient. Normal physiological uptake of gallium in the hilar is common. It is faint and symmetric and is not accompanied by mediastinal activity or corresponding abnormalities on a CT scan. Bowel uptake mimicking intraabdominal adenopathy has already been described and can be reduced by delayed imaging.

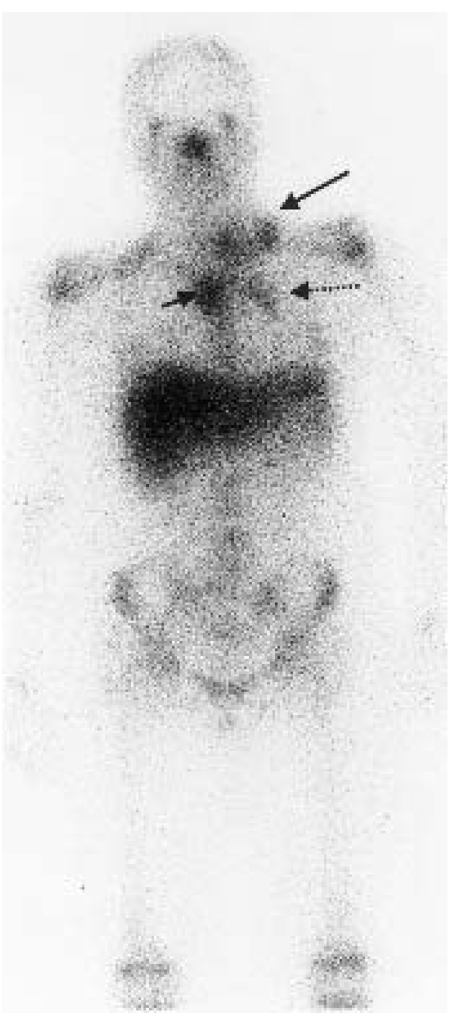

Figure 6 Gallium-67 scan in a 19-year-old woman with newly diagnosed Hodgkin lymphoma showing intense gallium accumulation in the left supraclavicular nodes (solid arrow), mediastinum (small arrow) and left hilum (dashed arrow). These findings were confirmed on the SPECT images (not shown).

Other Roles

Areas of increased activity can also be seen in other forms of tumour. Gallium is avidly taken up at sites of melanoma and has been used in the diagnosis of hepatocellular carcinoma.

MONOCLONAL ANTIBODIES

Within the past several years, several monoclonal antibodies with radioisotope labels, long investigated for the detection of tumour, have received FDA approval and become commercially available in the United States. Now in use are satumomab pendetide for colorectal and ovarian carcinoma (Oncoscint from Cytogen), capromab pendetide for prostate carcinoma (Prostascint from Cytogen), nofetumomab merpentan for small cell lung carcinoma (Verluma from DuPont) and arcitumomab for colorectal carcinoma (CEA-scan from Immunomedics).

Basic Principles

Each of these monoclonal antibodies will bind to an antigen that is found in fairly high abundance on the tumours in question. These antibodies are produced in cell cultures from murine (mouse) lymphocytes that are combined (hybridized) with myeloma cells. Specific cell lines are then screened, isolated and the antibody-producing cells are cloned. The antibodies are then radiolabelled with indium-111 (Oncoscint and Prostascint) or with the superior imaging agent technetium-99m (Verluma and CEA-scan). Scanning with these agents is generally used in situations wherein there is the suspicion of tumour recurrence or metastases (e.g. an elevated CEA or PSA) but other imaging studies (e.g. CT or bone scanning) have failed to detect disease.

Imaging Protocol

Imaging acquisitions differ slightly for each of the agents utilized. The indium-labelled agents are imaged starting 2–4 days after the dose administration. Owing to variable and potentially confusing bowel excretion, the studies are coupled with bowel preparation with laxatives and possibly delayed sets of imaging. It is typical to image Prostascint along with a blood pool label (technetium-99m) in a dual window setting to separate out normal Prostascint activity within the vasculature. Technetium labels provide a higher count rate and, therefore, can be imaged earlier. CEA-scan is performed at 4 h and Verluma at 16 h postinjection.

Scan Interpretation

Areas of metastatic or recurrent prostate cancer in Prostascint scans usually appear as focal abnormalities, most often in the prostate bed or pelvic lymph nodes (see **Figure 7**). Great care must be taken to separate normal from abnormal activity. As mentioned above, normal activity within bowel and blood pool is common. It is also normal to see activity in the liver, spleen, kidneys and bladder as well as bone marrow. Faint uptake in a normal prostate does occur. Prior irradiation may also be a cause of increased activity. Correlation with other imaging studies, such as CT, is often very helpful for delineation of normal anatomy. Other antibodies have a similar appearance; all have relatively high background activity.

Accuracy of Imaging

At present, monoclonal antibody imaging is not indicated as a first-line imaging procedure for diagnosis or staging.

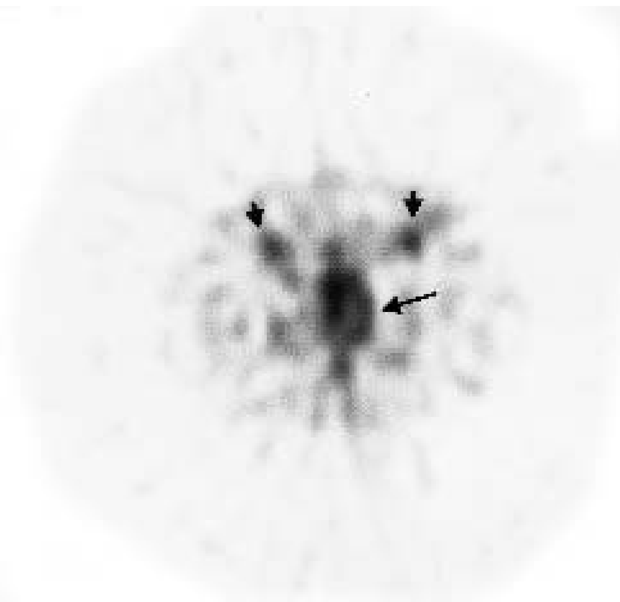

Figure 7 [^{111}In]Prostascint (capromab pendetide) SPECT scan in a 68-year-old man with a history of prostate cancer s/p radical prostatectomy with a rising PSA. Transaxial image through the pelvis shows evidence of recurrence in the prostate bed (solid arrow). The two anterior foci of radiotracer uptake (short arrows) reflect blood pool activity within the illiac vessels.

Because these agents are typically used to detect occult disease not uncovered by other modalities, the sensitivity is not extremely high. The sensitivity of Oncoscint for detecting recurrent colon carcinoma is reportedly 75% in the pelvis and 67% in the extrahepatic abdomen and for recurrent ovarian carcinoma 59%. The accuracy of Prostascint for the detection of pelvic lymph node metastases in presurgical patients has been reported to be 76% (Babaian *et al*., 1994). This is still considerably higher than with CT. With care taken to exclude false-positive studies, especially by paying attention to bowel and blood pool activity, the specificity of these studies can be fairly good. Imaging with monoclonal antibodies has been shown, in multiple studies, to be of value in the detection of occult disease (Manyk, 1998).

Precautions

Monoclonal antibodies are proteins that are, technically speaking, foreign to the human body and, as such, can cause allergic reactions. Serious side effects are few but these agents need to be administered with care. Also, because of the nature of these proteins, patients may form antibodies against these agents. These are known as human anti-mouse antibodies (the 'HAMA' reaction). This reaction occurs with variable frequency but the significance of the production of HAMA is that it may lead to reduced sensitivity of subsequent studies performed with murine antibodies.

Future Directions: Therapy

By labelling monoclonal antibodies with potentially β-emitting isotopes such as iodine-131, it is possible that these agents can be useful therapeutically. The antibody will theoretically deliver a high dose of radiation directly to the tumour itself and avoid the side effects that occur with general systemic treatment. Owing to the variable uptake of the agents that exist today, this science should be considered to still be in the early stages of development. With present antibodies, the radiation dose to the bone marrow is frequently the dose-limiting factor.

PEPTIDES

Peptides are small compounds composed of sequences of amino acids. Only one peptide has been in common use in nuclear medicine, pentetreotide or Octreoscan (Mallinckrodt).

Basic Principles

Pentetreotide is an analogue of another peptide, somatostatin. Receptors to somatostatin are found in abundance on many neuroendocrine tumours, particularly gastrinoma, glucagonoma, small cell lung cancer and carcinoid. Somatostatin receptors are also frequently found on other tumours, including lymphoma, medullary cell carcinoma of the thyroid, breast cancer and meningioma.

Imaging Protocol

Pentetreotide is labelled with indium-111, and is administered intravenously. Images are acquired 4 and 24 h and sometimes 48 h later. SPECT imaging of the region of interest is normally performed. There is intense uptake in kidneys and spleen and normal activity is also seen in the liver and, in varying amounts, in the bowel.

Indications

Indications for performing of [^{111}In]pentetreotide imaging can be divided into several categories. First, patients with a known neuroendocrine tumour can be scanned for the presence of metastases. The converse can also be applied: patients with a known metastasis can be scanned in search for the primary lesion. Studies have shown that of [^{111}In]pentetreotide can add information beyond CT and MRI (Olsen *et al*., 1995). Finally, scans are performed in patients with known disease to determine the receptor status of a tumour (**Figure 8**). Somatostatin receptors

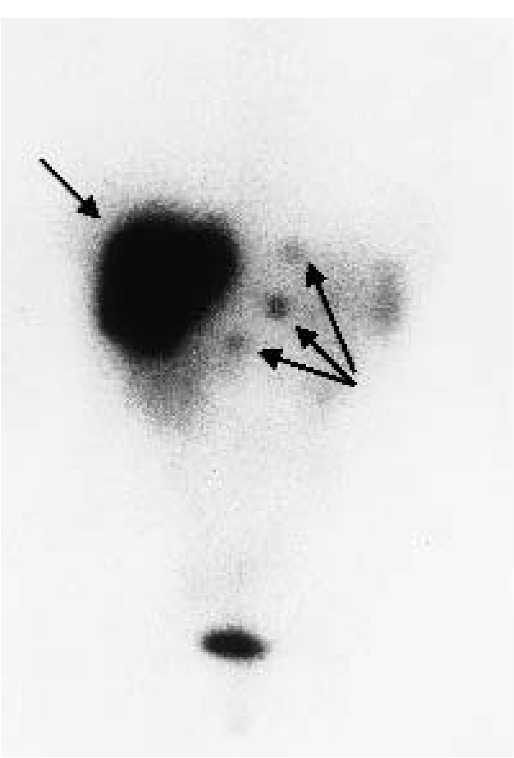

Figure 8 [^{111}In]pentetreotide scan in a 40-year-old woman with metastatic carcinoid showing multiple hepatic metastases (arrows).

occur in amounts that may vary from patient to patient. If uptake of [^{111}In]pentetreotide is confirmed with the imaging study, the patient can be considered a candidate for therapy with nonradioactive octreotide acetate, an inhibitor to neuroendocrine tumour growth.

Future Prospects

Other peptides are in development and play roles in tumour imaging. One of them, depreotide (Neotect, Diatide) has recently received approval from the FDA for small cell lung cancer. This agent is also a somatostatin analogue but is coupled to technetium, an isotope with imaging characteristics that are superior to those of indium.

As was mentioned with the monoclonal antibodies, there are potential therapeutic capabilities with peptides. The peptides may be labeled with β-emitters and studies are under way involving the administration of high-dose Octreoscan to evaluate tumour treatment with emitted conversion electrons.

SCINTIMAMMOGRAPHY

In recent years, scintigraphic techniques have been devised for the imaging of primary sites of breast cancer. Known most commonly as scintimammography, [^{99m}Tc]sestamibi has been the agent most frequently used for this purpose.

Principles and Indications

The mechanism for sestamibi concentration by breast carcinoma cells (and several other tumours) is not well understood. It is possible that the agent is localized in the intracellular mitochondria of metabolically active tumour cells. Nevertheless, uptake tends to be a good predictor of malignancy.

Scintimammography is not indicated as the first-line imaging study in patients with suspected breast cancer but is used in complicated situations where additional information is needed above what has been determined by conventional mammography or ultrasound. Indications include additional workup of the indeterminant mammographic lesion or of a palpable mass not detected by mammography, as may occur in patients with dense breasts.

Imaging Protocol

Sestamibi is administered intravenously in a dose of 20 mCi into the arm contralateral to the suspected lesion. This is done to avoid potentially confusing lymph node uptake that may occur normally if some of the injected dose is infiltrated in the arm. If there are suspicious lesions in both breasts, another site, such as the foot, should be used. Imaging commences about 10 min later and is typically performed in the anterior and lateral projections. Lateral images are improved with the patient positioned prone on a customized scintimammographic pad. This is a device with a cut-out that allows the breast to hang dependently away from the chest wall. Tomographic imaging may also be performed but its value has not been defined.

Scan Appearance and Utility

Uptake of the tracer within malignancy typically appears as a focal area of increased activity with a substantial target to background ratio (**Figure 9**). It is possible to find multiple lesions in addition to uptake within axillary adenopathy. Scintimammography has several advantages over conventional mammography with considerably higher specificity (89% compared with around 30% for mammography) (Khalkhali *et al*., 1995). In addition, imaging is not hindered by dense breasts.

Pitfalls

The greatest limitation of scintimammography is that it utilizes a technology with a relatively low spatial resolution. Lesions under 1 cm in size are difficult to visualize. For lesions >1 cm the sensitivity is >92%. False-positive uptake occurs in some benign lesions such as cellular fibroadenomas and active inflammation.

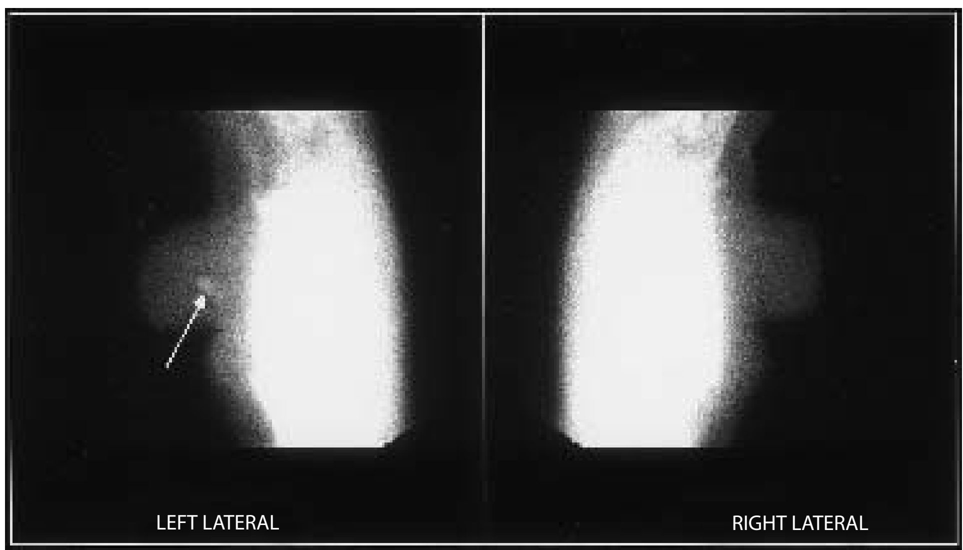

Figure 9 Scintimammogram using [^{99m}Tc]MIBI in a 55-year-old woman with an indeterminate left breast mass on mammogram and ultrasound showing intense focal uptake of tracer (arrow). Invasive ductal carcinoma was confirmed at biopsy.

MIBG

MIBG or Meta-iodobenzylguanidine is a pharmaceutical that has been utilized for a number of years for imaging phaeochromocytoma and neuroblastoma. It has only recently, however, received FDA approval and is now commercially available.

Principles

MIBG is an analogue of norepinephrine that is labelled with the iodine isotope ^{123}I or ^{131}I (although only the ^{131}I-labelled MIBG is produced commercially). MIBG is concentrated by the adrenal medulla and in adrenergic tumours, most significantly phaeochromocytoma and neuroblastoma. Most of the uptake of MIBG occurs as an active process with localization of the molecule in catecholamine hormonal storage vesicles. Iodine-131 emits β-particles and high-energy γ-rays. It has a long half-life and can only be utilized in the relatively low dose of 0.5–1.0 mCi. This results in a relatively low count study. Sites that are approved for use of the ^{123}I label find better image quality owing to the higher administered dose (^{123}I has no β-emissions and more ideal γ-energies and a shorter half-life than ^{131}I).

Indications

MIBG is used in patients who are suspected to have a phaeochromocytoma based on biochemical analysis but no detectable tumour in other imaging studies (e.g. CT, MR). This agent has the advantage of easily allowing scanning of the entire body. It should be kept in mind that 10% of phaeochromocytomas can occur in an extra-adrenal location. It can also be used in patients with known tumour for the detection of sites of metastases (10% are malignant) or in a search for multiple primary sites (as may occur in the multiple endocrine neoplasia syndrome). In patients with neuroblastoma, MIBG also may be used for the detection of metastases. MIBG also plays a role in treatment planning. Patients may be candidates for a therapeutic trial of MIBG if the tumour can be visualized with a diagnostic scan (see below).

Imaging Protocol

The exact protocol depends on whether ^{131}I or ^{123}I is utilized. The ^{131}I-labelled agent will be discussed. The pharmaceutical is administered intravenously with a slow push (to avoid the development of acute hypertension). Images are acquired 48 h later and should be tailored to the areas of concern. Planar images of the entire body can be obtained and it is possible to perform SPECT (although this is vastly superior with the higher dose of ^{123}I) of the chest or abdomen as needed. Patient preparation is needed for this examination. A number of medications can inhibit the uptake of MIBG by phaeochromocytoma and must be discontinued. These include Labetalol, calcium channel blockers and phenylephrine. It is also necessary to pretreat the patient with potassium iodide (oral SSKI or Lugol's solution) in order to block thyroid uptake of radioactive iodine and hence to reduce the radiation dose to the thyroid.

Accuracy and Limitations

Phaeochromocytoma (or neuroblastoma) will appear as a focal area of abnormal activity. Sensitivities for the detection of phaeochromocytomas with MIBG have been

estimated to be about 85%. Care must be taken to avoid confusing adrenal tumour with excreted activity in the renal pelvis. To clarify the position of the kidney relative to the suspected abnormal activity, a dose of a renal agent such as [^{99m}Tc]DTPA can be administered when the MIBG imaging is complete. Phaeochromocytoma can also occur in or near the bladder. It may be necessary to place a bladder catheter and flush the bladder to remove normally excreted activity (McEwan *et al*., 1985).

Future Directions

The use of MIBG for therapy remains in the early stages of development. Because this is an iodinated pharmaceutical, the β-emissions from ^{131}I can be used to administer a high dose of local radiation when administered in large amounts. MIBG has been used for the treatment of neuroblastoma in children.

POSITRON EMISSION TOMOGRAPHY

General Principles

Positron emission tomography uses both different isotopes and different camera systems to image the distribution of radioisotopes within the body, but as with conventional nuclear medicine techniques it is a functional imaging method. While most single photon-emitting isotopes such as ^{99m}Tc decay through the emission of a single γ-ray, positron-emitting isotopes decay through the emission of a positron of variable energy. This positron travels 1–5 mm through the tissues, the distance depending on the energy of the positron before colliding with a nearby outer-shell electron. This 'annihilation reaction' converts matter to energy and results in the production of two 512-keV γ-rays at almost exactly 180° to each other. It is these paired γ-rays which are detected by the PET camera, which consists of rings of multiple scintillation crystals (each like a tiny gamma camera only using different crystal technology) linked in pairs 180° across from each other. All PET images are multiplanar (in a similar way to SPECT). The physics of PET result in superior image resolution compared with SPECT and the production of the positron-emitting radiotracers is relatively easy owing to the smaller atom size. Many of the PET isotopes are radioactive isotopes of atoms normally present in many physiological compounds such as carbon, nitrogen and oxygen. This means that most PET radiotracers are much closer in composition to normal physiological substrates. On the other hand, ^{18}F, a commonly used isotope, can substitute for hydroxyl ions ($^{-}$OH). These factors enable PET to image a wide variety of physiological processes such as blood flow, metabolism (glucose, amino acid, fatty acid, protein, etc.) and receptor density *in vivo* with very good anatomical resolution. The oncological potential is extensive and only recently has become realized.

There are two major problems that have prevented the wide availability of PET. The first is the expense of the camera system, at $1–2 million at 2000 prices. The second is that most PET isotopes have to be produced by a cyclotron, an even more expensive piece of machinery with high upkeep demands in both manpower and cost. The half-life of PET isotopes is much shorter than those of single-photon isotopes: whereas the ^{18}F half-life is 110 min, ^{11}C is only 20 min, ^{13}N 10 min and ^{15}O only 2 min. This significantly limits the distribution of these isotopes from central cyclotrons. Recently, two advances have led to the much wider availability of PET. First, conventional SPECT-enabled gamma cameras can be upgraded at reasonable cost to detect the paired 512-keV γ-rays (so called 'coincidence detection') although with lower but acceptable spatial resolution than dedicated PET cameras. Second, several networks of cyclotrons have been set up to distribute commercially [^{18}F]Fluorodeoxyglucose (^{18}FDG), the most commonly utilized PET radiotracer. These two factors are currently leading to an explosion of PET across many countries in the world. It is likely that within a few years, ^{18}FDG PET will become an essential component of oncological patient management in most oncology centres. For the purposes of the following sections, dedicated PET and coincidence detection will be discussed as a single entity. Increasingly the technical advances in coincidence detection are bringing its accuracy closer and closer to that of dedicated PET.

In oncology, most clinical PET imaging uses ^{18}FDG, with other isotopes being mainly investigational and mentioned briefly in a later section. Imaging can be of a local region (e.g. the head or chest) or of the entire body in one session.

^{18}[F]Fluorodeoxyglucose Imaging

Principles of ^{18}FDG Imaging

[^{18}F]Fluorodeoxyglucose is an analogue of glucose. It enters the cell at rate proportional to that of glucose, using the same glucose transporter system. It also undergoes the first step in glycolysis to produce ^{18}FDG-6-phosphate (via hexakinase) but is not a substrate for the next enzyme in the cascade (glucose-6-phosphatase). ^{18}FDG-6-phosphate does not readily cross the cell membrane and hence remains trapped in the cell. The local concentration of ^{18}FDG-6-phosphate as recorded by the radioactivity 30+ min after ^{18}FDG injection is therefore a measure of the local glycolytic rate. This method has advantages over another PET method for measuring glycolysis, with [^{11}C]glucose, as the latter, by passing readily through glycolysis and beyond, results in imaging of a combination of glucose uptake, metabolism and metabolite distribution.

For decades, glycolytic rates have been known to increase in neoplasms and for many neoplasms this rate is proportional to the degree of malignancy (anaplasia) of the tumours. In benign processes, the glycolytic rates tend to be low. ^{18}FDG imaging therefore has the potential to distinguish between benign and malignant processes, grade tumours, identify metastases and diagnose tumour recurrence. ^{18}FDG is a very nonspecific tumour imaging agent, and it has been used in practically every tumour type for one or more of the above indications although currently only a handful are in routine clinical usage (typically in the USA those covered by Medicare). As of 2000, these include differentiating benign from malignant lung nodules, staging of non-small cell lung cancer, lymphoma staging, melanoma staging, oesophageal cancer staging, head and neck cancer and diagnosing colorectal tumour recurrences. These and some of the other more common indications not currently covered by Medicare are described below.

Solitary Pulmonary Nodule (Coleman, 1999)

Previously, CT and plain films along with biopsy have been the mainstays for solitary pulmonary nodule evaluation. ^{18}FDG PET has an important role to play, however. Malignant nodules have increased rates of glycolysis, and hence increased ^{18}FDG uptake relative to benign processes such as hamartomas and granulomas. The sensitivity of PET is 90–100%, with a specificity of 75–95% for differentiating benign from malignant nodules. Nodules which are positive on ^{18}FDG scanning should therefore be biopsied; those which are negative are generally safe to follow. By following this protocol, the number of potentially harmful and expensive lung biopsies can be reduced significantly. Some centres incorporate a semiquantitative measure of ^{18}FDG uptake into their evaluation – the standardized uptake ratio (SUR), which estimates the amount of the injected radiotracer taken up into the tumour relative to the injected dose and patient's body mass. This may help differentiate further between benign and malignant processes, although not all authorities agree. Several studies have indicated that the SUR is inversely proportional to survival times in primary lung cancer. False-positive scans do occur occasionally in inflammatory processes in particular and false-negative scans have been reported in slow-growing carcinoid and occasionally bronchoalveolar tumours. Continued monitoring over time of ^{18}FDG PET-negative tumours by CT or CXR should identify these patients.

Lung Cancer Staging (Coleman, 1999; Kalff *et al.*, 2001)

The identification of lymph node and distant metastases is a major component of the staging of non-small cell lung cancer. This staging determines the patient's potential operability. Both CT and MRI rely on the size of the lymph nodes as a criterion for malignancy, with a 1-cm short axis dimension conventionally being used as the cut-off for potential malignancy. Obviously smaller nodes than these may be malignant, and larger nodes benign. The sensitivity and specificity of CT for staging lung cancer have been reported to be as low as 50–70%. This leads to frequent mediastinoscopies and even patients being found to be inoperable (or at least incurable) at the time of surgery. By imaging function rather than anatomy, ^{18}FDG PET significantly adds to the preoperative work-up of these patients with accuracies of 80–100%, considerably superior to CT or MRI. PET has been found to change lung cancer staging in up to 30% of patients – even after CT scanning has been performed (**Figure 10**). The ability to image the whole body allows the additional identification of unsuspected distant metastases including evaluating the adrenal glands, a common site of lung cancer metastases. In this latter area PET has been reported to have a 100% sensitivity and 80% specificity for metastatic involvement. The addition of ^{18}FDG PET to the routine preoperative evaluation of patients with lung cancer has been shown to result in significant cost savings – calculated as $98 million per year across the USA if all potentially resectable patients underwent PET scans. ^{18}FDG PET has also been used to evaluate for local tumour recurrence following surgery and/or radiotherapy or chemotherapy. These patients are typically very difficult to assess by CT owing to the considerable postoperative or postradiotherapy changes. Focally increased ^{18}FDG uptake in these patients is indicative of tumour recurrence with extremely high accuracy.

Lymphoma Staging (Delbeke, 1999b)

Although ^{67}Ga is currently the major functional imaging method for the staging of lymphoma, ^{18}FDG PET has some significant advantages. The resolution is significantly better, not all lymphomas are gallium avid whereas most are ^{18}FDG avid and the imaging can be performed on a single day rather than stretched out over several days as with gallium (Moog *et al.*, 1997). The uptake of ^{18}FDG is proportional to the grade of lymphoma, and hence inversely proportional to prognosis. Bone marrow involvement will show on the PET scan better than on a gallium scan. Very low-grade lymphomas may be ^{18}FDG negative. In the posttherapy patient, the advantages become more marked with ^{18}FDG PET predicting the response to treatment, even in the presence of residual masses on CT. Of importance, ^{18}FDG PET like gallium cannot be used to differentiate lymphoma from sarcoidosis (a not uncommon problem), as both are ^{18}FDG avid.

Melanoma Staging (Delbeke, 1999b)

Melanoma is a highly malignant tumour that may metastasize to any organ of the body. For this reason, staging and monitoring these patients is difficult, frequently requiring several different imaging modalities and metastases to unexpected areas such as the bowel and extremity subcutaneous tissues may frequently be missed. Owing to

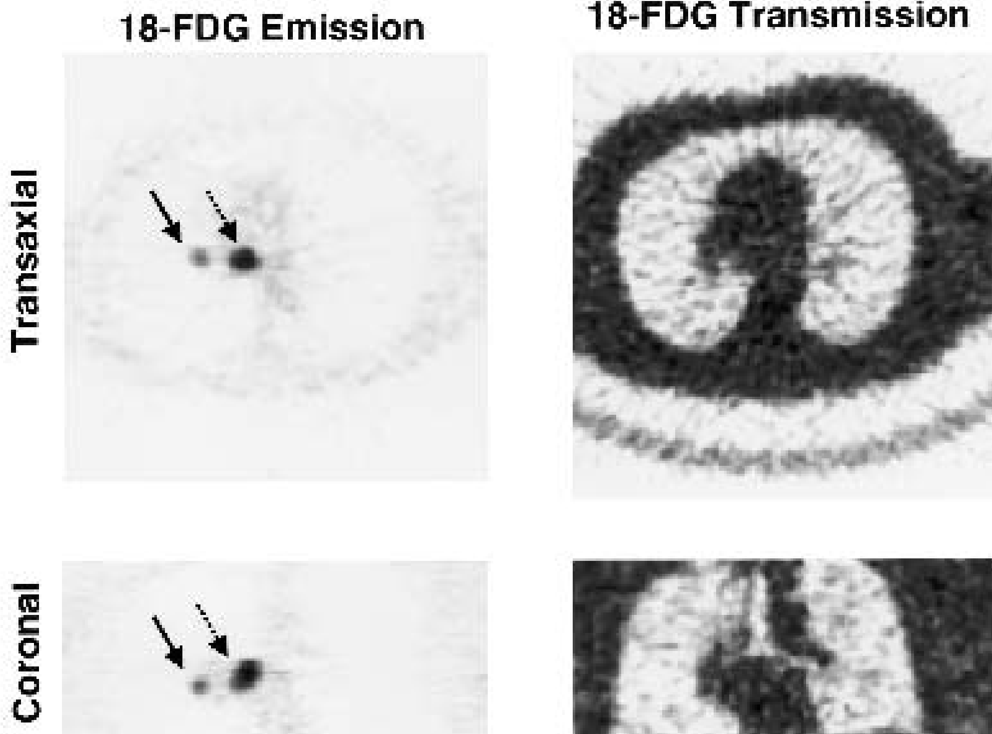

Figure 10 Transaxial ^{18}FDG emission scan through the thorax at two levels with corresponding transmission scan at the same level to show localization in a 62-year-old man with known lung cancer (primary tumour not shown). Focal uptake of ^{18}FDG in the mediastinum (dashed arrow) and right hilum (solid arrow) were due to nodal metastases confirmed at surgery. (Images courtesy of the Clinical PET Centre, United Medical Schools of Guy's, St. Thomas' and King's Hospitals, London, UK.)

its high degree of malignancy, even small melanoma metastases are typically intensely ^{18}FDG avid and the whole-body imaging capability of PET enables a single scan to assess for metastases literally from head to toe. ^{18}FDG PET scanning has been shown to be an accurate (88–100%) and cost-effective method of staging melanoma (Rinne *et al.*, 1998).

Colorectal Tumour Recurrence (Delbeke et al., *1997)*

The postoperative evaluation of colorectal tumours by CT is hampered particularly in the surgical site by postsurgical and/or radiotherapy changes. Small hepatic metastases may also be missed. Serum markers such as CEA may indicate a recurrence but these are nonspecific and nonlocalizing. Monoclonal studies such as CEA scan (described above) have limited sensitivity and specificity for detection owing to high background activity and poor resolution. ^{18}FDG, on the other hand, is not taken up by postsurgical and chronic radiation changes, and has lower background activity and higher resolution than monoclonal studies. Activity within the bladder and normal bowel activity must, however, be carefully distinguished from tumour recurrence. ^{18}FDG PET has been shown to be highly accurate (92%) for diagnosing and localizing local and distant colorectal tumour recurrence, including hepatic metastases, changing surgical management in 28% of patients after CT (Delbeke *et al.*, 1997). In patients with negative CT scans but rising CEA levels, PET identified the site of metastases in 87% of patients (Maldonado *et al.*, 2000). Scans performed within 6 months of radiotherapy may result in false-positive results owing to local inflammation. The response of hepatic metastases to chemotherapy can be predicted by ^{18}FDG PET scans 4–5 weeks into treatment.

Brain Tumours (Delbeke, 1999b)

Some of the earliest ^{18}FDG PET studies investigated brain tumour metabolism. The uptake of ^{18}FDG was found to be highly correlated with tumour grade (Jolesz, 1983), and in fact a better marker of prognosis than histology. ^{18}FDG PET has therefore been used as a prognostic marker, as a method of indicating the areas of highest malignant potential (hence highest ^{18}FDG uptake) for biopsy and for diagnosing tumour recurrence. The primary energy source for the brain is glucose, and this leads to high physiological cortical uptake of ^{18}FDG. Tumours which have lower metabolic activity than the surrounding cortex (such as grade 1 and 2 gliomas) may be difficult to distinguish from surrounding cortex. Despite this, ^{18}FDG PET has an

important role to play in differentiating tumour recurrence from radiation necrosis in a similar manner to thallium, particularly in the higher grade tumours. ^{18}FDG PET has been used to differentiate lymphoma from toxoplasmosis in AIDS patients, again similar to thallium with very comparable results.

Breast Cancer (Delbeke, 1999a)

^{18}FDG PET has been used for the diagnosis, staging and evaluation of recurrence in breast cancer. The sensitivity and specificity for primary diagnosis ranges from 80–100%, with false negatives occurring in <1-cm tumours and slow growing tumours (Avril *et al*., 1996). It may be useful in patients with dense breasts, after augmentation mammoplasty and those with equivocal mammography. The sensitivity for axillary lymph node metastases is around 95%, but it will miss micrometastases so the role here is less clear (**Figure 11**). It will, however, indicate the presence of internal mammary and distant metastatic disease. Osteolytic bone metastases are more easily detected on ^{18}FDG PET than with routine bone scanning.

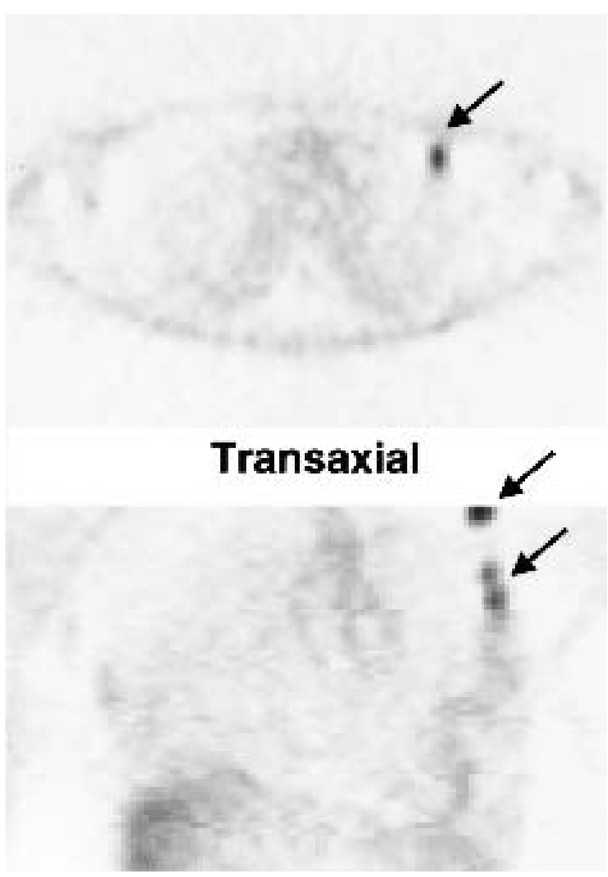

Figure 11 Transaxial and coronal ^{18}FDG emission scan through the thorax in a 58-year-old woman with left breast cancer. Multiple foci of left axillary radiotracer uptake (arrows) were due to axillary metastases. (Images courtesy of the Clinical PET Centre, United Medical Schools of Guy's, St. Thomas' and King's Hospitals, London, UK.)

^{18}FDG PET also has a potential role in the evaluation of breast cancer recurrence, particularly in the brachial plexus region where anatomical studies are particularly difficult to interpret.

Other Tumours (Delbeke, 1999a)

As indicated previously, ^{18}FDG PET scanning has been investigated for the diagnosis and staging of many tumour types. Areas that show particular promise are in the staging of head and neck tumours where improved accuracy over CT and MRI has been shown in several studies. In pancreatic cancer ^{18}FDG PET distinguishes between benign and malignant pancreatic processes with 85–93% accuracy, altering the surgical management of patients with pancreatic masses in 41% of patients in one study. ^{18}FDG PET has been of value in distinguishing between benign and malignant musculoskeletal tumours, guiding biopsy to areas of greatest malignant potential, as well in predicting the preoperative response to chemotherapy. Anaplastic ^{131}I-negative thyroid tumours may be successfully staged with ^{18}FDG PET. ^{18}FDG PET has been shown to be more sensitive than CT in detecting recurrent ovarian cancer. Considerable promise has also been shown in oesophageal tumours where again CT is limited.

Protocols

Patients are typically injected with 5–10 mCi of ^{18}FDG intravenously after a 6–12 h fast (the latter to decrease cardiac and soft tissue uptake). The patient should be resting and not talking during the uptake period. Imaging usually takes place 30–120 min later. There is some evidence that delayed imaging may improve lesion detection. Imaging may be performed of the local tumour area alone (e.g. a head and neck tumour), of the whole body (e.g. melanoma staging) or both (e.g. lung cancer staging). Local scans usually correct for the attenuation of the radiation by the body tissue through the use of a 'transmission scan,' in reality a quick and dirty CT scan using a radioactive source. This improves the resolution of deep structures and enables semiquantitative measures such as SUR measurements to be performed (see above). The studies are typically reconstructed in multiple imaging planes.

Image Registration

Image registration or image fusion is the production of an image that combines both the patients anatomical (CT or MRI) scan with the PET study. This is usually produced by some form of software manipulation with or without markers placed on the patient. This combines the anatomical information from the CT, with the functional information from the PET scan. Thus the exact localization of abnormal areas of ^{18}FDG uptake can be identified. Image registration has the potential to add considerably to PET image interpretation (**Figure 12; see colour plate section**). Recently available are combined CT and PET

scanners where both sets of scans may be obtained sequentially without moving the patient resulting in inherently registered CT and PET images.

Interpretation and Pitfalls

PET scans are evaluated for abnormal areas of significantly increased local ^{18}FDG uptake. Wherever possible, PET ^{18}FDG scans should be interpreted with knowledge of the patient's history and current anatomical studies. This is aided by image registration as described above. Physiologically intense uptake of ^{18}FDG occurs in the brain, heart (variable amounts) and urine. Moderate uptake may be seen in Waldeyer's ring, muscle and bowel. The thyroid and thymus may accumulate moderate amounts of ^{18}FDG, the latter in children and postchemotherapy patients. Very low activity is seen in fat, lung and bone, but diffuse bone marrow activity can be seen immediately after chemotherapy courses. Muscle activity (even through tension and talking) during the uptake period can significantly increase local muscle activity.

False-negative studies may occur in low-grade tumours such as low-grade lymphoma and sarcoma, in tumours with extensive necrosis and in very small lesions, particularly if of lower malignant potential (<1 cm, although smaller lesions are frequently seem when the glycolytic activity is high). Sclerotic bone metastases from prostate cancer are frequently under-diagnosed. Hyperglycaemic diabetic patients may produce false-negative studies, presumably through competition for glucose uptake. False-positive studies have been reported in inflammation and infection (such as abscesses, tuberculosis), sarcoidosis and occasionally in inflammatory nodes. With the exception of sarcoidosis, the uptake of ^{18}FDG is usually mild to moderate in these cases, and it is possible that the use of SURs or similar ratios may help in diagnosis. Scans performed too soon (<6 months) after radiotherapy may show ^{18}FDG uptake into areas of inflammation. Extravasated tracer taken up into local lymph nodes may be mistaken for metastases. Physiological activity in the bowel can sometimes be relatively intense, and the evaluation of pelvic malignancies may be impaired by urine activity in the bladder. In these patients, catheterization and possibly bladder irrigation can be helpful. Prostate cancer is particularly problematic with PET, as both primary and nodal metastatic lesions are obscured by urinary activity, and frequently the primary tumour has a low relative uptake of ^{18}FDG except in more aggressive cases.

Other Positron-emitting Radiotracers

Several other PET radiotracers are currently under investigation in oncology.

Protein Synthesis Markers

^{11}C-labelled methionine, leucine and others have been used to evaluate tumour protein (amino acid) metabolism (typically raised relative to normal tissue). Most work has been done in brain tumours, where they have the advantage over ^{18}FDG of lower background activity, and hence easier visualization of lower grade tumours from normal cortex (Kaschten *et al*., 1998) (**Figure 13**). The short half-life of these tracers (20 min) limits geographic availability, and there is some debate as to whether they image protein metabolism or a more complex combination of metabolic processes.

DNA Synthesis Markers

^{11}C-labelled thymidine and uridine have been used to assess for rapid DNA synthesis in tumours. As yet, the role of these radiotracers have to play is unclear.

Fluoride Bone Scans

$^{18}F^-$ acts as an analogue of hydroxyl ions, being incorporated into the bone matrix as a marker of osteoblastic activity. In this way a bone scan similar physiologically to [^{99m}Tc]MDP is produced. The advantages over conventional bone scans are a superior resolution and the inherently multiplanar images leading to improved accuracy for the detection of bone metastases. Its main disadvantage is the significantly increased cost.

Blood Flow Studies

Tumour blood flow (typically, but not inevitably, increased over normal tissues and benign processes) can be measured using radioactive water, $H_2{}^{15}O$. This has not yet found clinical utility, partially because of the poor resolution of these studies and the extremely short half-life of ^{15}O (2 min).

Drug Markers

By attaching a positron-emitting radioactive label to a chemotherapeutic agent, PET allows one to assess *in vivo* if a particular tumour or metastasis in an individual patient accumulates and metabolizes that drug. This has been used in colorectal tumours by labelling 5-fluorouracil (5-FU) with ^{18}F, where it appears in preliminary studies to give useful prognostic information regarding the effectiveness of this agent. These types of studies have the potential to individualize chemotherapy to optimize gains rather than waiting until after several courses of chemotherapy to assess tumour response.

Neuroreceptor Markers

PET has been used extensively in neuroimaging to assess neuroreceptor distribution and density. [^{18}F]fluorodopa is an analogue of dopamine and is taken up by the pituitary in low concentrations in the normal brain, being converted into dopamine. In functioning pituitary adenomas, markedly increased [^{18}F]fluorodopa uptake is seen. This uptake is rapidly blocked by the administration of bromocriptine

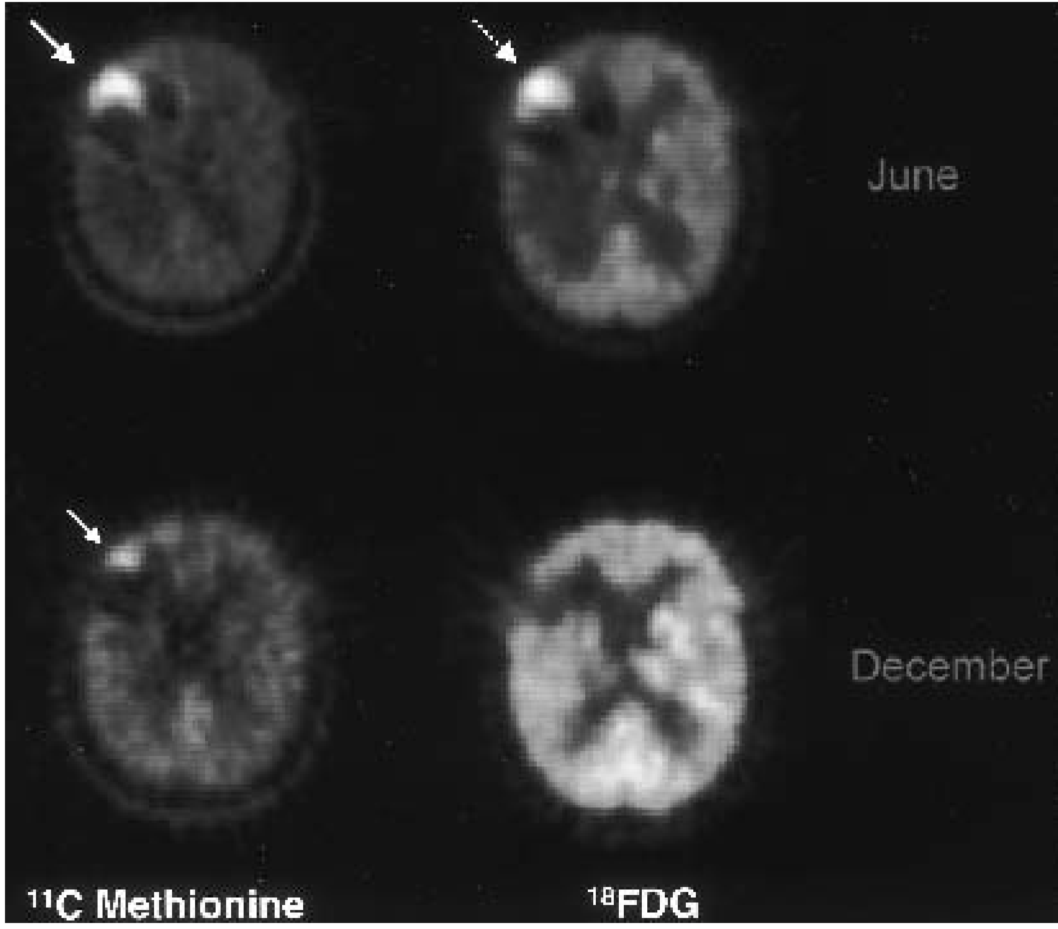

Figure 13 [^{11}C]methionine and ^{18}FDG scans in a patient with a grade 3 glioma of the right frontal lobe at two dates 6 months apart. In June (preradiotherapy), increased uptake at the tumour site is seen on both the [^{11}C]methionine (solid arrow) and ^{18}FDG (dashed arrow) studies. Postradiotherapy (December), whereas the [^{11}C]methionine scan still shows uptake consistent with residual tumour (small arrow), the tumour uptake on the ^{18}FDG scan is equal to the background cortical activity and cannot be distinguished. (Images courtesy of the Clinical PET Centre, United Medical Schools of Guy's, St. Thomas' and King's Hospitals, London, UK.)

(within hours) in those patients in whom a response to bromocriptine is later seen on MRI. In this way the PET scan predicts the success of bromocriptine therapy.

SENTINEL NODE LOCALIZATION

Principles and Indications

In recent years techniques have been developed which aim to avoid full regional lymph node dissections in patients with breast cancer and melanoma. The 'sentinel' node(s) – the node or nodes to which the area of the tumour initially drains – is identified and excised. Only those patients in whom the sentinel node contains tumour cells undergo full loco-regional lymph node dissections. The sentinel node may be identified by two methods: injecting isosulfan blue dye at the tumour site and tracing back blue lymphatics to the first draining blue node(s) or by injecting ^{99m}Tc sulfur colloid at the tumour site and using a handheld gamma probe to localize the hot nodes in the operating room at the time of surgery. In many centres both procedures are performed to maximize the sensitivity of node localization. Only the gamma probe procedure will be addressed here.

Protocol

The techniques differ between melanoma and breast cancer patients.

Melanoma

In melanoma, a total dose of 200 μCi of ^{99m}Tc sulfur colloid which has been filtered to reduce the particle size to <0.2 μm is injected intradermally at four sites around the tumour or incision site, usually using no more than 0.1 mL per injection. As the draining nodal basin is not always

predictable, especially in truncal lesions, imaging is performed immediately for 15 min, followed by delayed images at 2 h. A transmission scan is usually performed to provide a body contour for better localization. The site of the first visualized node can be marked on the patient's skin to aid localization in the operating room using the gamma probe. Usually a node with a count rate greater than 10 times the background counts when measured *ex vivo* is acceptable.

Breast Cancer

Sentinel node procedures are still controversial in breast cancer, although a recent multicentric study with over 500 patients appears to validate the technique (Tafra *et al*., 2001). There has been as yet no uniform agreement on the method of injecting the radiotracer in breast cancer. Studies have shown that unfiltered ^{99m}Tc sulfur colloid is more sensitive (with a larger particle size), but methods have included intradermal injections in the skin above the tumour, subareolar injections and injections around the tumour or excision site within the breast. Peritumoural and subareolar injections usually use a larger volume of injectate (4–5 mL), and injected doses range from 0.1 to 1 mCi. The intradermal injections are similar to those done in melanoma patients. The tumour is localized by ultrasound or palpation usually. Surprisingly, these different methods, which are sometimes performed in combination, appear to give very similar results. Imaging may or may not be performed as the drainage routes are less variable than in melanoma. Imaging may be of value in medial lesions to assess for sentinel nodes in the internal mammary chain, but its role has yet to be defined.

Accuracy and Limitations

In melanoma patients, the combined technique results in an identification rate of a sentinel node in >98% of patients, with a false-negative rate (compared with full node dissections) around 1% (Lange, 2000). In breast cancer patients various studies have shown localization rates of 87–97%, with a false-negative rate of 4.3% in the recent multicentric study (Tafra *et al*., 2001). Surgical experience in localizing the node is important.

CONCLUSION

Nuclear medicine, by virtue of its ability to image function, plays an integral role in the evaluation of patients with tumours or suspected tumours. This includes diagnosis (differentiating benign from malignant processes), staging and the evaluation of recurrence. In most cases, it acts as an adjunct to anatomical imaging methods such as plain films, CT or MRI, but on occasions it is the primary imaging method of choice (e.g. bone scanning, ^{131}I scanning). Frequently, the combination of the anatomical and functional information has a synergistic effect and this often overcomes the inherently poorer resolution of nuclear imaging. As PET becomes more widely available, it is likely that it will play an increasingly vital role in the management of oncology patients.

- Conclusion

INTRODUCTION

Mammography, a low dose X-ray examination of the breast, is performed to screen asymptomatic women for breast cancer and to diagnose and manage benign and malignant breast disease in screened and symptomatic patients. High-quality mammography is dependent on properly trained technologists using dedicated mammography equipment and physicians who are educated and trained in the subtleties of mammographic interpretation (Smith and D'Orsi, 2000). These issues have been addressed in the United States with the passage of the Mammography Quality Standards Act in 1992 which requires mammography facilities to pass periodic rigorous inspections.

Mammography is the only reliable method of consistently detecting nonpalpable breast cancer, but some cancers may not be detected owing to observer error, the location of the lesion such that it may be difficult to include on the film, a dense parenchymal pattern which can obscure a lesion or because the lesion fails to produce a recognizable abnormality (Sadowsky and Levin, 1994). It is therefore important that the mammogram be interpreted with all the available clinical information.

The field of breast imaging continues to evolve as mammographic technology improves and new technologies such as ultrasound, contrast-enhanced magnetic resonance imaging (MRI) and percutaneous biopsy procedures have been adopted. Full-field digital mammography has recently become available for clinical use. The traditional film screen cassette is replaced with a specialized detector which converts the latent X-ray image into an electronic digital image. The major advantages of digital mammography include the acquisition speed and also the ability to optimize the image by adjusting contrast and brightness, which may enhance lesion detection, particularly in the dense breast (Feig and Yaffe, 1995). The digital format allows for teleradiology, long-distance consultation and computer analysis. Studies have shown that double reading of screening mammograms can increase the number of cancers detected by 4–5%, but this is not always practical or feasible (Burhenne *et al*., 2000). A computer can function as a second reader and potentially reduce the false-negative rate of screening mammography (Burhenne *et al*., 2000).

SCREENING

Mammographic screening is the most reliable method to find early breast cancer in large populations and consists of a craniocaudal and mediolateral oblique view of each breast. In 1997, the American College of Radiology recommended annual mammographic screening for asymptomatic women beginning at age 40 years, since there was mounting evidence that younger women have a shorter lead time for mammographic detection of breast cancer (Feig *et al*., 1998). Women at high risk of breast cancer (genetic predisposition, significant family history or those receiving chest irradiation for Hodgkin disease) should begin screening before age 40 years.

Controlled studies have shown that breast cancer mortality rates can be reduced by 25–30% by screening with mammography and physical examination. The HIP (Health Insurance Plan of New York) study of 1963–1969 was the first prospective randomized controlled trial designed to evaluate the efficacy of breast cancer screening with mammography and clinical breast examination. Ten years after entry into the study, there were 30% fewer breast cancer deaths in the study group compared with the controls (Smith and D'Orsi, 2000).

The largest randomized trial of breast cancer screening is the Swedish Two-county study which included 133 000 women aged 40–74 years of whom 77 000 were invited for

screening. A single-view mammogram (MLO), without clinical breast examination, was performed every 24 months in women aged 40–49 years and every 33 months in women aged over 50 years. After 8, 11 and 14 years of follow-up, the study group had approximately 30% fewer breast cancer deaths (Smith and D'Orsi, 2000).

There has been controversy regarding the benefits of screening women in their forties with mammography. The Gothenburg randomized trial of breast cancer screening began in 1982 with approximately 52 000 women between ages 39 and 59 years, randomized to screening and control groups. After 11 years of follow-up, there was a statistically significant reduction of breast cancer mortality (44%) in women aged 39–49 years. The most recent updated reports of the Malmo trial also showed a statistically significant reduction of breast cancer mortality (36%) in women aged under 50 years at the time of randomization (Smith and D'Orsi, 2000). A meta-analysis of the screening trials was performed to overcome the limit of small sample sizes by combining age-specific results. The most current data showed 18% fewer breast cancer deaths when all trials were combined, 26% fewer deaths when only population-based trials are combined and 29% fewer deaths for all five Swedish randomized controlled trials (Smith and D'Orsi, 2000). The results of the Canadian randomized trial of breast cancer screening in women aged 40–49 years have been controversial owing to questions regarding the study design, quality of mammography and excess of advanced breast cancers in the screening group (Kopans and Feig, 1993).

Since the risk of developing breast cancer increases with age, screening of elderly women should continue at yearly intervals unless there are significant comorbid conditions. Women aged over 64 years account for almost 50% of newly diagnosed cases of breast cancer, which is the leading cause of cancer deaths in this age group (Field *et al*., 1998).

A retrospective review of 119 consecutive women aged 65 years and older with newly discovered breast cancer, who had a previous normal screening evaluation (mammography and clinical breast examination) 8–30 months before diagnosis, showed significantly smaller tumours, a higher incidence of minimal disease and DCIS (ductal carcinoma *in situ*), fewer palpable interval tumours and less axillary node involvement when elderly women were screened annually versus biennially (Field *et al*., 1998). Similar results were obtained in a retrospective review of women aged 40–79 years. In this study, annual screening resulted in the detection of smaller tumours which had a more favourable prognosis (Hunt *et al*., 1999). Annual screening mammography also resulted in lower rates of recall, for further definition of questionable findings, than when screening was performed every 2 years (Hunt *et al*., 1999). In another retrospective review of 103 malignant breast tumours detected in 102 women aged 65–74 years, there were statistically significant differences between the screened and nonscreened group with respect to the size of the lesions (11 vs 21 mm), the incidence of minimal tumours (63 vs 37%) and incidence of lymph node metastases (11 vs 30%) (Gabriel *et al*., 1997). The overall positive predictive value of mammography for the 65–74-year-old patients was 47% versus 28% in the general population (Gabriel *et al*., 1997). Annual mammographic screening also resulted in a higher likelihood of finding smaller DCIS lesions than biennial screening, and small, low grade noncomedo DCIS was more common in the annual mammographic screening group than in the biennial screening group in a retrospective review of 166 consecutive mammograms of women evaluated for DCIS (Carlson *et al*., 1999).

Although the benefits of screening mammography have been documented, it is still underutilized, especially in women aged over 65 years (Harrison *et al*., 1997). The most important barrier to screening mammography is the lack of a recommendation by a woman's physician (Rimer, 1997). Another common reason cited is that women do not need to have one in the absence of symptoms. Other less common reasons include concerns about pain and about radiation risk and anxiety about the results. It is important for physicians to recommend screening because this has been one of the most important predictors of mammography use.

Mammography is the primary imaging modality for breast cancer screening. The sensitivity of mammography decreases in women who have predominantly dense fibroglandular tissue because cancers can be obscured. Ultrasound can detect malignant lesions that are occult to mammography, but since it cannot routinely detect calcifications and it is operator dependent, it cannot be used for mass screening. It may be useful in a subset of high risk patients, particularly those with dense breast tissue on mammography (Gordon and Goldenberg, 1995). In a prospective study of screening ultrasound in women with dense breast tissue, the overall cancer detection rate increased by 17%, and the number of cancers detected with imaging alone increased by 37% (Kolb *et al*., 1998).

Contrast-enhanced MRI can also detect lesions occult to mammography and ultrasound, but it is not designed for mass screening because of cost and low throughput. It may be useful in screening of high-risk patients with dense breast tissue but current trials are in the preliminary stages (Kuhl *et al*., 2000).

DIAGNOSTIC MAMMOGRAPHY

A diagnostic mammogram is a problem-solving examination performed in patients with either clinical findings or abnormalities detected on screening mammography. It is a comprehensive evaluation that should be monitored by a breast imaging radiologist who can perform ancillary

procedures such as ultrasound, contrast-enhanced MRI or percutaneous needle aspiration or biopsy in order to provide specific management recommendations (see **Figures 1** and **2**).

A diagnostic mammogram begins with the routine craniocaudal and mediolateral oblique views. Any clinical findings should be marked on a diagram and denoted with a radiopaque marker placed on the skin over the area in

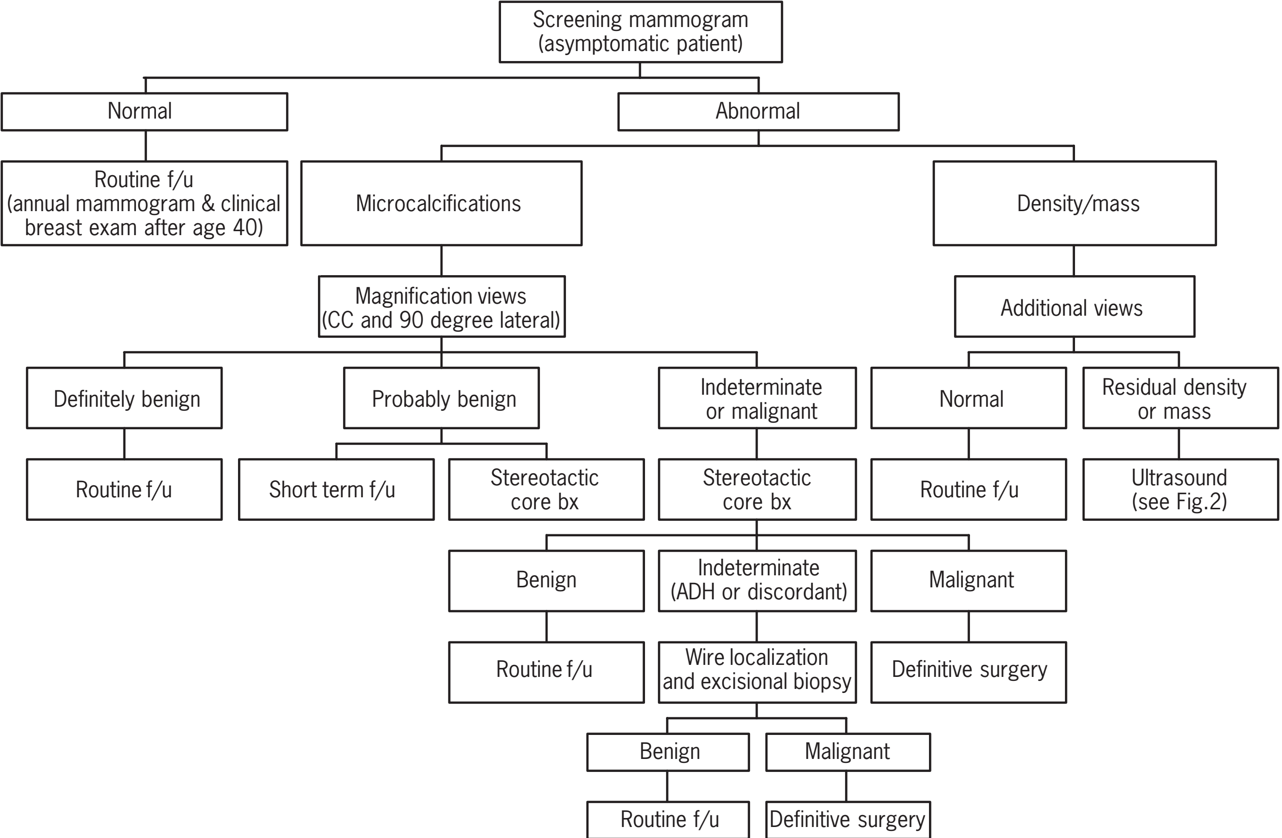

Figure 1 Breast imaging evaluation of the asymptomatic patient. f/u, follow-up; bx, biopsy.

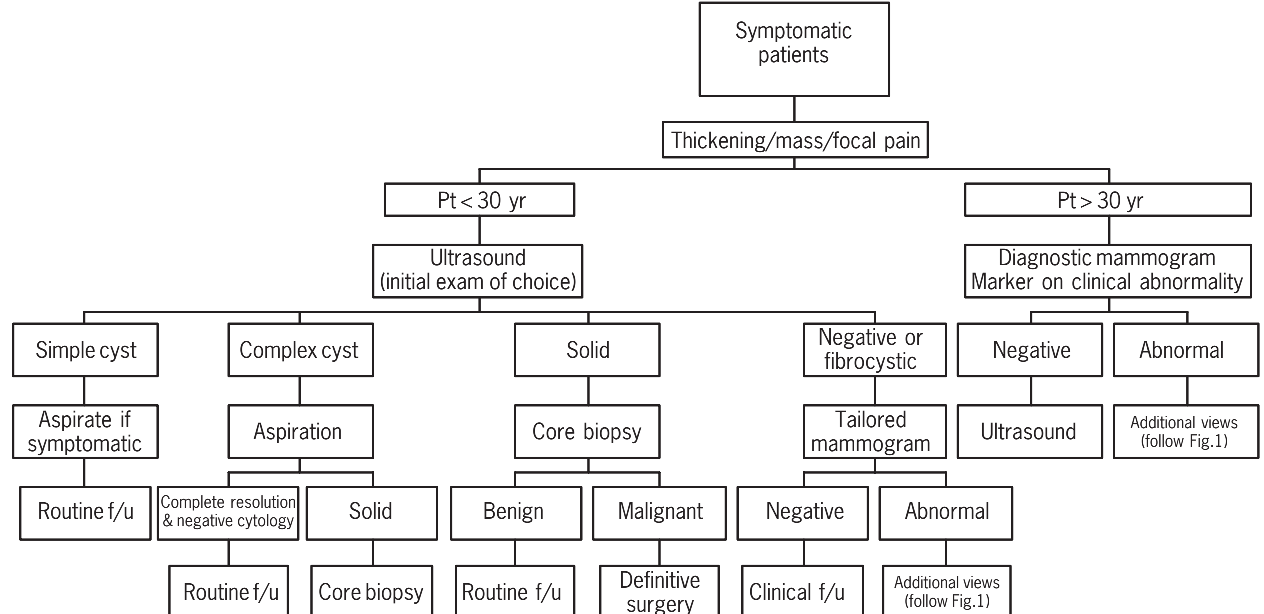

Figure 2 Breast imaging evaluation of the symptomatic patient.

question. Additional special mammographic views are performed following evaluation of the initial routine images to clarify mammographic or clinical findings. When used appropriately, additional views may reduce the number of biopsies and unnecessary short-term follow-up examinations by showing a characteristically benign mammographic sign. Alternatively, a biopsy may be indicated by suspicious features that may not be appreciated on routine films.

Mammographic findings that require further evaluation include microcalcifications, masses, architectural distortions and developing densities (particularly in post-menopausal women who are not on hormone replacement therapy).

Calcifications are often identified on both screening and diagnostic mammograms. The morphology, size and distribution of the microcalcifications are features that must be analysed to differentiate between benign and malignant calcifications. Magnification views in the craniocaudal and 90° lateral projections should be performed to characterize better calcifications that are seen on routine views. Calcifications that can be classified as definitely benign include dermal, vascular, secretory, eggshell and coarse calcifications related to involuting fibroadenomas or fat necrosis. Calcifications which occur in micro- or macrocysts can be confidently diagnosed as benign by their change in appearance between the craniocaudal and true lateral view forming a meniscus on the 90° view (milk of calcium). Features that favour a benign aetiology of microcalcifications include round, smooth calcifications that are scattered, diffuse and often bilateral (Monsees, 1995).

Malignant calcifications tend to appear pleomorphic, granular or linear in shape (**Figure 3**). Orientation in a linear or segmental distribution should raise the suspicion for malignancy. Calcifications that cannot be classified as benign or malignant are considered indeterminate and biopsy must be considered for definitive diagnosis.

Microcalcifications account for approximately 50% of biopsies performed for nonpalpable lesions and, of these, 35–70% are found to be ductal carcinoma *in situ* (Monsees, 1995). In the past, indeterminate or malignant calcifications were biopsied surgically following image-guided wire localization. Stereotactic large-core needle biopsy has been shown to be a safe, cost-effective alternative to open biopsy (Lee *et al*., 1997; Liberman, 2000). In one study, patients were spared an open surgical biopsy in 88% of indeterminate clustered calcifications by using stereotactic core biopsy as the initial diagnostic procedure (Lee *et al*., 1997). If the calcifications prove to be benign at histological review, the patient can be placed back into routine screening. If the biopsy shows atypical ductal hyperplasia (ADH), surgical biopsy must be performed since carcinoma can be found in a significant percentage of cases when more tissue is removed. Approximately 20–56% of lesions yielding ADH by 14-gauge automated core biopsy will prove to have carcinoma at surgery (Liberman, 2000). The directional vacuum-assisted device, especially when used with an 11-gauge probe, decreases but does not eliminate the problem of histological underestimates including the upgrading of DCIS to invasive carcinoma (Brem *et al*., 1999; Darling *et al*., 2000; Philpotts *et al*., 2000).

If malignancy is diagnosed by stereotactic core biopsy, treatment options can be discussed with the patient. In one study, a single surgical procedure was performed in 84% of patients who underwent core biopsy versus 29% of patients who underwent surgical biopsy initially for diagnosis (Liberman *et al*., 1997). Smith *et al*. found that the average number of surgeries performed was 1.25 in women whose carcinoma was diagnosed by percutaneous core biopsy versus 2.01 in women with surgically diagnosed carcinoma (Smith *et al*., 1997). There was no difference in the likelihood of obtaining tumour-free margins whether the patient underwent open surgical or core biopsy as the initial diagnostic procedure (Liberman *et al*., 1997; Gundry and Berg, 1998). These studies indicate that percutaneous core biopsy provides the information needed to plan surgery and can decrease the number of surgical procedures required, which reduces the overall cost of treatment (Liberman *et al*., 1997; Smith *et al*., 1997; Gundry and Bery, 1998).

A screening mammogram may also require further evaluation when a mass or density is identified. A lesion is described as a density when it is seen in only one projection while the term mass is applied to a space occupying lesion seen in two orthogonal projections (Evans, 1995). Spot compression views can show that an apparent 'mass' on a screening mammogram is due to overlapping glandular tissue by providing better compression to the area in question. Once a mass is identified, it should be characterized as to its size, shape, margins and density as well as its location. Features that favour a mass being benign include round or oval shape with well circumscribed margins. Fat-containing masses such as hamartomas, lymph nodes and lipid cysts can be accurately classified as benign requiring no further intervention. The likelihood of malignancy increases with irregularly shape and obscured, poorly defined or spiculated margins. These features are easier to appreciate on spot compression magnification views (**Figure 4**).

Ultrasound is the most important adjunct to the mammographic evaluation of masses and can help localize a lesion seen only on one view (Sadowsky *et al*., 1997). When strict criteria are applied, ultrasound is 98–100% accurate in distinguishing between cystic and solid lesions. A cyst should be anechoic, have a sharp posterior wall and be enhanced through transmission. A cyst does not need to be aspirated if these criteria are met unless it is causing symptoms or to prove that the cyst accounts for the mammographic abnormality (Sadowsky *et al*., 1997). Solid masses identified at ultrasound should be evaluated

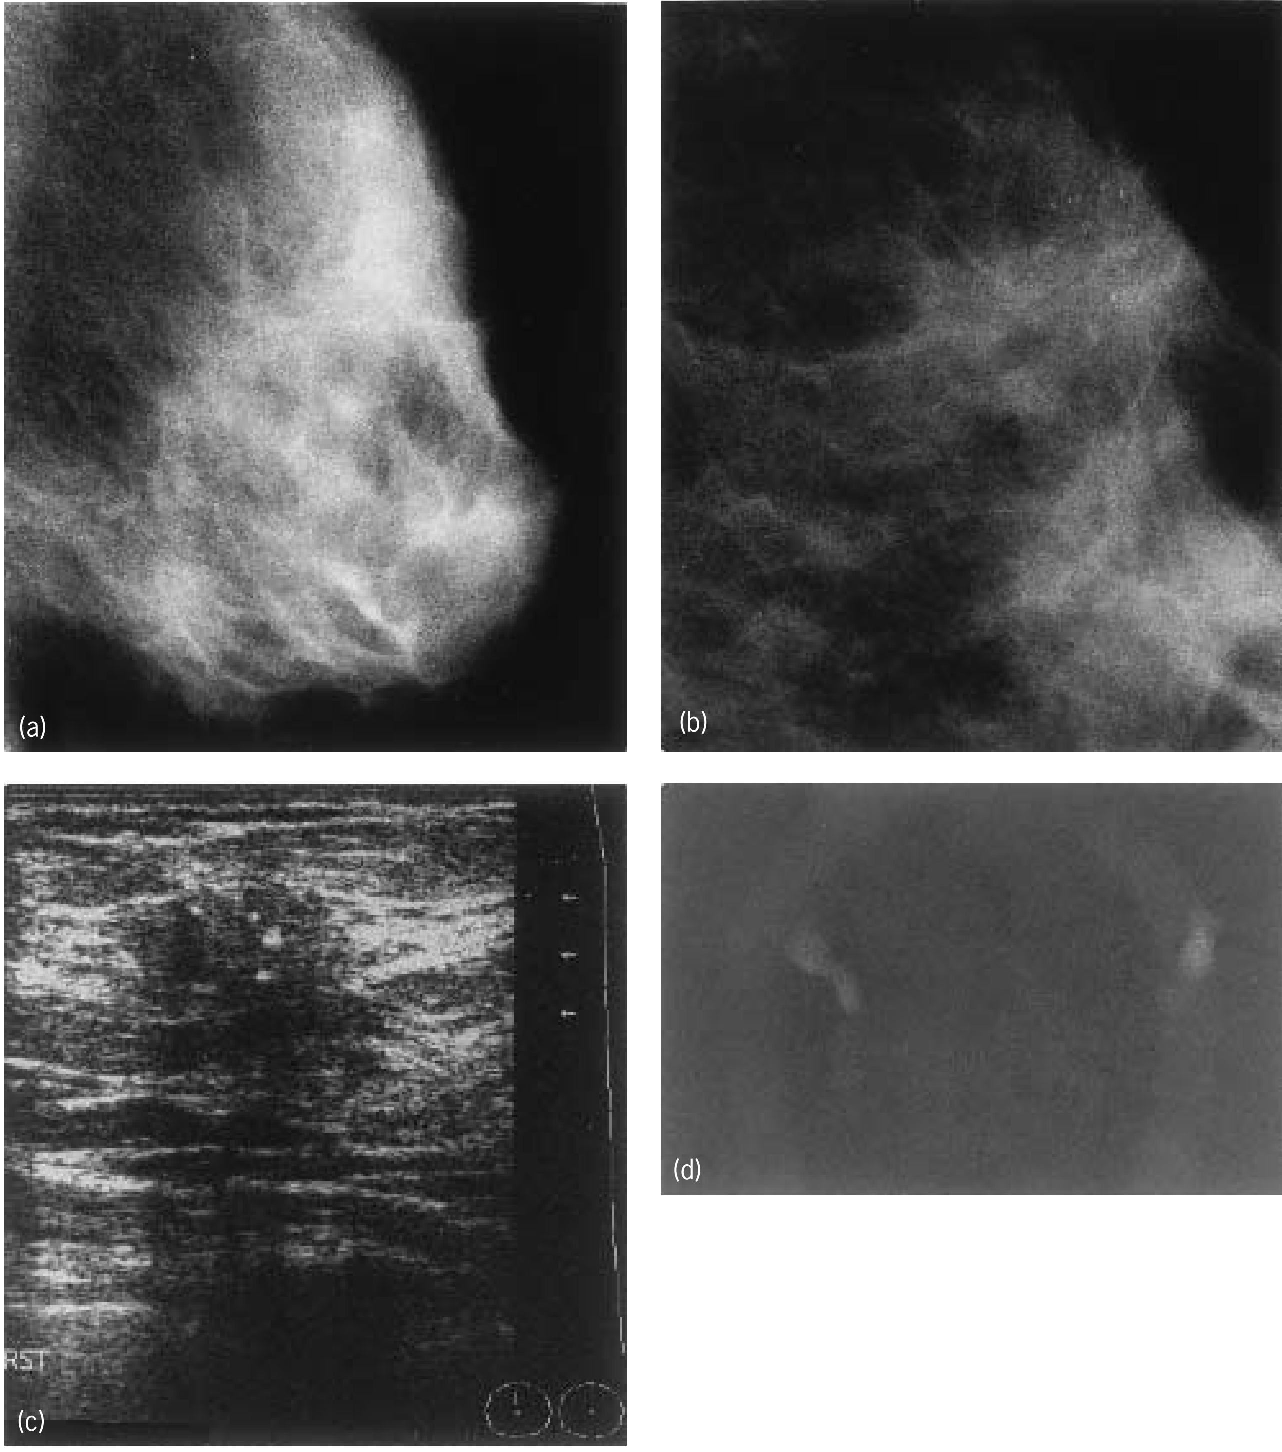

Figure 3 Baseline mammogram of a 39-year-old woman with dense breast tissue. Her mother was diagnosed with breast cancer at age 49 years. (a) The oblique view shows calcifications above the nipple which are difficult to appreciate. (b) A 90° lateral spot magnification view confirms the presence of suspicious linear, pleomorphic calcifications. (c) Ultrasound reveals an unsuspected, irregular mass containing calcifications. (d) The specimen X-ray obtained after ultrasound guided core biopsy was performed confirms that calcifications were removed. After consultation with the multidisciplinary team, the patient was treated by lumpectomy, radiation and chemotherapy for node-negative invasive ductal carcinoma.

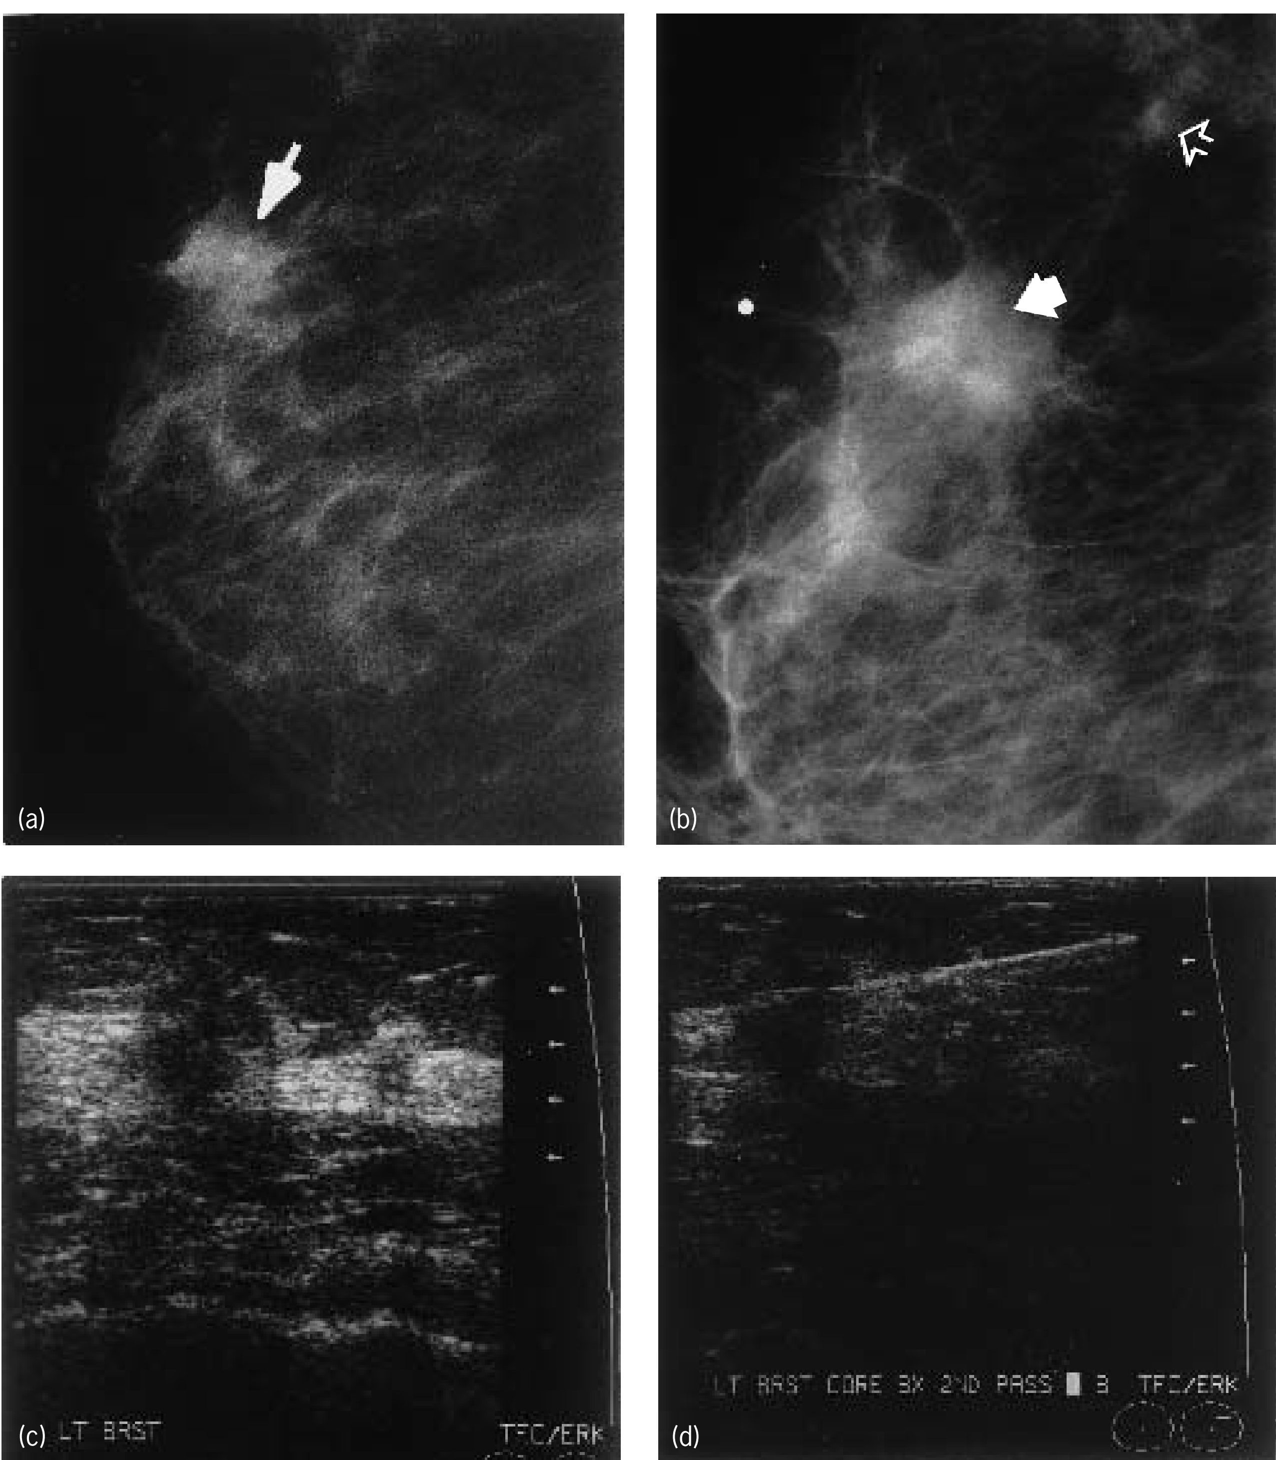

Figure 4 Screening mammogram of a 59-year-old women with fatty replaced breast tissue. (a) The oblique view showed a new mass in the superior left breast (arrow). (b) A 90° lateral spot magnification view demonstrates the irregular margins of the mass (solid arrow) and also shows a second smaller spiculated mass containing microcalcifications (open arrow). (c) Ultrasound features of both masses are also suspicious (irregular contour, taller than wide). (d) Ultrasound image of core biopsy needle passing through the larger mass. Both masses proved to be moderately differentiated invasive ductal carcinoma with an extensive intraductal component. A mastectomy with immediate reconstruction was performed.

for size, shape and margins to help differentiate between benign and malignant breast masses (Stavros *et al*., 1995; Skaane and Engedal, 1998; Rahbar *et al*., 1999). Breast carcinoma can be suspected when a solid mass has irregular margins, is taller than it is wide and is associated with acoustic shadowing. There can be overlap between the ultrasound features of benign and malignant breast masses, and for this reason breast ultrasound should be performed by the breast imaging radiologist who can correlate the mammographic, ultrasonographic and clinical findings (Sadowsky *et al*., 1997). Contrast-enhanced breast MRI is emerging as another useful imaging modality when mammography and ultrasound findings are indeterminate (Hrung *et al*., 1999; Lee *et al*., 1999).

Ultrasound is invaluable in the evaluation of palpable breast masses and is the initial examination of choice in patients aged under 30 years (Evans, 1995). If the ultrasound is negative or shows fibrocystic tissue, a tailored mammogram is performed primarily to look for calcifications which can be missed on ultrasound. In patients over 30 years old, a diagnostic mammogram is performed with a radiopaque marker on the palpable mass. If the mammogram shows a mass or calcifications, additional mammographic views are obtained as described previously.

In one study, the sensitivity of mammography alone for the detection of cancer was 83% but improved to 91% after mammography and ultrasound were combined. Improved sensitivity was particularly evident in patients aged under 50 years (Zonderland *et al*., 1999). It is important to remember that although a diagnostic mammogram is performed to answer a specific clinical question, the remainder of both breasts must be screened for nonpalpable breast cancers (Rosen *et al*., 1999).

If a cyst is diagnosed at ultrasound, aspiration can be performed for symptomatic relief. If the mammogram and ultrasound are both negative, the decision to biopsy a palpable abnormality must be based on the clinical examination. When a solid mass is identified by ultrasound, whether palpable or nonpalpable, a core biopsy can be performed to establish the histological diagnosis (Liberman *et al*., 1998). Ultrasound-guided core biopsy is easier on the patient than stereotactic core biopsy and can be performed faster with no ionizing radiation and at lower cost. In one study, percutaneous image guided biopsy of palpable breast masses spared 74% of patients an additional diagnostic tissue sampling procedure (Liberman *et al*., 2000). If the imaging and clinical findings suggest a benign lesion and the patient wants the lesion removed regardless of the tissue diagnosis, surgical excision may be preferable. The use of core biopsy on indeterminate masses increased the malignancy rate at open biopsy from 21 to 55% with a reduction in billed charges estimated at $368 000 per 100 biopsies (Rubin *et al*., 1995). If a mass proves to be malignant after ultrasound-guided core biopsy, the therapeutic options can be discussed with the patient and a single surgery can be planned.

Contrast-enhanced MRI is also being used to stage newly diagnosed breast cancer patients prior to surgery since it may reveal unsuspected multifocal, multicentric or contralateral breast cancer (Orel *et al*., 1995; Orel, 1998). In one study, the therapeutic procedure was changed in 14.3% of patients because the MRI findings were more extensive than appreciated on clinical, mammographic and ultrasonographic exams (Fischer *et al*., 1999).

GALACTOGRAPHY (DUCTOGRAPHY)

Galactography is a contrast examination of a major lactiferous duct and its branches which is performed after a significant nipple discharge has been identified (Tabar *et al*., 1983; Jones, 1992; Cardenosa *et al*., 1994). A patient who presents with nipple discharge should initially be evaluated clinically to determine whether the discharge is physiological or pathological (see **Figure 5**). A significant discharge is usually unilateral, from one duct orifice and most often occurs spontaneously. The discharge should be tested for occult blood and the colour and consistency of the discharge should be noted. Serous, serosanguineous, bloody and clear watery discharge should be investigated further. Bilateral, multiple duct milky discharge is usually related to hormonal factors or can be secondary to various medications. Thick green, yellow or brown discharge is usually related to duct ectasia and most often is a nonspontaneous discharge which comes from multiple ducts.

Once it is determined that a significant nipple discharge is present, a ductogram can be performed to identify the cause of the discharge and the location of the lesion. If no recent mammograms are available, preliminary films should be obtained. The study is usually performed with the patient in the oblique supine position with the nipple at the highest point of the chest, but some prefer to have the patient seated. Infection can be prevented by meticulous cleansing of the nipple and areola with Betadine and alcohol and observing aseptic technique. Following cleansing of the nipple, a tiny drop of discharge is produced to identify the nipple orifice, which is easier to see with use of a fluorescent lamp with magnifying lens. A special 30-g cannula bent at 90° is used to probe the nipple gently until the duct orifice is entered and then contrast material is slowly injected using a 1-mL syringe with attached tubing. Mammograms are then obtained in the craniocaudal and mediolateral projections followed by spot compression magnification views once the location of the duct system has been identified. Following the ductogram, fluid can be collected for cytological evaluation.

Galactography is a safe, well tolerated procedure with few complications, but it is contraindicated in patients with acute mastitis or breast abscess since it may exacerbate the inflammatory process. If there is a strong allergic history, nonionic contrast can be employed with or without

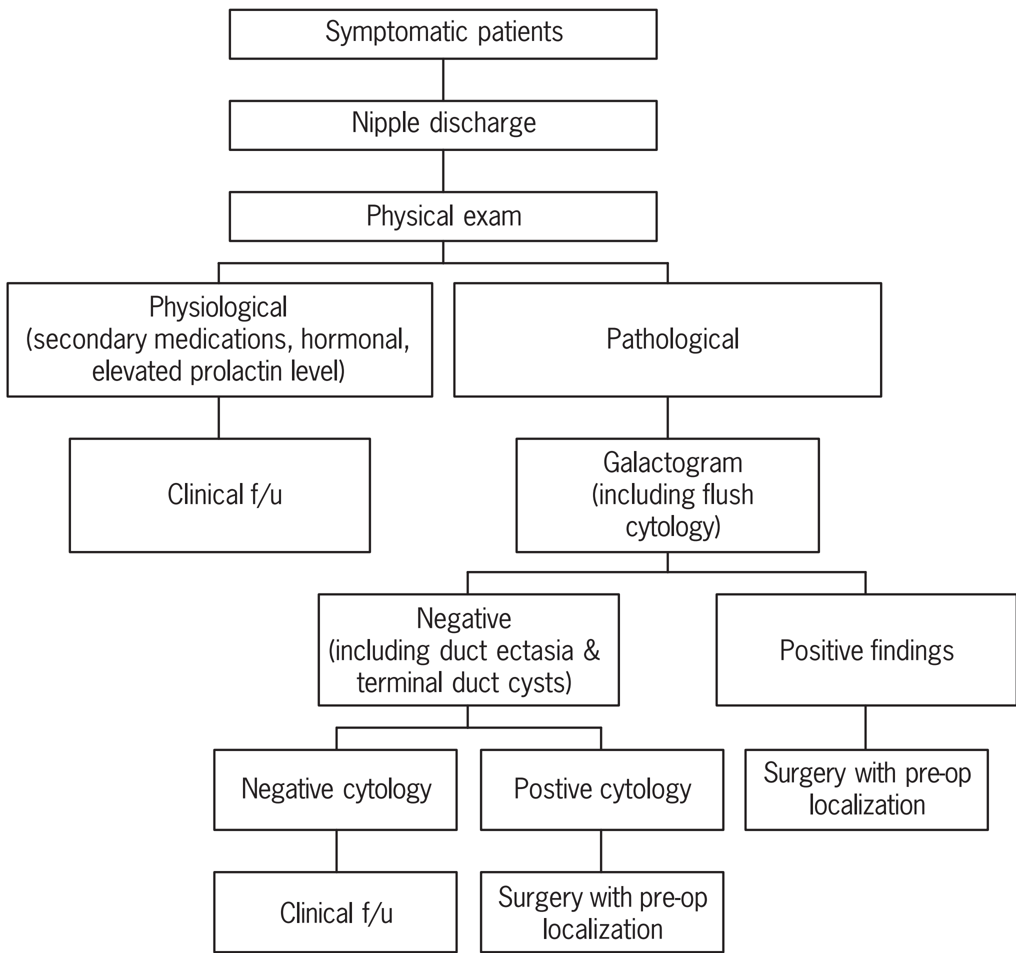

Figure 5 Evaluation of nipple discharge.

pretreatment with steroids and antihistamines (Levin and Sadowsky, 1996).

Galactographic findings suggestive of papillomas include solitary or multiple intraluminal filling defects or complete obstruction to the retrograde flow of contrast (Tabar *et al*., 1983; Woods *et al*., 1992). Most solitary papillomas occur centrally in the large subareolar ducts while multiple papillomas (papillomatosis) are usually peripheral in location, arising within the terminal duct lobular unit. It can be difficult to distinguish between a benign intraductal papilloma and intraductal carcinoma, especially since there can be microscopic involvement of a papilloma with DCIS. Findings suggestive of carcinoma include irregular filling defects, ductal irregularity, distortion, displacement or encasement of ducts (Cardenosa *et al*., 1994). Additional findings suggestive of carcinoma include parenchymal pooling of contrast or opacification of a duct which leads to a suspicious mass, area of increased density or microcalcifications.

Galactographic findings which do not require surgical intervention include duct ectasia and terminal duct cysts. If significant pathology is demonstrated, preoperative localization galactography can be performed using a combination of two-thirds contrast and one-third methylene blue to stain the involved duct. If the lesion is peripheral in location, or several branch points from the main duct, the preoperative galactogram can be supplemented by placement of a localizing hook-wire to guide the surgeon further. These preoperative localization procedures allow for a more conservative surgical excision while ensuring complete removal of the lesion and affected duct (Van Zee *et al*., 1998). In one study, when preoperative localization procedures were not employed, 20% of lesions (6/30) shown by galactography were not identified at histopathological examination (Baker *et al*., 1994).

Currently, galactography is the only diagnostic study available for the evaluation of nipple discharge. Preliminary reports indicate that contrast-enhanced MRI of the breast may be an alternative diagnostic tool for the evaluation of nipple discharge (Orel *et al*., 2000).

Even though galactography is a safe, well-tolerated procedure, it has not gained widespread acceptance by physicians (Jones, 1992; Woods *et al*., 1992). In postmenopausal women, some surgeons advocate excision of the major subareolar ducts while solitary duct excision is performed in premenopausal women without performing

preoperative diagnostic imaging (Woods *et al.*, 1992; Cardenosa *et al.*, 1994). This type of surgery will treat the symptom of nipple dischage but does not ensure that the lesion causing the discharge has been removed. Significant breast deformity can occur following excision of the major subareolar ducts.

CONCLUSION

Mammographic screening is the most reliable method to find early breast cancer in large populations. The detection of both benign and malignant breast disease has increased as more women participate in screening. The secondary costs resulting from screening mammography can account for 50% of the total cost of diagnosing breast cancer. The psychological and economic costs should not be underestimated and therefore when an abnormality is detected on a screening examination, a thorough diagnostic evaluation must be performed to characterize the lesion. Periodic mammographic follow-up of probably benign lesions has been established as a safe, reasonable alternative to surgical biopsy (Sickles, 1991). If a lesion remains indeterminate after a complete mammographic and ultrasonographic evaluation, percutaneous image guided biopsy can be performed. When used appropriately, these procedures are not only cost effective but also truly cost saving. In most institutions, the overall cost for a needle biopsy is 25–30% that of wire localization and surgical excision. Considering the large number of biopsies performed each year, the cost savings has been estimated to between $200 million and $1 billion per year. The reasons to biopsy a probably benign lesion include patient anxiety due to high risk or family history, planned pregnancy, difficulty with follow-up (unreliable or relocating patient) or ipsilateral or contralateral breast cancer to confirm benign diagnosis prior to definitive treatment.

Digital mammography and computer-aided detection are emerging technologies which may improve both screening and diagnostic mammography. High-resolution ultrasound and contrast-enhanced MRI are important adjuncts to mammography in the detection and diagnosis of benign and malignant breast diseases.

INTRODUCTION

With advances in treatment regimes for many neoplastic processes, it is becoming increasingly important to make an accurate diagnosis in each patient. Although there are characteristic radiological appearances of many tumours, a histological diagnosis is preferable in most cases. Traditionally this has meant an open surgical biopsy; percutaneous biopsy, however, has become an increasingly used diagnostic tool. All but the most superficial biopsies are now performed by interventional radiologists using image guidance. The purpose of this chapter is to outline the indications, techniques and success rates of percutaneous biopsy and explain its many uses.

TECHNIQUE

When presented with a diagnostic dilemma, the usual scenario involves a patient with a suspected diagnosis and a mass seen on imaging. The aim of the biopsy is to obtain sufficient cells or a tiny core of tissue from the mass to enable the pathologist to arrive at a diagnosis. Obtaining cells through a tiny needle is termed a fine-needle aspiration biopsy (FNAB). By definition, these needles are 20, 22, 23 or greater in gauge. The other percutaneous approach involves obtaining a core of tissue, usually with a 16–18-gauge needle. There are few contraindications to performing such a procedure. In most cases a large-gauge needle (16–18) can be inserted into a lesion and both large cores and FNA can be obtained through this needle. A mass located deep within the abdomen or pelvis or adjacent to vital structures may increase the technical difficulty of the procedure but these are not contraindications. Even a coagulopathy is only a relative contraindication to FNAB and then only if the mass is deeply located. In these cases, blood products can be given to correct the coagulopathy. Superficial masses may be aspirated despite an abnormal coagulation status. There is no organ or area in the body apart from the skull which is not amenable to percutaneous biopsy. Lung masses, liver, lymph nodes, renal, adrenal, pancreatic and prostate masses are the most commonly biopsied lesions. Musculoskeletal, breast and thyroid lesions are also amenable to a percutaneous approach. Several imaging modalities are available to guide the procedure: fluoroscopy, ultrasound, computed tomography (CT) and, in some institutions, magnetic resonance imaging (MRI).

Fluoroscopy is used primarily in aiding lung mass biopsies and today this is becoming uncommon. The initial lesion is usually identified on a chest radiograph. If the lesion can be seen on fluoroscopy then the patient is placed in the appropriate position on the fluoroscopy table with the lesion uppermost. The use of a 'C' arm aids needle localization in the 90° plane. A 20–22-gauge needle is directed into the lesion under fluoroscopic guidance. Once the needle is confirmed to be within the lesion, the aspirates are taken. Fluoroscopy has little value in assisting percutaneous biopsy in other organs.

Ultrasound is more frequently used in assisting percutaneous biopsy. Many organs are accessible to ultrasound guidance, particularly the liver, kidneys, spleen, thyroid, prostate and pancreas. Ultrasound is easy to perform, inexpensive and free from ionizing radiation. It allows real-time imaging of the biopsy needle, ensuring that the correct area is sampled. More recently, ultrasound has been used to guide biopsy of chest wall lesions and even hilar and mediastinal masses through areas of collapsed lung.

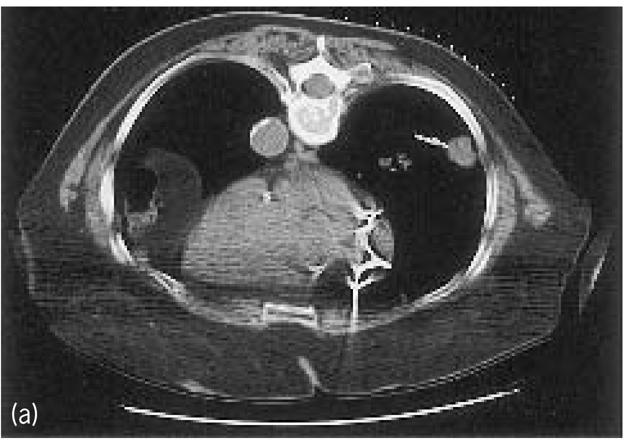
CT is also frequently used to assist percutaneous biopsy. It is particularly valuable for localizing lesions which are not clearly visualized by ultrasound, such as adrenal lesions and retroperitoneal structures. These tend to lie deep within the body cavity and CT gives a better overview of the target area. CT can also be used for solid organ biopsy. It enables smaller lesions to be located more accurately. A useful addition to the CT technique is to create a window through which the needle can reach the target. This has been reported as an approach for the adrenal glands (Karampekios *et al*., 1998).

Normal saline is injected into the paravertebral space to create a wider pathway for the needle insertion. The artificial window that is formed by displacing the pleura laterally allows a direct and safer access route to the retroperitoneum, thereby decreasing the risk of damaging adjacent structures, especially the pleura. A similar approach has been reported in the thorax for biopsying a posterior mediastinal mass through an extrapleural window created by dilute contrast (Bhagat *et al*., 1999).

The technique for biopsy remains similar irrespective of the imaging modality used. The lesion must first be located on a preliminary scan. Following this, an access route which is safe, effective and convenient must be chosen to approach the lesion. The patient should then be positioned accordingly. For all but the most superficial lesions, conscious sedation is recommended in the form of midazolam and fentanyl. The skin is then prepared and draped in a sterile manner. The skin is infiltrated with 1% lidocaine as a local anaesthetic. In a typical case, a 17-gauge Temno (Allegiance, McGaw Park, IL, USA.) coaxial needle is positioned within the lesion to be biopsied. This is done under real-time imaging in the case of ultrasound. Having positioned the 17-gauge needle correctly, fine-needle aspirates may be obtained using 20–22-gauge needles while aspirating with a 20-mL syringe. These samples are spread on to slides and immediately placed in formalin before they can air dry. An 18-gauge biopsy needle can then be passed through the coaxial needle and samples taken as required. Following the procedure, the patient should be observed for a period of 2–4 h. The procedure is usually very well tolerated by the patient. In other cases of superficial lesions such as thyroid or breast, conscious sedation is not routinely required. In thyroid lesions, the biopsy is performed using a 25-gauge needle. Between five and six passes are usually made. This usually provides sufficient cells for diagnosis. In cases near vital organs, 20-gauge core biopsies can be obtained without using a coaxial system.

LUNG AND MEDIASTINUM

There have been many studies looking at the accuracy of FNABs and core biopsies relating to nearly every organ in the body. One large study reviewing the results and complications of FNAB of lung lesions reviewed 651 pulmonary FNABs (Swischuk *et al*., 1998). The number of needle passes and needle size were correlated with the rates of pneumothorax and chest tube placement; 18–22-gauge needles were used. There was a diagnostic accuracy of 94% with a sensitivity for malignancy of 95%. The major complication when performing lung biopsies is pneumothorax. This study reported a pneumothorax rate of 26.9% with 9.2% requiring a chest tube placement. The pneumothorax rate has been shown to be independent of the depth of lung tissue traversed, number of passes and size of needle used, but does correlate with the number of pleural surfaces crossed. This study demonstrates excellent results for the technique. Similar results for FNAB have been reported by other investigators. A sensitivity of 92% for diagnosing malignancy was reported in another study involving 150 cases, with a pneumothorax rate of 2% (Subhannachart *et al*., 1999) (**Figure 1**). These results show that the technique is accurate, effective and safe for lung lesions.



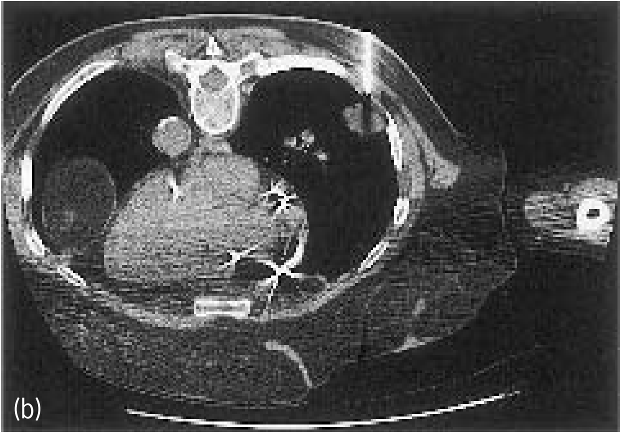


Figure 1 An example of a percutaneous lung biopsy. With the patient prone, (a) shows a right lung mass (arrow) with a localizing grid on the patient's back; (b) shows the same lesion with the biopsy needle placed at the posterior surface of the mass.

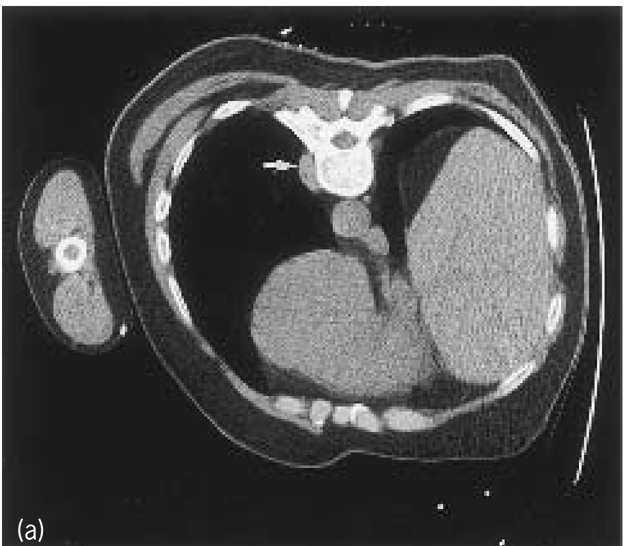

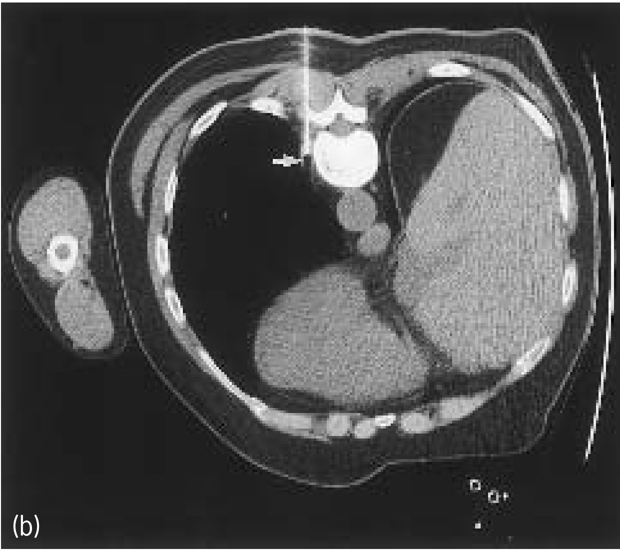

Figure 2 (a) A paravertebral soft tissue mass (arrow) in a 33-year-old male patient. The patient is in a left lateral decubitus position to create an intercostal window for biopsy. (b) The same lesion with the needle tip within it. This proved to be non-Hodgkin lymphoma. Note the black streak at the tip of the needle (arrow) indicating that the exact location of the needle tip has been imaged.

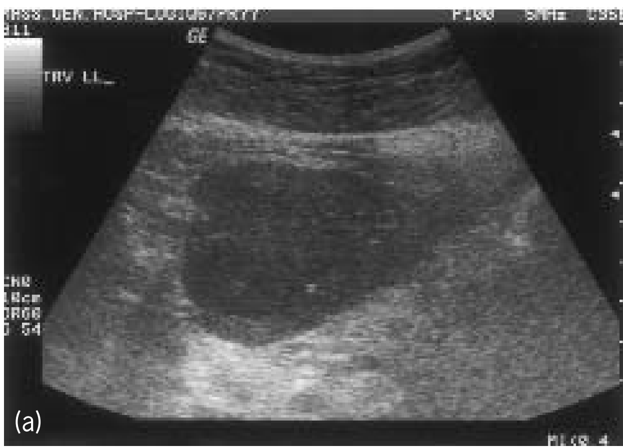
It can often be difficult to decide whether a small lesion is amenable to biopsy and to this end the results of biopsying lesions smaller than 2 cm was addressed by investigators in France (Laurant *et al*., 2000). They biopsied 202 lung lesions and recorded the sensitivity and specificity of the biopsy by lesion size. Lesions smaller than 2 cm had a sensitivity of 89.5% and specificity of 100% for malignancy. The corresponding figures for lesions larger than 2 cm were 95.5% and 100%. The pneumothorax rate was 15% and 16%, respectively. Thus the accuracy and complication rate for CT-guided biopsy using a 20-gauge core was similar for large and small lesions.

A percutaneous approach may be used for mediastinal lesions also (**Figure 2**). Lymphoma is the cause of many mediastinal masses. If tissue can be obtained without the risks of even minimal thoracic surgery then this is of great benefit to the patient. In the case of lymphoma, it is also useful to know the subhistiotype for treatment. In a study group of 83 cases of mediastinal masses, core needle biopsy had an overall sensitivity of 81% for diagnosing lymphoma and the subhistiotype was accurately assessed in 93% of these (Zinzani *et al*., 1999). This study concluded that core needle biopsy is an effective and safe method of diagnosing mediastinal lymphoma, with a high likelihood of determining the subtype and thus defining subsequent specific treatment. A similar study reported a diagnostic success rate of 71.5% for core biopsy in diagnosing mediastinal lymphoma, with no complications reported (Sklair-Levy *et al*., 2000). As a result, the authors recommended the technique as the initial diagnostic procedure of choice. In a review of all types of mediastinal tumours, an overall sensitivity of 91.9% has been reported (Greif *et al*., 1999) with sufficient tissue obtained for diagnosis in 88.6%. A pneumothorax rate of 11% was encountered during the study. These and many other studies prove the value and efficacy of the percutaneous approach in the thorax.

LIVER, SPLEEN AND KIDNEY

Excellent results have been reported for abdominal biopsies also. The liver is probably the organ most commonly biopsied when malignancy is suspected (**Figure 3**). Large studies have repeatedly shown that percutaneous biopsy is both safe and effective; 244 liver lesions underwent a FNAB as reported by Herszenyi *et al*. (1995), with a reported diagnostic sensitivity of 93% and specificity of 100% with only one complication, that of tumour seeding along the biopsy tract. This compares favourably with the sensitivity and specificity of 18-gauge needle biopsy reported by Yu *et al*. (1998). They found a sensitivity and specificity of 96.4% and 100% respectively for the detection of both benign and malignant liver lesions. In a direct comparison between FNAB and core needle biopsy on the diagnosis of focal liver lesions suspected to be malignant, 55 patients had both a FNAB and core needle biopsy. In 41 cases of 48 with proven malignancy, both biopsies were positive. In the remaining seven cases, only FNAB yielded malignant cells. The tumour grading of six adenocarcinomas was more accurate with the histological (core needle) sample. This study performed by Jacobsen



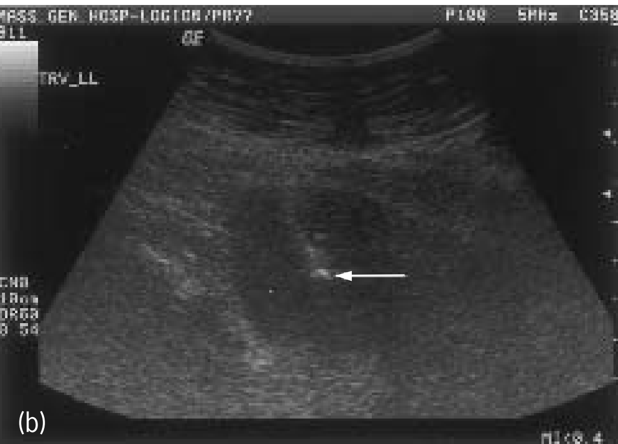


Figure 3 Large hypoechoic mass in the liver (a) in a 48-year-old female with the cirrhosis. In (b) the biopsy needle can be seen as an echogenic line lying within the mass. This was hepatocellular carcinoma.

et al. (1983) concluded that given that FNAB requires fewer prebiopsy precautions, core needle biopsy could be restricted to those cases in which FNAB does not yield sufficient information.

The ability of FNAB to detect malignancy in small liver lesions was examined by Middleton *et al*. (1997). They examined 30 liver lesions 1.5 cm or smaller which underwent an ultrasound-guided FNAB. The reported diagnostic accuracy rate for detecting malignancy was 93% using a 22-gauge needle. All these series, and many more, suggest that percutaneous biopsy is both safe and effective for liver lesions.

The spleen is amenable to biopsy when the need arises, although it is preferable to avoid splenic biopsies where possible given the highly vascular nature of the organ. The major indication for splenic biopsy is for a lesion which cannot be characterized on imaging, in patients in whom management will be altered significantly based on the result of the biopsy. Lymphoma, metastases and infection are the most frequently biopsied lesions. Twenty splenic lesions biopsied over a 2-year period were reported by Keogan *et al*. (1999). These were not all malignant lesions. A specific diagnosis was obtained in 16 cases (88.9%). No complications occurred. Diagnostic accuracy rates for other abdominal organs are similar (**Figures 5 and 6**). An 89% success rate has been reported for percutaneous biopsy of renal masses which proved to be renal cell carcinoma (Lechevallier *et al*., 2000) (**Figure 4**).

MUSCULOSKELETAL SYSTEM

The effectiveness of percutaneous biopsy of the musculoskeletal system has also been well established. In one review of 77 cases over a 24-month period, the diagnostic accuracy was found to be 83.8% overall. The accuracy for bone lesions was 85.5%, and for soft tissue lesions 76.9%. Accuracy was slightly better for lytic than sclerotic lesions (Hodge, 1999). A larger study involving 144 patients with primary bone tumours reported a diagnostic accuracy of 98.4% (Saifuddin *et al*., 2000) when needle biopsy was compared with surgical findings. FNAB has also been found to be accurate in the diagnosis of metastatic bone tumours (Collins *et al*., 1998).

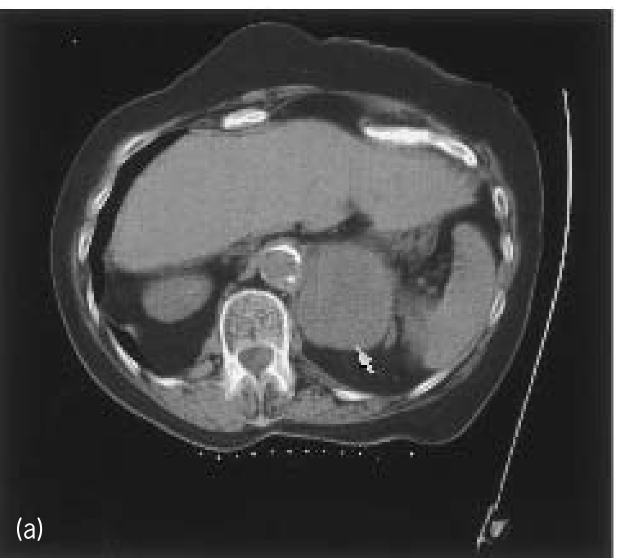
MISCELLANEOUS SITES

A percutaneous approach may even be used in the diagnosis of colonic carcinoma. The technique may be used following a negative colonoscopic biopsy or in cases of an inaccessible lesion on colonoscopy. Ultrasound is used for image guidance. One series reported a sensitivity for FNAB of 91.8% with a specificity of 100% in the diagnosis of colonic lesions when compared with surgical findings (Javid *et al*., 1999). In this series of 50 patients, only two minor complications were reported, supporting the utility, in certain cases, of ultrasound-guided percutaneous biopsy.

Percutaneous biopsy is also used with increasing frequency in diagnosing breast carcinoma. One difficulty with this lies in deciding how many cores should be obtained at the time of the procedure to make an accurate diagnosis without resorting to a second procedure. Breast biopsies are performed either under ultrasound guidance or stereotactically with radiographic control. The sensitivity for detecting malignancy has been reported as 84.3% when two cores are obtained. This rises to 97.7% when six cores are taken (Rich *et al*., 1999).

CONCLUSION

Percutaneous biopsy using either fine-needle aspiration or core biopsy is a straightforward technique which



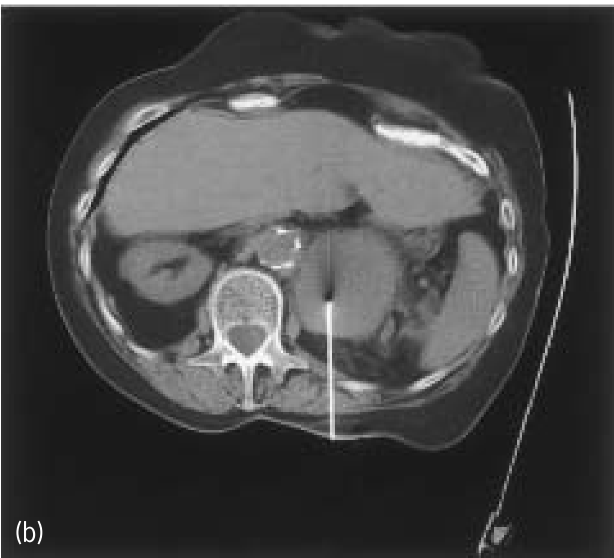


Figure 4 (a) A large, well-defined, soft tissue mass in the region of the upper pole of the left kidney in a 55-year-old female (arrow). Note the marking grid on the patient's skin. (b) An ideally located needle tip for good core biopsies.

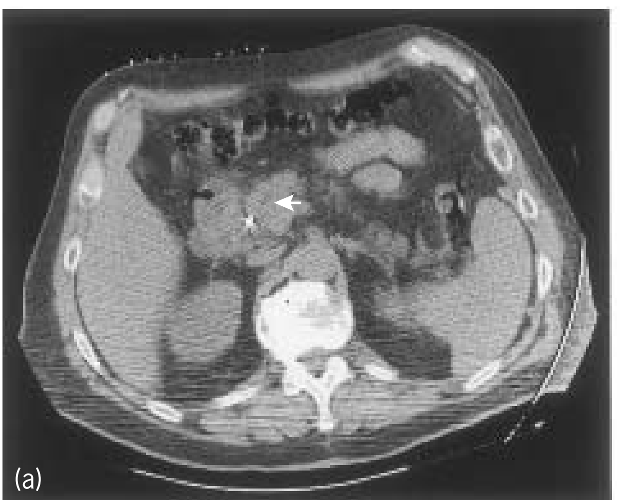

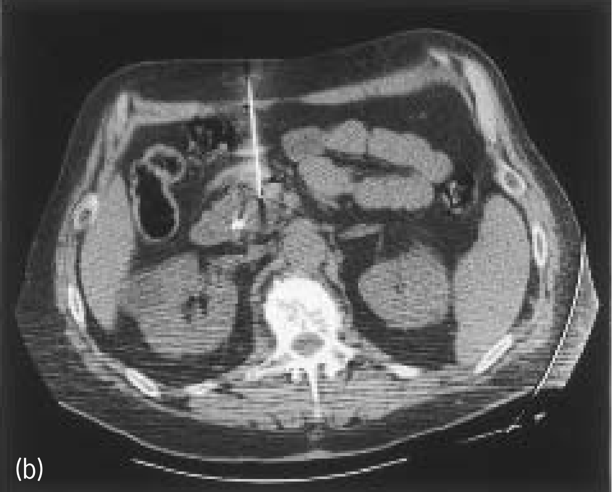

Figure 5 (a) A CT scan showing an irregular low attenuation mass in the head of the pancreas (arrow) surrounding a previously placed biliary stent in a 68-year-old male. (b) The needle within the mass. Puncturing the bowel with a 20-gauge needle is not associated with an increased complication rate.

may be used for almost any organ. The image guidance modalities are chosen according to local availability. The success rates are excellent and serious complication rates are low. There are few contraindications to the procedure, as demonstrated by the widespread use of percutaneous biopsy. Allowing for slight variations and tricks, the procedure is similar for most organs and modalities, which makes mastering the technique easier. As a tool for aiding both the initial diagnosis of malignancy and for assessing evidence of either recurrence or metastases, percutaneous biopsy has become invaluable.

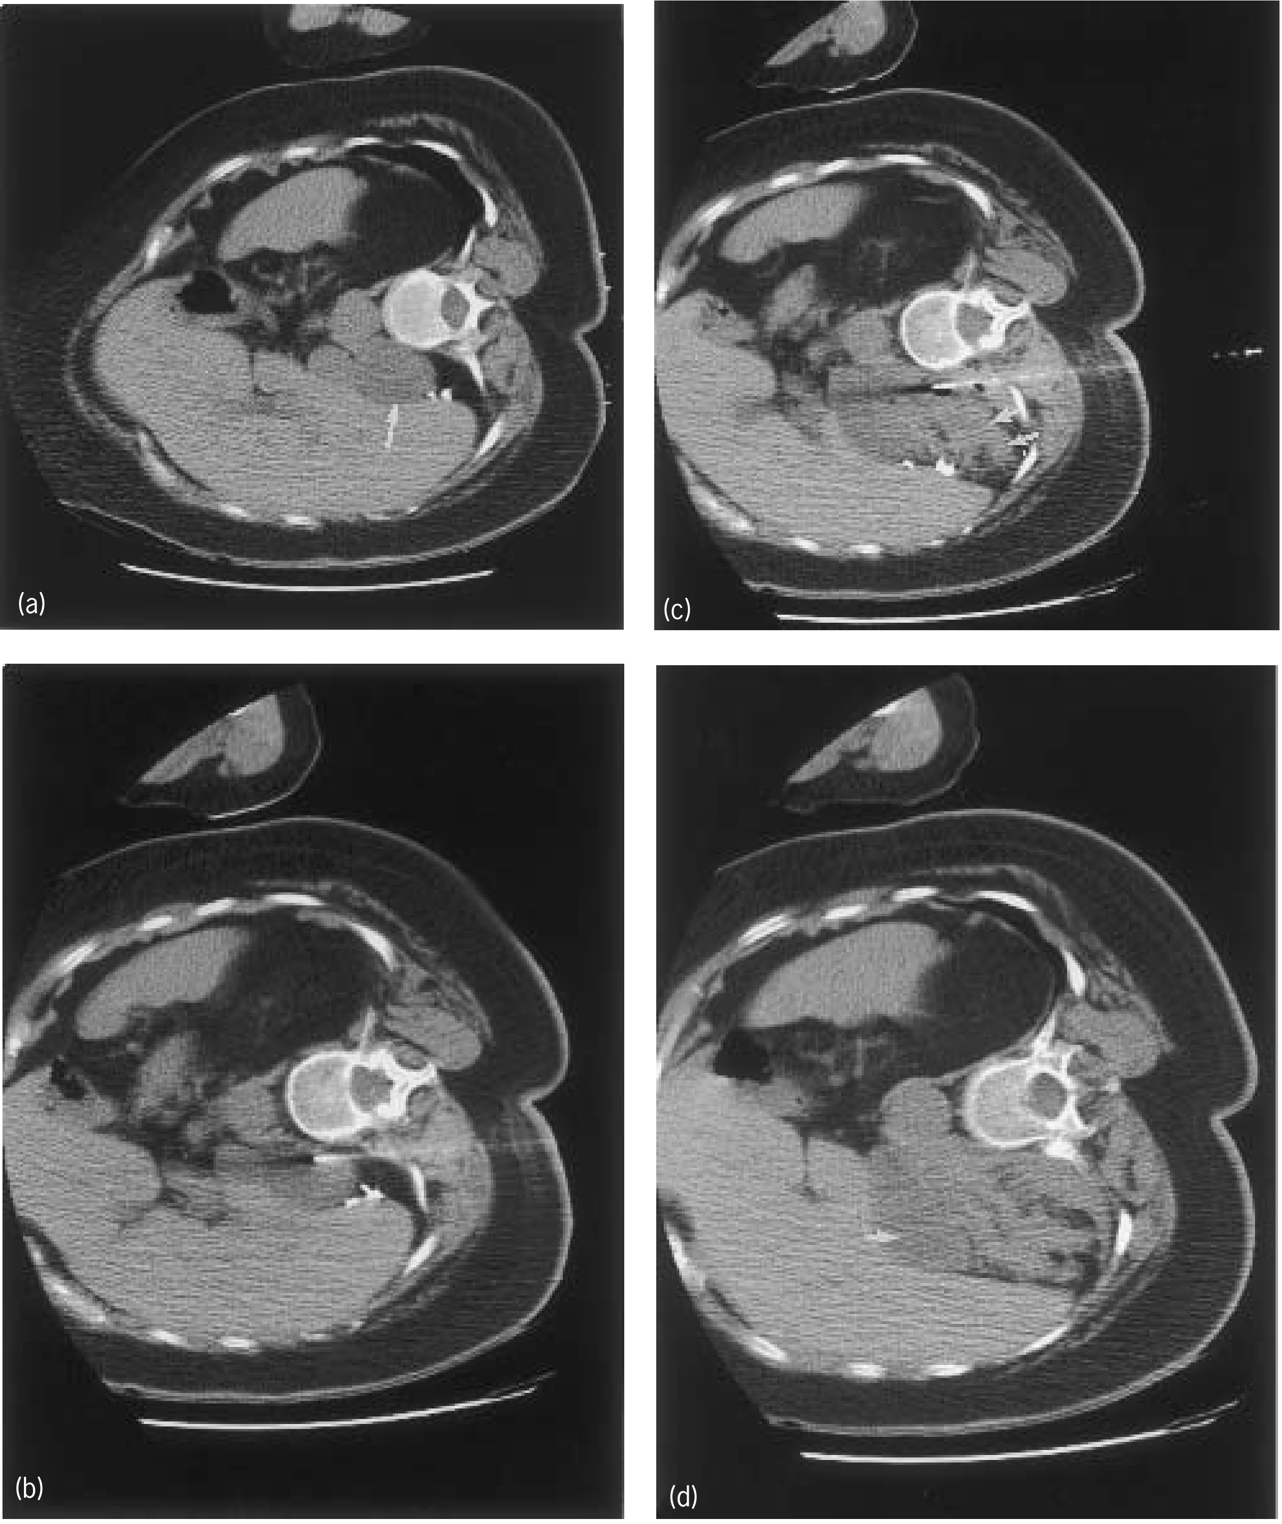

Figure 6 (a) Soft tissue mass in the right renal fossa (arrow) found on a surveillance CT following right nephrectomy for RCC. The decubitus position (right side down) decreases the risk of crossing the pleura. (b) Peri-procedural CT image demonstrating excellent needle location. This lesion proved to be an adrenal metastasis from the RCC. (c) CT image during the same procedure showing retroperitoneal haemorrhage postbiopsy. (d) Postprocedural CT scan demonstrating a large retroperitoneal haemorrhage (arrow) displacing the adrenal mass anteriorly (arrow). The patient was observed overnight and no intervention was required.

- Conclusion

INTRODUCTION

Transcatheter therapy has an innate logical appeal. The basic aim of such therapy is to deliver one or more chemotherapeutic agents directly to a tumour through the vascular tree. If possible, the therapy is also delivered in such a manner as to make it remain in the treated tumour for relatively long periods of time. This general aim has been approached in various ways, for many years. For example, one approach to the treatment of colorectal carcinoma metastatic to the liver has been to place a catheter in the hepatic artery surgically, with a port implanted subcutaneously (Kemeny *et al*., 1999). This port can then be utilized for continuous or intermittent infusion of chemotherapy directly into the liver. Others have proposed placement of indwelling arterial catheters radiographically, via the upper or lower extremity arteries, for the same purpose. This approach has the advantage of being less invasive than surgical placement, with fluoroscopic guidance for accurate placement. The focus of this chapter, however, will be on transcatheter, short-term delivery of chemotherapeutic agents, a method which has been widely used throughout the world. This approach is usually referred to as 'chemoembolization.'

BASIC PRINCIPLES

Chemoembolization is performed starting with placement through the skin of a catheter, a small plastic tube, into a peripheral artery. Using the technique developed by Seldinger, a Swedish radiologist, in 1954, access to the artery is gained by advancing a needle through the skin. Through the centre of the needle, a guidewire is placed. The needle is then removed and the catheter is placed directly into the artery over the wire. The usual access to the artery is gained via the femoral vein in the groin, but any artery which is relatively superficial, such as an artery in the axilla or upper arm, can also be utilized. The catheter is then directed selectively into the vessels supplying the tumour to be treated (**Figure 1**). This is accomplished by utilizing catheters and guidewires of various shapes, combined with fluoroscopic, real-time monitoring. After the appropriate arterial position has been selected, the chemotherapeutic agent is delivered. In general, this consists of infusion over a short period, e.g. 5–10 min. Longer infusions, with the use of rescue medications, have also been used (Kemeny *et al*., 1999). After treatment, the catheter is removed and haemostasis is achieved. Ancillary therapy is generally employed to prevent or to treat complications of the chemotherapeutic agent and the procedure, and most often, chemoembolization is done with hospitalization of the

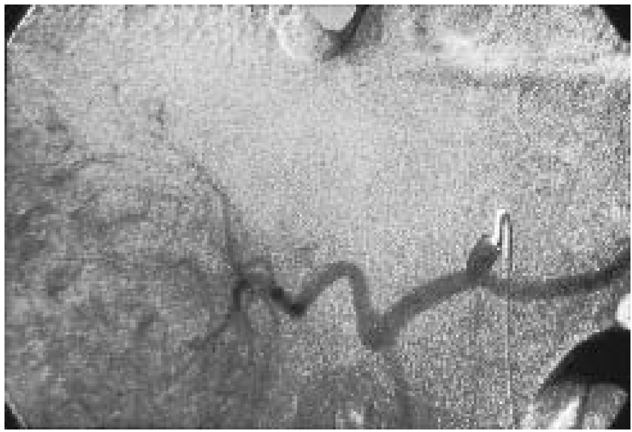

Figure 1 Catheter in place in coeliac axis. Contrast injection shows filling of the splenic artery and the hepatic artery. There is increased vascularity and draping of vessels around a large hepatocellular carcinoma in the right lobe of the liver.

patient. Additional treatment focuses, first, on pain control, since infusing material into an artery can lead to occlusion of that artery and resultant ischaemia. In part, the aim of this approach is to cause ischaemia and tumour necrosis. Opiates are often required for pain control, usually only for 24 h or less after the procedure. Other medications that are frequently used include corticosteroids, to help limit the inflammatory reaction to the treatment, and antiemetics. As with chemotherapy, nausea and vomiting are relatively frequent complications, but as with pain, tend to be limited to the first 24 h.

Chemoembolization in this fashion is often repeated one or more times, depending on the response to the treatment and the condition of the patient. Chemoembolization can be performed in essentially any area of the body, depending on the blood supply to the tumour and the organ that it involves. Transcatheter therapy has been widely used to treat head and neck tumours, renal malignancies, malignancies of the central nervous system and musculoskeletal lesions. The greatest experience, however, has been in the treatment of primary or metastatic liver malignancies, and that will be the major focus of this chapter.

The types of liver tumours treated by chemoembolization can be divided into three categories: (1) primary hepatocellular carcinoma, (2) metastatic carcinoma, primarily adenocarcinomas, and (3) neuroendocrine tumours (primary or metastatic).

TRANSCATHETER THERAPY OF LIVER MALIGNANCIES

Chemoembolization as a concept implies the use of both a chemotherapeutic agent and an embolic agent. That is, a specific anticancer drug is injected, in combination with a material that will block arterial inflow into the lesion, allowing direct delivery of the agent to the site at which it is needed, and then prolonged retention. In theory, as noted, there is also a beneficial effect in decreasing or eliminating blood flow to all or part of the tumour. To achieve these aims, various combinations have been utilized (Charusangavej, 1993). Among the chemotherapeutic agents that have been used are adriamycin, mitomycin, cisplatin, FUdR and 5-fluorouracil, and among the embolic agents used are poly(vinyl alcohol) (PVA) beads, absolute alcohol, Gelfoam and Ethiodol (Lipiodol). PVA beads are minute plastic particles available in various sizes, ranging from <100 μm to >1 mm. Several different types of calibrated plastic beads or particles are commercially available. PVA particles do not dissolve, so they cause permanent occlusion of whatever vessels into which they are instilled. In reality, some recurrence of blood supply generally occurs, either because of the recanalization through or around these beads or because of tumour neovascularity formation. Absolute alcohol is another agent which leads to permanent occlusion. It has been used widely as a primary treatment for hepatomas in Asia, both by infusion through a catheter and by percutaneous injection directly into tumour nodules (see the chapter on *Percutaneous Biopsy*). Absolute alcohol leads to occlusion of small vessels (capillaries and arterioles) and to direct tissue death by causing rapid and complete dehydration of cells into which it comes in contact, including blood cells, cells of the vessel wall and tumour. Gelfoam, or surgical gelatin sponge, is a material which dissolves and is resorbed from the vessels it occludes over the course of 2–4 weeks. This is a disadvantage, in that reflow to the treated area occurs, but an advantage in that the use of Gelfoam encourages prolonged retention of the chemotherapeutic agent in the tumour and the ability to re-treat the area fairly easily subsequently. Ethiodol is a radiographic contrast agent, one of the first, developed in the 1920s. It is a poppy seed oil derivative, a nonsoluble lipid. When infused into the hepatic artery or branches, it is thought to pass through the portal triad and be taken up into and then obstruct the portal vein capillaries. Over time, it is taken up by the reticuloendothelial system of the liver, and is then largely broken down and excreted. Empirically, it seems also to block hepatic arterial branches. It has the advantage, then, of relatively long-lasting obstruction of blood flow at a small vessel level, but without associated damage to larger vessels (**Figure 2**).

A major reason for both the interest in and the success of transcatheter therapy in the liver is that the liver has two blood supplies: the hepatic artery and the portal vein. Normally, the bulk of the blood flow to the liver is from the portal vein (about 70%) with the remainder from the hepatic artery. If the hepatic artery is acutely occluded, as by surgical ligation, portal flow increases to a sufficient level to maintain normal liver function. Further, liver malignancies receive the bulk of their blood supply from the hepatic artery. It is thought that some of the blood supply to the periphery of the tumour may be from the portal vein, which is not as readily accessible percutaneously as is the hepatic artery. This portal vein supply, in theory, is obstructed by Ethiodol. In most other organs, if the supplying arterial supply is obstructed, cell death results. In these organs, then, it is very important that only arterial flow to the tumour, and not to normal tissue, be embolized. This is often technically very difficult to achieve. In normal liver, however, more effective transcatheter therapy can be given, since liver adjacent to the tumour can be embolized without complications.

INDICATIONS FOR LIVER CHEMOEMBOLIZATION

Lesions which are most amenable to chemoembolization are those with a high degree of macroscopic neovascularity. Not only are such lesions technically fairly

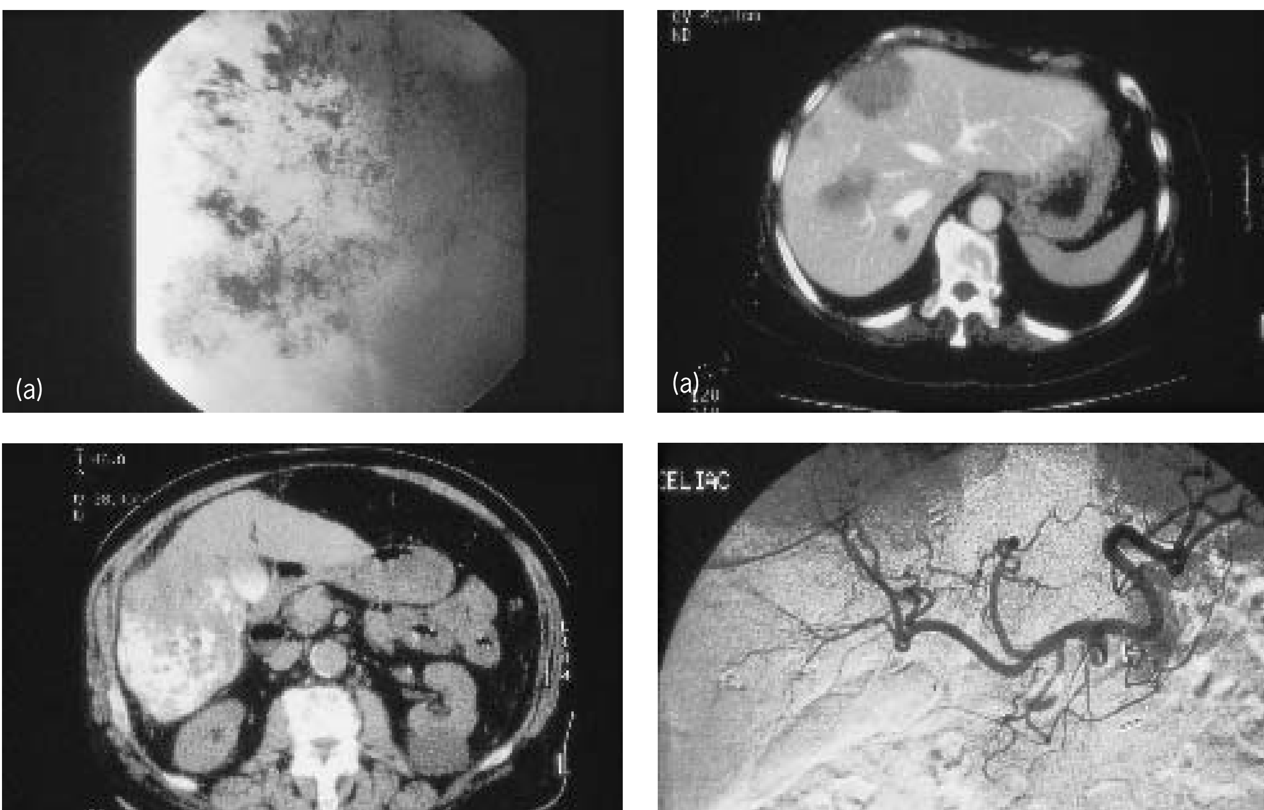

Figure 2 Same patient as in **Figure 1**. (a) Angiographic image immediately following chemoembolization, showing retention of Ethiodol in the tumour; (b) image from computed tomography performed 1 day later demonstrates retention of the oily contrast in much (but not all) of the tumour.

Figure 3 Patient with colon adenocarcinoma metastatic to the liver. (a) Image from contrast-enhanced CT shows four distinct lesions which have low density (relative to normal liver parenchyma, which shows contrast enhancement); (b) image from a coeliac axis arteriogram shows a faint blush (increased density) in the liver lesions, without visible neovascularity.

accessible to chemoembolization, but also treatment tends to be more effective than in lesions with minimal neovascularity. Clearly, all malignancies have a vascular supply, but in many, e.g. colorectal adenocarcinoma, lesions are relatively avascular on angiography (**Figure 3**). Primary hepatocellular carcinoma tends to be hypervascular angiographically (**Figures 1** and **4**). Similarly, most neuroendocrine tumours which are metastatic to the liver tend to be hypervascular (**Figure 5**).

The results of chemoembolization for hepatocellular carcinoma have been documented better than those for other lesions. One difficulty in interpreting results of the various studies, however, is that so many variables exist. These include the chemotherapeutic agent utilized, the embolic agent utilized, the number of treatments, the use of ancillary treatments such as radiation or systemic chemotherapy, the patient's liver function and the stage of the hepatocellular carcinoma (HCC). Most often, HCC that is treated by chemoembolization is considered non-operable. This is either because there are multiple lesions, with the presence of lesions in multiple lobes, because of the large size of the primary tumour, or because the patient's liver function is considered so poor that the operative risk, balanced against the likelihood of cure, is unacceptably high. At best, the cure rate for lesions considered surgically resectable is of the order of 30%, and mean survival is <18 months (Dusheiko *et al*., 1992; Colombo, 1993). Further, there is currently no effective systemic chemotherapeutic agent or regimen. For these reasons, in addition to its high incidence as a result of the high prevalence of hepatitis B or C, chemoembolization has been used widely for the treatment of HCC. Treatment is often repeated, at intervals ranging from 1 month to several years. One study demonstrated no statistically significant increase in survival when chemoembolization was compared with standard chemotherapy, although there was a trend toward prolonged survival (Groupe d'Etude et de Traitement du Carcinome Hepatocellulaire, 1995).

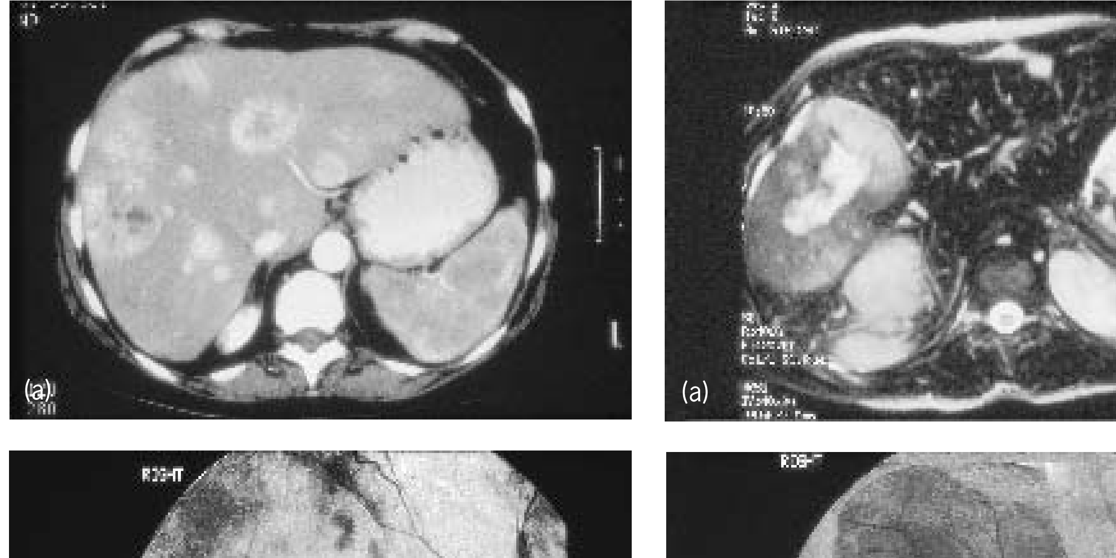

Figure 4 Elderly woman with hepatocellular carcinoma. (a) Image from a contrast-enhanced CT study shows numerous lesions with dense peripheral enhancement, greater than surrounding normal liver; (b) corresponding image from selective hepatic angiography shows dense lesions with marked neovascularity (tumour-induced, somewhat disordered appearing new vessels).

Other series have shown median survival of up to 2 years in patients treated with chemoembolization, a result which certainly rivals the efficacy of surgery in the relatively small proportion of lesions that are considered operable (Colombo, 1993; Simonetti *et al*., 1997). Another small study examined the effectiveness of chemoembolization with and without Ethiodol and gelatin sponge particles and demonstrated improved efficacy with the combination therapy, consisting of a chemotherapeutic agent, gelfoam and Ethiodol (Hatanaka *et al*., 1995). Another alternative is to combine embolization with percutaneous ablative techniques (Pacella *et al*., 2001). Over the last few years, with the emergence of radiofrequency ablation (see the chapter on *Molecular Mechanisms of Radiotherapy*), a combination of chemoembolization and percutaneous radiofrequency has been employed for discrete lesions, generally those ≤ 5 cm in overall size, even if multiple.

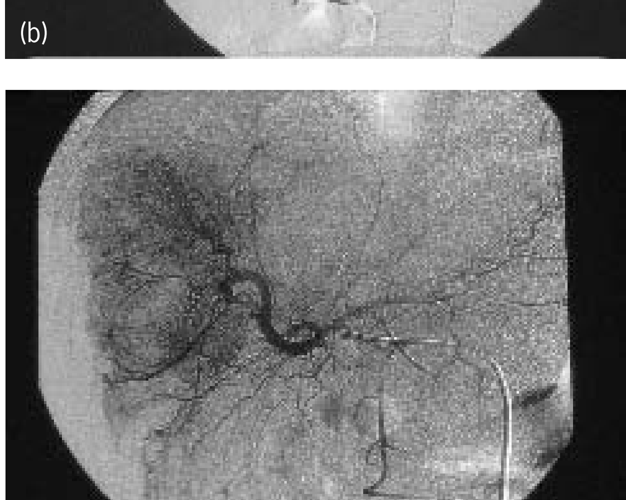

Figure 5 26-year-old woman with neuroendocrine tumour involving the liver, with unknown primary. (a) Contrast-enhanced MRI scan shows signal enhancement in a large lesion in the right lobe of the liver, with markedly increased signal enhancement centrally, suggestive of necrosis; (b) Selective arteriogram in right hepatic artery shows dense hypervascularity of this lesion; (c) repeat arteriogram 4 months after initial chemoembolization shows that this lesion is substantially smaller and less hypervascular. Repeat chemoembolization at this time led to a further marked decrease in the size of this and other liver lesions.

As HCC is often well circumscribed and hypervascular angiographically, it is reasonable to hypothesize that chemoembolization, particularly in combination with a percutaneous ablative technique such as radiofrequency, will be curative for single lesions. To date, however, although such an approach has been used, its true efficacy in terms of cure or improved survival has not been definitively evaluated.

Chemoembolization for the treatment of neuroendocrine tumours, perhaps because of the lesser frequency of such lesions, is less well documented. In general, all neuroendocrine tumours, including carcinoid, gastrinoma, insulinoma and pheochromocytoma, can be treated. It is relatively common for neuroendocrine tumours to present with widespread liver involvement, with multiple small lesions. Again, there is no widely effective systemic chemotherapy, although octreotide acetate may be useful, particularly in controlling symptoms. In general, patients who are treated appear to be more likely to respond favourably if the primary tumour is identified and removed. Survival for 2–5 years or more is not uncommon in such patients, even with widespread liver metastases, but again, chemoembolization cannot be considered curative. In one series, mean survival was ~4 years from the last chemoembolization (Stokes *et al*., 1993). It is relatively common for such lesions to shrink markedly after chemoembolization (**Figure 5**) but the occurrence of additional lesions and damage to the normal liver, as well as decreased vascular accessibility due to occlusion by the treatment, may limit the option of retreatment.

Many types of metastatic lesions have been treated by chemoembolization, either with one or more chemoembolizations or in combination with other therapy, such as percutaneous radiofrequency ablation, surgical resection or systemic chemotherapy. Some success has been reported in the treatment of highly lethal metastatic ocular melanoma, and there has also been some success in the treatment of GI stromal cell tumours (Soulen, 1997). As noted above, treatment is realistically directed at prolonging life rather than achieving a cure. The greatest experience to date with lesions other than HCC has been in the treatment of metastatic colorectal carcinoma. Unlike with more vascular lesions, such tumours tend not to shrink following chemoembolization. It is common, however, for such lesions to stabilize. Since most patients who undergo chemoembolization for metastatic colorectal carcinoma have multiple liver metastases which make them unresectable surgically or have metastatic disease elsewhere in the body, it is likely that survival is not prolonged by chemoembolization as currently practised. It is likely, however, that such treatment does prolong good quality of life. This approach is most appropriate, therefore, in patients who are unresponsive to standard systemic chemotherapy but remain in fairly good general condition, and often is considered after failure of first-line systemic chemotherapy.

CONTRAINDICATIONS AND COMPLICATIONS

As indicated above, chemoembolization should not be performed in certain patients, primarily those who are unlikely to gain substantial benefit from the procedure, in terms of prolongation of life or improvement or stabilization of quality of life. Thus patients who have far advanced tumours with failing liver function are not good candidates. At this point, it is not clear whether or not there are certain types of tumours which are so unlikely to benefit that the discomfort and other risks outweigh potential benefits in quality of life or prolongation of life. Chemoembolization of liver lesions can be considered in any otherwise suitable patients who are in sufficiently good general health (activity level, liver and renal function) and do not have other good options for treatment.

There are, however, several risk factors which are strong relative contraindications (Chung *et al*., 1996; Sakamoto *et al*., 1998). Patients with markedly compromised liver function are far more likely than those with normal liver function to develop progressive and even fatal liver failure. As a general rule, patients with a significant elevation in bilirubin should not undergo chemoembolization, although some of these patients may benefit from embolization with Ethiodol alone. This treatment is unlikely to damage liver function further if Ethiodol is injected selectively into the tumour. This is probably not true if a chemotherapy agent is used; even if injected selectively, some of the drug is likely to leak out of the tumour and be delivered systemically and to the liver as a whole (Raoul *et al*., 1992). Similarly, any patient with an obstructed portal vein should be treated with great caution. As noted, the principle of chemoembolization in the liver is that the tumour will be deprived of its blood supply, the hepatic artery, but normal liver will be preserved since it is also supplied by the portal vein. In the absence of portal vein blood flow, embolic occlusions of portions of the hepatic artery may lead to focal hepatic infarcts or to hepatic failure. Although in theory chemoembolization is performed solely to the arteries which supply the tumour, in practice such precise treatment is not usually feasible. This is because of multiple feeding arteries to the tumour(s) as well as technical limitations in placing the catheter sufficiently selectively.

The usual precautions with chemotherapy agents and with X-ray contrast agents must be observed. The dose of the particular agent used must be modified based on prior treatment and the individual's cardiac, renal and hepatic function. This procedure relies on localization of vessels and lesions by the injection of contrast agents. In patients with markedly compromised renal function, these contrast agents may lead to renal failure, even requiring dialysis (Tepel *et al*., 2000). Again, the risk/benefit ratio must be carefully assessed.

OTHER USES AND TECHNIQUES

As noted, selective high-dose arterial chemoembolization with systemic rescue has been used with some success in the treatment of head and neck cancer. Embolization without the addition of chemotherapy has been shown to be valuable in the treatment of renal cell carcinoma, primarily to control bleeding into the urinary tract, to diminish pain caused by a large vascular tumour or to decrease bleeding interoperatively and thus facilitate surgery. This is usually done using a permanent occlusive agent, such as PVA or absolute alcohol, infused as selectively as possible into the tumour. The reason why no chemotherapeutic agent is given is that none are thought to be effective, and they may add toxicity. The use of indwelling arterial catheters, with ports, is likely to prove increasingly useful. Such arterial catheters allow long-term percutaneous access and, if indicated, continuous infusions, and they can be safely placed on an outpatient basis.

CONCLUSION

A variety of transcatheter methods have been in use for many years for the selective treatment of tumours and organs. These techniques are most widely utilized currently for the treatment of primary and secondary lesions of the liver. Their use is also promising for other areas. Many questions remain regarding the specific efficacy of chemoembolization, because of the wide variation in the drugs utilized, the stage of tumour treated and the embolic agents employed. Over the next few years, there is likely to be increased use of transcatheter therapies with specifically targeted agents, such as genetic vectors and specific antitumour antibodies. As the ability to treat cancers selectively improves, the use of transcatheter approaches to deliver such therapy selectively to tumours is likely to increase also.

CONTENTS

- Introduction
- Target Sites for PAT
- Goals of PAT
- Imaging Related to PAT
- Specific Forms of PAT
- Conclusion

INTRODUCTION

With the introduction, wide acceptance and refinement of medical imaging techniques over the past 40 years, the approach to diagnosis and treatment of malignancy has significantly changed. Computed tomography (CT), magnetic resonance imaging (MRI) and ultrasound in particular have tremendously improved the ability to detect and characterize many malignancies, allowing for earlier diagnosis of primary and metastatic tumours. In addition, less invasive forms of therapy are made possible by imaging guidance.

Percutaneous treatment of malignancy utilizes imaging for the delivery of ablative agents. Percutaneous ablative therapy (PAT) includes thermal ablation and chemical ablation. Thermal ablation currently includes radiofrequency ablation (RFA), interstitial laser photocoagulation, microwave coagulation, cryotherapy and instillation of heated fluids (Scudamore *et al*., 1997; Yoon *et al*., 1999; Dodd *et al*., 2000). Chemical ablation currently includes instillation of absolute alcohol (95–99.5% ethanol) and acetic acid (Shiina *et al*., 1987; Livraghi *et al*., 1995; Liang *et al*., 2000).

TARGET SITES FOR PAT

The bulk of published literature on PAT is devoted to interventions within the liver. The liver is an attractive target not only because of its frequent involvement by metastatic disease, but also because of its large size, which provides organ reserve and frequently provides access to the tumour through normal tissue. Multiple tumour foci, large tumour size, and location next to sensitive areas such as the diaphragm, porta hepatis or liver capsule provide technical challenges.

PAT has also been used to treat malignancies within the kidney, lung, breast, adrenal glands, prostate, pancreas, head and neck and brain (Anzai *et al*., 1995; Zlotta *et al*., 1998; Jeffrey *et al*., 1999; Mack and Vogl, 1999; Merkle *et al*., 1999a,b; Polascik *et al*., 1999; Dupuy *et al*., 2000; Shibata *et al*., 2000). Successful treatment of benign conditions, such as autonomously functioning thyroid nodules and symptomatic vertebral body haemangiomas, has also been reported (Doppman *et al*., 2000; Tarantino *et al*., 2000).

Results of interventions within one organ cannot be generalized to interventions elsewhere, given differences in tissue characteristics. A comparison of *in vivo* RFA within calf liver versus calf muscle showed a 95% greater average diameter of ablation within muscle than within liver (Goldberg, 1999). It will be important in the future to verify separately the effectiveness of various forms of PAT within specific target tissues.

GOALS OF PAT

Currently, the primary goal of PAT is palliation for patients who are not candidates for curative surgery. These patients are usually categorized as unresectable because of unfavourable location and extent of tumour, or general debility compounding the risks of major surgery. Local ablative therapy is employed to shrink tumours, or to slow or halt tumour growth, usually in the liver. Given that hepatocellular carcinoma (HCC) is the most common malignancy in the world and that 20–25% of all cancer deaths can be related to hepatic metastases, there is a large population that may benefit from PAT (Stone and Cady, 1994; D'Agostino and Solinas, 1995).

The early results for PAT reported in the literature suggest that curative therapy is possible, especially with

further refinements in technology and technique. While there is no clear consensus on the largest tumour amenable to PAT, tumour size is a critical factor in treatment planning. If tumour diameter is larger than the diameter of the zone of ablation, multiple overlapping treatments are necessary and the possibility of persistently viable tumour cells increases. Precise probe, or needle placement, reliable delivery of ablative agent and rigorous imaging follow-up, with retreatment as indicated, are necessary to effect a cure (see **Figure 1**). It has been suggested that tumours within cirrhotic livers, typically seen in patients with HCC, may have enhanced tumour kill with thermal ablation due to an 'oven effect' caused by the cirrhotic tissue limiting heat diffusion away from the tumour (Livraghi *et al*., 1999). Complete necrosis in up to 71% of HCC 3.1–5.0 cm in diameter and 25% of those 5.1–9.5 cm in diameter has been reported with radiofrequency ablation (Livraghi *et al*., 2000). A series including microscopic evaluation of liver metastases, 2.0–4.0 cm in diameter, treated with RFA reported complete necrosis in eight of nine (89%) resected specimens (Scudamore *et al*., 1999).

Differences in equipment, technique, indications and the relatively small size of early series make the application of published data regarding PAT to individual patients somewhat difficult. However, it seems that effective local control is a reasonable expectation for patients with small- to medium-sized tumours in the liver. Patients with localized disease may deserve aggressive treatment, given the possibility of cure. Multi-modality treatment including surgery, chemotherapy, chemoembolization and radiation, in addition to local ablative therapy, should be considered.

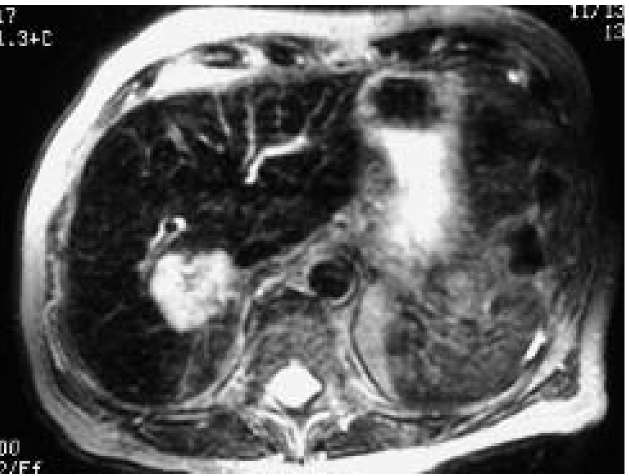

Figure 1 Axial MRI enhanced with intravenous ferumoxides showing a high signal lesion in the right lobe of the liver, which represents a metastasis from colon carcinoma.

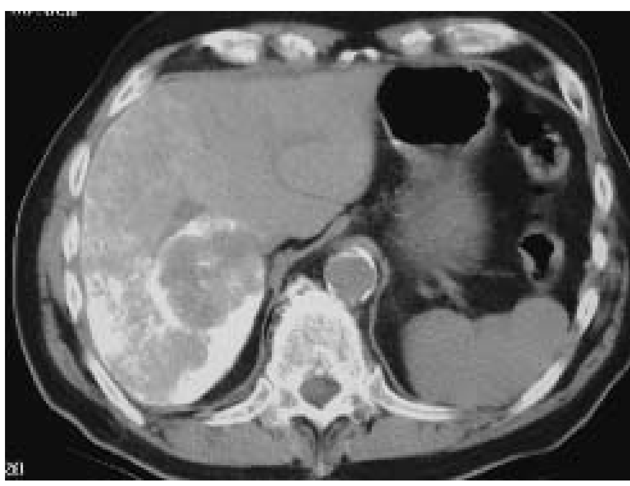

Figure 2 CT image showing the same lesion as in Figure 1. This image was obtained after ethiodol embolization of the right hepatic artery. The high-attenuation ethiodol is seen throughout the right lobe of the liver and outlines the relatively low-attenuation tumour.

IMAGING RELATED TO PAT

The main roles for imaging in PAT are initial tumour detection and characterization, PAT guidance, and follow-up. Contrast-enhanced CT and MRI are most often used for lesion detection and characterization, and follow-up (**Figure 1**). Thorough preprocedure imaging is imperative in order to select the appropriate therapy and to ensure that all areas of tumour are treated if possible. CT scanning following hepatic artery infusion of lipiodol (iodized oil) has been described as the most sensitive method of detecting HCC (90–97% sensitivity) (**Figure 2**) (Palma, 1998). This technique is also helpful in improving the conspicuity lesions treated under CT guidance (**Figure 3**).

The imaging modality used for PAT guidance is generally selected according to operator preference. Ultrasound is popular because of availability, ease of use and its ability to provide real-time monitoring. CT guidance is also common and MR guidance is possible with specialized equipment (particularly for injection therapy and laser ablation). The goals of imaging guidance are to ensure precise delivery of the ablative agent, to detect potential complications early and accurately, and to ensure as complete treatment as possible.

Postprocedure follow-up generally consists of contrast-enhanced CT or MR. Ultrasound is generally considered to be less reliable owing to the heterogeneous appearance of treated lesions and the need to demonstrate absence of lesion enhancement. Ultrasound contrast agents and Doppler sonography, however, may make this modality more useful for follow-up (Koito *et al*., 2000). Imaging is generally performed 1–2 months after treatment and then at 3–6 month intervals for 1 year, followed by more widely spaced intervals if the patient and lesions remain stable.

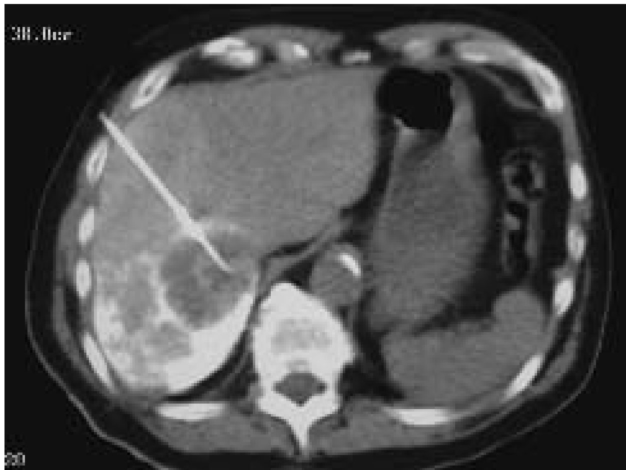

Figure 3 CT image obtained during RFA showing the RF probe within the tumour.

Completely necrotic lesions are of low signal intensity on T2 weighted MR and often have thin enhancing rims. Nodular areas of enhancement on MR or CT indicate residual tumour. Successfully treated lesions remain the same size or become smaller.

SPECIFIC FORMS OF PAT

Radiofrequency Ablation (RFA)

Radiofrequency electrocautery devices have been used throughout the last century to directly ablate exposed tissue, particularly to achieve haemostasis. Advances in technology have allowed for percutaneous, image-guided placement of electrode containing probes. These probes deliver an alternating current in the RF wave range (460 kHz), resulting in ionic agitation that produces heat and at temperatures above 60 °C, cell death occurs rapidly. The distance the generated heat is conducted with the tissue determines the zone of ablation. The power of the RF current, time of application, the impedance of the tissue and the size, number and spacing of the electrodes affect the zone of ablation. As tissue is ablated, the impedance of the tissue increases. Generators with increased power and pulsed current have been developed. Probes now may include multiple electrodes that, in some designs, have variable diameters of expansion, and in other designs are saline cooled. Saline cooling directly improves conduction and can limit charring of tissue, which increases impedance. Techniques to enhance the efficacy of PAT include preprocedure chemoembolization, concomitant injection of chemotherapeutic agents and intraoperative RFA combined with clamping the porta hepatis (Pringle manoeuvre). The Pringle manoeuvre and preprocedure chemoembolization are believed to increase the area of ablation by decreasing heat loss via flowing blood (heat sumping). The direct injection of chemotherapeutic agent as well as chemoembolization have the added benefit of targeted tumour toxicity (Goldberg *et al*., 2000).

The three currently available RFA devices are marketed by RITA Medical Systems (Mountain View, CA, USA), Radionics (Burlington, MA, USA) and Radiotherapeutics (Mountain View, CA, USA). All function on the basic principle of delivery of an alternating current via one or multiple electrodes inserted into the target area with repositioning or retreatment as needed based on lesion size, location and success of initial placement (Scudamore *et al*., 1997; Dodd *et al*., 2000). These three devices are designed to create zones of ablation 3–4.5 cm in diameter in the liver. In practice, however, ablation diameters as small as 1.2 cm, with ranges of 1.2–3.5 and 1.8–3.6 cm, have been reported with use of a single type of RF electrode (Radionics; Goldberg *et al*., 1998; Scudamore *et al*., 1999). These differences in ablation diameter are likely related to local factors such as blood flow and lesion density and underscore the need for precise imaging to determine if viable tumour remains. The small ablation diameters previously reported are also likely related to older electrode and generator designs, which have been improved upon.

The RITA device consists of a 15-gauge probe with seven or nine retractable electrodes at the needle tip that expand to 3–5 cm diameter in a ‘star burst’ array. It uses temperature as an endpoint, while the other two devices use tissue impedance. Its generator creates a 50–150 W alternating current and monitors the temperature at the tip of five electrodes and automatically diverts current when an electrode exceeds a preset temperature (e.g. 100 °C). The electrodes are retracted into the probe needle prior to placement, and are then deployed into the target tissue once ideal position is confirmed. Recently developed probes offer the option of increasing the diameter of the electrode array in a sequential fashion to allow for consecutive ablations at increasing diameters. The manufacturer recommends ablating large tumours in a stepwise fashion (e.g. first at 3 cm, then at 4 cm and finally at 5 cm) to ensure complete treatment.

The Radionics device utilizes 1–3 saline-cooled straight 17 F probes with 1–3-cm lengths of active electrode and a 100–200-W alternating current generator. A multiprobe array in a triangular configuration (cluster probe) offers the possibility of larger zones of ablation than the single probe model. In situations where the cluster probe is not feasible (e.g. intercostal approach), two parallel probes may be placed. Power from the generator is delivered in pulses that automatically adjust to recorded tissue impedance. Theoretically, current is directed away from ablated tissue in the target area that has high impedance toward areas of lower impedance resulting in uniform ablation. The generator shuts off when there is a sharp rise in tissue impedance, which is thought to indicate tissue necrosis. Saline

cooling of the electrodes represents a technical improvement from the original design. The Radionics and RITA devices may be used for electrocautery of the tract as the needle is withdrawn.

The Radiotherapeutics device has a multi-electrode 14-gauge probe that is similar to the RITA device in appearance and deployment characteristics and is available in three diameters. Ten electrodes expand into a 2.0-, 3.0- or 3.5-cm spherical umbrella-like configuration once the probe is in the target area. A probe with electrodes that expand to 5.0 cm is being developed (Dodd *et al*., 2000). The generator monitors both electrode temperature and tissue impedance. A pulsed alternating current is delivered to the target area. The generator is shut off when there is a sharp rise in tissue impedance.

Reported results with RFA have indicated major complications ranging from 0 to 10% and local control ranging from 48 to 98.2% (Scudamore *et al*., 1997, 1999; Goldberg *et al*., 1998, 2000; Curley *et al*., 1999; Livraghi *et al*., 1999, 2000; Rhim and Dodd, 1999; Dodd *et al*., 2000). The vast differences in local control are probably due to differences in reporting standards, length of follow-up, equipment differences and operator experience. Each of the three devices has compelling features or data to support their use, and recent design updates make it difficult to compare previous data with present performance. No single device has yet demonstrated clear superiority.

Percutaneous ethanol injection therapy (PEIT)

PEIT has been extensively studied, largely in Japan and Italy, with promising results and low complication rates (Shiina *et al*., 1990; Livraghi *et al*., 1995, 1999; Shibata *et al*., 2000). The relative simplicity of technique and availability of tools are attractive features. Needles are generally 20–22-gauge Chiba and spinal needles or 21-gauge needles with a closed conical tip and multiple terminal side holes (PEIT needle, Hakko, Tokyo, Japan, or Cliny needle, Yokohama, Japan). Absolute alcohol (95–99.5% ethanol) is injected in small aliquots (fractions of a millilitre) with real-time ultrasound guidance both at the time of needle placement and during injection. Usually, 1–8 mL are injected per treatment session with the volume dictated by the size of the lesion, imaging findings during injection and the patient's tolerance to the procedure. Injection is typically halted once pooling of ethanol is seen within the lesion (the ethanol no longer disappears rapidly from the needle tip) or if leakage of ethanol outside the target area is detected. Treatment sessions can be performed 2–3 times per week until the entire lesion has been treated. Therapeutic efficacy is assessed by follow-up imaging and clinical assessment (AFP and CEA assay).

Large-dose, 'single-session' treatment has been described with doses up to 165 mL (mean, 75 mL). However, general anaesthesia was required and the patients were medicated with 1000–1500 mg of i.v. fructose 1,6-diphosphate (Esafosfina; Biomedica Foscama, Ferentino, Italy) and 1200 mg of i.v. glutathione (TAD 600; Biomedica Foscama) to neutralize the systemic effects of the alcohol (Livraghi *et al*., 1995). Furthermore, two cases of prolonged hypotension, one of which resulted in death, were reported with injection of 35 and 80 mL respectively (Gelczer *et al*., 1998).

PEIT causes cell death by two mechanisms. The first is diffusion into cells, which results in dehydration and coagulation necrosis. The second is vascular occlusion caused by direct endothelial damage and platelet aggregation. PEIT is felt to be less effective in the treatment of liver metastases than for HCC. It has been suggested that HCC respond favourably due to hypervascularity and to the contrast in tissue density between hard cirrhotic tissue and softer HCC (Dodd *et al*., 2000).

In comparing PEIT with RFA in the treatment of HCC 3.0 cm or less in diameter, RFA was found to require fewer treatment sessions, 1.2 vs 4.8 sessions per tumour, and to have a higher rate of complete tumour necrosis, 90% (47/52) vs 80% (48/60) (D'Agostino and Solinas, 1995). Complications with PEIT are reportedly slightly less frequent than with RFA. However, most PEIT series report treatment of smaller lesions than those treated with RFA. A large series of PEIT treatment of sizeable HCC ($\geq$3–5 cm in diameter) reported a 1.7% rate of severe complications (10 patients) and one death (0.13%). There was a 27% rate of residual tumour in resected specimens (Livraghi *et al*., 1995).

Percutaneous Acetic Acid Injection

Percutaneous instillation of acetic acid is similar in principle and technique to PEIT. Small quantities of acetic acid are injected through a multihole infusion needle, placed into the target tissue with image guidance. Acetic acid appears to have stronger cytotoxic effects than ethanol, which may allow for larger ablation zones. Excellent local control of small lesions (1.5–3.0 cm in diameter) has been reported, with severe pain (11%), high fever (4%) and segmental wedge infarction (4%) noted as complications (Liang *et al*., 2000). Additional experience is needed to determine safety, efficacy and general treatment guidelines.

Interstitial Laser Photocoagulation (ILP)

ILP utilizes ND:YAG laser energy (approximate wavelength 1064 nm) delivered via a thin optical fibre placed through needles or guiding sheaths positioned within the target tissue, usually at 1–1.5-cm intervals. An MRI-compatible applicator kit (Somatex, Berlin, Germany) is available in 'conventional' and 'power' laser forms. The kits consist of a cannulation needle, guidewire, 7–9F

dilator or sheath and a 4–7F, 40-cm protective Teflon catheter. The conventional applicator delivers a maximum power of 6 W for up to 22 min and creates a diameter of necrosis of <2 cm. The power applicator is liquid cooled, can deliver up to 30 W for 14–23 minutes and creates a mean diameter of necrosis of 3.3 cm (Mack and Vogl, 1999; Vogl *et al*., 1999; Dodd *et al*., 2000).

Limited reports are available to determine the efficacy of ILP. One series employed contrast-enhanced CT, from 6 weeks to 3 months following treatment, to determine the degree of tumour necrosis. Complete necrosis of 21/35 lesions <4 cm was reported, but none of 20 lesions >4 cm showed complete necrosis (Amin *et al*., 1993). A larger series (659 lesions in 230 patients) did not report degree of necrosis, but instead reported median survival, which was significantly increased in treated patients compared with historical controls of untreated patients: median survival of 36.4 months compared with 10–21 months expected median survival (Vogl *et al*., 1999).

Percutaneous Microwave Coagulation Therapy (PMCT)

Several groups in Japan have reported on PMCT in the treatment of HCC (Seki *et al*., 1994; Murakami *et al*., 1995; Ohmoto *et al*., 1999). A 1.6-mm, 30-cm polytetrafluorethylene-coated bipolar electrode is passed through a needle guide into the target area and a 1.5- or 3.0-cm inner conductor delivers 2450-MHz microwaves at 60–150 W, usually for 60–120 s. Generally, ultrasound guidance is utilized and multiple overlapping treatments are administered per treatment session. Each application results in a relatively small diameter of ablation, approximately 2 cm. Follow-up contrast-enhanced CT or MRI is obtained and residual areas of viable tumour are retreated. Cited complications have been infrequent with one of nine patients in one series developing a pleural effusion and ascites (Murakami *et al*., 1995). A local sensation of heat during the ablation and postprocedure fever are common. Local lesion control has been reported in 56–100%. The need for multiple overlapping treatments due to the small diameter of ablation makes completeness of ablation less certain. Despite this theoretical concern, successful induction of complete necrosis has been reported in lesions up to 6.0 cm in diameter, using intraoperative microwave coagulation therapy (Hamazoe *et al*., 1995).

The efficacy of PMCT in hepatic metastases is unknown. However, a study that compared intraoperative microwave coagulation therapy with hepatic resection for the treatment of multiple (2–9) hepatic metastases found them to be of equal efficacy (Shibata *et al*., 2000). Thirty patients with multiple liver metastases, felt to be amenable to hepatic resection, went to laparotomy and were randomized to hepatectomy (16 patients) or sonographically guided intraoperative microwave coagulation (14 patients). The 1-, 2- and 3-year survival rates and mean survival times were 71%, 57%, 14% and 27 months, respectively, in the microwave group and 69%, 56%, 23% and 25 months in the hepatectomy group.

Cryosurgical Ablation (CSA)

It is difficult to compare CSA with percutaneous ablative techniques, because CSA is typically employed intraoperatively. CSA produces tissue destruction by creating focal subzero temperatures adjacent to the tip of a probe, resulting in cellular dehydration and protein denaturation. Probes of 9–12 mm are generally used, although smaller probes have been developed for laparoscopic surgery. Ultrasound is used to guide probe placement and monitor 'ice-ball' formation. Several freeze–thaw cycles, lasting 7–30 min, are applied with each application. Lesions up to 17 cm have been treated, but complications increase with increasing treatment volume. A variety of serious complications have been reported, including myoglobinuria, surface liver cracking, haemorrhage, biliary fistula, abscess, portal vein thrombosis and thrombocytopenia (Mahvi and Lee, 1999; Wallace *et al*., 1999).

CONCLUSION

Recent advances in imaging and percutaneous ablative techniques have expanded cancer therapy. PAT offers hope for improved palliation and possibly improved long-term survival. As with other forms of cancer therapy, PAT is most effective when employed in a setting of multidisciplinary collaboration. Experience with PAT continues to increase. However, controlled trials are needed to confirm the safety and efficacy of the different forms of PAT and to explore the role of PAT in various organs.

Chapter 85

Drug Resistance and Reversal

Andrew Harbottle
University of Newcastle Upon Tyne, Newcastle Upon Tyne, UK

CONTENTS

- Introduction
- Transport Proteins
- Reversal of Multidrug Resistance

INTRODUCTION

One of the major obstacles to the ultimate success of cancer chemotherapy is the ability of malignant tumours to develop resistance to cytotoxic compounds and this can affect patients with a variety of blood cancers and solid tumours, including breast, ovarian, lung, and lower gastrointestinal tract cancers. Resistance may be to a single drug, e.g. resistance to methotrexate due to gene amplification of dihydrofolate reductase, or to a number of drugs. Clinical oncologists were the first to observe that cancers treated with a number of different anticancer drugs were able to develop cross-resistance to many other cytotoxic agents to which they had never been exposed, greatly decreasing the chance of curing these tumours with chemotherapy. In many cases, cells grown in culture from such multidrug-resistant tumours demonstrate similar patterns of resistance *in vitro* to those seen *in situ*. This observation suggests that multidrug resistance (MDR) is, in many cases, the result of heritable changes in cancer cells causing altered levels of specific proteins, or mutant proteins, which allow cancer cells to survive in the presence of many different cytotoxic agents. These genetic changes within the tumour cell population that confer drug resistance may affect cell cycle dynamics, uptake and efflux of drugs, cellular drug metabolism, susceptibility of cells to apoptosis, intracellular compartmentalization of drugs or repair of drug-induced damage (usually to DNA). Tumours usually consist of a mixed population of malignant cells, and as such multidrug resistance in tumours may develop owing to a selecting out of drug-resistant cells during the course of treatment, or indeed may be due to direct genetic changes within the population caused by exposure to the chemotherapeutic agents.

Multidrug resistance of tumours has been correlated to the expression of at least two molecular efflux pumps in tumour cell membranes, which actively expel chemotherapeutic drugs from the cell. The active efflux of drugs from the cell allows the cell to avoid the cytotoxic effects of the compounds. The two efflux pumps most commonly found in multidrug-resistant tumours are P-glycoprotein and the multidrug resistance-associated protein (MRP). Although most research has concentrated on efflux transport mechanisms of resistance, other possible mechanisms of resistance have been suggested including the expression of the metabolizing enzyme glutathione *S*-transferase P1, which is often overexpressed in multidrug-resistant tumours.

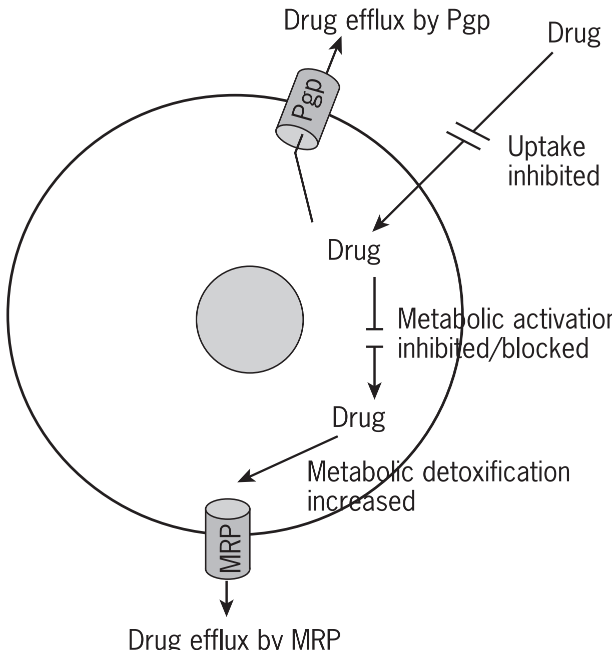

Figure 1 Summary of the major mechanisms of multidrug resistance.

A summary of the major mechanisms of MDR is shown in **Figure 1**.

TRANSPORT PROTEINS

The efflux transport of chemotherapeutic drugs and its role in multidrug resistance is well established, and this section will focus on the two major transport proteins involved in

multidrug resistance, those members of the ATP-binding cassette superfamily, P-glycoprotein and MRP.

The ATP-binding Cassette Superfamily

The ATP-binding cassette ((ABC)-ATPase) proteins constitute a very large and highly conserved superfamily found in large numbers in all organisms. This particular class of ATPase is usually found linked to transport protein, with all ABC systems made up of a highly conserved ABC-ATPase, and at least one cognate, but much less conserved membrane domain (MD). In these systems the ABC-ATPase acts as an energy generator and the membrane domain as a transport pathway.

One of the outstanding features about members of the ABC transporters is the huge range of compounds transported by different members of the family, from ions to large polypeptides, polysaccharides and xenobiotics. Another feature of this family of transporters is the ability of the transporters to act as either export or import pumps.

The binding and hydrolysis of ATP is the key to the energization of movement of substrates across the membrane by the ABC transporters. Many studies have shown that the two ABC domains of Pgp function cooperatively and that inactivation of one catalytic site completely abolishes all ATPase activity (Holland and Blight, 1999). Studies of vanadate trapping of ADP in the specific catalytic sites, ABC1 or ABC2, have led to the development of a model of ATP hydrolysis alternating equally between the two ABC domains, implying that ATP bound at one ABC site prevents hydrolysis at the second site. This model of the ATP catalytic cycle is still widely held and can be considered likely to hold for many ABC transporters.

The two transmembrane domains of ABC transporters are highly hydrophobic. Each is predicted, from its sequence, to consist of multiple α-helical segments that could span the membrane. The majority of transporters are predicted to have six membrane-spanning segments per domain, with the N- and C-termini on the cytoplasmic side of the membrane and three extracellular and two intracellular loops per domain. An example of this classical structure of ABC transporters is that of P-glycoprotein, which is discussed in greater detail in the next section and is shown in **Figure 3**. Not all ABC transporters have this classical structure; MRP1 (discussed later) is believed to have an unusual arrangement of the membrane domains with five additional transmembrane domains at the N-terminus, making a total of 11 for MD1 and six for MD2 (**Figure 2**) (Borst *et al*., 1999).

P-glycoprotein

Introduction

The best-studied mechanism of multidrug resistance is that due to the overexpression of P-glycoprotein (Pgp). Pgp was first detected as a surface phosphoglycoprotein overexpressed in cultured cells selected for MDR (Juliano and Ling, 1976), and was subsequently cloned from human cells based on amplification of the *MDR* locus (Chen *et al*., 1986). Since its discovery, the overexpression of human *MDR1* cDNA has been shown to confer resistance to a number of cytotoxic anticancer drugs, and also many other hydrophobic pharmacological agents.

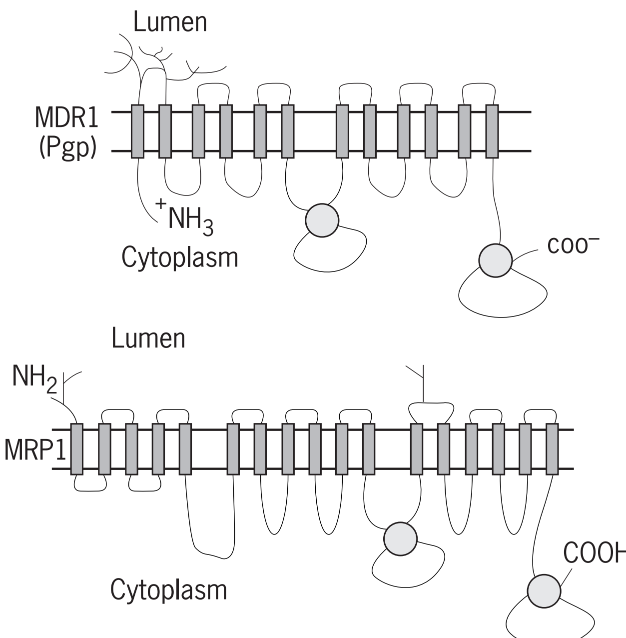

Figure 2 Proposed structures of P-glycoprotein and multidrug resistance-associated protein.

Table 1 Classes of *MDR* genes found in a number of species

	Class I	Class II	Class III
Human	*MDR1*		*MDR3*
Mouse	*mdr3*	*mdr1*	*mdr2*
Hamster	*Pgp1*	*Pgp2*	*Pgp3*

MDR1 Gene

The human *MDR1* gene, which encodes for Pgp, has been localized to chromosome 7, band q21.1. Pgp is composed of two homologous halves, each containing six transmembrane domains and an ATP-binding domain, separated by a flexible linker polypeptide (**Figure 3**). The protein-coding portion of the gene contains 27 exons: 14 coding for the left and 13 coding for the right half of the protein. There is no clear correlation between individual exons and specific structural units of the protein. Genetic analysis in a number of species has revealed the existence of a number of *MDR* genes (**Table 1**) (Juranka *et al*., 1989).

Expression in Normal Human Tissues

Expression of *MDR1* mRNA has been observed in a number of normal human tissues, with the highest levels of expression being found in adrenal gland, kidney, liver and colon (Gottesman *et al*., 1991), while lower levels were found in lung, jejunum, rectum, brain and prostate. Pgp shows specific localization within the plasma membrane of cells and has been immunolocalized on the apical surface of the brush border of the proximal tubule of the kidney, the apical mucosal surface of the colon, the luminal biliary canilicular surface of hepatocytes and ductular epithelium in the liver (Thiebaut *et al*., 1987).

Possible Normal Functions of P-glycoprotein

The localization of Pgp on the luminal surface of secretory organs such as the liver and kidney may have evolved to protect animals against toxic hydrophobic natural products, many of which are found in foodstuffs. Pgp can be viewed as a transmembrane energy-dependent drug efflux pump which uses energy derived from nucleoside triphosphates to pump hydrophobic amphipathic drugs, which have defused into the proximal tubule cells of the kidney, or the pericanalicular hepatocytes, into the urine or the bile. Another possible function for Pgp in the liver would be to act as a pump for normal metabolites that are excreted in the bile. The liver is an active modifier of circulating metabolites and also produces bile salts (which are hydrophobic, amphipathic molecules), some of which may be substrates for Pgp. Expression of Pgp in the mucosal cells of the jejunum and colon may be involved in the prevention of reabsorption of compounds excreted in bile, and indeed the prevention of absorption of dietary toxins. (See chapter on *Dietary Genotoxins and Cancer*.)

The function of expression of Pgp within the adrenal gland is more uncertain. The high level of expression of Pgp observed in the adrenal cortex may suggest a role for Pgp in steroid transport. Progesterone has been shown to interact with Pgp in multidrug-resistant cells and in the endometrium gravid uterus (Yang *et al*., 1989).

Expression of Pgp in the placenta could act as a barrier protecting the foetus from xenobiotics. Experiments using mice, which had no placental Mdr1a (Pgp), showed increased foetal exposure to [^{3}H]digoxin, [^{14}C]saquiniavar and paclitaxel, indicating that placental expression of Pgp is important in limiting the foetal penetration of various potentially harmful or therapeutic compounds (Smit *et al*., 1999).

Similarly expression of Pgp on the luminal surface of specialized endothelial capillary cells of the brain and testis indicates that Pgp may have an important function as part of the blood–brain or blood–testis barrier.

Structure and Function of P-glycoprotein

One of the first and most consistent alterations observed in MDR tumour cells was a decrease in cellular chemotherapeutic drug accumulation. There is considerable evidence that Pgp is involved in removal of chemotherapeutic drugs from the cell; however, the exact mechanism by which this occurs is still open to debate.

The most prevailing hypothesis is that Pgp functions as a transmembrane pore-forming protein, which acts in an energy-dependent manner to export compounds. The identification of ATPase activity associated with P-glycoprotein provides a mechanism by which energy may be transduced for active drug efflux. This hypothesis of drug efflux through a single pore formed by Pgp leaves a number of aspects not fully explained, such as the broad substrate specificity observed for Pgp (see the next section), and the inability to correlate the initial rate of transport with the Pgp concentration. Gottesman and Pastan hypothesized that the MDR1 transporter might act as a 'hydrophobic vacuum cleaner' by removal of compounds directly from the plasma membrane before they reached the cytosol (Gottesman and Pastan, 1993). Under the model proposed by Gottesman and Pastan the primary determinant of substrate specificity would be the ability of a compound to interact with the lipid bilayer and the secondary determinant would be its ability to interact with the binding site of the transporter. This is consistent with the observation that substrates for Pgp are lipophilic compounds and that the major determinant of a particular substrate to be transported by Pgp is its relative hydrophobicity (Zamora *et al*., 1988).

Photoaffinity labelling, mutational analysis and inhibitor studies indicate that transport of compounds by Pgp occurs through a single barrel of the transporter as illustrated in **Figure 3**. This model does not imply that different compounds enter the transporter in the same way, as the initial point of contact may vary from compound to compound, but it limits the passage of compounds through the transporter to a single transport channel.

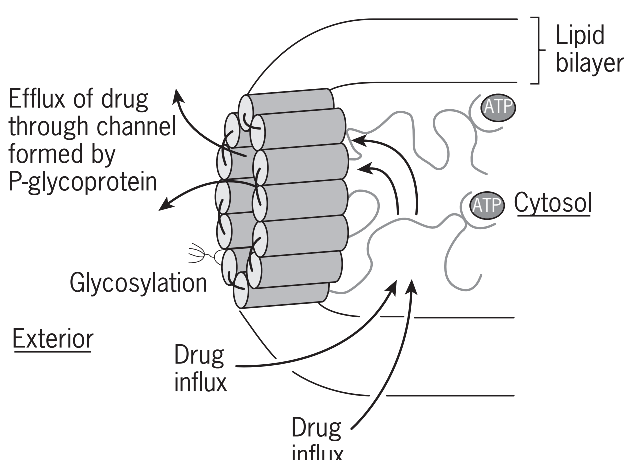

Figure 3 Schematic diagram of the proposed structure of P-glycoprotein, which functions as an energy-dependent drug efflux pump.

Very little is known about how the energy of ATP is harnessed by Pgp in order to facilitate drug transport, although it is know that binding of ATP to both binding sites is required for transport to occur efficiently (Azzaria *et al*., 1989). A number of hypothetical mechanisms of action for Pgp have been put forward, including possible action as a flippase (Higgins and Gottesman, 1992), or action as a proton pump and chloride channel providing motive force (Gottesman and Pastan, 1993). So far none of these mechanisms of action have fully explained all aspects of Pgp structure and function.

Substrates of P-glycoprotein

Pgp confers resistance against a wide spectrum of compounds that are hydrophobic, amphipathic natural product drugs (**Table 2**). These compounds include not only anticancer drugs, but also therapeutic agents. These compounds are chemically diverse, some of them may carry a positive charge at physiological pH and, because all of them are hydrophobic, they enter cells by passive diffusion. Substrates and antagonists for Pgp have been shown to interact with Pgp in different ways (Scala *et al*., 1997). In this study the interactions of a number of substrates and antagonists were examined, 35 compounds were identified as substrates only, while 42 were identified as antagonists only, with just seven compounds showing features of both substrates and antagonists. This suggests that antagonists bind to Pgp, but failing to be transported they block the binding and transport of other compounds, while substrates, in being transported, do not affect the transport of other compounds. Interestingly, this study noted that compounds in the antagonist group were relatively less toxic than compounds in the substrate group, with a median IC_{50} value of 22.5 μmol L^{-1} for the antagonist group, compared with 0.157 μmol L^{-1} for the substrate group.

Table 2 Common examples of substrates for P-glycoprotein

Compound type	Examples
Anticancer agents	*Vinca* alkaloids (vincristine, vinblastine)
	Anthracyclines (doxorubicin, epirubicin)
	Epipodophyllotoxins (etoposide, teniposide)
	Paclitaxel (Taxol)
	Actinomycin D
	Topotecan
	Mithramycin
	Mitomycin C
Other cytotoxic agents	Colchicine
	Emetine
	Ethidium bromide
	Puromycin
Cyclic and linear peptides	Granicidin D
	Valinomycin
	N-Acetylleucylleucylnorleucine
	Yeast a-factor pheromone
HIV protease inhibitors	Ritonavir
	Indiavir
	Saquinavir
Other compounds	Hoechst 33342
	Rhodamine 123
	Calcein-AM

Modulation of P-glycoprotein Activity

Not surprisingly, owing to the diverse nature of substrates for Pgp, the number of compounds that have been shown to be capable of modulating Pgp is also large and diverse, with the list including detergents, anthracycline analogues, progestational and antioestrogenic agents, antibiotics, antihypertensives and immunosuppressives. Some of the more commonly used modulators of Pgp are listed in **Table 3**. Perhaps the most important observation in the field of Pgp modulation came when Tsuruo *et al*. noted that verapamil, a membrane-active drug used in cardiology, could sensitize vincristine-resistant cells to the cytotoxic effects of vincristine and vinblastine (Tsuruo *et al*., 1981). Since verapamil blocks voltage-gated Ca^{2+} channels, other calcium channel blockers were studied and many such as nifedipine were also found to inhibit Pgp.

Many modulators, however, are not specific to Pgp, and may inhibit other transporters such as the multidrug resistance-related protein MRP (discussed later). For this reason, specific inhibitors have been sought. One such inhibitor is LY335979, which has been shown specifically to inhibit Pgp (Dantzig *et al*., 1999).

Expression of P-glycoprotein in Tumours

High intrinsic expression of MDR1/Pgp has been observed in a number of human tumours derived from tissues that normally express Pgp, including the kidney, the colon, the adrenal gland, and liver (Fojo *et al*., 1987; Gottesman *et al*., 1991). Examination of the level of expression of Pgp during various stages of colorectal carcinogenesis has shown that despite the initial high level of Pgp expression found in

Table 3 Commonly used modulators of P-glycoprotein activity

Type of modulator	Compound
Calcium channel inhibitors	Verapamil
	Nifedapine
Immunosuppressants	Cyclosporin A
	PSC 833
Other inhibitors	LY335979

normal colorectal tissue, the progression of normal tissue to adenomas and then to carcinomas shows a concordant stepwise increase in Pgp expression (Meijer *et al*., 1999).

Some other untreated cancers often show high levels of *MDR1* RNA, despite the tissue of origin not expressing MDR1. These cancers can include acute and chronic leukaemias of children and adults, non-Hodgkin lymphoma, neuroblastoma and sarcomas. The expression of the *MDR1* gene in tumours derived from tissues which do not normally express Pgp suggests that the process of malignant transformation in carcinogenesis can activate expression of the *MDR1* gene. This seems to have been confirmed in a study showing the *MDR1* promoter can be stimulated by Ras and mutant p53, two proteins commonly associated with tumour progression (Chin *et al*., 1992).

A group of tumours exist which show low or undetectable levels of Pgp, including breast cancers, non-small-cell lung cancer (NSCLC), small-cell lung cancer (SCLC), bladder cancer, oesophageal carcinoma, melanoma, ovarian cancer and prostate cancer. Despite low or undetectable expression of Pgp, some of these tumours often show a degree of multidrug resistance, indicating the possibility of the involvement of other mechanisms of drug resistance.

Increased or acquired expression of Pgp is commonly seen in tumours treated with chemotherapeutic drugs that have relapsed either during or after treatment (Fojo *et al*., 1987). The expression of Pgp in these tumours is thought be due to either selection of a small number of MDR1-expressing cells, present at the onset of treatment, or a direct induction of *MDR1* gene expression. There has been only limited study in this area owing to the difficulty in obtaining samples both before and after treatment, and for this reason most research has concentrated on the development of acquired resistance *in vitro*.

Expression of P-glycoprotein In Vitro

The intrinsic and acquired expression of Pgp *in vitro* has been studied extensively, through the use of both *in vivo* and *in vitro* selection procedures. (See chapters on *Basic Tissue Culture in Cancer Research*; *Models for Drug Development and Drug Resistance*.)

Intrinsic Multidrug-resistant Cell Lines

Many cell lines have been isolated from multidrug-resistant tumours from both humans and rodents. These cell lines often show classical characteristics of multidrug-resistant tumours, with increased expression of Pgp.

In Vivo Selection of MDR Cell Lines

Several MDR rodent tumour cell lines have been established, generally with transplantable tumour cell lines/grafts being inserted into an animal that is then exposed to a chemotherapeutic drug. For example, the murine leukaemia cell line P388 has been used to establish a doxorubicin-resistant subclone, by treating P388-inoculated mice with doxorubicin over repeated transplantation periods (Johnson *et al*., 1976). Generally, *in vivo* resistant cell lines show 10–100-fold resistance to various anticancer agents.

In vitro Selection of Cell Lines

Another procedure for the isolation of MDR cell lines is the exposure of cultured cells to a selective drug *in vitro*. There are two types of drug selection, first continuous exposure to a sublethal drug concentration, followed by gradual increases in the drug concentration. The second method of selection is a short exposure to a relatively high dose of the drug, followed by subsequent propagation of the cells in drug-free medium. The selection pressures under these circumstances are not the same as those experienced during the development of MDR during tumour chemotherapy, but a number of similarities are seen between cells selected in this manner and drug-resistant tumours.

An example of the *in vitro* establishment of a multidrug-resistant cell line is the selection of the doxorubicin-resistant human laryngeal carcinoma cell line HEp2A, from HEp2 cells (Redmond *et al*., 1990). In this case, human laryngeal carcinoma cells were exposed to increasing doses of doxorubicin over a 14-month period. HEp2A cells were found be 100-fold more resistant to doxorubicin compared with HEp2 cells, and they were 10–20-fold more resistant to the *Vinca* alkaloids vinblastine and vincristine. Pgp is usually found to be overexpressed in the *in vitro*-selected multidrug-resistant cell lines compared with the relevant drug-sensitive parental cell line.

Multidrug Resistance-associated Protein

Introduction

The multidrug resistance-associated proteins (MRPs) are members of the ATP-binding cassette superfamily of transport proteins. Although Pgp overexpression has been associated with multidrug resistance in many tumours and cell lines, there are a number of examples of multidrug-resistant cell lines and tumours where Pgp is not involved. Probably the most extensively characterized of these cell lines is H69AR, a small-cell lung cancer cell line derived from the H69 parental line, through stepwise selection in doxorubicin (Mirski *et al*., 1987). Through the use of differential hybridization, a 6.5-kb mRNA sequence was identified as being approximately 100-fold higher than in parental cells. Sequencing of cDNA clones derived from this mRNA revealed that it had the potential to encode a 1531 amino acid protein that was predicted to be a member of the ABC transporter superfamily and was subsequently named the multidrug-resistance protein (MRP) (Cole *et al*., 1992). The *MRP* gene has been mapped to chromosome 16 at band p13.13–13.12, and is amplified relatively frequently in drug-selected human cell lines that overexpress *MRP* mRNA.

The Mammalian MRP Family

Since the discovery and cloning of *MRP* in 1992 by Cole and Deeley (Cole *et al*., 1992), at least seven members of the MRP family have been discovered in mammals (Borst *et al*., 1999). The original *MRP* cloned by Cole is now known as MRP1, complicating early expression data for tissues, tumours and cells, with the specificity of early studies on MRP towards MRP1 not being clear. The next MRP transporter to be cloned was *MRP2* in 1996 (Buchler *et al*., 1996), although it had been characterized as the canalicular multispecific organic anion transporter (cMOAT) a number of years earlier. Within the MRP family the greatest sequence homology is between MRP1, -2, -3 and -6 (Borst *et al*., 1999).

Expression of MRPs in Normal Tissues

The expression of MRPs in normal tissues has been examined using both mRNA and protein analysis (Borst *et al*., 1999). MRP1 and MRP5 have been found to be ubiquitously expressed in normal tissues, with only relatively low levels of MRP1 in the liver. MRP2 is found in the liver, the kidney and the gut, while MRP3 has been shown to be expressed in liver, adrenals, pancreas, kidney and gut. MRP4 is expressed in prostate, lung, muscle, pancreas, testis, ovary, bladder and gall bladder, while MRP6 is only found in liver and kidney.

The localization of some MRPs in transfected polarized kidney epithelial cells has shown MRP1, MRP3 and MRP5 to localize to the basolateral membrane, while MRP2 localizes to the apical membrane (Borst *et al*., 1999; Konig *et al*., 1999).

Physiological Functions of MRPs

MRPs are thought to be like Pgp, having both physiological roles and a protective role against xenobiotics.

MRP1 is the major high-affinity transporter of leukotriene C_4 (LTC_4), as shown by biochemical experiments and the knockout (KO) mice (Wijnholds *et al*., 1997). Interestingly, in KO mice the absence of this major LTC_4 pathway does not have any observed negative effect on the mice within the confines of an animal house; on the contrary, the KO mice are more resistant than wild-type mice against inflammatory stimuli. This suggests that there may be a possible overlap in function between MRPs, with another MRP being able to compensate for a lack of MRP1; evidence for such a hypothosis may lie with MRP2, which has also been shown to be capable of transporting LTC_4 (Cui *et al*., 1999).

As MRP1 is located at the basolateral side of epithelial cells, it tends to pump drugs into the body, rather than away from it via the bile, urine or the gut in the way that Pgp does. However, MRP1 has been shown to protect vital cell layers from destruction, e.g. the basal stem cell layer in the oral mucosa (Wijnholds *et al*., 1998). There are also other important organs in the body that require a basolateral transporter for protection, e.g. the testicular tubules, where a ring of Sertoli cells protects the male germ cells, with their apical surface towards the lumen. The high concentration of MRP1 in the basal membrane of the Sertoli cells helps to protect the germ cells by pumping out drugs from the testicular tubule. Another position in the body where a basolateral transporter is required for protection is the choroid plexus, which protrudes into the cerebrospinal fluid (CSF) and is essential for exchange of metabolites between blood and CSF. The epithelial layers of the plexus contain high levels of MRP1 and the absence of MRP1 in KO mice results in the accumulation of etoposide in the CSF, as well as in brown adipose tissue, colon, salivary gland, heart and the female urogenital system (Wijnholds *et al*., 2000).

In the liver MRP2 is localized in the biliary canalicular membrane, and there is a lot of evidence that both MRP1 and MRP2 provide a major route for the secretion of organic anions such as bilirubin glucuronides from the liver. Rats and humans lacking MRP2 develop the liver disease Dubin–Johnson syndrome, mainly owing to the inability of the liver to excrete bilirubin glucuronides (Konig *et al*., 1999).

The expression of MRP3 on the basolateral membrane in the intestine and liver suggests a role for MRP3 in the intestinal uptake of organic anions and the removal of organic acids from bile and liver cells under conditions of cholestasis (Borst *et al*., 1999).

Substrates of MRPs

Following the demonstration in 1994 that MRP1 functions as a unidirectional ATP-dependent efflux pump for the endogenous glutathione *S*-conjugate LTC_4 (Jedlitschky *et al*., 1994), the substrate specificity of MRPs has been intensively studied. The substrate spectrum comprises amphiphilic anions, particularly conjugates of lipophilic compounds with glutathione, glucuronate or sulfate, including cysteinyl leukotrienes, bilirubin glucuronosides, 17β-glucuronosyloestradiol and sulfatolithocholyltaurine as endogenous compounds.

So far the glutathione *S*-conjugate LTC_4 is the substrate with the highest affinity for MRP1 ($K_m = 0.1\ \mu mol\ L^{-1}$) (Konig *et al*., 1999). The range of substrates for MRP1 and MRP2 is very similar, although MRP1 exhibits a 10-fold greater affinity for the model substrate LTC_4, while MRP2 has a higher affinity for the bilirubin glucuronides (Jedlitschky *et al*., 1997).

Modulators of MRPs

The identification of potent and specific inhibitors of MRP-mediated transport function has been sought since the characterization of the family. The most potent inhibitors reported so far, and tested against MRP1-mediated

transport in isolated vesicles, are analogues of cysteinyl leukotrienes, such as the LTD_4 analogue MK571. This analogue is a monoanionic quinoline derivative developed as a LTD_4 receptor antagonist, and has so far been shown to inhibit MRP1 transport and to a lesser extent MRP2 transport (Buchler *et al*., 1996).

MRPs and Multidrug Resistance

To date MRP1, MRP2 and MRP3 have been shown to be expressed in multidrug-resistant tumours and cell lines.

MRP1

Since its discovery in the highly resistant H69AR lung cancer cell line, MRP1 has been found overexpressed in multidrug-resistant cell lines derived from many different tissue and tumour types, including small- and large-cell lung cancers, carcinomas of the colon, breast, bladder, prostate, thyroid and cervix, glioma, neuroblastoma, fibrosarcoma, and various forms of leukaemia. Many of these cell lines have been established using selection to various chemotherapeutic agents such as doxorubicin and vincristine, although intrinsic expression of MRP1 in cell lines derived from tumours has also been observed.

In order to circumvent many of the problems associated with the use of drug-selected cell lines, namely the induction of multiple proteins such as MRPs, Pgp and xenobiotic-metabolizing enzymes, MRP1-mediated multidrug resistance has also been investigated through transfection with MRP1 expression vectors. The resistance profiles of MRP1 transfected cells are similar to those of cell lines expressing Pgp, and typically include resistance to anthracyclines and *Vinca* alkaloids. In contrast to Pgp, human MRP1 expression also confers low-level resistance to arsenical and antimonial oxyanions. Like Pgp, MRP1-mediated resistance is usually linked to a decrease in cellular accumulation of xenobiotics, e.g. MRP1-transfected cells accumulate less vincristine and daunorubicin than control cells (Cole *et al*., 1994). Again like Pgp, active transport of compounds corresponds to ATPase activity, and this has also been shown to be stimulated in isolated membrane vesicles from MRP1-transfected cells, via the addition of the anthracyclines daunomycin and doxorubicin and the *Vinca* alkaloids vincristine and vinblastine (Chang *et al*., 1997).

MRP2

Like MRP1, stable transfection of MRP2 has been shown to confer resistance to the cytotoxic drugs etoposide (4-fold), cisplatin (10-fold), doxorubicin (7.8-fold), and epirubicin (5-fold) in human embryonic kidney cells (HEK-293) (Cui *et al*., 1999). Further evidence of a role for MRP2 in multidrug resistance was provided by the transfection of antisense cDNA in the human hepatoma cell line HEpG2 in order to reduce MRP2 expression (Koike *et al*., 1997). Upon transfection of the antisense *MRP2* cDNA HEpG2 cells showed increases in intracellular glutathione levels and enhanced sensitivity to cisplatin, doxorubicin and vincristine.

MRP3

Only a limited amount of data exists on the relationship between MRP3 and multidrug resistance. A survey of lung cancer cell lines has shown a strong correlation between MRP3 expression and doxorubicin resistance (Young *et al*., 1999). In the same study a weaker, yet significant, correlation between MRP3 expression and resistance to vincristine, etoposide and cisplatin was also found.

Role of Glutathione in MRP-mediated Drug Resistance

Despite the link observed between MRP1 expression and resistance to various chemotherapeutic agents, the *in vitro* transport of these compounds using MRP1-enriched membrane vesicles had not been observed. Evidence for the reasons behind the lack of detectable transport in these models first came from studies using buthionine sulfoxamine (BSO). BSO is a potent irreversible inhibitor of γ-glutamylcysteine synthesis, the enzyme that catalyses the first, rate-limiting step in the synthesis of glutathione (GSH). Treatment of cells with BSO results in reduction of intracellular GSH levels by up to 90% within 24 h, depending on the cell line examined. A number of studies have shown that BSO-treatment is capable of enhancing drug accumulation and toxicity in MRP1-overexpressing cell lines (Lautier *et al*., 1996). The mechanism by which BSO inhibits drug transport by MRP is believed to be as a direct result of depletion of GSH, and not an interaction between BSO and MRP. Evidence supporting this includes the finding that acute exposure to BSO had no effect on drug accumulation (Schneider *et al*., 1995), and treatment with GSH ethyl ester increased cytoplasmic GSH and decreased daunorubicin accumulation in two BSO-treated MRP1-overexpressing cell lines (Versantvoort *et al*., 1995).

Observations that the glutathione-conjugated chemotherapeutic drugs doxorubicin and daunorubicin but not the unconjugated drugs were capable of competitively inhibiting the MRP-mediated transport of LTC_4 *in vitro* (Priebe *et al*., 1998) have led to speculation that MRP-mediated drug resistance occurs by the transport of drug conjugates from cells, and in fact MRPs had previously been called MRP/GS-X pumps (Ishikawa, 1992). This, however, has been shown to be inappropriate since, as previously discussed, MRPs, particularly MRP1 and MRP2, have been shown to be capable of transporting compounds not conjugated to glutathione such as bilirubin mono- and diglucuronides. Although many substrates for MRPs are conjugated compounds, the conjugation is not thought to be critical for transport; there has been some evidence suggesting that reduced GSH can also act as

either a co-substrate or possess the ability to activate MRPs. Evidence for this came from the observation that unconjugated chemotherapeutic agents, such as doxorubicin, daunorubicin, vincristine and vinblastine, fail to inhibit LTC_4 transport in isolated vesicles even at very high doses (Loe *et al*., 1996). However, on addition of reduced GSH, the inhibitory potency of some of these drugs is markedly increased, with the most dramatic effect occurring with vincristine and vinblastine. Further to this, vincristine uptake into membrane vesicles from MRP1-transfected HeLa cells has been shown to be both ATP and GSH dependent and could be inhibited by the MRP1-specific mouse antibody QCRL-3 (Loe *et al*., 1998). In this study, vincristine transport in the absence of GSH was extremely low and showed no ATP dependence, whereas active vincristine transport increased with increasing concentrations of GSH. As GSH appears not to be a substrate for MRP1, there is strong evidence for the co-substrate theory, provided by a study showing that the ATP-dependent uptake of [^{3}H]GSH into membrane vesicles from MRP1-transfected cells could be stimulated by vincristine in a dose-dependent manner (Loe *et al*., 1996).

Taken as a whole, the evidence so far collected on the transport of compounds by MRPs suggests that GSH is required and may act as a co-substrate during transport of compounds. The mechanism by which this occurs is not clear, but it may be that GSH acts as a co-substrate with unconjugated compounds, or if the compound is already conjugated, the conjugate attached to the compound acts as a co-substrate, negating the need for a second GSH molecule.

Expression of MRPs in Tumours

To date, most studies on the expression of MRPs in human tissues and tumours have examined mRNA levels through the use of Northern blot analysis and reverse transcriptase polymerase chain reaction (RT-PCR). There are inherent problems involved in the use of these techniques, owing to the lack of quantification of protein expression and function by these techniques. Bearing this in mind, mRNA of MRPs has been detected in various tumours including many leukaemias, non-small-cell lung cancers, squamous cell carcinomas of the lung, neuroblastomas, oesophageal squamous cell carcinomas and colon carcinomas.

Expression of MRP1 in a number of human cancers shows that MRP1 expression in tumours falls into three groups. The first are tumours with frequently high MRP1 expression above those of normal tissues, including chronic lymphocytic leukaemia and polymorphocytic leukaemia. The second group of tumours described were those that often exhibit low expression but on occasions can express high levels; these included oesophageal squamous cell carcinoma, non-small-cell lung carcinoma and acute myelocytic leukaemia. The third group were those tumours with predominantly low levels of MRP1 expression, comparable to those found in normal tissues, and these included soft tissue tumours, melanomas and cancers of the prostate, kidney, bladder, testis, ovary and colon. Interestingly, this study found no significant difference in the expression of MRP1 in chemotherapy-treated versus untreated tumours, suggesting that MRP1 does not play a significant role in acquired multidrug resistance, and is more important in the intrinsic resistance of particular types of tumours.

The expression of MRPs in lung tumours has been extensively studied, primarily due to the high levels of expression found in normal lung tissues. Analysis of the expression of *MRP1* to *MRP5* mRNA by RT-PCR showed expression of *MRP1* in 88% of small cell lung cancer samples and 100% of non-small-cell lung cancer samples (Young *et al*., 1999). *MRP2* was detected in 75% of small-cell lung cancer samples and 57% of non-small-cell lung cancer samples, while *MRP3* was found in only 12% of small-cell lung cancer samples and 86% of non-small-cell lung cancer samples. Expression of *MRP4* and *MRP5* was found in 100% of small-cell lung cancer samples and 71% and 100% of non-small-cell lung cancer samples, respectively. Interestingly, analysis of expression of MRPs in unselected cell lines established from patients at various stages of treatment in the same study showed a strong correlation between *MRP1* and *MRP3* mRNA levels in these cells and doxorubicin and vincristine resistance, as determined by a modified MTT method.

Analysis of the expression of MRPs has been carried out in normal colorectal tissue and tumours, showing MRP1 and MRP3 to be expressed at high levels in both normal and tumour tissues. In contrast, MRP2 expression is generally lower in normal tissue than in tumour samples.

Other Possible Mediators of Multidrug Resistance

Despite most research into the field of multidrug resistance focusing on mechanisms of drug transport, other factors should also be considered. One such factor is that of drug-metabolizing enzymes, and in particular glutathione *S*-transferase isoforms. In a variety of experimental models, increased tolerance to toxic xenobiotics and in particular chemotherapeutic compounds has been associated with increased GST expression. Examples of models include the multidrug-resistant phenotype of preneoplastic hepatocyte nodules in the rat (Farber, 1990), the analyses of tumour cells from patients before and after the onset of clinical drug resistance (Lewis *et al*., 1988), selection of resistance to chemotherapeutic agents in tumour cell lines (Wang *et al*., 1999), transfection of GST into mammalian cell lines (Puchalski and Fahl, 1990) and transfection of antisense genes causing increased drug sensitivity (Niitsu *et al*., 1998). Despite the large body of evidence supporting the involvement of glutathione *S*-transferase isoforms in

resistance to chemotherapeutic drugs, the area remains controversial, with many groups failing to show the involvement of GSTs in drug resistance (Townsend *et al*., 1992).

Expression of GST Isoforms in Tumours

The overexpression of GSTs in tumours has been observed in tumours derived from a number of tissues. Howie *et al*. showed increased total GST activity as measured by the CDNB assay in tumours of the lung, colon, stomach and breast (Howie *et al*., 1990). Expression of GSTs is not always increased in tumours, however, with the same study reporting a decrease in total GST activity in tumours of the kidney and liver compared with normal tissue. The increase observed in total GST activity seems to be due to an increase in the level of expression of the P1 isoform, which showed approximately a 2-fold increase in protein expression in lung, colon and stomach tumours. The decrease in total GST activity observed in kidney and liver tumours coincided with a decrease in the expression of the α-isoforms A1 and A2. Total GST activity measured in normal, peritumoral and tumoral colonic tissue supports the observations of Howie *et al*. showing a significant increase in activity in tumoral tissue compared with normal and peritumoral tissue, with a concurrent increase in GSTP1 expression in tumoral tissue (de Waziers *et al*., 1991).

In Vitro Expression of GSTs in Resistant Cells

Many groups have found that GSTs are overexpressed in a variety of human and rodent cell lines selected for resistance *in vitro* to doxorubicin, etoposide, cyclophosphamide, vincristine and vinblastine (Hayes and Pulford, 1995). In addition to changes in GST expression in acquired drug resistance, studies in cell lines showing differential intrinsic drug resistance have shown a correlation between resistance and increased expression of GST. The majority of resistant cell lines show an increase in the hGSTP1-1 isoform (**Table 4**).

Unfortunately, in most of the resistant cell lines studied there is overexpression of a number of detoxification enzymes, making it difficult to be certain that any increased resistance observed is due to the overexpression of GST isoforms and not a coinduced protein. In order to distinguish GST-mediated resistance from other detoxification mechanisms a number of studies have been carried out in GSH-depleted cells through the use of buthionine sulfoximine (BSO). In general, these studies have shown an increase in cytotoxicity of a variety of compounds, including doxorubicin, vincristine, etoposide, melphalan, cisplatin and daunorubicin, following GSH depletion with BSO. It must be noted, however, that in addition to the activity of GSTs, the depletion of GSH by BSO will affect the activity of glutathione peroxidase, which may also affect the resistance of cells to cytotoxic agents.

Limited studies have been carried out on the effect of inhibitors of GST activity and drug resistance. Ethacrynic acid has been shown to produce a 2–4-fold increase in the cytotoxicity of doxorubicin in primary cultures of lymphatic malignancies and normal peripheral blood lymphocytes (Nagourney *et al*., 1990). *S*-Alkyl GSH derivatives have also been shown to increase the

Table 4 Altered GST expression observed in drug-resistant cell lines

Drug	Resistance (-fold)	Cell line	Cross-resistance	Changes in GST
Doxorubicin	32	H69AR human small lung	Colchicine, daunomycin	10-fold increase in hGSTP1
Doxorubicin	75	SW620-ADR human colon	Actinomycin D, puromycin	2-fold increase in hGSTP1
Doxorubicin	84	P388 murine leukaemia	Not stated	2.2-fold increase in hGSTP1
Doxorubicin	100	HEp2A human laryngeal carcinoma	Vincristine, vinblastine, VP-16, VM-26	2.9-fold increase in hGSTP1
Chlorambucil	>10	Mouse fibroblast 3T3 (N50-4)	Not stated	>10-fold increase in α class GST
Cisplatin	>18	HeLa human cervix (HeLa-CPR)	Not stated	6-fold increase in hGSTA1 and A2
Etoposide (VP-16)	14	MCF-7 human breast (VP6E)	Vincristine	>10-fold increase in hGSTP1
Mitoxantrone	200	Caco-2 human colon	Not stated	>6-fold increases in hGSTP1, A1 and A2
Vincristine	3	MCF-7 human breast (VCR6E)	VP-16	>10-fold increase in hGSTP1
Vincristine	11	MCF-7 human breast (VCREMS)	Adriamycin/ doxorubicin VP-16	>10-fold increase hGSTP1
Doxorubicin	30–65	MCF7 human breast	Not stated	Overexpression of hGSTP1

(Adapted from Hayes and Pulford, 1995).

cytotoxicity of doxorubicin in human lung adenocarcinoma cell lines by the inhibition of GST activity (Nakanishi *et al*., 1997).

Transfection Studies

As a result of the unpredictable nature of intrinsic and acquired resistant cell lines, a number of groups have attempted to confer drug resistance by the transfection of GST isoforms. Although variable results have been obtained, some compelling evidence for a role for GSTs in drug resistance has been obtained. It should be noted, however, that the transfection of cells with GSTs may also lead to changes in other genes within the cell, such as changes in heat shock proteins, or enzymes involved in oxidative stress responses, which may modulate the intrinsic resistance of the cells.

The first demonstration that GST can confer resistance against toxic xenobiotics was reported by Manoharan *et al*. in 1987, who showed that transfection with rGSTA2-2 in COS cells provided resistance to the alkylating agent benzo[*a*]pyrene (±)-*anti*-diol epoxide (Manoharan *et al*., 1987). The same group later showed, through the use of cytotoxicity assays, that transfection with rGSTA2-2 conferred a 1.3–2.9-fold resistance to chlorambucil and melphalan, while expression of rGSTM1-1 conferred a 1.5-fold resistance to cisplatin and hGSTP1-1 conferred a 1.3-fold resistance to doxorubicin. Similar results have been found using NIH-3T3 and HEp2 cells, where expression of hGSTP1-1 conferred a 3-fold resistance to doxorubicin (Nakagawa *et al*., 1990; Harbottle *et al*., 2001).

A number of studies have reported no increased resistance to a number of chemotherapeutic compounds following the transfection of GSTs into MCF-7 cells (Townsend *et al*., 1992). It seems that mechanisms to induce the expression of GSTs, are very dependent on the type of cell into which transfection is carried out. This may indicate that other factors are required before GST-mediated resistance to cytotoxic compounds can occur. These factors may include the level of GSH present in cells or the expression of transport proteins from the MRP superfamily, which are expressed at very low levels in MCF-7 cells.

REVERSAL OF MULTIDRUG RESISTANCE

In an attempt to increase the success of chemotherapy, a great deal of research is taking place into methods of reversing the resistance of tumours to chemotherapeutic agents. These methods range from the development of compounds intended to be administered in combination with cancer chemotherapeutic drugs, that inhibit the transport proteins responsible for the efflux of drugs from target cells, to the use of antisense technology to develop drugs to block the synthesis of these transport proteins within tumour cells. As a result, a large number of companies currently have research programmes in the field of multidrug resistance, with a number of compounds being in phase I/II trials (Persidis, 2000).

As understanding of the structure and function of drug transport proteins and multidrug resistance increases, it is becoming clear that although a large number of chemotherapeutic agents are substrates for transport proteins, some are not. For example, S16020-2, a novel derivative of olivacine, has shown significant antitumour activity both *in vitro* and *in vivo* against multidrug-resistant cells (Pierre *et al*., 1998). The COMPARE programme of the US National Cancer Institute (NCI) for the identification of agents in the NCI database that would be predicted to be good substrates and/or inhibitors of P-glycoprotein may lead to the discovery of more potent inhibitors or indeed cytotoxic compounds that are not substrates for P-glycoprotein.

CONTENTS

- Introduction
- Ionizing Radiation and Free Radical Generation
- DNA Damage and Repair
- DNA Damage and its Relationship to Cellular Radiosensitivity
- Other Initiators and Sensors of Radiation Damage
- Pre-existing Molecular Pathways and the Response to Irradiation
- Conclusion

INTRODUCTION

Radiation therapy (RT) is an important modality in the treatment of cancer. The aim of RT is to deliver radiation doses and schedules that kill cancer cells while preserving normal tissue function. This therapeutic benefit is achieved in two ways. The first is by limiting the dose to the normal tissue by carefully planning the way in which the radiation is delivered. This involves exact calculation of the physical dose each organ receives. The second way is by exploiting the biological differences between tumour and normal tissues in their response to irradiation. This has led to the standard protocol for external beam RT, in which a dose on the order of 2 Gy is given daily to the tumour site for 5–8 weeks, depending on the clinical situation and the tolerance of the normal tissue in the field. This fractionated dose delivery regimen spares slowly proliferating normal tissues at the expense of tumours. (The unit of radiation dose, the gray, is equivalent to 100 rad and is an energy absorption of 1 J/kg.)

The most common forms of RT, whether delivered by external beam devices or radioactive implants, employ ionizing radiation. The biological effects of ionizing radiation vary with the dose, the dose rate, the physical nature of the radiation and the type of cell or tissue being irradiated. In other words, in addition to physical parameters, the manner in which cells sense and respond to radiation damage is critical for the outcome of RT. The molecular pathways that are triggered by radiation exposure act in an integrated fashion with those imposed by the molecular hardwiring of a cell to determine the multiple possible responses, whether they be DNA repair, cell cycle arrest, cell differentiation, cell death, adaptive responses, genomic instability or carcinogenesis. Most important from the perspective of RT is that these pathways provide a molecular explanation of why cell types differ in their response to irradiation.

The importance of the molecular phenotype is seen vividly in the clinic. Certain types of tumours, such as seminomas and lymphomas, respond well to RT while others, such as melanomas and glioblastomas, are relatively radioresistant. A similar rank order of radiosensitivity is obtained for different histological tumour types irradiated *in vitro* (Malaise *et al*., 1986). Furthermore, because molecular pathways within a cell can be altered by biological agents, such as growth factors, cytokines, monoclonal antibodies to cell surface receptors, or by gene transfer, it follows that the response to irradiation can be modified using the same approaches. Chemotherapeutic and physical agents, such as hyperthermia, hypoxia and radiation itself, can activate pathways that can also affect the outcome. The result is numerous novel approaches with potential to increase the efficacy of this powerful anticancer therapy. The molecular pathways that determine the intrinsic and induced cellular response to radiation are the focus of this chapter. For a broader discussion of radiobiological principles as they relate to RT, the reader is referred to standard texts (Withers and McBride, 1998; Hall, 2000).

IONIZING RADIATION AND FREE RADICAL GENERATION

Radiation is considered to have ionizing potential if it has a wavelength of $<10^{-6}$ cm. Such radiation has sufficient

energy in an individual photon to eject orbital electrons from a molecule or atom. The types of radiation used in RT, X-rays and γ-rays, produce several hundred thousand ionization events per cell per gray, but biological molecules are damaged largely indirectly. The absorbed energy causes ejection of primary electrons that go on to ionize other molecules leading to a complex chain reaction that continues until the energy is dissipated. In the process, free radicals, which are neutral atoms or molecules that have an unpaired electron, are generated. Because of their unpaired electrons, free radicals are very reactive and can reduce or oxidize biological molecules and break their chemical bonds.

Since the most abundant molecule in cells is water, the most common free radicals that are generated in a cell after exposure to ionizing irradiation are reactive oxygen species (ROS). Free radicals produced by radiolysis of water are responsible for about 60% of the biological damage caused by X-rays or γ-rays. The hydroxyl radical appears to be the most damaging primary product that is formed. Along with the hydrogen radical and aqueous electrons, it initiates cascade reactions that produce secondary products such as superoxide and hydrogen peroxide. Radicals are formed in organic molecules. In the presence of oxygen, additional radical peroxides, hydroperoxides and peroxides are formed that interfere with self-repair.

Some features of the molecular response to ionizing radiation can be explained by understanding the processes underlying these complex chemical events. First, the generation of ROS places ionizing radiation in the category of oxidative stress stimuli. The molecular signalling pathways that are responsive to ROS and to changes in redox homeostasis are part of the response to ionizing radiation. These pathways are shared with numerous other biological reactions, such as inflammatory processes, respiration, and damage caused by oxygen deprivation and reperfusion. Obviously, not all oxidative stress responses are the same and they do not always use the same signalling pathways. The spectrum of damage, and therefore the outcome, depend on the agent. Ionizing radiation is particularly effective at producing unrepairable lesions in DNA (Ward, 1988) which accounts for its relative efficacy in RT as a cytotoxic anticancer agent (see later).

A second consequence of the involvement of free radicals in radiation damage is that oxygen plays a major role as a modifier of radiation responses. Oxygen influences the nature of the free radicals and the lesions that are formed. The peroxides and hydroperoxides, in particular, inhibit repair. The result is that cells are typically 2.5–3 times more resistant to irradiation under hypoxic conditions than in the presence of oxygen (**Figure 1**). The concentration of oxygen must be low if radiation responses are to be affected; in general, less than 10 mmHg. Hypoxia is often considered significant in RT only when it reaches levels <5 mmHg, and reoxygenation between fractions may mitigate some of its influence. Some normal tissues may contain a small proportion of hypoxic cells, but only hypoxia within tumours is considered relevant in RT. Tumours vary considerably in their hypoxic status. There is also variation within one tumour. The chaotic organization of the tumour vasculature combines with tumour cell proliferation and cell death to form areas of chronic hypoxia with limited diffusion of oxygen, which may precede necrosis. Areas of acute reversible hypoxia also are found, which that may be the result of temporary closure of blood vessels, transient flow instability or changes in fluid pressure.

A number of studies have documented the importance of hypoxia to the outcome of RT. This may be due simply to depriving cells of the radiosensitizing effect of oxygen, but tumour hypoxia has other dimensions that must be considered. At the molecular level, hypoxia induces expression of a number of genes, in particular genetic programmes that are under the control of hypoxia inducible factor (HIF-1). Some of these (such as erythropoietin,

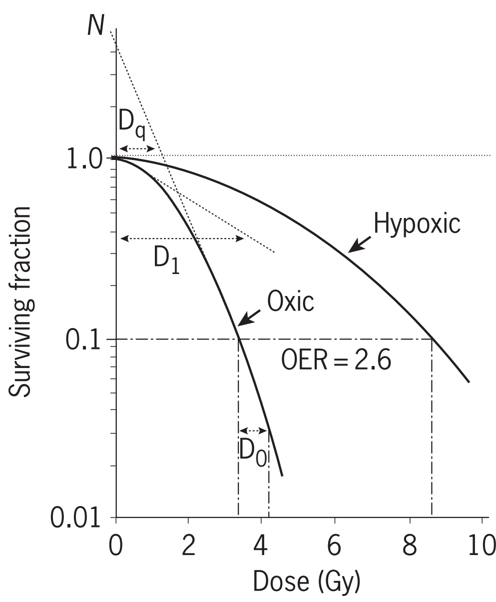

Figure 1 Survival curves for mammalian cells exposed to X- or γ-rays under oxic or hypoxic conditions. Cell survival is plotted on a logarithmic and radiation dose on a linear scale. There are two components to cell killing by radiation. At low doses, the survival curves have an initial linear slope (designated D_1). At higher doses the slope is steeper (designated D_0). D_q is a measure of the size of the shoulder. N is the extrapolation number on the ordinate. The oxygen enhancement ratio (OER) is the ratio of the dose required for a given effect under hypoxic conditions divided by the dose required to produce the same effect in oxic conditions. Since the slopes of the initial and final slopes depend on the presence of oxygen, the OER is 2.5–3.0 for high dose-related effects (2.6 for 10% survival in the figure) but is typically less for lower dose-related effects.

vascular endothelial growth factor and tumour necrosis factor alpha (TNF-α)) are clearly aimed at increasing angiogenesis and increasing oxygen delivery. Hypoxia can therefore play an important role in driving angiogenesis and tumour expansion. Other hypoxia-induced genes (such as *p53*) are part of a stress response that encourages cells to undergo cell death by apoptosis. Acting in this way, hypoxia serves as a selective force to favour expansion of cells mutated in *p53* (Green and Giaccia, 1998). These tumours will have an antiapoptotic and therefore a more malignant phenotype. These, and other, phenotypic and genetic cellular alterations induced by hypoxia, can affect the intrinsic cellular response to radiation through altering the molecular hardwiring of the cell (see later).

A third consequence of free radical involvement in the response to radiation is that agents that scavenge free radicals have potential as radioprotectors whereas those that mimic oxygen in 'fixing' radiation damage can act as radiosensitizers. The role that intrinsic redox active molecules play in the radiation response will depend on their specific intracellular location.

DNA DAMAGE AND REPAIR

Ionizing radiation is nondiscriminatory in that all molecular species in a cell may be damaged. However, DNA is the most important target for RT. The evidence comes from experiments showing that irradiation of the nucleus, but not the cytoplasm, results in cell death. The incidence of radiation-induced chromosome aberrations also correlates with cell death. The implications are that the most relevant radiation-induced free radicals are those generated within 2–4 nm of the DNA and that the concentration of redox-active agents in this location can influence the amount of damage that results.

Each gray of ionizing radiation causes in each cell thousands of single-strand DNA breaks (SSB), cross-links in DNA and with DNA-associated proteins, and 30–40 double-strand DNA breaks (DSB). Most of this damage is repaired. The most significant lesions from an RT standpoint are the unrepairable DSBs that arise from multiple events occurring close together in a short stretch of DNA (Ward, 1998). These lethal lesions are large, being of the order of 10–20 nucleotides in size, and represent less than a few per cent of the total DSB that are formed. Perhaps on average 25% of cells are killed by 1 gray although this percentage varies widely with the cell line. The relationship between survival and dose is generally log-linear (**Figure 1**), but, as the dose is increased, the probability of forming a multiply damaged site by interactions between lesions formed by separate ionization tracks increases and the slope of the dose–survival curve becomes steeper. The random nature of inactivation events means that a much higher radiation dose (by several $\log_{10}$) will be needed to sterilize organisms such as bacteria because they have considerably less DNA than do mammalian cells.

DNA repair mechanisms are, by necessity, highly efficient and come in many different forms. The involvement of any one repair mechanism is determined in large part by the nature of the damage, but other factors are influential. For example, damage in transcriptionally active genes or in S phase is more rapidly repaired. Repair of SSB and base damage is facilitated by the presence of an intact complementary DNA strand that can act as a template. A consequence is that repair of SSB is rapid with a half-time of minutes. However, overall repair of the diverse potentially lethal lesions is a slower process with an average half-time of around 1 h. 'Slow' and 'fast' repair components have been demonstrated in a number of systems (Canney and Millar, 1997). A comprehensive discussion of DNA repair mechanisms is beyond the scope of this chapter, which will concentrate on the relationship between repair and other molecular pathways, and the reader is referred to a more comprehensive review (Haber, 2000).

DNA repair mechanisms have evolved, in large part, to deal with errors produced during DNA replication as well as with damage resulting from free radicals generated through normal metabolism. Base excision repair processes with formation of apurinic/apyrimidinic sites and the sequential action of endonucleases, DNA polymerases and ligases repair most SSB and base damage. One of the earliest events following DNA strand breakage by radiation is the poly(ADP–ribosyl)ation of surrounding proteins by poly(ADP–ribose) polymerase (PARP). PARP binds to SSB and DSB to catalyse the transfer of successive units of ADP–ribose from NAD($^{+}$) covalently to itself and other nuclear acceptor proteins, including p53. PARP cycles on and off DNA, depending on its degree of polyribosylation. PARP-deficient cells are more radiosensitive and exhibit genomic instability and PARP cycling may be important in apoptosis, DNA replication and DNA repair. PARP has recently been identified as one of the intracellular 'death substrates' that can be degraded by proteolytic caspases activated during apoptosis. The finding that several molecules that are involved in the response to DNA damage are caspase substrates suggests a degree of coordination between repair and cell death processes, although PARP itself may play only a secondary role in repair. This may be true of a number of molecules that bind broken DNA ends, including the tumour-suppressor protein p53. Such molecules may influence radiosensitivity more by activating downstream pathways. The relationship between binding of proteins to DNA strand breaks, repair of those breaks and activation of downstream intracellular signalling pathways may be better developed in DSB repair.

The repair template that is used in the process of DSB repair is less easily identified than it is in SSB repair, but physiological models have shed light on how repair is

achieved. DSBs are created during meiosis and during the generation of diversity in the immune system. For example, in developing thymocytes, DSBs are generated by endonucleases RAG-1 and RAG-2 during initiation of V(D)J recombination within the T cell receptor (TCR) locus. Ligation of the DSBs that are formed is essential for the generation of the TCR repertoire. Very similar processes in B lymphocytes are responsible for the generation of immunoglobulin diversity. Failure to generate functional immunoglobulin or T cell receptors results in apoptosis. Ligation involves several proteins that are components of the nonhomologous end-joining pathway (NHEJ) of DNA damage repair (**Figure 2**). Ku autoantigen is a DNA end-binding heterocomplex of Ku70 and Ku80 (Jin and Weaver, 1997) that activates the DNA-dependent protein kinase catalytic subunit (DNA-PKcs) to form the active kinase DNA-PK (Chen *et al*., 1996). DNA-PK initiates DSB repair by processes that are poorly understood, although an essential role for binding of DNA ligase IV and XRCC4 has recently been demonstrated. Importantly, DNA-PK also appears to trigger signal transduction pathways that are involved in stress responses. If any of the DNA-PK complex of molecules is defective, both V(D)J rejoining and sensitivity to ionizing radiation are affected (Gu *et al*., 1997). The best known example of this link is the scid (severe combined immune deficiency) syndrome, which in mice and humans is caused by a mutation in DNA-PKcs and is associated with radiation sensitivity (Jhappan *et al*., 1997).

An alternative pathway for DSB repair is homologous recombination (HR). The difference between HR and NHEJ lies in their dependence on DNA homology and the degree of accuracy of the repair. HR uses the sister chromatid or homologous chromosome. NHEJ uses no or limited homology and inevitably makes more errors. Unlike yeast cells, mammalian cells appear to rely more on NHEJ as the principal method of DSB repair. Very little is known about how cells elect to perform HR or NHEJ; the choice may vary with the phase of the cell cycle.

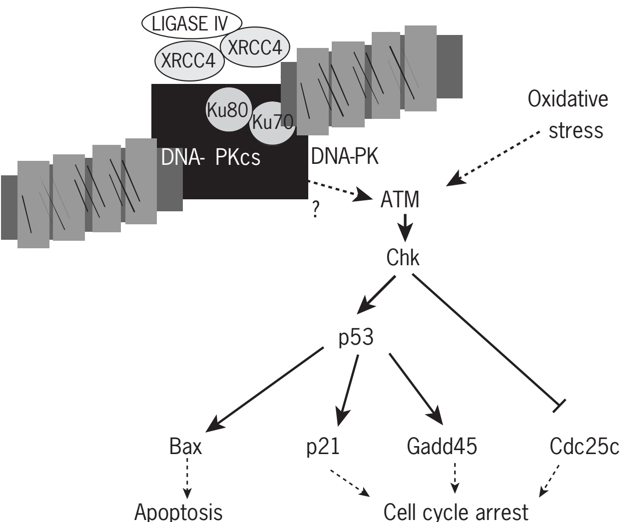

Figure 2 Nonhomologous end joining proteins involved in DSB repair recognize DNA end (Ku) and activate DNA-PKcs to the active kinase DNA-PK. XRCC4 and ligase IV are essential for repair. The ATM gene product is activated by DNA damage and by oxidative stress and initiates downstream p53-dependent pathways leading to apoptosis, cell cycle arrest or cell cycle progression.

Like NHEJ, HR is a complex process with subpathways involving gene conversion, single-strand annealing and break-induced replication. The key proteins were most often identified in yeast before their human homologues were cloned. They include active complexes of Rad51, Rad52 and Rad54, as well as complexes of BRCA1, NBS (Nijmegen breakage syndrome product), MRE11 and Rad50, and complexes of Rad51 with BRCA1 and BRCA2. Identification of BRCA tumour-suppressor gene products as sensors of DNA damage is of interest because these are mutated in hereditary cases of breast and ovarian cancer. Functional loss of BRCA may result in an increase in cellular radiosensitivity (Shen *et al*., 1998) although the extent to which this influences clinical outcome of RT has yet to be fully determined. Mutation in any of the HR gene products increases the risk of carcinogenesis as well as influencing radiosensitivity.

A major unanswered question is the extent to which variation in the level of expression of DNA repair enzymes influences the outcome of RT. Variation in DSB repair enzymes has been observed between different cells and tissues and it is known that considerable control is exerted at the post-translational level. However, so far this variation has not been convincingly shown to correlate with cellular or tissue radiosensitivity (Allalunis *et al*., 1995; Carlomagno *et al*., 2000). A particular problem is that the enzymes that critically determine the rate and extent of DNA repair by the different repair processes have, for the most part, yet to be determined. Such studies may indicate which molecules are most relevant to the outcome of RT.

DNA DAMAGE AND ITS RELATIONSHIP TO CELLULAR RADIOSENSITIVITY

Classically, DNA damage has long been considered the major factor causing cell death. However, recently, an important concept has developed from studies in molecular radiobiology. It is that cells possess sensors of radiation-induced damage that link damage to cellular outcome through stress-responsive signal transduction pathways (reviewed by Schmidt-Ullrich *et al*., 2000). The pathways that are involved vary to an extent with the cell type and the cell's microenvironmental context. However, in spite of these sources of variation and the problems imposed by the complexity of the integrated nature of the circuitry within cells, patterns are emerging that allow critical molecules and pathways to be recognized. Certain patterns

link DNA repair, DNA misrepair or failure to repair to classical outcomes of radiation exposure. Others identify non-genomic initiators of signal transduction pathways as influences.

The extent of initial DNA damage and the persistence of this damage are presumably critical factors in determining the cellular response to radiation, but how this information is usefully coordinated within the cell is still unclear. Assessment is made more difficult by feedback control from downstream pathways, such as those leading to apoptosis. When activated, these can influence DNA damage and repair processes. For example, DNA repair enzymes can serve as substrates of active caspases. Finally, there is a tendency to view these pathways as leading in a linear fashion to transcriptional activation of genetic programmes that mediate responses. This is true only to an extent. Post-transcriptional and post-translational mechanisms are also involved, in particular in the initial response to stress stimuli. Stabilization of mRNA and protein expression is the most rapid way to initiate a stress response and expression of many of the molecules involved in DNA repair, cell cycle and cell death are controlled, at least in part, at this level (Moll *et al*., 1999). There is little known about how radiation affects these levels of control but recently radiation-induced inhibition of proteasome function has been demonstrated (Pajonk and McBride, to be published) and this may be a mechanism of potential importance.

The two cellular responses to irradiation that have long been recognized as being highly relevant to RT are cell cycle arrest and cell death. Key transitions between cell cycle phases are regulated by the activities of various protein kinase complexes composed of cyclin and cyclin-dependent kinase (Cdk) molecules. Radiation activates multiple gene products that interfere with their interactions resulting in arrest at G1/S, S, or G2 phase checkpoints. The radiation dose dependence of arrest at the different checkpoints varies, with G2 arrest being the most dose sensitive and consistent response. It seems logical to suppose that a function of checkpoint arrest is to allow cells time to repair DNA damage before proceeding in their cell cycle. DNA damage is, however, not a prerequisite for cell cycle arrest, which can also be caused by exposure to growth regulatory cytokines. Another interpretation of the function of cell cycle arrest, which may be particularly applicable to G1 arrest, is that signals from all sources are evaluated so that cells with inappropriately activated pathways can be eliminated prior to proceeding through growth factor-independent cell-cycle phases that result in replication. Cells that fail to arrest at G1, such as cells with mutated *p53*, are less likely to undergo apoptosis at the G1/S checkpoint and may replicate lesions in S phase resulting in increased DNA mutations and fragility. For cells entering mitosis, the integrity of the chromosomes and the replication apparatus determines if the cell dies and repair during G2 arrest may restore this. In contrast with the G1/S checkpoint, when radiation-induced G2 arrest is abrogated, cells are more likely to die. The use of mice deficient in specific genes has been particularly useful in elucidating the cascade linking DNA damage to cell cycle arrest and cell death. Three major links in the chain are the ATM (ataxia telangiectasia mutated), the checkpoint kinase Chk2 and the p53 tumour-suppressor gene proteins (**Figure 2**).

Ataxia telangiectasia (A-T) is the archetypal human radiation sensitivity syndrome (reviewed by Lavin and Khanna, 1999) and ATM plays important roles in the maintenance of the cell homeostasis in response to oxidative damage (Takao *et al*., 2000). ATM is a member of a family of large phosphatidylinositol 3-kinase domain-containing proteins that includes DNA-PKcs. DNA-PK can phosphorylate ATM *in vitro*, but its role as the initiator of the cascade *in vivo* still needs substantiation. Some studies have indicated that p53-mediated apoptosis and cell cycle arrest are normal in DNA-PKcs knockout mice (Jongmans *et al*., 1996; Jhappan *et al*., 2000). Others suggest that DNA-PKcs selectively regulates p53-dependent apoptosis but not cell-cycle arrest (Wang *et al*., 2000). In studies of this type, the control and experimental cells have different levels of DNA damage/repair and radiosensitivity and this may complicate interpretation of dose–response relationships.

The role of ATM in the response to radiation-induced DNA damage has been investigated in some depth. ATM-deficient cell lines, unlike normal cells, do not up-regulate p53 expression after exposure to ionizing radiation, which indicates that ATM is upstream of p53. They do not undergo proper G1, S and G2 phase checkpoint arrest and they are hypersensitive to irradiation. Cells from A-T patients express the same phenotype. A number of target proteins have been identified for ATM. They include c-Abl, Chk2, BRCA-1, Ik$B\alpha$, MDM2 and replication protein A (RPA). This spectrum of proteins indicates the key position ATM holds in control of cell cycle arrest, cell replication, cell survival and death. The checkpoint kinase Chk2/hCds1 (Caspari, 2000) is involved in G2 arrest. This is because Chk2 phosphorylates the phosphatase Cdc25C, which is required to activate the Cdk for entry into mitosis (Chaturvedi *et al*., 1999).

Chk2 also phosphorylates p53 on serine 20, which interferes with the binding of its negative regulator Mdm2 (Mirao *et al*., 2000). This could affect its degradation through the ubiquitin/proteasome system and be responsible for stabilization of p53 expression, which is a feature of the normal response of cells to ionizing radiation. p53 is a multifunctional molecule. Amongst its many functions, it acts as a transcription factor to activate many downstream pathways, including ones that lead to cell-cycle arrest and apoptosis. It also induces production of its own negative regulator Mdm2, which could be viewed as an adaptive response to irradiation. The fact that *p53* is mutated in approximately 50% of human tumours indicates the importance of this pathway in preventing tumorigenesis.

The mechanism by which elevated p53 levels leads to apoptosis is not fully known, but transcriptional activation of apoptotic genes, such as *BAX*, is one mechanism. p53 activation can also cause cell cycle arrest at the G1/S transition. Pathways to cell-cycle arrest converge to induce or phosphorylate Cdk inhibitors (CKIs) and antagonize the formation of cyclin–CDK complexes to block entry into S phase (Shackelford *et al*., 1999). CKIs come from three families, Cip (e.g. p27)/Kip (e.g. p21), Ink4 (e.g. p16) and the pRb pocket-protein family. p53-dependent cell cycle arrest in G1 is largely through the p21/WAF1 pathway that inhibits CDK2 kinases. Other targets for p21 have been identified. For example, p21 forms complexes with PCNA to inhibit DNA synthesis. It may also play a role in maintaining G2 arrest after irradiation, although Gadd45, which is another p53-regulated stress protein, may be more important for arrest at the G2/M checkpoint (Jin *et al*., 2000).

Cell cycle arrest and apoptosis can be initiated through pathways other than those going through p53, but p53 knockout mice have distinct features that clearly indicate the central importance of this tumour-suppressor gene in radiation responses. Mouse embryo fibroblasts from *p53−/−* mice, lack radiation-induced G1/S arrest in addition to having other cell cycle checkpoint abnormalities, and are more radioresistant than wild type cells (Whang *et al*., 2000). On the other hand, damage accumulated consequent to *p53* mutation may also affect cellular radiation sensitivity (Denko *et al*., 2000). The *in vivo* relationship between p53 and apoptosis after irradiation has been investigated in several tissues. Apoptosis occurs spontaneously in cells going through specific developmental stages within tissues. It has a homeostatic role in regulating the numbers of cells in stem cell areas or sites of rapid proliferation. Irradiation strikingly increases the extent of apoptosis in these specific populations (Potten *et al*., 1994). This suggests that cells predisposed to apoptosis are most readily and most rapidly killed by irradiation. Radiation-induced apoptosis is frequently associated with rapid up-regulation of p53 expression, e.g. in the stem cell areas of the jejunal crypt, although the p53 dependence is not present in all sites. Introduction of wild-type *p53* into tumour cells lacking *p53* generally results in an increase in radiation sensitivity (McBride and Dougherty, 1995) that is frequently associated with an increased tendency towards apoptosis.

What has not been fully explained by use of *p53−/−* mice is the relationship between apoptosis and the final tissue response to irradiation. *In situ* assays show that survival of stem cell clonogens following irradiation may be unaltered in *p53−/−* mice, even if radiation-induced apoptosis is defective (Hendry *et al*., 1997). Since p53 has more than 100 downstream target genes, knockout of this gene affects many functions and the response to irradiation could be influenced through pathways other than those involved in apoptosis. The same argument holds for lack of correlation that is often found between *p53* mutations in human tumours and response to RT. Multiple pathways are affected by loss of one gene and, in cancer, multiple genes are mutated. While *p53*, like *DNA-PK*, *ATM*, *CHK2*, *BAX*, *p21* and other genes in this pathway, are important in mediating the cellular response to irradiation, signal transduction pathways have many tributaries. Branches of different pathways may neutralize or accentuate each other. The outcome can vary with the cell type depending on the way radiation-induced signals integrate into the hardwiring in the cell, and upon the overall gestalt of the multiple signals the cell is receiving through multiple pathways (Bouvard *et al*., 2000).

In spite of these reservations, there is little doubt that the molecular pathways linking DNA damage to cell cycle arrest and cell death are important in determining the outcome of RT. Indeed, the relationship extends further. Cancer susceptibility genes have been classified into two groups; caretakers or gatekeepers. In general, caretakers are DNA repair genes whose inactivation leads to genetic instability and a marked increase in chromosomal aberrations, including breakage, translocations and aneuploidy. This does not normally lead to a dramatic increase in the risk of cancer unless gatekeeper genes that control cell proliferation and death are also affected. For example, loss of Ku80 synergizes with loss of *p53* to promote early tumorigenesis (Difilippantonio *et al*., 2000). Communication between molecular programmes involved in DNA repair, cell cycle and apoptosis is therefore essential for the integration of DNA integrity and cellular homeostasis.

OTHER INITIATORS AND SENSORS OF RADIATION DAMAGE

Although DNA may be the most important initiator of signalling responses following cellular exposure to ionizing radiation, there is increasing evidence for critical contributions from other sources. Oxidative damage to cytoplasmic, mitochondrial and membrane structures, changes in the homeostatic redox balance, alterations in protease activity and the production of lipid peroxides in membranes following radiation have all been suggested as influences on the cellular response to irradiation. Mitochondrial damage may be particularly important in amplifying some of the ROS effects of ionizing radiation. The molecular pathways that mediate these effects have in some cases been identified, but their importance is still a matter of some controversy and will vary with the cell type and its microenvironmental context.

Ionizing radiation shares with cytokine death signals, such as TNF-α and Fas ligand (FasL), the ability to generate the second messenger ceramide through a sphingomyelin pathway (Haimovitz-Friedman *et al*., 1997). The phospholipid sphingomyelin is hydrolysed in the cell

membrane by activation of neutral or acidic sphingomyelinases or ceramide synthase. The consequences of ceramide production depend on the cell type, but it most commonly serves to initiate an apoptotic response. Recent work has defined two cascades activated preferentially by pro-inflammatory cytokines, such as TNF-α and IL-1, as well as ceramide, ionizing radiation and stress (**Figure 3**). One converges on the mitogen-activated protein kinase (MAPK) subfamily known as the 'stress activated' protein kinases (p38 SAPKs). The second pathway recruits the Jun N-terminal kinases (JNK)s. These signalling pathways are sensitive to intracellular thiol-redox and protease–antiprotease status and are linked to activation of at least two well-defined transcription factors, NF-κB and AP-1 (c-Fos and c-Jun). The apoptotic response resulting from activation of the sphingomyelin pathway, at least in some cell types, involves release of cytochrome *c* from mitochondria, and is particularly influenced by the actions of members of the Bax/Bcl-2 pro- and antiapoptotic family of proteins that functions at this level (Tepper *et al*., 1999).

The close association between radiation exposure and inflammation is also seen in radiation-induced responses. *In vitro* and *in vivo* irradiation of cells and tissues frequently increases expression of TNF-α, FasL, IL-1, IL-6 TGF-β and other cytokines and cytokine receptors, as well as cell adhesion molecules and proteases/antiproteases (Kasibhatla *et al*., 1998; Hong *et al*., 1999). This 'danger' response plays an important role in initiating tissue recovery and remodelling. NF-κB-dependent pathways are major components that are further amplified by infiltrating host inflammatory and immune cells. The extent of the response varies with tissue and dose. The classical dose of 2 Gy does not induce a particularly strong pro-inflammatory response, which may be part of the reason for its use in the clinic. The other more substantiated reason is that 2 Gy spares late-responding, slowly proliferating normal tissue at the expense of more rapidly proliferating tumours. The proinflammatory response to radiation may be particularly relevant in situations where bystander effects of radiation have been observed and in adaptive responses to subsequent exposures. Proinflammatory cytokines, in consort with their up-regulated receptors, provide a positive feedback loop that may affect subsequent responses to radiation.

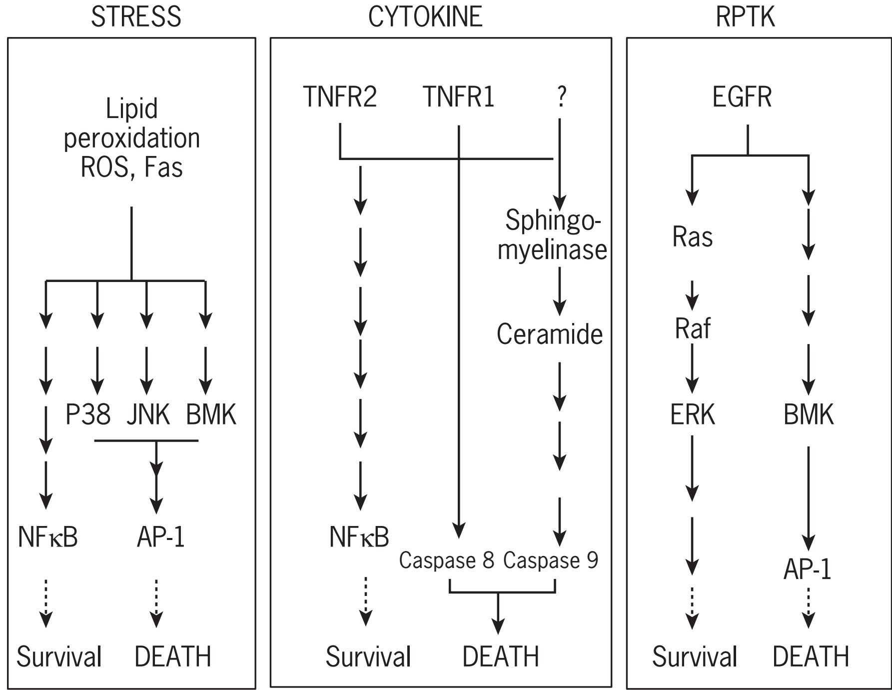

Figure 3 Responses to radiation can be initiated by several mechanisms other than DNA damage. This oversimplified diagram indicates three general pathways that influence the cellular outcome of irradiation. The pathways are distinguished by their preferential utilization by distinct classes of stimuli, but there is considerable cross-talk. For example, the mitogen activated kinase (MAPK) pathways involving c-Jun N-terminal kinase (JNK) and p38/stress-activated protein kinase (SAPK) are activated by many stimuli, including cytokines and lipopolysaccharide. The big MAP kinase pathway (BMK) is highly redox-sensitive, but is also activated through protein tyrosine kinase receptors (RPTK) such as epidermal growth factor receptor (EGFR), as are extracellular signal-regulated kinases (ERK1/2). The sphingomyelinase pathway feeds into a stress response involving ROS. The pathways converge on multiple downstream factors that initiate transcriptional and nontranscriptional mechanisms in a complex combinatorial fashion, but preferentially appear to favour cell death or survival, although the outcome is, to an extent, cell-type dependent.

Two major transcription factors, AP-1 and NF-κB, mediate responses to free radicals, ceramide, proinflammatory cytokines and ionizing radiation. AP-1 has been implicated in certain apoptotic responses. In contrast, NF-κB has generally been found to encourage survival of many cell types, most likely through activation of inhibitors of apoptosis (IAP) family members (You *et al*., 1997). The classical pathway for NF-κB activation is in response to signals like TNF-α. IκBa, which is bound to NF-κB in the cytoplasm, becomes phosphorylated on serine residues and is degraded through the ubiquitin/proteasome system. NF-κB is freed to translocate to the nucleus to initiate transcriptional programs. Ionizing radiation activates NF-κB, at least in some cell types. However, an alternative pathway that may involve tyrosine phosphorylation may operate (Raju *et al*., 1998) as it does in response to certain other oxidative stresses. This emphasizes the danger of generalizing about common pathways activated by diverse agents. The consequences of constitutive or radiation-induced AP-1 and NF-κB on the response to radiation is not completely established. Inhibition of NF-κB expression induces apoptosis in many cell lines (Duffey *et al*., 1999) and may radiosensitize, but this is not always the case (Pajonk *et al*., 1999).

Another signal transduction cascade generated at the plasma membrane by radiation involves activation of cell membrane receptors, including that for epidermal growth factor (EGFR). This tyrosine kinase receptor has been shown to autophosphorylate shortly after irradiation of tumour cells both *in vitro* and *in vivo* (Akimoto *et al*., 1999; Todd *et al*., 1999). Other cytoplasmic and membrane-bound kinases are also probably activated after radiation exposure. The mechanism of receptor activation is not clear. ROS action on cysteine residues may lead to cross-linking and receptor aggregation. Alternatively, inactivation of phosphatases might be involved. EGFR-mediated pathways trigger the prototypical p44 and p42 MAP kinases (ERK1, ERK2) and the newly described big mitogen-activated kinase-1 (BMK1). The former pathway is activated by many growth factors and oncogenes, including *ras* and *raf*, which a number of studies have shown to be associated with cellular resistance to radiation. Both p44/p42 and BMK pathways may be activated by ROS, but the latter seems particularly redox sensitive. Both seem to generate cytoprotective responses, at least in certain cell types (Schmidt-Ulrich *et al*., 2000).

PRE-EXISTING MOLECULAR PATHWAYS AND THE RESPONSE TO IRRADIATION

The fact that cell types vary in their response to irradiation indicates the importance of molecular pathways that are hardwired into the cell. The best example of this comes from gene transfer studies aimed at disrupting these pathways. Expression or knockout of proto-oncogenes, tumour-suppressor genes, cytokines, cytokine receptors, cell adhesion molecules, redox-active genes and many other genes that are important in determining cell behaviour, can influence the outcome of irradiation (McBride and Dougherty, 1995; Dougherty *et al*., 1996; Biaglow *et al*., 1997; Chiang *et al*., 1998). For example, radiation resistance can often be achieved by transfer of genes for growth factors or growth factor receptors that cause cell proliferation, tyrosine kinase genes or products such as Ras and Raf on MAPK1/2 pathways, or mitochondrial proteins such as Bcl-2 or manganese superoxide dismutase. A dominant negative approach (Reardon *et al*., 1999) antisense, or antibody (Milas *et al*., 2000) directed against, for example EGFR, can result in cellular radiosensitization and the level of expression of EGFR by a tumour can determine radiocurability (Akimoto *et al*., 1999). High constitutive NF-κB levels may also affect radiocurability and targeting this pathway using a COX-2 inhibitor (Kishi *et al*., 2000), or other approaches, seems feasible. Radiosensitization often results from transfer of cytokine genes or receptors that slow cell cycle progression or encourage apoptosis.

It follows that carcinogenesis-related molecular pathways in tumours may determine the outcome of RT. They do this not because they are directly involved in transformation *per se*, but because they influence pathways downstream of damage recognition (Chiang *et al*., 1998) As has been mentioned, carcinogenesis is a multistep process and interactions between pathways will occur that may not always give a predictable outcome in terms of radiation response. Assessments of patterns of gene expression are likely to give more reliable information than examination of any one gene product. The outcome of ongoing studies to determine the value of gene array studies for predicting outcome of RT is awaited with interest.

If constitutive gene expression is important in radiation responses, a further logical extrapolation is that genetic differences between individuals may result in different responses to irradiation. A classical example is the differences between C57Bl and C3H mouse strains in response to irradiation (Dileto and Travis, 1996; Franko *et al*., 1997). Several genes are responsible that have been mapped, some within the major histocompatability complex. In addition, mice lacking the TNFR2 molecule, which can trigger NF-κB responses, have recently been shown to be radiosensitive (Daigle *et al*., 2000). Genetic differences in the radiation response of fibroblasts from different individuals have also been observed (Eastham *et al*., 1999). Since the dose that is normally given in RT is often based on the dose that the normal tissue in the field can be expected to tolerate, identification of radiosensitive and radioresistant individuals would allow more individual tailoring of the maximum dose that can be delivered. This could increase the cure rate. Screening individuals to determine if they are carriers of the *ATM* gene, or other

genes known to confer radiosensitivity, might help in this regard, but recognition of patterns of response by multiple genes may be more universally valuable.

CONCLUSION

Recognition by a cell that it has received radiation damage has numerous downstream consequences. DNA lesions that can not be repaired may result in chromosome abnormalities that will interfere with cell function and cause death directly. At the same time and in addition, radiation initiates genomic and non-genomic molecular pathways that network with constitutive pathways to form integrated signals that are channelled into making concerted and meaningful cellular responses. Such responses may, in part, be characteristic of a given cell type and its environment but, all other things being equal, the failure or success of RT is determined by the characteristics of these pathways. Specific groups of genes are activated, progression through cell cycle checkpoints is blocked, replication and transcription are affected, apoptosis may be induced, tissue recovery and remodelling processes are initiated and the tissue is adaptively primed in preparation for future insults.

The functional relevance of any single molecular response that is observed may not always be clear, but the purpose of the response overall is presumably damage control at the level of the individual cell and signalling damage at the tissue and whole animal level to initiate healing. Apoptosis following radiation exposure is an altruistic response that may prevent carcinogenesis from misrepaired or unrepaired DNA damage. In support of this suggestion are findings that mice lacking proapoptotic genes generally have an increased incidence of cancer. On the other hand, only a small proportion of irradiated normal and tumour cells die by rapid apoptosis and this pathway can often be subverted by stimulation by growth factors. It seems that most cells that die after irradiation die a mitotic death, sometimes after several division cycles, depending on the dose. Mitotic death can have an apoptotic component, but more often it is necrotic. This failure to undergo rapid apoptosis in response to irradiation has important implications for tumour sterilization; as cells divide, a proportion of the progeny may die, but the clone may still survive. A more important role for radiation-induced apoptosis in a tissue may be to initiate repopulation, although solid evidence for this hypothesis is still lacking.

Although radiation-induced death is in many cases nonapoptotic, the order of radiosensitivity of tumours of different histological types suggests that those cells with a propoptotic tendency are more radiation sensitive. Based on what we know about the level of integration and cross-talk between molecular pathways, it is possible that the proapoptotic phenotype overlaps at the molecular level with other processes, such as DNA repair or proliferation. If this is the case, apoptosis may not be the best measure of radiosensitivity, but the pathways that are involved would still be useful targets for therapeutic intervention. On the other hand, if the apoptosis and repair pathways are distinct, increasing the fraction of cells that apoptose following irradiation may have only limited overall impact on cure rates.

Molecular radiobiology has clearly reached the stage where preliminary conclusions can be reached as to the impact of specific signalling pathways on the outcome of RT. The studies have exposed numerous potential targets for therapeutic manipulation of radiation responses. The general proven efficacy of ionizing radiation as therapy against many tumours, together with the knowledge that has accumulated over the last century of treatment, gives an excellent base from which to launch these novel approaches to extending the usefulness and increasing the efficacy of RT. Combined with molecular evaluation of the probability of tumour cure and normal tissue complications in individual patients, as well as more precise delivery methods, the future of RT looks promising.

- Conclusion

INTRODUCTION

An increasingly sophisticated understanding of cancer biology and immunology, advances in molecular biology and the improved capacity for production of recombinant proteins have made it possible to employ cytokines and antibodies for the treatment of cancer. Several products including the cytokines interferon-alpha and interleukin-2 and the monoclonal antibodies rituximab (antibody to the lymphoma surface antigen CD20) and trastuzumab (antibody to the cell surface receptor Her2/neu) have found a place in the standard treatment of certain human malignancies. In addition, a large number of antibodies and cytokines have undergone clinical evaluation or are currently in clinical trials, and several will likely prove to have benefit and become part of the standard practice of oncology.

CYTOKINES

Biological Basis for Application of Cytokines in Cancer Treatment

Cytokines are naturally produced proteins that interact with specific cell surface receptors, which then generate intracellular signals that produce transcription factor binding to DNA. The resulting increases or decreases in expression of certain genes modify cell function, proliferation or survival. The many and diverse biological effects of most cytokines *in vivo* have made it difficult to define and understand fully the mechanisms underlying their anticancer activity. For example, administration of a single cytokine will induce the production of a cascade of other cytokines that can originate from a variety of cells in the body, including the tumour cells. Cytokines are also able to induce their own production or production of soluble receptors that can enhance or limit their biological effects. Depending on the distribution of receptors, an individual cytokine or secondary induced mediators can have effects directly on tumour cells, immune effector cells, the tumour vasculature and/or the tumour stroma. The biological and antitumour effects of a cytokine may be highly dose and schedule dependent, and may vary with the specific histological type of tumour and stage of growth, the site of metastases and the underlying condition of the host. Some biological effects of cytokines have the capacity to promote tumour growth.

Perhaps the most important biological property of cytokines that impacts the growth of a tumour is the recruitment and activation of immune effector cells. In animal models, the antitumour activity of many of the cytokines can be abrogated by depletion of one or more specific lymphocyte cell subsets. Much attention has been focused on nonantigen-specific natural killer (NK) lymphocytes, since cytokine activation of these cells can enhance their cytotoxicity against tumour cells and production of secondary cytokines, and therefore increase their potential for mediating antitumour activity *in vivo*. However, the majority of animal models involving cytokine administration indicate that antitumour effects require the activation, at some point, of CD4+ and/or CD8+ T lymphocytes that specifically recognize a tumour antigen. Once within the tumour, lymphocytes are capable of eliminating tumour cells directly through cell–cell interactions, or by producing additional cytokines, some of which attract other immune effector cells such as monocytes and macrophages to the tumour microenvironment.

In the modulation of antigen-specific immune responses, cytokines may have pleiotropic effects, e.g. by activating or inducing the maturation of professional antigen-presenting cells such as dendritic cells, by promoting the proliferation, survival and cytokine production

of various T cell subsets or by directly increasing tumour cell expression of antigen and antigen presentation molecules. The role of cytokine administration in inducing production of tumour-specific antibody responses has not been fully explored.

Cytokines in the Treatment of Cancer

Cytokines used to treat cancer have been delivered by systemic and local administration, or have been added to *ex vivo* cultures for activation and expansion of immune effector or antigen-presenting cells. The genes encoding the production of a cytokine can be also transferred to a tumour or tumour stromal cells *in vitro* or *in vivo* using various delivery vectors. Cytokine production by gene-modified cells, which is used primarily to increase the immunogenicity of autologous or allogeneic cancer cell vaccines, will be covered in the chapters on gene therapy and cancer vaccines.

Only three recombinant cytokines (interleukin 2 (IL-2), interferon-alpha, tumour necrosis factor (TNF)) have reached the level of general acceptance for systemic or regional treatment of cancer, as determined by regulatory agency approval in one or more countries. Various other cytokines have been tested in clinical trials but were found not to have sufficient activity for clinical development to be continued. In the now substantial clinical experience with various cytokines, several obstacles to rational and efficient clinical evaluation have become apparent and are common to most cytokines, including the following: incomplete understanding of mechanism of antitumour activity in animal models and, consequently, a lack of a surrogate marker for antitumour activity that can guide the choice of an optimal dose and schedule for patients; inability to define tumour characteristics that would predict for responsiveness to cytokine antitumour effects; inability to administer doses equivalent to the effective doses in animal models because of excessive toxicity; and uncertainty as to whether the cytokines must demonstrate activity in advanced disease before evaluation in the adjuvant (micrometastatic) settings, where they are most likely to show a beneficial effect.

The clinical activity of antitumour cytokines is summarized in **Table 1**.

Interleukin 2

With the possible exception of interferon-alpha, perhaps no other antitumour cytokine has received more attention in basic studies, animal models and clinical trials than IL-2.The initial experiments to treat cancer in animals and patients were based on *in vitro* observations that IL-2 could activate and expand lymphocytes with cytotoxic effects against tumour cell lines. The mouse models demonstrated that IL-2 could be effective in treating small, moderately to strongly immunogenic tumours, although optimal antitumour activity required the administration of near-maximum tolerated doses. The effective IL-2 dose in some animal models could be reduced, or overall antitumour effects increased, if IL-2 was administered together with adoptive transfer of lymphokine-activated killer cells (LAK) or tumour-infiltrating lymphocytes (TIL). LAK are generated by short-term (days) *in vitro* culture of natural killer cells with high concentrations of IL-2. TIL are composed of CD8+, CD4+ lymphocytes that expand over periods of weeks when tumours are resected and placed in *in vitro* culture with IL-2. In contrast to the IL-2/LAK combination, prior treatment with cyclophosphamide was required in order to observe the anti-tumour activity of IL-2 combined with TIL in some tumour-bearing animals. The exact role of cyclophosphamide in these models has not been determined with certainty, but has been attributed to depletion of a suppressor T cell population, or creation of ‘space’ *in vivo* for the ‘take’ of adoptively transferred cells, or partial tumour bulk reduction.

Although direct and indirect evidence in most animal models points to activation or expansion of tumour antigen-specific CD8+ lymphocytes as a necessary requirement for IL-2’s antitumour activity, the exact mechanisms by which this occurs are unclear. IL-2 may be activating and expanding dormant or anergic pre-existing tumour antigen-specific T cells, similar to effects observed *in vitro* when tumours are cultured in IL-2. IL-2, either alone or through induction of secondary cytokines, could also be activating antigen-presenting cells that lead to primary T cell immune responses directed towards tumour antigens. In addition, secondarily induced cytokines such as TNF and interferon-gamma may be necessary to increase expression of antigen and self-major histocompatibility complex (MHC) molecules by tumour cells, thus allowing their recognition by T cells. The role of IL-2 *in vivo* may be substantially more complex, since IL-2 knockout mice have the phenotype of lymphocyte accumulation and autoimmune disease, suggesting perhaps that high-dose IL-2 could also be eliminating suppressive immune cells that inhibit the anti-tumour immune response. In different human tumours, different biological effects may be more important for anti-tumour response, e.g. induction of secondary cytokines or activation of natural killer cells, rather than activation of antigen-specific cytotoxic T cells (CTL). Furthermore, some biological effects such as activation of NK cells may be more optimal for combinations, for example, with monoclonal antibodies, since NK cells have receptors for the Fc portion of antibodies and mediate antibody-dependent cellular cytotoxicity.

Incomplete understanding of tumour–host biology, and its modulation by IL-2 relevant to an antitumour immune response, has made rational application of IL-2 to the

Table 1 Clinical activity of antitumour cytokines

Cytokine	Major common toxicities (including toxicity at highest doses)	Clinical antitumour activity[a]	Comments[a]
Interleukin 1	Constitutional symptoms, fever, chills, nausea, vomiting, diarrhoea, acute hypertension, hypotension, dyspnea, confusion, creatinine elevation, abdominal pain, leucocytosis	Low response rate noted in nonvisceral metastases of metastatic melanoma	Not fully evaluated, no longer in clinical trials
Interleukin 2	High dose: constitutional symptoms, fever, chills, nausea, vomiting, diarrhoea, hypotension, cardiac arrythmias, vascular leak, weight gain/oedema, pulmonary insufficiency/hypoxia, creatinine elevations, decreased urine output, liver function test abnormalities (bilirubin, transaminases), confusion/coma/altered mentation, metabolic abnormalities, skin erythema, thyroid dysfunction	High dose produces 15–20% ORR in MM and mRCC, 5–10% durable CR; combination with interferon-alpha and chemotherapy increases ORR in MM; objective responses reported in several other malignancies, but no consistent activity; in trials to increase relapse-free survival following chemotherapy-induced CR in haematological malignancies	Approved for treatment of MM and mRCC
Interleukin 4	High dose: constitutional symptoms, fever, nausea, diarrhoea, nasal congestion, erythema, liver function test elevations, increased creatinine, oliguria, dyspnea, cardiac arrythmias and ischaemia, gastrointestinal bleeding, fluid retention/vascular leak syndrome, disorientation	Low response rates noted in NHL, rare response in MM and mRCC trials	Primary use now *in vitro* to generate dendritic cells for cancer vaccine trials
Interleukin 6	Constitutional symptoms, fever, nausea, vomiting, liver transaminase and bilirubin levels, hypotension, atrial fibrillation, neurological toxicities (motor and mentation), anaemia, neutropenia, thrombocytosis	Low response rate noted in MM and mRCC	No longer in clinical trials
Interleukin 12	High dose: constitutional symptoms, fever, chills, headache, lymphopenia, thrombocytopenia, neutropenia, stomatitis, liver transaminases and biliribin, autoimmune phenomema, renal insufficiency, confusion/tremors, gastrointestinal bleeding	In early studies, high rates of ORR in CTCL and KS; low response rates observed in MM and mRCC	Remains in clinical trials, studies in lymphoma, myeloma, breast cancer, and combinations with other biologics

(Continued)

Table 1 (Continued)

Cytokine	Major common toxicities (including toxicity at highest doses)	Clinical antitumour activity[a]	Comments[a]
Interferon-alpha	Acute: constitutional symptoms, transient leucopenia, anorexia, nausea and vomiting, reversible transaminase elevations Chronic: hypothyroidism or other autoimmune phenomena, fatigue, depression, other neurological complaints including difficulty in concentrating	High haematological and low (~30%) major cytogenetic remission rate in chronic phase CML, prolongs survival; ~50% complete and partial remission rate in HCL; 15% ORR in MM and mRCC; increases ORR in MM in combination with chemotherapy and IL-2; prolongs PFS in Stage 2b/3 melanoma; prolongs PFS in combination with chemotherapy in poor prognosis indolent lymphoma; has activity in multiple myeloma and KS	
Interferon-gamma	Constitutional symptoms, fever, chills, nausea, vomiting, hypotension, cardiac arrythmias, hepatic and renal dysfunction, granulocytopenia, coagulopathy	Minimal activity noted, although low response rates in MM and mRCC, responses reported with intraperitoneal or regional administration (ovarian carcinoma)	Approved for noncancer indications
Tumour necrosis factor	Acute hypertension, hypotension, liver function test elevations, thrombocytopenia, transient leucopenia, fever, chills, nausea, vomiting, diarrhoea and constitutional symptoms	Minimal activity noted with systemic administration; high (>80%) ORR in limb perfusion studies of MM and sarcoma when used with melphalan and hyperthermia, also high ORR in liver metastases in liver perfusion study	
GM-CSF	At clinically used doses: rare and mild constitutional symptoms and fever	Low responses when tested alone in mRCC, report of increased PFS in fully resected MM patients compared with historical control, responses noted in neuroblastoma in combination with anti-GD2 antibody	Phase 3 trials in stage 4 NED melanoma, with anti-GD2 in neuroblastoma; used primarily as adjuvant in cancer vaccine studies, or *in vitro* with IL-4 to generate dendritic cells for cancer vaccines
FLT3-ligand	Minimal systemic effects at clinically used doses	In phase 2 clinical trials	

[a]ORR, objective response rate, complete plus partial tumour regression; CR, complete response; MM, metastatic melanoma; mRCC, metastatic renal cell carcinoma; HCL, hairy cell leukaemia; CML, chronic myeloid leukaemia; CTCL, cutaneous T cell lymphoma; KS, Kaposi sarcoma; NHL, non-Hodgkin lymphoma; PFS, progression-free survival; NED, no evidence of disease.

treatment of cancer more difficult. This has led to a large number of IL-2 regimens tested in patients, with substantial variations of dose and schedule in an attempt to maximize certain biological effects felt to be associated with antitumour activity. In addition, a very large number of studies have examined the antitumour activity of IL-2 combined with various types of adoptively transferred effector cells, other cytokines, monoclonal antibodies and chemotherapeutic agents.

Clinical Experience

The vast clinical experience with IL-2 alone and in combination with standard and investigational agents and with adoptive immunotherapy still leaves many questions unanswered as to its optimal application to the treatment of cancer. A major limitation in systemic administration of IL-2 is toxicity, which is dependent on dose and duration of exposure. For any given dose, administration by continuous infusion over 24 h is more toxic than administration by short intravenous bolus or subcutaneous injection. At the maximum tolerated doses of any given schedule, IL-2 affects nearly every organ system and produces systemic changes reminiscent of sepsis. Despite the development of severe adverse effects, toxicities are generally completely reversible once IL-2 is discontinued. Proper selection of patients with well-preserved organ function and good performance status has minimized the overall morbidity and mortality from high-dose IL-2 regimens (Kammula *et al*., 1998).

Consistent anti-tumour activity of IL-2 in clinical trials has only been demonstrated for metastatic melanoma and renal cell carcinoma. Although few randomized studies have been conducted, the clinical activity of IL-2 appears to be dose related. Very low-dose chronic administration regimens have not been associated with objective responses in metastatic disease, except in rare circumstances. Nevertheless, the low-dose regimens produce serum concentrations of IL-2 that are sufficient to activate high-affinity IL-2 receptors and substantially expand a subset of natural killer cells (Caligiuri *et al*., 1990; Soiffer *et al*., 1996). The latter underscores the complexity of IL-2 antitumour mechanisms *in vivo*, and indicates that the additional biological effects of higher doses are probably necessary for activity in patients with advanced or metastatic cancer. Higher dose regimens of IL-2 that are associated with modest toxicity and usually administered in an outpatient setting have had variable but low response rates in metastatic renal cell carcinoma with few durable complete responses. A broad examination of the data suggests that the regimens with modest toxicity may be relatively inactive in metastatic melanoma.

IL-2 regimens that require inpatient administration because of their more severe toxicity appear consistently to produce low-level response rates in metastatic melanoma and mRCC in the region of 15%, but with a fraction of responding patients achieving long-term durable responses (Fyfe *et al*., 1995; Atkins *et al*., 1999). The standard regimen involves the administration of two courses of 600 000–720 000 IU kg^{-1} by intravenous infusion every 8 hours for up to 14 doses separated by a 9–12-day rest, and repeated every 8–12 weeks. The administration of IL-2 is unique in that individual doses may be skipped for acute and rapidly reversible severe toxicity, and patients continue to receive doses until they have reached their individual tolerance. Long-term follow up for separate cohorts in excess of 250 patients with metastatic RCC and melanoma demonstrate that between 5 and 10% of all patients have durable relapse-free complete responses lasting years. Equitoxic regimens administering IL-2 by continuous infusion are also active, although direct comparisons with the bolus regimen have generally not been made, and the impression from the combined data is that the response rates and number of durable responses may be lower for continuous infusion regimens.

A formal evaluation of the activity of IL-2 in other malignancies has not been completed, primarily because of the toxicity of the high dose and some of the modest dose regimens. Nevertheless, objective responses have been observed in patients with metastatic colon cancer, ovarian cancer, breast cancer, lung cancer, head and neck cancer, lymphoma, acute myeloid leukaemia and several other malignancies treated with IL-2 either systemically or by regional administration. Randomized trials are ongoing to assess the activity of IL-2 following high-dose chemotherapy and stem-cell support for relapsed lymphoma and AML.

None of the many measured immunological parameters in IL-2 trials have been consistently associated with objective antitumour responses, although some small trials have found correlations between certain variables such as maximum lymphocyte counts following treatment and response. The best predictor for IL-2 response in renal cell carcinoma and metastatic melanoma has been excellent performance status and lack of symptoms. For patients with melanoma, response rates are highest in patients with disease limited to cutaneous and/or cutaneous sites.

IL-2 and Adoptive Therapy

Many of the initial clinical trials of IL-2 included the adoptive transfer of lymphocytes. Patients received a 3–5-day course of IL-2, which produced a marked lymphocytosis approximately 24 h later. The lymphocytes were harvested from the patient and placed in culture with high concentrations of IL-2 for 3–4 days, during which the lymphocytes were activated and developed broad cytotoxicity against tumour cell lines. The LAK were transferred back to the patient together with IL-2. After many trials including some randomized studies, LAK did not appear to contribute substantially to the antitumour activity of high-dose IL-2 (Rosenberg *et al*., 1993).

Subsequent studies involved the adoptive transfer of TIL with IL-2. TIL were generated by placing a surgically

excised tumour in *in vitro* culture with IL-2 for several weeks, during which the infiltrating lymphocytes would expand and tumour cells were eliminated. In some animal models, the resulting lymphocyte population is CD8+, oligoclonal and specifically recognizes and kills the tumour from which they are grown. Similar experiments conducted with human tumours have demonstrated consistent expansion of tumour antigen-specific CD8+ TIL only in patients with metastatic melanoma. Clinical studies conducted with IL-2 and TIL suggest that in some patients with metastatic melanoma the addition of TIL to IL-2 may have benefit, as demonstrated by objective responses in patients who had previously progressed on IL-2 alone. Studies conducted by the Surgery Branch, National Cancer Institute, also demonstrated overall higher response rates with IL-2 and TIL, although the process required to make TIL may also have selected for patients more likely to respond to IL-2 alone. The few studies of TIL conducted in patients with other malignancies, particularly renal cell carcinoma, have not demonstrated superior activity over that expected with IL-2 alone. Clinical studies of IL-2 combined with adoptive transfer of cloned and expanded tumour antigen-specific CTL are now ongoing in patients with metastatic melanoma.

IL-2 and Other Cytokines, Antibodies, Vaccines

In animal models, the addition of systemic IL-2 improves the antitumour activity of various other biologics including multiple different cytokines (interferon-alpha, interferon-gamma, TNF, IL-12), antibodies and cancer vaccines. Toxicity and activity can be highly dose and schedule dependent and can vary between animal models. Various regimens of IL-2 in combination with interferon-alpha have been examined extensively, including some randomized trials in metastatic melanoma and renal cell carcinoma, but these studies have not demonstrated a meaningful improvement in activity over the single agents. Combinations of IL-2 with TNF and IL-2 with interferon-gamma did not progress past phase 1 and early phase 2 trials. Previous trials of murine antibodies raised to human cancer antigens and combined with IL-2 were not promising, but these studies have been reinitiated with humanized monoclonals that have longer serum half-lives and do not raise human antimouse antibody responses (HAMA), thus permitting repeated administration of the antibody. Phase 1 clinical trials of IL-2 and IL-12 were recently initiated on the basis of marked antitumour activity observed in animal models. The combination was also fairly toxic in the animal models and required a specific schedule of pulse IL-2 followed by more chronic IL-12 administration to achieve improved levels of antitumour activity safely.

IL-2 and Chemotherapy

Cytotoxic agents have been combined with IL-2 in several clinical settings. The chemotherapy, often cyclophosphamide at low dose, is given prior to IL-2 alone or IL-2 with cellular adoptive transfer, as a means to reduce *in vivo* immunosuppressive elements, or cause tumour bulk reduction, or 'create space' for 'take' of adoptively transferred cells. Despite many trials, evidence for the benefit of adding cyclophosphamide to IL-2 is equivocal.

In several studies, IL-2 and interferon-alpha have been given either sequentially or concurrently with a combination chemotherapy regimen for melanoma. These studies have almost invariably produced higher objective response rates than chemotherapy alone and, indeed, the higher response rates are being confirmed in randomized trials (Legha *et al*., 1998; Rosenberg *et al*., 1999). The higher response rates, however, translate into small or no survival advantage for patients with metastatic disease. Studies in the high-risk surgical adjuvant setting are ongoing. The mechanisms responsible for the higher response rates with the bio-chemotherapy are not yet defined. Although activation of a melanoma-specific immune response is possible, there is some evidence to suggest that IL-2 induced cytokines together with interferon-alpha may have direct effects on tumours cells that sensitize to the cytotoxic effects of the chemotherapy.

Tumour Necrosis Factor

TNF is another complex cytokine with multiple biological activities *in vivo*. Much has been learned regarding the intracellular signalling pathways for the TNF receptor and other members of the TNF receptor family. Signalling through the receptor activates both a cell death pathway that involves cleavage of caspases and a cell survival pathway that involves activation of the Nf-kappaB transcription factor.

Administration of TNF to mice bearing subcutaneous implanted tumours produces marked central haemorrhagic necrosis and granulocyte infiltration within the tumours, through mechanisms that are still not fully understood today. These effects are observed independent of the sensitivity of the tumour cell lines to TNF *in vitro* and independent of the *in vivo* immunogenicity of the tumour. Furthermore, induction of central haemorrhagic necrosis, presumably through effects on tumour vasculature and perhaps involving cell-mediated events, is observed in both nude and fully immune-competent mice. TNF also has direct antiproliferative or cytotoxic effects against some tumour cell lines, and can sensitize some tumour cells lines to the effects of chemotherapy. The role that TNF's many other biological effects play in its antitumour activity, e.g. effects on different subsets of lymphocytes, granulocytes, endothelial cells, monocytes/macrophages and dendritic cells, is unclear.

Many clinical trials were conducted with single- and multiple-dose and continuous infusion schedules of recombinant TNF in the 1980s, with little observed antitumour activity. The maximum tolerated doses in patients were far less than doses tolerated by mice if normalized

to weight or body surface area. Major clinical toxicities included hypotension, liver function test elevations, thrombocytopenia, transient leucopenia, fever, chills and constitutional symptoms. Investigators subsequently explored the administration of TNF into isolated limb vascular perfusion circuits, for patients with sarcoma or melanoma localized to an extremity. The isolated perfusions allowed delivery of high TNF concentrations to the affected area while minimizing systemic exposure. The response rate was low in the few patients receiving TNF alone by isolated limb perfusion, but the combination of melphalan and TNF, under conditions of hyperthermia and together with a dose of systemic interferon-gamma, produced very high complete and overall tumour response rates in perfused limbs (Eggermont *et al*., 1996; Fraker *et al*., 1996). Some subsequent studies have eliminated the interferon-gamma without an apparent effect on response rate. Although randomized studies to determine the role of TNF have not been completed, on the basis of historical data and the high response rates in the single-arm trials, isolated limb perfusion with TNF, melphalan and hyperthermia is now approved in Europe.

Early clinical trials combining systemically administered TNF with IL-2 or interferon-gamma did not yield sufficient activity to pursue further development. Similarly, some clinical trials combining systemically administered TNF with chemotherapy were performed, but none provided compelling evidence for continued clinical trials. TNF is being explored currently for *in vitro* maturation of dendritic cells used in cancer vaccine studies.

Interferon-alpha

As with other cytokines, many different mechanisms probably account for the antitumour activity of interferon-alpha in patients, and perhaps different mechanisms are active depending on the patient, the disease and stage. Interferon-alpha directly inhibits the growth of some tumour cell lines *in vitro*. Interferon-alpha also enhances immune-mediated antitumour responses, by enhancing NK cell activity, by modulating survival of T cells and the function of professional antigen-presenting (dendritic) cells and by increasing expression of MHC molecules on tumour cells, thus enhancing their recognition by T cells. Low-dose chronic interferon-alpha has been shown to inhibit tumour angiogenesis by down-regulating production of bFGF and matrix metalloproteinases by tumour cells.

A large range of doses and various schedules and routes of interferon-alpha administration have been explored in clinical trials. Acute toxicity is mostly manifest as constitutional symptoms, transient leucopenia, anorexia, nausea and vomiting and reversible transaminase elevations, although severe hepatic toxicity has been reported. The acute effects of flu-like symptoms and occasional elevations in transaminase levels often resolve with continued administration. However, chronic administration of interferon-alpha can be associated with hypothyroidism or other autoimmune phenomena, debilitating fatigue, depression and other neurological complaints including difficulty in concentrating.

As a single agent, interferon-alpha has antitumour activity in several malignant diseases including hairy cell leukaemia, chronic myeloid leukaemia, non-Hodgkin lymphoma, multiple myeloma, Kaposi's sarcoma, renal cell carcinoma and metastatic melanoma. In hairy cell leukaemia, administration of interferon-alpha produces a high percentage of partial to complete haematological remissions (approximately 50%), usually occurring gradually over several months (Grever *et al*., 1995). Discontinuation of treatment eventually results in relapse in most patients, although many will be responsive to reinstitution of treatment. In chronic-phase CML, interferon-alpha prolongs overall survival, with the major benefit to the approximately one-third of patients who achieve major cytogenetic responses (Silver *et al*., 1999). Median time to response in CML is 12 months.

Response rates in the other interferon-alpha sensitive diseases are modest and few durable complete remissions are observed. The benefit of interferon-alpha in stage 2b/3 melanoma patients (following resection of deep primaries or involved regional lymph nodes) remains controversial. In randomized trials, a high-dose interferon-alpha regimen appears to produce some improvement in disease-free but not overall survival, based on the combined results of two randomized trials conducted by the Eastern Oncology Cooperative Group. For stage 2a patients, some randomized trials have shown improved DFS for low-dose interferon regimens, but an effect on overall survival has not been demonstrated unequivocally.

Many different combinations of interferon with standard and investigational agents have been tested in the clinic, and new combinations involving interferon with newer cytokines (IL-12) or antiangiogenic agents (thalidomide) are in early clinical trials. In randomized trials, interferon-alpha combined with multiagent chemotherapy for poor-prognosis low-grade lymphoma has demonstrated an improvement in disease-free survival (and, in one study, overall survival), but the results have not been consistent. Other initially promising results with interferon-alpha in combination with chemotherapy have not been unequivocally confirmed in randomized studies.

Other Cytokines

A number of other cytokines have been or will be evaluated in clinical trials. Interleukin 1 (IL-1) was evaluated only in a limited number of trials, and produced toxicities similar to TNF and few antitumour responses. Interferon-gamma underwent extensive testing in humans, alone and in combination with other agents, and although some clinical responses were observed (primarily in melanoma

and renal cell carcinoma), development in cancer has been mostly discontinued. Despite the ability of interferon-gamma to increase antigen and MHC expression in human tumours, it did not appear to improve clinical response rates when used in combination with IL-2, IL-2 and adoptive immunotherapy, or radiolabelled antibodies in single-arm phase 1 and 2 studies.

Much of the initial impetus to develop interleukin 4 (IL-4) in cancer stemmed from the *in vitro* demonstration that addition of IL-4 and IL-2 in cultures of tumour-infiltrating lymphocytes enhanced the generation of antigen-specific CTL, and suppressed the development of non-specific NK/LAK activity. IL-4 was also shown to inhibit directly the growth of some tumour cell lines *in vitro* (although at high concentrations), to enhance LAK activity in certain situations and, more recently, to inhibit angiogenesis. The opposing effects of IL-4 sometimes reported from different experiments could be explained in part by the sequence with which cells were exposed to other cytokines and their activation status prior to IL-4 exposure. Thus, for example, LAK activity was suppressed by culture of lymphocytes concurrently with IL-2 and IL-4, but enhanced when the lymphocytes were exposed to IL-2 followed by IL-4. Various doses/schedules of IL-4 were examined in the clinic, ranging from daily subcutaneous injections to high-dose thrice-daily intravenous injections. Although some clinical responses were observed, particularly in lymphoma, the activity was not sufficient to merit continued clinical development. Several studies of IL-2 in combination with IL-4, again testing various sequences and regimens, did not demonstrate promising activity. Similarly, broader clinical experience using IL-2 in combination with IL-4 *in vitro* did not improve the yield, specificity or antitumour activity of TIL.

While a role for systemically administered IL-4 has not been found, there is substantial interest in the use of IL-4 *in vitro*, in combination with GM-CSF, to generate dendritic cells for cancer vaccine trials (Romani *et al*., 1994). The dendritic cells generated from PBMC cultured in IL-4 and GM-CSF are potent activators of antigen-specific T-cells. Several trials of peptide-pulsed dendritic cells have demonstrated the ability to induce clinical regression of advanced melanoma in a small fraction of patients. Recent work indicates that a vaccine composed of autologous tumour cells fused to allogeneic dendritic cells (generated in IL-4 and GM-CSF) can produce complete and partial regressions in approximately one-third of patients with advanced renal cell carcinoma. Further exploration of dendritic cell cancer vaccines may depend on the continued availability of IL-4, although a related cytokine, interleukin 13 (IL-13), may have similar properties.

Interleukin 6 (IL-6) exhibited single-agent antitumour activity in various murine tumour models and was therefore examined in phase 1 and phase 2 clinical studies. Although a low rate of partial responses was observed in metastatic melanoma and renal cell carcinoma, at the relatively high doses employed IL-6 produced unacceptable cardiac (atrial arrthymias) and neurological toxicities.

Interleukin 12 (IL-12) has several unique features among the cytokines, including its two chains and a prolonged serum half-life of several hours. In murine tumour models, IL-12 showed substantial antitumour activity alone and in combination with other cytokines (Brunda *et al*., 1993). The antitumour activity is abrogated in most models by antibodies against interferon-gamma or depletion of CD8+ T cells, and partially reduced by antibodies against the interferon-gamma induced chemokines IP-10 and Mig (Nastala *et al*., 1994). IP-10 has been shown to inhibit angiogenesis in various assays.

Depending on dose, schedule and animal model, IL-12's antitumour effects *in vivo* may be mediated by different mechanisms. In the stimulation of antigen-specific T cell responses, either as a single agent or as a vaccine adjuvant, single low doses may be sufficient and perhaps optimal. However, in many animal models, chronic administration of maximum tolerated doses appears to have the greatest antitumour activity. The latter regimens appear to inhibit the induction of antigen-specific T cell responses, at least temporarily, and probably cause tumour regression by inducing high levels of interferon-gamma that cause tumour cell death or production of antiangiogenic cytokines within the tumour. Other mechanisms are likely to be involved since direct administration of interferon-gamma does not have similar antitumour activity. The complexity of these cytokine biological effects has made effective translation into the clinic more difficult.

A variety of dose/schedule regimens for IL-12 have been explored in the clinic. An additional level of complexity was added to the clinical development by the finding that an initial dose of IL-12 could decrease the toxicity and biological effects (i.e. induction of interferon-gamma) of subsequent treatment with IL-12. The induction dose of IL-12 affected subsequent IL-12 administration even if given up to 2 weeks earlier. The mechanisms involved are not well understood. In some animal models, the induction dose increases the amount of IL-12 that can be administered subsequently, but does not necessarily improve the therapeutic benefit. A regimen consisting of an i.v. induction dose, followed 2 weeks later by intravenous administration, daily for 5 days, every three weeks, did not have sufficient antitumour activity in metastatic melanoma and renal cell carcinoma, as measured by objective tumour regression, to justify continued clinical evaluation of that schedule.

Attempts to give IL-12 on a continuous basis have been limited by toxicity, but once and twice weekly schedules have been reasonably well tolerated in advanced cancer patients. High rates of objective partial tumour regression have been reported in early trials of twice weekly subcutaneous administration in patients with early-stage CTCL and with Kaposi sarcoma. In a phase 1 trial of twice

weekly i.v. administration, evidence of tumour regression was observed in a small fraction of patients with metastatic renal cell carcinoma, although patients required months of therapy before response was documented (Gollob *et al.*, 2000). Of note, clinical activity was correlated with the ability of lymphocytes to remain responsive to IL-12 with continued administration. The blunted *in vitro* response to IL-12 in some patients could be enhanced by addition of IL-2, forming the basis of a clinical trial combining IL-12 and IL-2.

Based on *in vitro* and *in vivo* data, studies of IL-12 in combination with other agents have also been initiated, including interferon-alpha, IL-2, monoclonal antibodies and vaccines. A variety of mechanisms serve as the basis for the combinations: enhanced intracellular signalling and tumour antiproliferative effects with interferon-alpha, enhanced NK cell production of interferon-gamma in the presence of tumour and a tumour-specific antibody and potentiation of vaccine-induced antitumour immune responses.

Although not commonly thought of in terms of its potential antitumour effects, Granulocyte–monocyte colony-stimulating factor (GM-CSF) has been reported to enhance the production and activation of monocytes/ macrophages and to promote the development of antigen-presenting cells from monocytes (in combination with IL-4). Based on its effects on monocytes, GM-CSF has been combined with several monoclonal antibodies in clinical trials, but response rates in metastatic disease have been low. Nevertheless, clinical responses were observed in combination with an anti-GD2 antibody in some patients with neuroblastoma, and these results have prompted the initiation of a randomized phase 3 trial of the GM-CSF and anti-GD2 in patients that have been cytoreduced with high dose chemotherapy. As a single agent, GM-CSF has been associated with a low response rate in metastatic renal cell carcinoma, and appeared to increase progression-free survival compared with historical controls in melanoma patients with fully excised metastatic disease. The latter observations formed the basis of an ongoing randomized phase 3 trial comparing GM-CSF to observation (placebo) in stage 4 melanoma patients that have had all metastatic disease resected. GM-CSF has also been administered systemically in combination with IL-4 to increase circulating dendritic cells, and its use together with IL-4 for the same purpose *in vitro* was described above. GM-CSF is a commonly used adjuvant in experimental cancer vaccine trials.

Another cytokine, FLT3-ligand (flt3l), was shown to expand circulating and tissue dendritic cells in animal models (Maraskovsky *et al.*, 1996). As a single agent, flt3l had antitumour activity in several murine models. Although the presumed mechanism of antitumour activity is induction of tumour antigen-specific responses by the flt-3l expanded DC, depletion of NK cells in one tumour model partially reduced the antitumour effect of flt3l administration. Phase 1 trials have confirmed the ability of flt3l to expand circulating DC in patients, and phase 2 studies have been initiated. The ability of flt3l to enhance immune responses to tumour antigens in cancer vaccines is currently being explored. Clinical and preclinical studies to date have not reported an increased incidence of autoimmune disease, and the flt3l has in general been very well tolerated by patients. A fusion protein of flt3l attached to GM-CSF is also in clinical trials.

Several other cytokines are likely to enter or have already entered clinical trials, including interleukin-7, interleukin-15 and interleukin-18. Rational clinical development of these cytokines will depend on careful characterization of their biological properties and relevant mechanisms of antitumour activity in animal models.

ANTIBODIES

Biological Basis for Application of Antibodies to Cancer Treatment

Antibodies are large proteins made by specific blood cells called B lymphocytes, or B cells, which can attach to specific targets with great selectivity and strength, and can then recruit innate immune defence mechanisms to eliminate the bound protein, and any cell to which it is attached. Since it is critical that the immune system does not attack 'self', humans do not normally produce antibodies against normal human proteins. It is possible, however, to generate many different antibodies by injecting viral, bacterial or human proteins into other species, such as mice. Following these injections, the animals will produce abundant antibodies in their blood, and this 'immune serum' has been used to treat several human diseases. In the 1970s, Kohler and Milstein first developed technology to isolate the individual B cells from the immunized animals that were injected with selected antigens, and to induce those B cells to produce a single antibody clone ('monoclonal') against selected antigens (Kohler and Milstein, 1975). It was apparent that specific mouse (murine) antibodies could be produced against human antigens, and the potential to target the human immune system against specific antigens and diseases has driven tremendous research efforts in subsequent decades.

Antibodies mediate their anticancer effects through various mechanisms that depend in part on the particular antigen target. Upon recognition and binding to the tumour antigen, an antibody can mediate complement (CDC) or cell dependent (ADCC) lysis of tumour cells. Cell-mediated cytotoxicity is dependent on the presence of granulocytes, natural killer cells or monocyte/macrophages that bear a receptor for the constant region (Fc) portion of the antibody. The ability of an antibody to mediate CDC or ADCC in humans is dependent on its class and isotype.

In recent years, the mechanisms by which antibodies can mediate anti-cancer activity have broadened to include blocking growth factor receptors on tumour cells, binding and sequestering growth factors, inducing an apoptotic intracellular signal by binding to a cell surface molecule, disrupting tumour vasculature or preventing angiogenesis and modulating an anticancer immune response.

Further improvements in antibody-mediated direct antitumour effects can be obtained by recombinant engineering techniques that join the antigen-binding portions of the antibody to various effector molecules. The tumour-targeting capacity of antibodies permits the delivery of molecules that would otherwise be too toxic to administer systemically. Various toxins have been attached to antibodies, and one, an antibody to CD25 carrying a diphtheria molecule, has been approved in some countries for the treatment of cutaneous T cell lymphoma. Some effector molecules do not have a requirement for internalization into the tumour cell, e.g. cytokines, radioactive isotopes or prodrug-converting enzymes. The latter provide a 'broad field' or bystander effect, and bypass the need for each cancer cell to express the target for the antibody, as long as the antigen-negative tumour cells are in relatively close proximity to the target antigen-expressing tumour cells.

Antigen Targets

Identification of an appropriate target antigen is critical to effective anticancer antibody therapy. It is relatively straightforward to identify targets on nonhuman pathogens such as viruses or bacteria. However, in cancer, the targets are generally common to both normal and cancerous cells, so that any antibody against a common antigen has the potential to affect both normal and malignant tissues, leading to toxicity. Therefore, an appropriate antigen should be tumour specific, expressed uniquely on the tumour or at a much higher level in tumour tissues than on normal cells. It should also be readily available on the cell surface to allow for antibody binding, since under normal conditions antibodies are unable to penetrate into cells. A large number of potential antigens that meet these specified criteria have been identified. Furthermore, many more potential target antigens are being identified by techniques that characterize differential gene expression between normal and tumour cells. Some of the tumour or tumour-associated antigens currently targeted in clinical trials are listed in **Table 2**.

Appropriate selection of an antibody or antibody-targeted therapeutic is also dependent on certain characteristics of the antigen and the intended mechanism of antibody cell killing (**Table 3**). Antibodies that utilize the immune system to kill cancer cells require antigens that are maintained on the cell surface. Antibodies attached to certain toxic agents that must enter cells for their effect must recognize antigens that are internalized after antibody binding. An additional consideration includes the selection of targets that mediate some internal reaction within the cell – either initiating a cell death pathway (apoptosis) or altering cellular mechanisms in some way that may make the cell more susceptible to other therapeutic modalities such as chemotherapy or radiation.

Antibody Types

The fact that all antibodies to human targets are made in nonhuman species presents a significant problem. These nonhuman antibodies are recognized as being alien when they are infused into patients, and are rejected by the recipient over a period of about 2 weeks after initial exposure, and almost immediately after subsequent treatments. Further, the effector arms of the immune system do not interact optimally with these alien molecules, so that their ability to recruit the host's immunity to eliminate a bound target may also be limited. During the last two decades, technologies have been developed that allow the conversion of these murine antibodies into chimeric molecules, where half or more of the protein is replaced with equivalent human parts while the antigen recognition sequence, the part of the molecule that binds to a target, remains unchanged. The standard reference to a chimaeric antibody describes a form that contains approximately 60% human protein sequence, while 'humanized' antibodies contain 90–95% human sequence. These formulations appear to have distinct advantages over their murine counterparts. They do not induce immune reactions and are therefore not rejected by the patient's own immune system, and can consequently persist in a recipient's blood for weeks to months. They can also be given repeatedly. Most antibodies currently in the clinic are either chimaeric or humanized.

As technology has developed further, it is now possible to create completely human molecules. The human immunoglobulin genes have been inserted into mice, which then produce human rather than murine antibodies. An alternate technology involves cloning immunoglobulin genes from human B cells and expressing them on the surface of bacteriophage which can be easily used to select for antibodies against specific targets, including human antigens. Antibodies to specific targets can then be selected and manipulated to create a desired molecule with specific antigen-binding properties. These fully human molecules are relatively simple to make, and could significantly decrease the time necessary to produce new therapeutic antibodies. Whether fully human antibodies will offer improved antitumour effects has yet to be determined.

The source species for an antibody is defined in the agent's generic name. Murine antibodies contain the suffix 'momab,' while chimaeric antibodies use 'ximab' and humanized antibodies are called 'zumab.' The suffix 'umab' identifies fully human antibodies.

Table 2 Tumour targets for antibodies currently used in patients

Antigen	Disease	Normal tissue expression	Antibody	Comments
Idiotype (immunoglobulin receptor)	B cell NHL	None	Anti-idiotype antibodies (murine)	Patient-specific agents requiring individualized production
CD20	B cell NHL or CLL	B cells	Rituximab (chimaeric)	Approved
			B1 (murine)	Radiolabelled
CD22	B cell NHL or CLL	B cells	Epratuzumab (humanized)	Bare and RIT
CD19	B cell NHL or CLL	B cells		Fusion protein
CD25 (IL-2 receptor)	B or T cell lymphoma or leukaemia	Activated B and T cells	Daclizumab (humanized)	Approved as immunosuppressive for renal transplantation
CD52	Lymphoma or leukaemia	Leukocytes	CAMPATH-1H (humanized)	Approved for CLL
CD33	Acute leukaemia	Myeloid stem cells	Hum195 (humanized)	Advanced development as bare antibody
			CMA-676 (humanized)	Immunotoxin approved for AML
CD45	Acute leukaemia	Myeloid stem cells	BC8 (murine)	Radiolabelled
HLA-DR	Lymphoma, leukaemia, and potentially solid tumours	Variable	Hu1D10 (humanized)	Early trials for lymphoma
Her2/*neu*	Overexpressed in epithelial malignancies	Skin, GI tract	Trastuzumab (Herceptin®) (humanized)	Approved for breast cancer. In trial for other diseases
EGF receptor	Overexpressed in epithelial malignancies	Skin, GI tract	C225 (chimaeric)	Advanced clinical development
VEGF	Many malignancies	Regenerating/ healing tissues	Bevacizumab (humanized)	Advanced clinical development
EpCAM	Epithelial malignancies	GI tissues	Edracolomab (17-1A) (murine)	Advanced clinical development. Mechanism unclear
Tag72	Epithelial malignancies	GI tissues	CC49 (humanized)	Radiolabelled
$\alpha v \beta 3$ integrin	Tumour vasculature	None	Vitaxin (humanized)	Early clinical development
GD2 ganglioside	Melanoma, neuroblastoma	Peripheral nerve	Chimaeric 14.18	Advanced clinical development

Table 3 Mechanisms of action for antibody antitumour activity

Mechanism	Description
CDC (complement-dependent cytotoxicity)	Recruits innate complement mechanisms to kill bound cells
ADCC (antibody-dependent cellular cytotoxicity)	Recruits cellular killing via monocytes and NK cells
Apoptosis	Induces spontaneous cell death via signalling mechanism induced by binding. Often related to antigen cross-linking
Signalling inhibition	Blocks ligand/receptor interactions by binding either molecule. Can deprive cell of growth stimulus, etc.
Vaccination	Induces immunity against bound antigen
Immune stimulation	Augments immune recognition of bound cell, or nonspecifically stimulates innate antitumour immunity

General Toxicities of Antibody Infusions

The infusion of biological proteins into humans is associated with a unique syndrome characterized by fevers, chills, low blood pressure, shortness of breath and an assortment of other symptoms. This syndrome is often observed with the initial infusion of antibodies and with subsequent infusions of non-humanized antibodies. In general, it can be controlled by common medications such as acetaminophen or antihistamines.

Antibodies that target immunologically active cells can also cause a more dramatic infusional syndrome that presents the same spectrum of side effects, but often in a more severe form. This syndrome is likely due to a 'cytokine storm,' where the cells rapidly release an assortment of biologically active molecules (interleukin-6, interferon-gamma, TNF) in response to antibody binding, and these cytokines then cause a broad spectrum of side effects. Slowing or delaying the infusion, administering standard prophylactic medications or splitting the dose can reduce these complications. When the target cells have been depleted, or their cytokine load is reduced, the infusional syndrome is reduced or eliminated. Thus, subsequent infusions of the antibody induce few to no side effects.

Unlabelled Antibodies

Many different types of monoclonal antibodies have been tested against tumours. Initial trials suggested limited therapeutic effects, prompting the development of antibodies attached to toxic agents that could mediate cell death in target cells. However, with the selection of new antigen targets and the introduction of chimaeric and humanized antibodies, several unmodified monoclonal antibodies have demonstrated the capacity to induce meaningful tumour regressions in patients.

Stevenson's group first suggested that the antibody made and expressed by B cells could actually be an antigen itself (Hough *et al*., 1976). In B cell lymphomas, the antibody made by the malignant B cell (the 'idiotype') is not found on other cells and can serve as a specific target for antibody therapy. Levy's group first established the use of murine anti-idiotype antibodies as treatment for B cell lymphoma in 1981 (Miller *et al*., 1982; Meeker *et al*., 1985). Up to 75% of patients who were treated on initial clinical trials developed significant reductions in their tumours that lasted a median of approximately 9 months. Some patients experienced complete remissions lasting over 10 years. The fact that a different therapeutic monoclonal antibody had to be produced for each patient made this approach impractical for general patient use. Additionally, many patients developed their own immune response against the murine antibodies (human antimurine antibodies (HAMA)), which rapidly neutralized the therapeutic antibodies from the bloodstream, limiting the amount of time that the therapeutic agent could remain in the patient. A small percentage of patients developed tumour recurrences that had lost or mutated the idiotype target in such a way that the therapeutic anti-idiotype antibody no longer recognized the tumour and could not be used again. Effectively, this treatment selected for malignant cells that did not have the antigen and thus escaped treatment. Such antigen loss is still a critical issue in antibody therapy.

Rituximab

CD20 is a cell membrane antigen that is expressed on mature B cells, but not on B cell precursors or other cells. It appears to be a calcium channel that is involved in activation and proliferation of B lymphocytes. It does not internalize with antibody binding, so that bound antibodies are available on the cell surface for immune system interactions. In addition, CD20 is expressed by over 90% of B cell malignancies. These features make it a good target for antibody therapy, and several different monoclonal antibodies have been developed against this antigen.

Rituximab is a chimaeric mouse–human antibody that binds CD20. It can activate both ADCC and CDC, and has been shown to induce apoptosis in CD20 expressing B cell lymphoma cell lines. Infusion into nonhuman primates resulted in profound depletion of circulating B cells with little toxicity. The initial phase 1 clinical trials did not identify any dose-limiting side effects, and the standard clinical dose was defined by practical issues such as infusion duration and the ability to sustain antibody levels in the blood with depletion of normal B cells. Rituximab demonstrated clear activity against indolent lymphomas, which are generally not cured by available therapies and make up about 40% of all lymphomas. In the pivotal studies, 50% of patients experienced significant benefit, demonstrated in part by a delay of a year or more in chemotherapy treatment for patients who had objective responses (McLaughlin *et al*., 1998).

Rituximab-induced tumour shrinkage progresses over several months after completion of the four weekly antibody infusions, possibly owing to the long duration of rituximab levels in the blood that persist for 2–6 months. Rituximab can also be effective in patients who have responded and then progressed after a previous course of rituximab, with about half of patients responding to a second or third course, thus further delaying other treatments and potentially prolonging lives. Based on at least additive anti-tumour activity *in vitro*, clinical trials are evaluating rituximab and chemotherapy combinations in all types of CD20-positive lymphomas, and initial results are very promising, suggesting that adding the antibody to more traditional treatments may significantly increase patient benefit. Definitive randomized trial evaluations are still in progress.

The use of rituximab in other diseases that express CD20 is still under evaluation. Malignant diseases in

which this drug may provide benefit include acute and chronic lymphocytic leukaemia, small lymphocytic lymphoma, Waldenstrom macroglobulinaemia, high-grade non-Hodgkin lymphoma, hairy cell leukaemia and multiple myeloma. Many different autoimmune diseases may also be responsive to rituximab. Augmenting rituximab's effects is a subject of intense research that includes elucidating the details of mechanism of action and optimizing the clinical dose and schedule.

Trastuzumab (Herceptin®)

The antigen HER2/*neu* is a member of a family of epithelial growth factor receptors. Most skin and gastrointestinal (epithelial) tissues express HER2/*neu* at some point in their development, but usually at relatively low levels. When the gene for HER2/*neu* is inserted into cell lines or mice, it can mediate the transformation of cells into a malignant phenotype. HER2/*neu* overexpression is found in a small percentage of many epithelial cancers and presumably is tied to their transformation into malignant cells. Furthermore, HER2/*neu* expression in certain tumours has been correlated with more aggressive disease and worse outcome for the patient. The overexpression of HER2/*neu* is often, though not always, a result of gene amplification that produces multiple copies of the gene in malignant cells. While this antigen is present in many normal cells, the high overexpression in a subset of tumours makes it a reasonably specific tumour target.

Trastuzumab, (Herceptin®) is a humanized monoclonal antibody that specifically targets the HER2/*neu* receptor. Like rituximab, it can mediate CDC and ADCC and can halt the proliferation of HER2/*neu* expressing cell lines *in vitro*, although the latter may involve direct effects on signalling through the receptor. Clinical development of trastuzumab has been focused on HER2-positive metastatic breast cancer, which accounts for approximately 30% of all metastatic breast cancer patients. When used alone, trastuzumab causes tumour shrinkage in 15–20% of patients, but it appears to improve significantly the antitumour effect of concurrently administered chemotherapy and can prolong the survival of patients with advanced or widespread disease (Pegram *et al*., 1998; Baselga *et al*., 1999; Pegram and Slamon, 1999).

Trastuzumab infusions are generally associated with mild infusion reactions, although some reactions are severe and can be fatal. There are relatively few other side effects. However, in clinical studies of trastuzumab combined with chemotherapeutic drugs that are known to decrease heart function (anthracyclines such as doxorubicin), a surprisingly high incidence of cardiac damage was observed. The cause for augmentation of anthracycline-induced cardiac toxicity is not yet known, since normal heart tissue does not express appreciable amounts of HER2/*neu.* It has been proposed that heart muscle which is regenerating after some toxic insult may have increased expression of the HER2/*neu* receptor and could therefore be more susceptible to damage from trastuzumab.

Trastuzumab's role in the treatment of early-stage breast cancer, and other cancers that overexpress HER2/*neu*, has yet to be defined. Complicating the continuing development of the agent is the unsettled controversy regarding the optimal method to identify tumours that overexpress this antigen. (See the chapter *Signalling by Tyrosine Kinases*.)

CAMPATH-1H (Anti-CD52)

The CD52 antigen is expressed on all lymphocytes and some other haematological cells, but not on the majority of normal tissues. An anti-CD52 antibody made by Cambridge Pathology Associates (alemtuzumab or CAMPATH) has been developed for the treatment of lymphoma and leukaemia. This antibody very effectively depletes all lymphocytes, and has shown promise in the treatment of acute and chronic leukaemias and lymphomas. The primary efficacy appears to be in patients with chronic lymphocytic leukaemia, where CAMPATH-1H (the humanized version of the antibody) can induce significant cancer regression in up to 30% of patients. CAMPATH has also been used to suppress immunity, and thus enhance engraftment, in recipients of allogeneic bone marrow transplants. Because of the severe lymphocyte depletion, CAMPATH administration has been associated with significant immune suppression and opportunistic infections, potentially limiting its clinical use. However, anti-infectious prophylaxis may be able to prevent infectious complications. While immunosuppression may still preclude its use in combination with chemotherapy, there is significant potential for use of CAMPATH in combination with other antibodies or cytokines. This antibody has been approved by the US FDA for the treatment of relapsed CLL.

C225 (Anti-epidermal Growth Factor Receptor)

C225 is a humanized antibody that targets the epidermal growth factor receptor. This antigen is present on many solid tumours, but is also expressed on normal skin and gut. C225 appears to have limited antitumour effects when used at clinically tolerable doses, but preliminary experience suggests that the antibody may be able to augment the effects of either radiation or chemotherapy. The most promising results have been reported in pilot studies of C225 used in combination with radiation therapy for patients with cancer of the head and neck, but it may also sensitize tumours to chemotherapy. Indeed, C225 in combination with cisplatin has produced responses in patients who had previously failed treatment with cisplatin-based therapy. More definitive evidence that it provides significant benefit for patients is pending the outcome of randomized clinical trials.

Anti-angiogenic Antibodies

The concept of disrupting angiogenesis as a means to inhibit tumour growth has been validated in numerous animal models. Tumour neovasculature presents several antigens with restricted distribution in normal tissues, and has receptors for growth factors whose effects are also relatively specific to blood vessels. On this basis, several antibodies targeting proteins essential to the angiogenic process have been developed and are being evaluated in clinical trials.

Several antibodies against vascular epithelial growth factor (VEGF), which supports the growth of new blood vessels, or against the VEGF receptor, are currently in development. VEGF is expressed in any tissue that is developing a new blood supply, but is highly expressed by most cancers, and appears to be essential in their survival. VEGF also has complicated interactions with other biological systems. It appears to suppress immune function, including the inhibition of dendritic cell maturation, and could serve dual roles in promoting the development of a blood supply for the tumour and blocking its rejection by the immune system. Antibodies against VEGF or the VEGF receptor have shown substantial antitumour activity in animal models, which is further enhanced when combined with chemotherapy. The initial results from clinical trials of an antibody to VEGF suggest that circulating VEGF can be cleared from the blood, but it is difficult to determine whether all VEGF in the tumour has been inactivated. Some early results suggest that a small percentage of lung, colon and breast cancers may respond to anti-VEGF therapy alone, and small randomized trials indicate that there may be improved effects when this antibody is used with chemotherapy.

An alternative antiangiogenic target is the family of molecules called integrins. Integrins are expressed in blood vessels, and different members of the family can be selectively expressed in different blood vessels. The antibody identified as Vitaxin targets $\alpha v\beta 3$, an integrin that appears to be selectively expressed in new vasculature and tumour vessels. In addition to the usual killing mechanisms of antibodies, blockade of $\alpha v\beta 3$ could directly induce apoptosis in developing neovasculature. Phase 1 trials have been initiated, and further development is planned, but the results of preliminary studies are not yet available. (See the chapter *Angiogenesis*.)

Immune Stimulants and Anti-idiotype Vaccines

Antibodies can serve as nonspecific immune stimulants that result in an effective antitumour immune response. Antibodies can directly stimulate the proliferation of T cells, deliver positive costimulatory signals to T cells in the context of tumour antigen presentation, block negative costimulatory signals, or provide maturation signals for dendritic cells. Various approaches to enhance T cell antitumour immune responses with immune-stimulating antibodies have been attempted both in preclinical models and in the clinic.

The murine T cell stimulating antibody OKT3 (anti-CD3) causes proliferation of T cells *in vitro* and enhances the effect of IL-2. However, in phase 1 clinical trials, OKT3 alone did not produce tumour regressions, and did not appear to enhance the immune effects or antitumour activity of IL-2. Humanized versions of the antibody are now available, and rather than attempting immune stimulation, consideration is being given to its application in CD3-expressing T cell malignancies. Antibodies to CD3 are still in use for *in vitro* expansion of T cells in adoptive immunotherapy trials. Stimulating antibodies to CD28, which transmits a positive T cell costimulatory signal, are also under investigation for *in vitro* expansion of T cells.

Blocking antibodies to CTLA-4 have generated substantial interest, since CTLA-4 transmits a negative costimulatory signal to T cells, and its blockade *in vivo* enhances native and vaccine-induced antitumour immune responses. Preclinical studies of anti-CTLA-4 alone and in combination with a GM-CSF transfected tumour cell vaccine have shown substantial antitumour activity in mice bearing at least weakly immunogenic tumours (Leach *et al*., 1996). The antibody has been humanized and is being evaluated in phase 1 clinical trials in the near future. An alternative approach involves stimulation of the CD40 molecule, which is predicted to enhance function and maturation of dendritic cells. Preclinical models have shown that an anti-CD40 antibody can cure mice with lymphoma, although the contribution of immune stimulation versus direct effects on malignant B cells is unclear (French *et al*., 1999).

Antibodies can form *in vivo* which recognize the antigen-binding site of other antibodies. The antigen-binding portion of the anti-antibody (AB2) can bear a physical resemblance to the antigen target (e.g. a cancer antigen) of the original antibody (AB1). When the AB2 is used as an immunogen in a vaccine, it is capable of inducing antibody responses (AB3) with similar specificity to AB1. The AB2 is referred to as an anti-idiotype, and anti-idiotypes are sometimes able to generate stronger immune responses to the original antigen than would be possible if the original antigen were used as the immunogen in the vaccine. Various anti-idiotype vaccines are in clinical development, including vaccines that target CEA and the ganglioside GD2 and GD3 antigens, each of which is currently in or will enter phase 3 clinical trials. More discussion on anti-idiotype vaccines can be found in the chapter on *Genetic and Cellular Vaccines*.

Antibodies as Therapeutic Targeting Agents

Early evidence that monoclonal antibodies alone had only limited ability to initiate the rejection of tumours led to

the development of antibodies as targeting molecules to deliver toxic payloads. The toxic payload can either be a radioisotope that provides intense local radiation to damage cellular DNA, or a toxin that can kill the cell if it is internalized. Where possible, it is preferable to deliver therapeutic agents that can affect antigen-negative bystander cells. The choice of antigen is also critical, since toxins may require internalization into the cell, whereas the effect of bound radioisotopes may be diminished by cellular processing.

Radiolabelled Antibodies

The delivery of radioisotope-labeled antibodies for both tumour imaging and targeted radiotherapy has been pursued for several decades. The theoretical benefits of this approach include the ability of the radioactivity to kill both the cells bound by the antibody and also bystander tumour cells that might not express the targeted antigen. Important considerations for effective treatment include tumour radiosensitivity, an appropriate surface antigen and the selection of radioisotope. For the last, availability and cost, radioactive half-life and type and energy of the emitted particle (which affects pathlength) are all relevant issues. A comparison of some available radioisotopes is included in **Table 4**.

Various radiolabelled antibodies have been investigated in solid tumours, either as single agents or in combination with cytokines such as interferon-gamma that upregulate expression of the surface antigen target. In general, few objective responses have been observed, perhaps because of the radio-resistance of tumours, and the relatively small doses of radiotherapy that have been delivered to tumours with acceptable toxicity. Furthermore, most trials were conducted with murine antibodies, and re-treatment was not possible owing to the formation of HAMA. To overcome these problems, investigators are developing new antibody constructs that are humanized, have lower molecular masses to enhance penetration into tumours, and maintain relatively short circulating half-lives in order to achieve high tumour to normal tissue ratios.

Radiolabelled antibodies, and in particular antibodies targeting CD20, have shown substantial antitumour activity in non-Hodgkin's lymphoma. Extensive experience has been developed with anti-CD20 antibodies carrying the isotope ^{131}I, which is readily available and comparatively inexpensive. ^{131}I produces primarily gamma irradiation (photons) that can penetrate deeply into tissue, and has a half-life of approximately 8 days. It does localize to the thyroid gland, so that some preventative measures must be taken to protect the thyroid prior to radioiodine infusions. The therapeutic agent [^{131}I]tositumomab (murine anti-CD20) has been well tolerated with little symptomatic toxicity, although uptake in bone marrow produces marrow suppression. When given in doses that do not eliminate or ablate the bone marrow, up to 80% of patients with indolent lymphomas can experience profound tumour shrinkage that lasts for 1 year or more (Kaminski *et al*., 1993; Vose *et al*., 2000). Blood counts are suppressed for up to 12 weeks, but the complications can generally be managed. HAMA develops in a significant number of patients, which prevents repeated therapy.

When [^{131}I]tositumomab is used at doses that ablate the marrow, a stem cell transplantation procedure is necessary, and toxicity to other organs, such as liver and lung, become limiting. The response rate with this intensive dosing may be higher than with the lesser doses (86% reported response rates in small trials) (Liu *et al*., 1998), and response durations of up to 10 years have been reported, but the complicated therapeutic procedure has limited extensive development of high-dose radioimmunotherapy. The possibility of prolonged toxicity, including thyroid damage and marrow dysfunction (myelodysplastic syndrome), is also a concern with this approach.

An alternative therapy incorporates a different anti-CD20 antibody, the murine parent of rituximab (2B8), bound to ^{90}Y. This isotope produces primarily β particles (electrons) that travel with high energy but penetrate only a

Table 4 Radioisotopes used for radioimmunotherapy

Radioisotope	Radiation[a]	Decay half-life	Maximum pathlength (mm)	Comments
^{131}I	β, γ	8 days	2	Inexpensive, images, significant whole-body radiation with localization to thyroid
^{90}Y	β	2.5 days	12	Minimal normal tissue irradiation, poor imaging, localizes to bone
^{67}Cu	β, γ	2.5 days	2	Scarce, images well, localizes to liver but less whole-body irradiation than iodine
^{125}I	Electron capture	60 days	0.02	Does not image, cell kill in immediate proximity only
^{212}Bi	α, β	1 h	0.08	Alpha particles provide potent cell kill in immediate proximity

[a]Radiation particles: α, two protons (equivalent to a helium ion); β, electron; γ, photon.

small distance (1 cm) into the tissues. The latter produces more intensive local irradiation while decreasing the radiation to normal tissues and to the environment. The half-life is 2.5 days, so the radioactivity clears from the system more quickly. ^{90}Y–2B8 (Y2B8) has also been tested extensively in B cell lymphomas with evidence of similar toxicity and equivalent efficacy to [^{131}I]tositumomab. Both agents will be evaluated by the US Food and Drug Administration (FDA) and may be available for general usage in the near future.

Immunotoxins

Antibodies or ligands for cell surface receptors can be coupled chemically to carry certain toxins or engineered as recombinant DNA products that have a biological toxin attached to the targeting aspect of the molecule. In many, but not all, cases the toxin's mechanism of entry into cells is removed and replaced by the antibody or ligand-targeting molecule, thus markedly reducing its potential nonspecific toxicity for normal tissues. Two immunotoxins have been approved for use in the USA.

Two different immunotoxin therapies that target CD33, an antigen expressed on most cases of acute myeloid leukaemia (AML) and on precursors of some white blood cells, are currently in development. One of immunotoxins carries ozogomycin (calicheamicin), an extremely potent analogue of doxorubicin that can permanently damage cellular machinery. Gemtuzumab ozogomycin efficiently kills bound myeloid and leukaemic cells *in vitro*, and when administered systemically causes complete disappearance of detectable leukaemia in approximately 30% of treated AML cases (Bernstein, 2000). Although the responses are not durable, patients in remission could then be eligible to receive high-dose chemotherapy with stem cell support, a potentially curative treatment for this disease. Gemtuzumab ozogomycin has been approved in the US for clinical use in elderly patients with relapsed AML.

Several other immunotoxins have been extensively evaluated. Their use has been limited by nonspecific damage to the vascular system, leading to increased vessel permeability and fluid leakage, which can seriously impair normal organ function. Another limitation to their usage has been the patient's neutralizing immune response against both the murine antibody and the toxins, which are often derived from bacteria or marine organisms and are therefore immunogenic. This immune response effectively limits the dosing of these agents to a single cycle of therapy, whereas most drugs effective against cancer are given repeatedly in order to achieve benefit. As the toxins are improved to eliminate nonspecific toxicity and supportive agents become available to suppress the immune response, immunotoxins may be administered in dose/schedule regimens with potential for increased antitumour activity.

Despite current limitations, several immunotoxins are showing significant efficacy. The DAB389–IL-2 fusion toxin targets the CD25 IL-2 receptor present on several B and T cell lymphomas and leukaemias, and has been approved for treatment of patients with relapsed mycoses fungoides (cutaneous T cell lymphoma). The molecules LMB-2 and BL-22, both developed at the US National Cancer Institute, are antibody-based immunotoxins that target CD25 and CD22 (a B lymphocyte marker), respectively. CD22 is also present on lymphomas and leukaemias. LMB2 and BL-22 have shown a reasonable toxicity profile with distinct efficacy against advanced chronic lymphocytic leukaemia and hairy cell leukaemia (Kreitman *et al*., 2000). Fortunately, the disease-related immune suppression present in diseases such as CLL and HCL limits immunity against the therapeutic molecule so that repeated doses can be given.

Pre-targeting Antibody Therapeutic Approaches

While antibody conjugates circulate in the blood, they cause damage to the normal tissues and organs through which they circulate. Several different approaches are being developed to enhance the rate and specificity of localization of the toxic molecules into the targeted tumours and limit exposure for normal tissues. In the 'pretargeting' technology, an antibody is labelled with one side of a pair of linking molecules, such as biotin and streptavidin, which will function as a specific glue, and infused into the bloodstream. Over approximately 24–48 h the antibody is allowed to localize to the tumour. A separate compound can be infused to clear the antibody remaining in the blood. Subsequently a toxic compound, either a radioisotope or toxin that is attached to the molecule that will bind to its partner on the antibody, is administered systemically. When this compound is infused, it is able to enter the tumour rapidly owing to its small size, and will attach to the antibody that is already bound to the tumour cells. This approach allows for very rapid localization of the toxic agents into the tumour, and will hopefully reduce the toxicity that results from circulating toxins.

An alternate approach relies on toxins that need to be activated in order to kill cells. The antibody can be attached to a nontoxic enzyme or other activating compound and infused. The unbound antibody can be cleared from the circulation. A prodrug, or inactive toxin, is then infused and allowed to circulate throughout the system. Only the prodrug that penetrates into the tumour will be activated by the enzyme on the antibody, which can lead to a high local concentration of toxic drug within the tumour, but negligible levels throughout the normal tissues. However, backleak from the tumour of activated drug and low-level conversion in normal tissues may lead to toxicity. The general approach has been termed antibody-directed prodrug enzyme therapy (ADEPT). Enzymes being investigated in preclinical systems include carboxypeptidase G2 (CPG2), nitroreductase, cytosine deaminase and DT diaphorase. A CPG2-based ADEPT approach to

activate an alkylating agent prodrug has entered phase 1 clinical trials.

Bispecific Antibodies

A bispecific antibody contains two connected antibodies to make a single molecule that targets two different antigens. Thus a single molecule functions as a bridge or glue, bringing together other molecules, structures or whole cells.

Some bispecific antibodies target a tumour antigen and a toxic molecule or its carrier. The bispecific antibody can be infused with little innate toxicity. The secondary toxic molecule can then be infused at low concentrations, perhaps repeatedly, in such a way that it too has minimal toxicity. The homing mechanism will then concentrate the toxin at the tumour to kill tumour cells selectively.

A second approach uses the second binding site of the bispecific antibody to attract cytolytic killing cells from the immune system. If an antibody against a tumour antigen is coupled to an antibody against a molecule on NK cells, or T cells, the immune effector cell can be attracted to the tumour cell and activated to kill the malignant target. Bispecifics have been produced which include anti-CD16 and anti-CD64 (Fc receptors on NK cells) and anti-CD3 (non-specific activation of T-cells). Anti-Her2/neu × anti-CD16 or × anti-CD64 have been evaluated in the clinic. As expected, the binding to and activation of NK cells and other cells bearing CD16 or CD64 produce cytokine release and its attendant toxicity, but in general, the bispecific antibodies can be administered safely. The effectiveness of the approach has been clearly demonstrated in laboratory experiments, and clinical trials are ongoing.

CONCLUSION

Cytokines and antibodies have become an established part of the cancer treatment armamentarium. Several agents are approved by regulatory agencies, and particularly for antibodies, many more are likely to demonstrate clinical efficacy. There are substantial hurdles that remain to develop effectively optimal therapeutic regimens with cytokines, and progress will come only with an increased understanding of tumour–host biology and the mechanisms of antitumour activity in animal models and in patients. Even for antibodies, the mechanisms of antitumour activity in animal models and humans are not well defined, thus complicating the choice of antigen and antibody, and limiting otherwise very rapid progress. Nevertheless, the rapid elucidation of tumour antigen targets and increased sophistication in creating and manipulating antibodies and delivering toxic payloads suggest that these agents will become increasingly important in the treatment of cancer.

- Introduction
- Cancer Vaccines
- Cellular Vaccines
- Genetic Vaccines

INTRODUCTION

Vaccines have been powerful tools for the prevention of human infectious disease for decades. These vaccines are protein based, containing attenuated or killed forms of microorganisms, or, more recently, defined natural or recombinant protein components of whole organisms. Even successful immunoprevention strategies for infectious diseases have had very limited applications in the therapy of existing disease, however. The development of immunotherapies for the treatment of existing cancer is an even more difficult problem since there are likely to be fewer significant antigenic differences between tumour and normal cells than between microorganisms and human cells. Cancer therapeutic vaccines may well require approaches very different from infectious disease vaccines if they are to be successful. With the limited effectiveness of conventional treatments for most cancers (particularly the solid tumours) there is a great need for novel approaches. It is hoped that increased understanding of the genetic basis of cancer, in addition to continuing advance in our understanding of the immune response on a molecular level, will allow the design of successful immunotherapeutic strategies.

In this chapter, we will survey the use of cell-based and genetic vaccines for the therapy of cancer. In brief, cell-based vaccines utilize intact mammalian cells as the vaccine, and genetic vaccines rely on expression of the target antigen from transferred nucleic acids. These approaches (and their combination) will be discussed.

Cancers are derived from a clone of normal cells that have undergone malignant transformation. During the process of malignant transformation, a normal cell becomes a neoplastic cell and a series of genetic lesions occur that result in the loss of normal growth regulation and the acquisition of the ability to avoid recognition and destruction by the immune system. Malignant transformation is usually accompanied by the expression of protein, lipid or carbohydrate molecules on the tumour cells that are not expressed at all or are present in much lower quantities than on normal cells. Such molecules, called tumour antigens, potentially allow the immune system to distinguish cancer cells from the normal ones (Wang and Rosenberg, 1999). There are likely to be fewer such distinguishing antigens in a cancer cell than in bacteria or viruses, and this may be one reason why clinically evident tumours manage to avoid induction of an effective immune response, and why anticancer vaccine development has been so difficult. In fact, very little evidence of immune responses against tumours can be detected in most patients. Thus, in addition to defining tumour antigens, understanding the reasons for weak or absent host immune responses induced by clinical tumours is an important step in the development of effective cancer immunotherapy. Several of the new approaches described below are aimed at augmenting weak host immune responses to tumour antigens using potent antigen presenting cells or a variety of genetic manipulations.

CANCER VACCINES

Many approaches have been tried to induce or boost immunity against cancer. The major approaches are shown in **Table 1**. Most cancer vaccines attempt to treat tumours that have already demonstrated this ability to avoid immune recognition. Since a primary requirement for cancer vaccines is to overcome the issues that caused the immune response to fail in the first place, all of these approaches use some strategy to overcome this problem in addition to simply providing tumour antigen. These strategies take the form of adjuvants or cytokine modulation in active immunotherapy or provision of preformed immune effectors in passive strategies.

It has become clear that induction and regulation of immune responses is a complex process involving positive

Table 1 Classification of cancer immunotherapy[a]

Classification	Examples
Active immunotherapy	
Nonspecific	Immune adjuvants such as BCG - activate macrophages. Anti-CD3 antibodies - polyclonal Activation of T cells. Cytokines: IL2, TNF, IFNα, IFNγ, GM-CSF, etc. - to enhance one or more components of cellular immune function
Specific	Immunization with tumour vaccine Cellular vaccine: tumour-specific antigen Genetic vaccine: introduction of genes (cytokines and costimulatory molecules) into tumour cells
Passive immunotherapy	
Antibodies	Monoclonal or polyclonal antibodies alone or coupled with toxins or radiolabels or drugs as 'magic bullets'
Cells	Tumour-infiltrating lymphocytes (TIL), lymphokine-activated killer (LAK)
Indirect	Removal or blocking factors, inhibition of growth factors or angiogenic factors

[a]Adapted from DeVita, V. T., Jr, *et al.*, 1997, *Cancer, Principles and Practice of Oncology* (5th edn) (Lippincott-Raven: Philadelphia).

and negative regulatory factors. Improved understanding of these processes could help design improved immunotherapeutics. These response are both innate, or antigen non-specific, and antigen specific. Antigen-specific responses can be against protein, carbohydrate or lipid antigens expressed uniquely or at least primarily on tumour cells. To be recognized by the cellular immune system, protein antigens from the cell surface or within the cell must be broken down into peptides and presented on the cell surface bound to class I and II major histocompatibility complex (MHC) molecules. While antigen presented this way is necessary for specific responses, it is not sufficient, and a large array of 'costimulatory' molecules modulate the stimulation of specific antibodies and activation of the cytotoxic lymphocytes whose job it is to kill cells expressing these foreign antigens. To induce and regulate these effectors efficiently, there are specialized cells in the body called professional antigen presenting cells (including Langerhans cells and dendritic cells) whose job it is to take up antigen, effectively process it and present it to T cells. Once the antigen is effectively presented on these cells, the T cells must then recognize this antigen, activate and proliferate to result in an effective response. Finally, the target cells must themselves present the antigen in a form that is recognizable by the antigen-specific activated T cells. There are therefore many potential mechanisms, both structural and functional, by which this response can fail.

Tumours may escape immune recognition by either avoiding expression of tumour antigens or by interfering with the induction of an effective response to them. In recent years, investigators have found many mechanisms that may contribute to the failure of immune control of tumour growth. First, tumour cells often have decreased expression of MHC molecules on their cell surface (Seliger *et al.*, 1998). MHC molecules are primarily responsible for antigen presentation and cytotoxic T lymphocyte (CTL) induction. Essential components of the antigen-presenting pathway in tumour cells, including the MHC molecules themselves, may be mutated or deleted, resulting in a complete lack of recognition by CTL. Second, naturally arising tumours often express very 'weak' antigens that are not readily targeted by the immune system (Restifo *et al.*, 1993). Third, most tumour cells lack critical costimulatory molecules, such as CD40, CD80 and CD86, or adhesion molecules, such as ICAM-1 and LFA-3 (Costello *et al.*, 1999), which can contribute to activating T cells. Fourth, recent data show that tumour cells produce and secrete many factors such as TGF-β10, PGE_2 and vascular endothelial growth factor (VEGF), which function to inhibit the function of antigen presenting cells and immune effector cells (Costello *et al.*, 1999, p. 266).

If a tumour has completely lost the ability to process and present antigens to CTL, antigen-specific immunotherapy is likely to be unsuccessful. It is only when immune induction fails for other reasons that cancer vaccine approaches may succeed, and there are data showing that the majority of solid tumours fall into this category. Thus, in addition to identification of the most potent antigens, most immunotherapeutic approaches have focused on optimum methods of immune induction to a particular antigen.

Virtually all modern vaccine strategies include both antigenic and immunostimulatory components, aimed at

inducing or augmenting host immune responses to these weak naturally occurring tumour antigens. In this chapter we will discuss genetic and cellular vaccines in tumour immunotherapy. Cellular vaccines rely on intact tumour cells or antigen-presenting cells activated or 'loaded' with tumour-derived antigens. With genetic vaccines, instead of using protein, genetic material encoding for antigens or cytokines is introduced into cells in culture or directly into a patient.

CELLULAR VACCINES

Tumour cell vaccines can consist of disaggregated autologous or allogeneic tumour cells or tumour cell lines. These can be administered with a chemical or biological adjuvant and there is some evidence of efficacy in several retrospectively controlled clinical trials in colon cancer and melanoma (Rosenberg *et al*., 1998; Restifo and Rosenberg, 1999). Large-scale randomized clinical efficacy trials are currently under way using an autologous tumour vaccine for colon cancer and a mixture of allogeneic cell lines for melanoma. The use of allogenic tumour cell lines in melanoma is based on the finding that many of the observed T cell responses in patients target common antigens shared by many tumours. The complexities of preparing autologous tumour cell vaccines can be avoided by using well-characterized cell lines known to express the common antigens.

One strategy to increase the efficacy of tumour cell vaccines is to engineer them genetically to produce immunostimulatory cytokines (Adris *et al*., 2000). Early-phase clinical trials have been completed using intact autologous tumour cells modified to secrete large quantities of various cytokines, especially GM-CSF, to enhance their immunogenicity, and some immune induction has been observed in several tumour systems (Simons and Mikhak, 1998). Coimmunization of autologous tumour cells with autologous fibroblasts or allogeneic cells engineered to produce cytokine has also met with some technical success at induction of immune responses (Elder *et al*., 1996).

In addition to intact tumour cells or gene-modified tumour cells, another approach is to improve the potency of immune induction by using autologous professional antigen-presenting cells (APCs). The most potent of the antigen-presenting cells is the dendritic cell (DC). These are the cells whose role is to induce and modulate natural immune responses, and thus they are a logical choice for attempts at cancer immunotherapy. Antigen-presenting cells in culture can be isolated, purified, activated or loaded with antigen and administered in such a way as to optimize their potency for activating specific T cells. The potential advantage of this approach is the reduced reliance on antigen uptake, processing and presentation by endogenous antigen-presenting cells, thought to be required for approaches that use non-cell-based or tumour cell-based vaccines. Endogenous APCs may be ineffective owing to the effects tumour-derived suppressive factors. Current therapeutic approaches include the isolation and *in vitro* culture of dendritic cell progenitors with activating cytokines followed by their loading with nucleic acid, peptide or protein antigens either for single protein antigens or complex mixtures derived from cell extracts. There has even been some success when APCs have been fused with intact tumour cells to form antigen-presenting chimaeras (Trefzer *et al*., 2000). We will briefly discuss issues of endogenous dendritic cell dysfunction and then their loading with protein antigens here and then discuss the use of nucleic acid antigens under genetic vaccines.

Dendritic Cells in Cancer

APCs play a central role in the induction of antitumour immune responses. Dendritic cells, as the most potent APC, have high levels of expression of MHC class I and II molecules and express a variety of costimulatory and adhesion molecules required for effective immune induction. Autologous dendritic cells can be cultured from cancer patients and used as vehicles to deliver tumour-specific antigens for the immunotherapy of cancer. It has been observed that these *in vitro*-produced DCs can effectively stimulate specific T cell responses (Gilboa *et al*., 1998; McArthur and Mulligan, 1998).

The principle underlying the *ex vivo* growth or manipulation of dendritic cells for reinjection is based on the assumption that tumours fail to induce specific responses due to a failure of effective antigen presentation. *In vitro* expanded and activated dendritic cells may be effective by virtue of their number and the concentration of antigen, but it has also recently been observed that tumours inhibit the host immune system, at least in part, by interfering with the effectiveness of antigen presentation (Seliger *et al*., 1996). The introduction of DC cultured, activated and loaded with antigen in the absence of inhibitory tumour-associated factors may overcome this problem. In recent years, several groups have shown decreased numbers and functional activity of DC in tumour-bearing mice and human cancer patients. Evidence shows that tumours have a major systemic impact on DC differentiation, maturation and function. Tumour-derived soluble factors such as IL-10, TGF-β, PGE2, VEGF and others directly have the ability to inhibit DC function. DC isolated from peripheral blood, lymphoid tissue and tumours from cancer patients and tumour-bearing mice contain large numbers of DC-like cells which express abnormally low levels of MHC class II molecules and low or undetectable levels of costimulatory molecules . They are unable or impaired in their ability to process and present antigen and therefore do not induce effective antigen-specific or antitumour CTL responses. Defective DC function may therefore be a major factor in the defective immune response observed in patients with

cancer. However, functionally competent DCs can be generated from progenitors isolated from the peripheral blood of cancer patients and cultured *in vitro* in the presence of appropriate cytokines. When loaded with the appropriate antigen, these antigen-loaded DCs form a vaccine that may be more potent than simple introduction of the antigen into a tumour-bearing host.

In Vitro-produced Autologous Dendritic Cells or Monocyte-derived APCs (MD-APCs) as a Tumour Antigen Delivery Candidate

DCs pulsed with tumour-specific peptide can be used as a cellular vaccine if a tumour-specific peptide has been identified (Jager *et al*., 2001). Specific examples of peptides currently under investigation include several from melanoma derived from melanoma-associated antigens such as gp100 and tyrosinase, and also MUC1, Her2/neu, Bcr-Abl fusion peptides, mutant p53 and mutant Ras. These will be discussed in more detail below. Induction of peptide-specific responses is regularly observed in these studies, associated with occasional clinical responses, especially in melanoma (Thurner *et al*., 1999), but the absolute clinical impact of these responses is still uncertain. Multiple doses of pulsed DC vaccines or coadministration with systemic cytokines may be required for efficacy, and the optimum conditions for preparing and delivering antigen-loaded DCs are unclear and are currently being addressed.

Peripheral blood mononuclear cells processed outside the patient's body (*ex vivo*) can differentiate into effective antigen-presenting cells. These monocyte-derived APCs (MD-APCs) can then be grown in the presence of crude tumour protein extracts, tumour cell lysates or tumour apoptotic bodies from allogeneic cell lines or autologous tumour. These autologous DCs, or MD-APCs derived from the patients' own monocytes and then pulsed with tumour-specific peptide or fragments of autologous tumours, or of a relevant tumour cell line, comprise an 'autologous cellular vaccine'. Autologous cellular vaccines may have the capability to more effectively present specific tumour antigens than endogenous APCs provided with exogenous tumour antigen (Nouri-Shirazi *et al*., 2000).

A major problem in studies of whole tumour cell vaccines (or any antitumour vaccine) is the difficulty of monitoring relevant specific immunity induction. This is particularly difficult when the specific antigen is unknown, as is the case with whole tumour cell or extract vaccines. The efficiency of immune induction is often monitored by testing specific T-cell immune cytolytic or cytokine release responses against autologous tumour targets or by more crude *in vivo* assays such as DTH. In addition to being very cumbersome to use as 'intermediate markers' of immune response, the presence of contaminating antigens in the antigen preparation (such as bovine serum albumin (BSA) from foetal calf serum or collagenase used to disaggregate tumour cells) limits the specificity of these assays to measure biologically relevant responses. Importantly, none of these assays has been strictly validated as associated with improved clinical outcomes.

One should note that MD-APCs used in autologous cellular vaccine are only one type of DCs useful for clinical trial. Mature DCs obtained from circulating precursor cells or from $CD34^+$ cells can only be pulsed with peptide antigens. They may not phagocytose or process macroscopic cellular debris like MD-APCs. In addition to macrophage-like properties, MD-APCs have also been shown to present exogenous antigens on both MHC-I and MHC-II complexes.

Tumour Antigens — Shared Tumour-associated Antigens and Mutated Proteins as Vaccine Targets

A major challenge in the development of an antigen-specific tumour vaccine is to identify clearly antigens that will elicit an efficient and effective immune response, and be relatively tumour specific to avoid host autoimmune toxicities. A good tumour antigen can be recognized by its selective expression on tumour cells, and ideally also plays a direct role in malignant transformation (so its expression will not be readily lost). This will allow the immune system to be able to distinguish the cancer cells from normal cells, and prevent the tumour from escaping the immune response. Many candidate antigens are being tested preclinically and clinically.

Protein tumour antigens can be targeted with synthetic peptide vaccines. A variety of strategies have been used to enhance the immunological efficacy of peptide-based vaccines, including chemical, bacterial and mammalian cell-based adjuvants. Even so, the use of synthetic peptides as immunogens is complicated by their weak inherent immunogenicity and variable chemical and physical properties. Some peptides are nearly impossible to synthesize for chemical reasons. The use of autologous DC to present peptides as one form of cellular vaccines appears to be the most effective to date (Nestle *et al*., 1998).

Many melanoma antigens have been identified and include MAGE 1 and 3, gp100 tyrosinase and MART-1/Melan-A. Some of these are also widely expressed on other tumour types. MART-1 is widely represented in human melanomas and is recognized by the majority of HLA-A2 restricted cytotoxic T lymphocytes. One of the immunodominant peptides is MT27-35 from the MART-1 118 amino acid protein (13 kDa) and expressed by HLA-A2.1 melanoma cells (Storkus and Zarour, 2000).

Other examples include the HER-2/neu or c-erbB-2 oncogene product, PSA, CEA and MUC1. HER2/neu is overexpressed in various cancers such as breast, ovarian, lung, gastric, etc., and its overexpression was found to be

associated with high metastasis, chemotherapy resistance and poor clinical outcome. CEA and MUC1 are expressed on many adenocarcinomas.

Many somatically altered oncogenes or tumour-suppressor genes have been identified in human cancer. The mutation of these oncogenes or tumour-suppressor genes is unique to the tumour and also results in a function that contributes to the malignant phenotype, making them reasonable candidates as vaccine antigens. Mutant Ras and p53 are two examples of mutant oncogene and tumour-suppressor gene products with the potential to be good tumour antigens (Ciernik *et al*., 1995). Other oncoproteins that may be good tumour antigens include fusion proteins created by chromosomal translocation such as Bcr-Abl, which is well characterized, relatively common and generated by t(9; 22)(q34; q11) chromosomal translocation in certain leukaemias. Other promising lymphoma antigen targets are the somatically rearranged antibody idiotype sequences in B cell lymphomas. Other oncoprotein candidates are not somatically mutated, but are overexpressed in tumours, such as HER-2/neu.

p53 mutation has been known to be associated with many common human cancers, including lung cancer; 50% of all cancers and 60% of non-small cell lung cancers have p53 mutations. The ideal tumour antigen would be the mutant site in p53, since it is absolutely tumour specific. Other somatically mutated antigens such as the B cell idiotypes also may require customized (patient-specific) vaccine strategies. This approach is very cumbersome, but technological advances in molecular biology make such customized approaches possible, and these are also being tested clinically. For mutant p53-based vaccines, once the specific p53 mutation is determined from the patient tumour sample, a custom mutant peptide can be synthesized. The peptide can then be loaded on autologous dendritic cells produced *in vitro*. The p53 mutant peptide-loaded dendritic cells can be then used to immunize patients to induce cytotoxic T cells that specifically recognize and kill tumour cells expressing this mutant protein (DeLeo, 1998).

Mutant Ras can also be used as a target of cellular vaccine (Khlief *et al*., 1999). Ras mutations are present in 15% of cancers and in at least 40% of colon cancers. Unlike p53, a limited number of specific DNA base substitutions have been described. They are typically present at codons 12, 13, 59 and 61. Further, since Ras mutations are essential for the malignant phenotype, they should not, theoretically, be down-regulated by the tumour to prevent immune detection. Since the number of observed mutations in Ras is limited, all of the common mutant sequences can be manufactured ahead of time rather than being custom made for each patient.

The difficulties in defining tumour-specific peptides appropriate for each patient's class I MHC pattern, and also the observation by several investigators that single-epitope peptide-specific responses can occur in the face of rapid tumour progression, have prompted the continued investigation of polyepitope vaccines. These can consist of mixtures of peptides, but there are several approaches that use complex antigen mixtures (protein or RNA) derived directly from autologous tumour cells.

Cellular vaccines can also be combined with conventional protein-adjuvant immunization to treat cancer patients. In one pilot study by researchers at Stanford University, four patients with follicular B cell lymphoma received a series of three or four infusions of antigen-pulsed dendritic cells followed, in each instance, by subcutaneous injections of soluble antigen 2 weeks later. The tumour-specific idiotype protein produced by each tumour was obtained by cell fusion techniques. All patients developed measurable antitumour cellular immune responses. In addition, clinical responses have been measured with one patient experiencing complete tumour regression, a second patient having partial tumour regression and a third patient resolving all evidence of disease as detected by a sensitive tumour-specific molecular analysis (Hsu *et al*., 1996) (**Table 2**).

Clinical trials involving cancer patients with malignant melanoma (Panelli *et al*., 2000) and prostate cancer

Table 2 Summary of a few clinical trials of cellular vaccine against prostate, melanoma and lymphoma

Clinical trial and reference	Vaccine[a]	No. of patients treated and evaluated	Clinical response status[a]			
			CR	PR	NC	P
Prostate cancer phase II (Murphy *et al*., 1999)	DC pulsed with PSMA	37	1	10	8	18
Melanoma phase I (Trefzer *et al*., 2000)	Autologous melanoma fused with allogenic MHC II-bearing cells	16	1	1	5	9
B-Lymphoma phase I (Hsu *et al*., 1996)	DC pulsed with tumour-specific idiotype protein	4	2	1	0	1

[a]Abbreviations: DC, dendritic cells; PSMA, prostate-specific membrane antigen; CR, complete response; PR, partial response; NC, no change; P, progression.

(Murphy *et al*., 1999) are ongoing (**Table 2**) and are being used to evaluate the feasibility and safety of cellular vaccines, in addition to developing methods for quantitating immune responses as intermediate markers for treatment efficiency. There is cautious optimism that cellular vaccines may provide physicians with powerful new treatment options despite the practical drawbacks to this method. Many of the physical problems of protein- or peptide-based vaccines can be avoided by using a different vaccine approach, the genetic vaccine.

GENETIC VACCINES

A genetic vaccine, also known as DNA or polynucleotide immunization, is defined as using genetic material to encode an antigen that induces immunity. The genetic material can consist of whole cell cDNA or RNA, or cloned cDNAs in expression vectors. These are then commonly introduced into patients directly or into antigen-presenting cells in culture, either stably or transiently. Another type of genetic vaccine uses recombinant viruses such as vaccinia or adenovirus engineered to express the antigen gene of interest.

In its most basic form, a polynucleotide vaccine consists of an expression plasmid vector that drives expression of an antigen encoded by an inserted gene. Gene expression is usually directed by a strong viral promoter. It has several theoretical advantages over synthetic or purified protein antigen vaccines. First, transcription from the genetic vaccine is endogenous, resulting in protein trafficking that mimics that of 'natural' antigens. Second, expression can be continuous over long periods of time rather than relying on short-lived proteins. Third, DNA production, purification and characterization are far easier than for the corresponding proteins. Contamination with bioactive material is much less of a problem. In addition, certain protein structures are unstable or insoluble such as highly hydrophobic regions or those with sulfhydryl groups. This is not a problem with genetic vaccines. Lastly, totally synthetic sequences or fusions of multiple unrelated proteins of significant length can be readily manufactured.

Polynucleotide vaccines were first described in 1992 when Tang *et al*. (1992) showed that antibodies could be efficiently induced by genetic immunization. In 1993, Ulmer *et al*. (1993) showed that plasmid DNA encoding influenza nucleoprotein (NP) induced a cytotoxic T lymphocyte (CTL) response and cross-strain protection in mice. In 1996, Ciernick *et al*. (1996a) used genetic vaccination to induce cytotoxic immunity specific for mutant p53 and showed antitumour efficacy. Since then, the direct injection of plasmid DNA encoding antigenic proteins has been used to elicit humoural and cell-mediated immune responses in a variety of preclinical animal models for cancer, viral, bacterial and parasitic disease.

Another approach for genetic vaccination involves the use of dendritic cells transfected with tumour mRNA (Gilboa *et al*., 1998). It has been reported that mRNA-transfected dendritic cells are potent stimulators of T cell immunity *in vitro* and *in vivo* (Nair *et al*., 2000). A potential advantage of using RNA rather than DNA is that no viral promoter element has to be administered *in vivo* and no integration into the host genome is likely. mRNA should also provide an renewable source of tumour antigen, since modern techniques allow amplification from very small amounts of tumour tissue RNA. Because RNA is very prone to hydrolysis by ubiquitous ribonucleases, different strategies have attempted to prevent RNA hydrolysis in order to improve the efficiency of RNA-based vaccines. These include techniques such as condensation with the polycationic peptide protamine. There are also reports describing specific plasmid vectors engineered for *in vitro* transcription of RNA containing a cap structure and a poly(A) tail, which is then flanked at the 5′ end and 3′ end by untranslated regions (Conry *et al*., 1995). Sindbis virus self-replicating RNA vector engineered to target the antigen to the endosomal/lysosomal compartment via fusion to LAMP-1 (lysosome-associated membrane protein 1) has generated the highest E7-specific T cell-mediated immune responses and antitumour effects relative to RNA vaccines containing either wild-type E7 or Sig/E7 (Cheng *et al*., 2001).

Basic Structure of Vectors for Genetic Vaccine

DNA immunization in its simplest form involves the direct introduction of a plasmid DNA encoding an antigenic protein into the cells of the organism. The gene transferred by the plasmid requires the host cellular machinery to be expressed. DNA-based immunization resembles viral infection except these plasmids are non-replicating and usually lack direct pathological consequences to the expressing cell. Most plasmid DNA constructs are made of three major components: (1) a plasmid backbone for an origin of replication and convenient multiple cloning sites; (2) an antibiotic-resistance gene to ensure that only plasmid-containing bacteria will grow in antibiotic culture medium; and (3) a powerful (and sometimes tissue-specific) enhancer/promoter sequence with an mRNA transcript termination/polyadenylation sequence for directing expression in mammalian cells.

Common regulatory elements for DNA vaccines are those known to mediate high levels of gene expression under mammalian cell culture conditions. Examples include the human cytomegalovirus immediate/early promoter (pCMVIE), the rous sarcoma virus (RSV) LTR and the SV40 early promoter used in conjunction with the SV40 or bovine growth hormone 3′-untranslated region (BGH3′UTR) transcript termination/polyadenylation sequences (Lee *et al*., 1997). Most plasmid vectors also

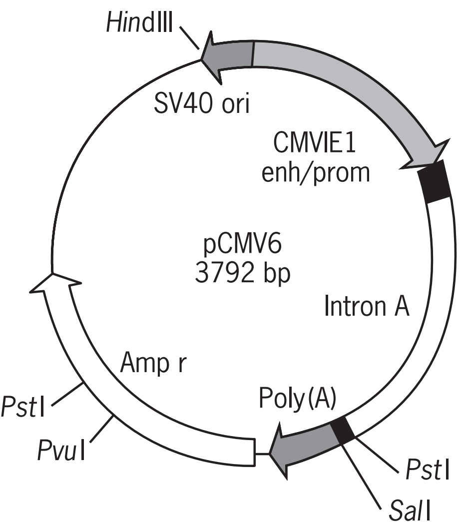

Figure 1 Map of plasmid pCMV6, a typical expression vector containing the CMVIE1 enhancer/promoter with intron A.

contain an intron, because expression of many mammalian genes may be dependent on or may be increased by the inclusion of an intron. To date, one of the most successful plasmids used for eliciting immune responses contains the CMVIE promoter and intron A with the BGH3′UTR (**Figure 1**). It is probable that no single construct will be optimal for all possible genes. One possible concern is the fear of uncontrolled or permanent expression. Owing to the lack of an origin of replication that is functional in eukaryotic cells, these plasmids neither replicate in the mammalian host nor efficiently integrate within the chromosomal DNA of an animal.

Retrovirus and Adenovirus Vectors

Retrovirus-encoded genes depend on the ability of the virus to insert DNA copies of its RNA viral genome into the chromosomes of a host cell. Retroviral vectors take advantage of this ability to insert the gene of interest stably into host genome. The foreign gene replicates along with the host genome. While a definite advantage for gene-replacement strategies, such as the repair of genetic defects, this is only an advantage for genetic immunization when the cells of interest must grow or differentiate after gene transfer, such as when immature DCs are transduced then matured.

Adenovirus vectors are constructed as replication-deficient, E1-deleted versions of these double-stranded DNA respiratory pathogens. The gene of interest (in cDNA form) is usually driven by the CMV enhancer/promoter embedded in the viral backbone. Adenovirus vectors often demonstrate much higher transduction efficiencies than retroviral vectors, but transgene expression is temporary because the adenoviral vectors are replication deficient, and it cannot incorporate into the human genome. It is also able to drive gene expression in non-replicating cells, unlike retroviruses, and is more readily grown *in vitro*.

Genes for Inducing Immunity

Genes that Encode Whole Proteins

Genetic immunization with DNA sequences encoding whole proteins results in antigen production that more closely mimics naturally presented class I epitopes. Briefly, the protein product of genetic vaccine is endogenously synthesized and potentially targeted to the endoplasmic reticulum (ER) like other endogenous proteins. Efficient presentation of peptides derived from endogenously synthesized proteins is thought generally to occur via proteosomal lysis followed by transport into ER. These peptides bind to newly synthesized class I MHC molecules in the ER, which then transport them to the cell surface where they are presented to $CD8^+$ T cells (**Figure 2**). An example of the use of intact protein for immunization is the transduction of dendritic cells by an adenovirus expressing the intact wild-type p53. Normal cells express only very low levels of p53, whereas cells with mutant p53 massively overexpress the mutant protein, thus immunization with the wild-type p53 can generate immunity that can target the many wild-type epitopes in a variety of mutant proteins. Ishida *et al*. showed that this could induce effective antitumour immunity to several different overexpressed mutant proteins (Ishida *et al*., 1999).

There are several studies that have shown that plasmid DNA expression vectors encoding the entire cloned open reading frame of proteins may generate substantial humoural and cellular immunity when directly introduced into living animals (Donnelly *et al*., 1997). In the case of recombinant vaccinia vaccine, the major advantage over purified proteins seems to be extended expression of the protein product from viral genetic material. It is possible, however, that the most potent antitumour effects may occur if responses are directed to some epitopes on the antigen rather than others. Natural immunity or immunity derived from immunization with whole proteins may not induce CTL responses to the desired epitopes.

Minigene Coding for Single Epitopes

When immunity is desired that specifically recognizes one or a few epitopes on a larger molecule, just those portions can be cloned into the expression vector to accomplish this. These ‘minigenes’ or oligonucleotides may only encode a single epitope to obtain the desired defined immune response (An and Whitton, 1997).

A minigene consists of only part of the full open reading frame of a gene. It may encode a single specific T cell epitope that contains a mutant site in an oncoprotein, or simply a single or multiple portions of single or multiple molecules that are known to elicit T cell immunity. An

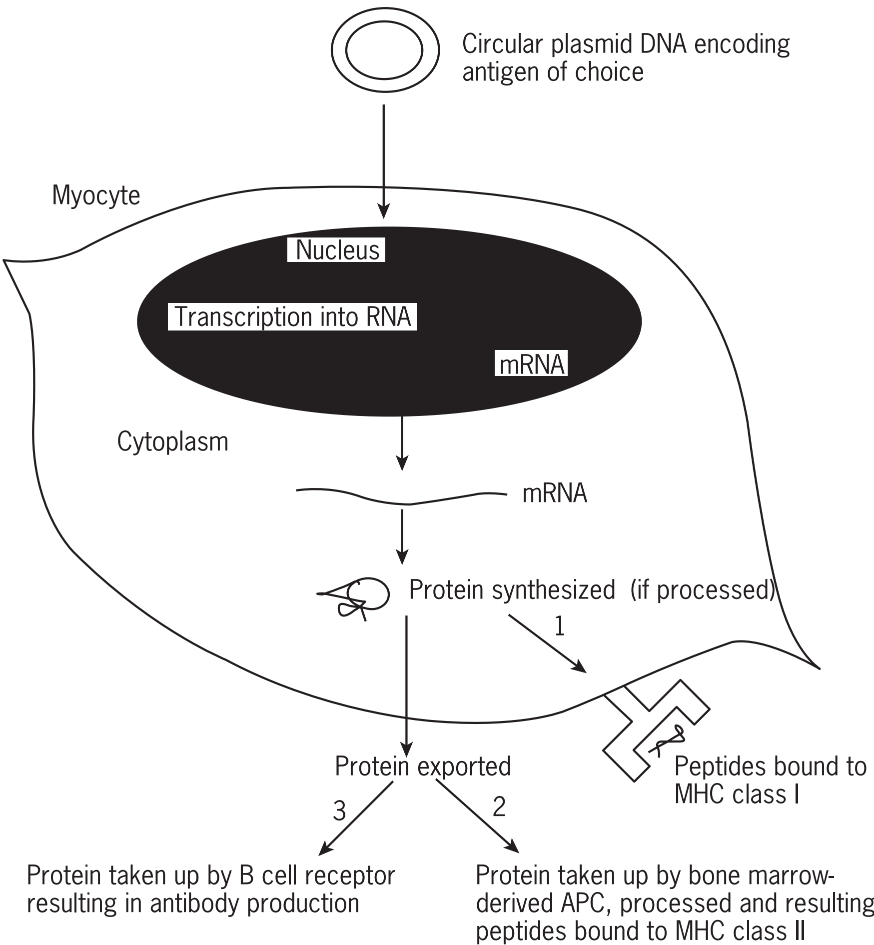

Figure 2 Schematic representation of steps required for immune response to DNA-encoded antigens. Circular plasmid DNA enters the myocyte and is transported into the nucleus. The DNA is transcribed into RNA and the resulting RNA is translocated to the cytoplasm and translated, producing the protein antigen. The antigen is then presented to the immune system by a number of mechanisms. (1) The antigen is processed intracellularly and the resulting peptides are presented on the cell surface bound to major histocompatibility (MHC) class I molecules, where they serve in the selection of cytotoxic T lymphocytes. (2) Protein antigen is transferred to bone marrow-derived antigen-presenting cell (APC), degraded and its peptides are presented on the cell surface bound to MHC II molecules, where they stimulate T-helper cells. (3) The exported protein is taken up by B cells, where it can serve in selection of B cells. (From Tuteja, 1999, *Critical Reviews in Biochemistry and Molecular Biology*, **34**, 1–24.)

example is a mutant *p53* minigene, as reported by Ciernik *et al*. (1996b). The expression vector used in that study only codes for the subunit of p53 from amino acids 128–145. The targeted point mutation is a cysteine to tyrosine at position 135. This sequence was fused in frame to an ER targeting sequence to route the product properly in the APC. Effective and specific T cell immunity was generated after direct injection of this vector. Thus, minigene DNA vaccination is an alternative to peptide-based techniques for eliciting effective immune responses targeted to defined epitopes.

Mutations in p53 are one of the most common somatically acquired genetic abnormalities in human cancer, and most of these mutant genes result in the production of a protein that is altered by a single amino acid substitution. In both p53 and Ras tumour model systems effective induction of mutation-specific CTL may successfully delay or inhibit tumour growth. Because missense mutant protein is present only in tumour cells and not in normal cells, this may make it a good target for tumour-specific cellular immunotherapy.

The use of cloned oligonucleotide epitopes has many theoretical and practical advantages over peptide- or protein-based vaccine. Pure peptides are generally poor immunogens, requiring adjuvants or attachment of lipophilic residues to the peptide for successful induction of CTL responses. One of the major mechanisms of action of adjuvants may indeed be increased antigen persistence. This persistence often causes increased local toxicity as well as efficacy. The production of the epitope from a

DNA template within the cell may result in increased intracellular persistence of the antigen.

Furthermore, it is not clear whether responses to more than a single epitope are necessary for optimal, and therefore biologically significant, immunity in humans. Each situation may require an optimal number and location of epitopes for inducing an efficient immune response.

DNA Vaccine Delivery

One form of cellular vaccine is when genetic material encoding an antigen is introduced into antigen-presenting cells before injection. Genes may be delivered to these cells *in vitro* by any one of the methods (plasmid or viral) mentioned above. These cells may be transduced *in vivo*, however, by a variety of different techniques, including the following.

Intramuscular (i.m.) administration: direct intramuscular and intradermal injection of a DNA vaccine in simple saline solution has been relatively widely used (Hanke *et al*., 1998). There are about 15% myocytes transfected in the vicinity of the injection site in the case of i.m. injection, but these may not be the real APC involved in immune induction. Techniques that are used to transfect cells *in vitro*, such as calcium phosphate precipitates or liposome preparations, do not seem to improve the efficiency of *in vivo* transfer.

Gene gun: devices have been manufactured to fire microscopic gold particles into living tissue. These can penetrate cell membranes and lodge within cells without killing them. DNA can be coated on to the gold particles by mixing the two in the presence of a polycation such as spermidine before firing them into the target tissue, typically the skin. Discharge of the gene gun results in penetration of 0.15 mm in the shaved area of skin. It has shown that this form of DNA injection often transduces cells in both dermis and epidermis (Mahvi *et al*., 1997; Porgador *et al*., 1998).

Other approaches include intravenous, intranasal, intradermal and subcutaneous immunization. A standard multi-tined tatooing device has also been shown to be effective. Since a low efficiency of gene delivery is a major obstacle in DNA vaccination, more studies need to be done to test the best routes for various DNA vaccinations.

Processing and Presentation of Antigens after DNA Vaccination

Generally, protein molecules made or taken up by DC are degraded by proteasomes in the cytosol and short peptide fragments of these proteins are actively transported from the cytosol to the endoplasmic reticulum by a heterodimer protein complex called the transporter of antigenic peptides (TAP). In the ER, these peptides bind to newly synthesized class I MHC molecules, which then carry them out to the cell surface and display them, within their peptide-binding groove, for recognition by $CD8^+$ T cells. The classical chain of events during induction of immune responses includes contact of these DC with antigen, uptake of this antigen and migration of DC to the draining lymph nodes. DCs naturally become activated either by the antigen itself, or by T cells or macrophages through direct contact or release of cytokines. Activated DC (also termed fully mature DC) stimulates antigen-specific T cells. This is followed by T cell migration to the site of antigen entry.

When DNA is directly injected intramuscularly, myocytes at the injection site appear to be the predominant cell type transfected. With gene gunning into the skin, the epidermal Langerhans cell (the cutaneous equivalent of the dendritic cell) may be the important cell type transduced. It is not yet understood how antigen processing and presentation actually occur when cells such as myocytes are expressing the desired antigen. Transfected myocytes may directly mediate antigen presentation, or professional APCs become transfected and serve as APCs, or antigen may be transferred from one to the other, perhaps after death or apoptosis of the myocytes. The mechanisms involved in viral antigen presentation via MHC class I molecules to naive $CD8^+$ T lymphocytes may be much more complex.

Immune Responses after DNA Vaccine Delivery

Immune responses induced by DNA immunization, are very much like those induced by viral infection. These immune responses include antibody production, cytotoxic T cell induction and cytokine secretion.

Humoural Immune Responses

There are a number of studies demonstrating that antibody responses can be induced by DNA vaccination. DNA vaccines encoding influenza NP and HA antigens, HIV envelope protein, bovine herpes virus glycoprotein, carcinoembryonic antigen (CEA), etc., have resulted in the generation of specific antibodies. The duration of antibody responses varies, and can be as long as months to years, or more short-lived. The effectiveness of a DNA vaccine to induce a humoural response, compared with conventional vaccine, appears to be favourable (Conry *et al*., 1996).

Cytotoxic T Cell Responses

Induction of CTL responses can be demonstrated with lymph node or spleen cells from mice that have been injected with plasmid DNA encoding viral antigens. These CTL responses can be detected when these T cells are co-cultured with APC pulsed with purified viral antigens or

infected with the virus. A good example of this is that CD8+ cytotoxic T lymphocytes recognizing an influenza NP peptide can be detected after intramuscular injection with DNA encoding the NP from influenza A virus (Zhou *et al*., 1995). CTL induction has also been shown after gene-gun or intravenous delivery of DNA plasmids encoding specific antigens.

Helper T Cell Responses

Helper T cells are T lymphocytes that secrete cytokines and boost the response of other immune cells such as macrophages, B cells and cytotoxic T lymphocytes. Helper T cells also facilitate the differentiation and development of effector and memory cells. There are two types of T helper cells. Type 1 (Th1) produce cytokines such as IL-2 and interferon-γ. They support the development of cellular immune responses including CTL. Type 2 (Th2) produce cytokines such as IL-4, IL-5, IL-6 and IL-10, which promote B cell activation and antibody production. There are studies showing that DNA intramuscular immunization generates memory T lymphocyte responses manifested by proliferation of antigen-specific T cells and secretion of cytokines during *in vitro* culture of splenocytes from vaccines (Shiver *et al*., 1996; Feltquate *et al*., 1997). High levels of IL-2 and interferon-γ with little or no IL-4 or IL-5 are found in the supernatant of proliferating lymphocytes cultured from immune animals. Therefore, DNA vaccines in these experiments elicited Th1-like cytokine responses (Leclerc *et al*., 1997).

In general, attempts to enhance immune responses against DNA encoded antigens have included varying the vaccination regimen with respect to dose and number of boosts. Coinjection of plasmids encoding cytokines such as GM-CSF, or costimulatory molecules such as B7-1 and B7-2, has also been attempted (Tuteja *et al*., 2000). However, immune resistance can also result from chronic expression of antigen for long periods after DNA injection.

Costimulatory Molecules for Immune Response

Muscle cells express or can be induced to express adhesion molecules, cytokines and MHC class I and II molecules, but they do not seem to express the costimulatory molecules required for efficient antigen presentation. Costimulatory molecules CD80 and CD86 on APC interact with the CD28/CTLA4 molecules on T cells, providing an important second signal in addition to ligation of the T cell receptor to the MHC complex. In a number of experiments, coinjection of CD80 or CD86 expression cassettes along with DNA vaccine resulted in a dramatic increase in CTL response or antibody response (Iwasaki *et al*., 1997).

Summary: the Advantages of DNA Vaccine over Protein- or Peptide-based vaccines

1. DNA can be more easily manipulated and custom designed to meet different needs.
2. In immunocompromised patients, DNA vaccines may be safer than certain live virus vaccines.
3. Antigens from several different proteins can be included on the same plasmid, thus decreasing the number of total vaccinations.
4. DNA is very stable, which is important for the storage, transportation and distribution of DNA vaccine.
5. The equivalent processes for the synthesis, purification and characterization of peptides are at least an order of magnitude more time consuming and expensive.
6. DNA has uniform handling and purification characteristics whereas synthetic peptides differ in a variety of ways, including solubility, optimum diluent and potential for disulfide bonds.
7. The major advantage of genetic vaccine over purified proteins and peptides seems to be extended, endogenous expression of the protein or the peptide product from which results in increased intracellular persistence of the antigen.

Safety Concerns about Genetic Vaccines for Human Use

1. The potential for integration of the plasmid DNA into the human genome and stable, even germ-line, transmission. The integrated antigenic open reading frame may remain silent, but even then could also be mutagenic or disrupt a cellular gene. One particular concern is that the plasmid DNA may cause inactivation of a regulatory gene for cell division or activation of an oncogene. To help combat this potential pitfall, researchers use plasmids without an origin of replication that is functional in eukaryotic cells. Furthermore, the transfected cells, mostly myocytes, sometimes including macrophages and dendritic cells, are for the most part non-dividing. Therefore, the chance of integration and transmission to cellular progeny is limited.
2. Potential for induction of immunological tolerance or unresponsiveness and autoimmunity. There have been various studies on immunological tolerance issues (Mor *et al*., 1997; Czerkinsky *et al*., 1999). Generally, age, species of the subject and the method of administration are key factors related to the ultimate response to DNA immunization. The other important concern is that the destruction of cells expressing foreign genes may lead to the release of cellular constituents theoretically capable of inducing autoimmune responses. However, this event occurs also in the course of viral and bacterial

infection as well as the normal process of tissue remodelling. It appears unlikely that DNA immunization would pose any greater risk in this regard than traditional viral or bacterial vaccine. Such an important issue needs more careful evaluation, however (Overwijk *et al*., 1999)
3. Potential for induction of anti-DNA antibodies, which are known to be associated with various human pathological conditions. It is not yet known whether DNA vaccines induce anti-DNA antibodies in humans, although preclinical animal studies suggest that this is unlikely (Donnelly *et al*., 1997).

The problems and potential of DNA vaccines are outlined in **Table 3**.

Current Human Clinical Trials of DNA Vaccine

There are a few reports detailing the use of DNA vaccines in phase I human clinical trials. One study involved three groups of three subjects (HIV-1 infected but asymptomatic), each of whom were given three doses of 100 μg of plasmid encoding the cDNA for either *nef*, *rev* or *tat* HIV-1 genes intramuscularly in distilled water. Detectable memory cells in all subjects and specific CTLs in eight out of nine subjects that were above preimmunization levels were reported. However, three of these responses were transient. No apparent side effects were detected (Calarota *et al*., 1998). Another group tested the immunogenicity of an HIV env/rev DNA vaccine in HIV-1-seronegative persons. In at least one of multiple assays, the six subjects who received the 300-μg dose had DNA vaccine-induced antigen-specific lymphocyte proliferative responses and antigen-specific production of both interferon-γ and β-chemokine (Ugen *et al*., 1998).

Table 3 The problems and potential of DNA vaccines

Advantages	Concerns and problems
Noninfectious/nonreplicating	Potential for insertion into the genome
Proteins produced in native conformation	Autoimmunity
Physicochemical homogeneity	Immunological tolerance
Stability for storage, transportation and distribution	Induction of anti-DNA antibodies
Easy manipulation/simplified production	
A single vaccine for multiple pathogens	
Extended expression of antigen	

Melanoma is the most immunogenic solid tumour, which makes it an ideal target for immunotherapy. DNA vaccine clinical trials against melanoma are ongoing and a number of genetically modified tumour vaccines (GMTVs), with various immunostimulatory factors, are being tested in phase I/II clinical trials, which include cytokines, tumour antigens (TAs), costimulatory molecules or HLA antigens. Some of these studies have shown enhanced survival of patients developing immune responses to melanoma vaccines (Ollila *et al*., 1998; Nawrocki *et al*., 2000). In addition, a phase III clinical trial of vaccinia melanoma oncolysate (VMO) vaccine showed minimal toxicity and clinical efficacy in patients with melanoma (Wallack *et al*., 1998). A phase I study using direct combination DNA injections for the immunotherapy of metastatic melanoma is ongoing at the University of Colorado Cancer Center. Results of two clinical trials are summarized in **Table 4**.

The release of further human clinical trial data is keenly awaited. Strategies may need to be modified to achieve higher efficiency of DNA vaccination such as enhancing the uptake of DNA, targeting oncoproteins or using a prime-boost strategy (DNA vaccine given in the initial dose followed by recombinant protein or virus).

Table 4 Two clinical trials of DNA vaccine against melanoma

Clinical trial and reference	Vaccine[a]	No. of patients treated and evaluated	Clinical response status[a]			
			CR	PR	NC	P
Phase I/II (Nawrocki *et al*., 2000)	Autologous tumour cells mixed with allogeneic melanoma engineered to produce IL-6 and sIL-6R	41	5	4	13	19
Melanoma Phase I (Soiffer *et al*., 1998)	Autologous melanoma cells engineered to produce GM-CSF	16[b]	3	4	3	5

[a]Abbreviations: sIL-6R, soluble Il-6 receptor; GM-CSF, granulocyte macrophage colony-stimulating factor.

INTRODUCTION AND RATIONALE FOR DIFFERENTIATION THERAPY

Cancer morbidity and mortality continue to be major problems worldwide despite improvements in diagnostic, preventive and therapeutic strategies. The improved understanding of genetic, molecular and cellular aspects of carcinogenesis over the last few years has revealed various new targets for intervention. Among these novel approaches is differentiation therapy, the subject of this chapter.

In a developing multicellular organism, cells achieve their specialized set of structural and functional characteristics through a process called differentiation. This process involves concerted changes in gene expression aimed at restricting the expression of a diverse repertory of genes in pluripotential cells to those required to attain the specialized phenotype in unipotent cells in a specific tissue. Cellular differentiation often leads to a mature nondividing cell (terminally differentiated cells). This is the consequence of the modulation of genes that are involved in regulation of cell proliferation, senescence, and programmed cell death (apoptosis).

The development of cancer usually involves aberrations in cellular differentiation; dividing cells that have the potential to differentiate, senesce or undergo apoptosis become immortalized and often fail to complete the differentiation programme owing to a block at a stage preceding terminal differentiation. That this block can be reversed is indicated by reports on tumour cells that undergo 'spontaneous' or induced differentiation *in vitro* and *in vivo* including in patients. Thus, neuroblastoma cells have been shown to differentiate into ganglioneuroma cells, and germ cell tumours (teratocarcinoma) into benign teratomas. In addition, keratin pearls characteristic of terminally differentiated keratinizing squamous epithelial cells are found within squamous cell carcinomas (Pierce *et al.*, 1978).

A series of elegant studies have demonstrated that the malignant phenotype is reversible and can be controlled by physiological signals mediated by soluble factors or cell–cell contacts provided by an appropriate developmental field. In one such experiment, embryonal carcinoma cells injected into mouse blastocysts and implanted into pseudopregnant female mice developed into normal cells in a variety of tissues of the chimaeric offspring. In contrast, the same cells developed into tumours when injected subcutaneously (Illmensee and Mintz, 1976). Similarly, myeloid leukaemia cells injected into embryos *in utero* at 10 days of gestation developed into normal granulocytes in the offspring, neuroblastoma cells have lost their tumorigenic properties when injected into fragments of neurula-stage embryos then transplanted into mice and melanoma cells injected into embryonic skin failed to form tumours. Certain human teratocarcinoma cells were found to differentiate into a variety of somatic cell types after injection into immunodeficient mice.

Additional support for the contention that the malignant phenotype can be reversed has come from *in vitro* studies, which have demonstrated that the aberrant differentiation of tumour cells can be restored at least partially to normal differentiation by interactions with adjacent normal cells (e.g. by epithelial–mesenchymal interactions) or with extracellular matrix. Several cell types have been found to undergo differentiation *in vitro* after treatment with cytokines that regulate normal differentiation or with other compounds, both physiological and pharmacological, that activate various differentiation pathways (**Table 1**).

Because normal terminal differentiation often results in non-proliferating cells that often undergo apoptosis as they complete their normal life span, it was plausible to develop strategies to activate normal pathways of differentiation in premalignant and malignant cells using physiological or pharmacological agents that can bypass the epigenetic and genetic abnormalities that abrogate differentiation. This approach, called differentiation therapy, can be used to

Table 1 Differentiation-inducing agents and their suggested mechanisms of action

Differentiation-inducing agent	Mechanism of action
Short-chain fatty acids (butyrate and derivatives)	Inhibit histone deacetylase, thereby enhancing gene expression, alter the methylation and phosphorylation of nuclear proteins and alter gene transcription
Aromatic fatty acids (phenylbutyrate, phenylacetate)	Inhibition of protein prenylation critical for signal transduction; activation of peroxisome proliferator-activated receptor, a transcription factor related to the steroid nuclear receptor superfamily; hypomethylation of DNA; depletion of circulating glutamine which is required for tumour growth
Trichostain A, SAHA	Inhibit histone deacetylase, thereby modulating gene expression
PPAR ligands	Activate nuclear receptors (PPARs) and modulate gene transcription
Haxamethylenebisacetamide	Modulate cell cycle and differentiation related genes
Vitamin A analogues (retinoids)	Activate nuclear receptors (RARs and RXRs) and modulate gene transcription
Vitamin D_3 analogues	Activate nuclear receptors (VDR) and modulate gene transcription
Cytokines (TNF-α interleukins)	Act via cell surface receptors to induce signal transduction pathways resulting in alterations in gene expression
Interferons	Activate transcription factors (Stats) and thereby alter gene transcription
5-Aza-2′-deoxycytidine	Decreases DNA hypermethylation and thereby restores expression of silenced genes
Diflouromethylornithine	Ornithine decarboxylase inhibition
Staurosporin	Protein kinase C inhibition
8-Choloro-cyclic adenosine monophosphate (8-Cl-cAMP)	Downregulates RI and upregulates the RIIb subunit of protein kinase A
Etoposide nondamaging (ICRF-193)	Topoisomerase II inhibition
Actinomycin D	DNA intercalation
Ultravoilet light; X-irradiation	DNA damage, AP-1 activation
Cytosine arabinoside; cyclophosphamides; aclacinomycin (at subtoxic concentrations)	Inhibition of DNA synthesis

prevent, suppress or reverse the malignant phenotype by inducing differentiation with the associated growth arrest, senescence and apoptosis (**Figures 1–3**). Even if only partially successful, differentiation therapy can convert malignant tumours into benign tumours. In this chapter, we discuss preclinical and clinical data on selected differentiation-inducing agents and their mechanisms of action.

PRECLINICAL ASPECTS OF DIFFERENTIATION THERAPY

A variety of compounds, both natural and synthetic, have been found to induce differentiation *in vitro* in various cell lines, including murine erythroleukaemia cells, human myeloid leukaemia cells and murine and human embryonal carcinoma cells. Some of these agents are presented in **Table 1** and selected ones are described below.

Histone Deacetylase Inhibitors

Histone acetylation status appears to be important in the regulation of differentiation, cell cycle control, hormone responsiveness, senescence and cancer because of its impact on chromatin structure and the control of gene transcription. The histone acetylation status is regulated by the equilibrium of histone acetyltransferase activity and histone deacetylase activity. Histone deacetylases (HDACs) are enzymes that catalyse the removal of acetyl groups from the N-terminal lysine residues of core nucleosomal histones. This action results in restoration of a positive charge to the lysine residues of the histones, which then bind tightly to the phosphate backbone of DNA. The subsequent condensation of the structure of the nucleosome inhibits transcription because transcription factors and their associated cofactors and RNA polymerase do not have access to the gene promoters (Marks *et al*., 2000). Several compounds have been found to inhibit HDACs and this is presumed to relax the structure of chromatin associated with programmed genes allowing them to be expressed. These compounds include butyroids (e.g. butyric acid), hydroxamic acids (e.g. trichostatin A (TSA) and suberoylanilide hydroxamic acid (SAHA)), cyclic peptides (e.g. trapoxin and apicidin) and benzamides. Most of these agents have been found to induce differentiation and/or apoptosis of transformed cells *in vitro* and some also suppressed tumour growth *in vivo* (Marks *et al*., 2000).

Butyroids

Butyrate, a naturally occurring four-carbon fatty acid found in abundance in milk fat, is also produced by microbial fermentation of dietary fibre, undigested starch

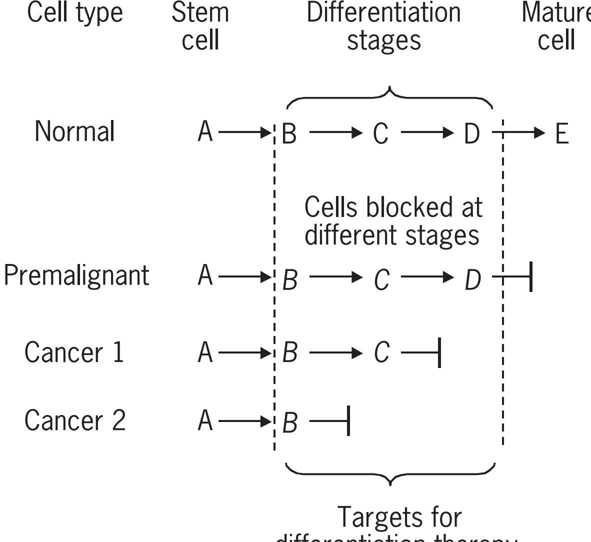

Figure 1 Targets for differentiation therapy. In a normal differentiation pathway, a hypothetical stem cell designated A is required to undergo a series of progressive changes in gene expression and resultant phenotypic changes represented by the letters B, C and D before reaching the terminally differentiated mature cell stage designated E. Cancer development is associated with aberrant differentiation. This can be represented by a block in differentiation that can occur already in premalignant cells. The scheme shows three possible blocks at late stages of the differentiation pathway (e.g. at stage D) and at early stages of the pathway (e.g. at stage B).

and proteins within the colonic lumen of mammals. Butyrate has been shown to inhibit proliferation and induce differentiation and apoptosis in a variety of tumour cell types including erythroleukaemia, embryonal carcinoma, colon carcinoma, pancreatic carcinoma, neuroblastoma, glioblastoma and haematopoietic malignancies (Newmark *et al*., 1994). Butyrate induced the expression of specific differentiation-associated genes characteristic of defined pathways of differentiation when used at concentrations between 0.5 and 10 mmol L^{-1}.

Specific effects of butyrate on gene regulation have been reported, both by transcriptional regulation and post-transcriptional modifications. It has been proposed that butyrate exerts its effects by a noncompetitive inhibition of HDACs and the consequent modulation of gene transcription. Some of the genes modulated in butyrate-treated cells are involved in cell differentiation, growth and apoptosis. Butyrate has been shown to induce cell cycle arrest in G_1. The mechanism of this arrest may be related to the ability of butyrate to increase the transcription of the cyclin-dependent kinase inhibitor $p21^{WAF1}$. In normal and malignant human breast cells, butyrate induced differentiation, decreased expression of cyclin D1, increased expression of $p21^{WAF1}$ and increased hypophosphorylated retinoblastoma protein pRB. Butyrate has also been shown to induce apoptosis in lymphoid cell lines and colon carcinoma cells.

Butyrate, delivered in liposomes to human colon carcinoma tumours growing in immunodeficient mice, was able to suppress tumour growth and enhance differentiation (Otaka *et al*., 1989). This study provided a proof of

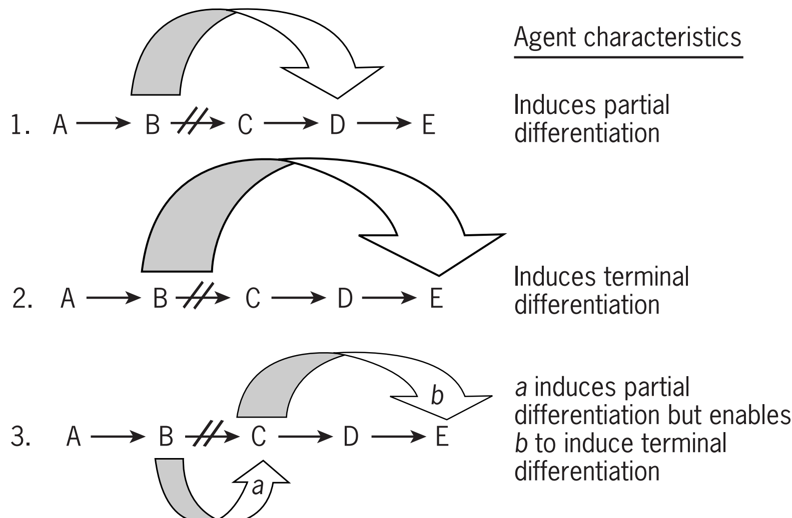

Figure 2 Characteristics of agents that are used to induce differentiation in malignant cells. In scenario 1 an agent can induce partial differentiation of cells blocked at stage B by inducing them to undergo changes to stage D. In scenario 2 the agent can induce cells blocked at stage B to undergo full differentiation to the mature cell E. In scenario 3, agent *a* can induce a partial differentiation (from B to C) but at the same time it renders the resultant cell C capable of responding to agent *b* that can complete the differentiation of cell C to the mature cell E. The latter example can serve as one of the rationales for combination of agents for differentiation therapy. The designation of the letters A–E is the same as in **Figure 1**.

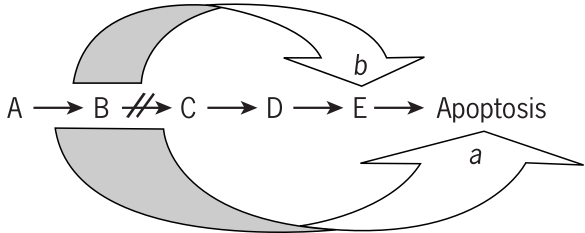

a: Induces apoptosis without inducing differentiation
b: Induces terminal differentiation and the mature cells eventually undergo apoptosis

Figure 3 Inter-relations between differentiation and apoptosis. Because many cell types undergo apoptosis as a normal consequence of terminal differentiation, treatment of cancer cell at stage B with agent *b* induces cell at stage B to undergo differentiation to the mature cell E and eventually to apoptosis. This scenario is contrasted with an agent such as *a*, which can induce apoptosis without inducing differentiation.

the principle that butyrate has a potential for use in differentiation therapy. However, the clinical development of butyrate was limited by the requirement for millimolar concentrations for efficacy combined with its very short metabolic half-life.

To overcome this problem, butyrate derivatives (butyroids) with a longer half-life than butyrate have been synthesized and characterized and some were found to be more potent than butyrate *in vitro* and *in vivo*. Among these derivatives, tributyrin was about fourfold more potent than either butyrate or monobutyrin in inducing monocytic differentiation of HL-60 myeloid leukaemia cells and erythroid differentiation of murine erythroleukaemia cells. Tributyrin has been shown to induce apoptosis in human prostate cancer cell lines irrespective of their androgen receptor expresssion status. Butyramide and monobutyrin also induced differentiation and inhibited DNA synthesis in hepatoma cells and mouse erythroleukaemia cells *in vitro*.

Pivaloyloxymethyl butyrate (AN-9), a prodrug of butyric acid, is a differentiation-inducing agent in a variety of cells. In myelomonocytic cell line (WEHI), AN-9 modulated the expression of the early regulatory genes, c-*myc* and c-*jun*, leading to growth arrest and differentiation. Even a short (4-h) pretreatment *in vitro* resulted in a marked reduction in the tumorigenicity of AN-9-treated cells. Similarly, a short (1-h) AN-9 treatment of Lewis lung carcinoma cells resulted in an almost complete loss of tumorigenicity. In both cell types butyric acid did not affect the tumorigenicity of the cells even when it was used at concentrations 10 times higher than those of AN-9. Thus, some butyroids with longer half-life and greater potency than butyrate might be useful for cytodifferentiation therapy of human malignancies.

Aromatic Fatty Acids

The aromatic fatty acid phenylbutyrate (PB) and its metabolite phenylacetate (PA) are natural derivatives of phenylalanine. When used at millimolar concentrations, which are pharmacologically attainable and nontoxic, these agents have been shown to induce differentiation of a variety of cell types including leukaemia, erythroleukaemia, prostate carcinoma, neuroblastoma, rhabdomyosarcoma, melanoma and neuroectodermal tumours (Samid *et al*., 1997). Although PB and PA are related structurally to butyrate, their mechanisms of action are distinct from butyrate and in some respects also from each other.

PA exhibited a marked activity against a highly tumorigenic human breast cancer cell line both *in vitro* and *in vivo*. *In vitro*, cell growth was inhibited and the anti-apoptotic protein Bcl-2 was down-regulated in conjunction with the appearance of apoptotic cells. *In vivo*, the treated tumours showed growth arrest, Bcl-2 down-regulation and differentiation. PA-induced growth arrest in human breast carcinoma MCF-7 cells was associated with enhanced expression of the cyclin-dependent kinase inhibitor $p21^{Waf1/Cip1}$ and dephosphorylation of pRB. The induction of $p21^{WAF1/CIP1}$ mRNA by PA was independent of the cellular p53 status and appeared to be required for growth inhibition because mouse embryonal fibroblasts from a p21−/− knockout mouse failed to undergo growth arrest by PA.

PA treatment of prostate cancer cell line LNCaP resulted in an increase in prostatic-specific antigen (PSA) mRNA and protein despite inhibition of tumour cell proliferation. A similar increase was noted in rats bearing subcutaneous LNCaP tumour implants that were treated systemically with PA. PA can alter tumour cell lipid metabolism and *ras*-encoded p21 via inhibition of protein isoprenylation. For example, PA inhibited protein isoprenylation and $p21^{ras}$ farnesylation and induced apoptosis in LNCaP prostate cancer cells transfected with the mutated c-Ha-*ras* gene. PA reduced the cellular levels of endogenous farnesyl-PP and inhibited activation of the $p21^{ras}$ downstream target, p42(MAPK)/ERK2. Exogenous farnesyl- and geranylgeranyl-PP reduced the effects of the drug on proliferation and apoptosis in LNCaP(T24-ras) cells.

Although both PB and PA promote differentiation in human prostate cancer cell lines, PB is more active at inhibiting growth and inducing programmed cell death in several human prostate cancer lines than PA at clinically achievable doses. PB caused prostate cancer cells to undergo apoptosis 2–10 times more than PA. Prostate cancer cell lines overexpressing P-glycoprotein or possessing p53 mutations were also sensitive to the effects of PB. *In vivo* experiments demonstrated that PB administered to rats orally delayed growth of an androgen refractory rat prostate cancer subline by 30–45% in a dose-dependent manner. These results demonstrate that PB

induces cytotoxicity via apoptosis in human prostate cancer, in addition to its differentiating properties. The pathway signalling apoptosis in prostate cancer cells exposed to PA included reduction in mitochondrial transmembrane potential, release of cytochrome *c* from the mitochondria to the cytosol, activation by proteolytic processing of caspase-3 and -7 and cleavage of the death substrates poly(ADP–ribose) polymerase and DNA fragmentation factor.

The chimaeric fusion product AML1-ETO, which is formed in acute myeloid leukaemia (AML) by the (8;21) translocation, recruits a transcription repression complex that includes the histone deacetylase 1 enzyme. PB could partially reverse ETO-mediated transcriptional repression, possibly through inhibition of HDAC. PB was also able to induce partial differentiation of the AML1–ETO cell line Kasumi-1. The relief of differentiation repression using PB may prove to be therapeutically beneficial.

Trichostatin A (TSA)

The fungistatic antibiotic TSA, isolated from the culture broth of *Streptomyces platensis*, was found to be a specific inhibitor of the cell cycle of normal rat fibroblasts in the G_1 and G_2 phases. In addition, TSA was found to be a potent inducer of erythroleukaemia cell differentiation at submicromolar concentrations. TSA inhibited the growth or induced differentiation of erythroleukaemia cells, colon carcinoma cells, neuroblastoma cells and pancreatic cancer cells. The level of histone hyperacetylation and $p21^{Waf1}$ expression increased, as reported also for butyrate. The mechanism of these effects was found to be reversible inhibition of HDACs presumably mediated by binding of the hydroxamic acid moiety of TSA to a zinc in a tubular pocket in the catalytic site of HDAC (Marks *et al*., 2000). Although the effect of TSA may appear to be nonspecific and could affect many genes, it is of interest that the activity of only about 2% of expressed genes is affected (Marks *et al*., 2000).

The (8;21) translocation, found in 12% of AML, creates the chimaeric fusion protein AML1–ETO. This protein binds to DNA and recruits a transcription repression complex that includes the histone deacetylase 1 enzyme. TSA could partially reverse ETO-mediated transcriptional repression and this could be the basis for its ability to induce differentiation (Ferrara *et al*., 2001).

In addition to its effects on established tumour cell lines *in vitro*, TSA has been shown to induce or enhance the differentiation of AML cells isolated freshly from clinical samples from patients with different AMLs ranging from M0 to M7.

Suberoylanilide Hydroxamic Acid (SAHA)

SAHA is the prototype of a family of hybrid polar compounds that inhibit histone deacetylase and are potent inducers of cell differentiation and/or apoptosis in certain transformed cells in culture including erythroleukaemia, myeloma, leukaemia, bladder carcinoma, breast carcinoma and prostate carcinoma (Marks *et al*., 2000). They inhibit HDACs and induce cell differentiation at very low concentrations ($0.01–1\ \mu mol\ L^{-1}$). The hydroxamic acid moiety of SAHA can bind to the putative catalytic site of HDACs in the same fashion as TSA (Marks *et al*., 2000).

Like other HDAC inhibitors, SAHA increased the level of $p21^{Waf1}$ by enhancing its transcription (Marks *et al*., 2000). The growth of human prostate tumour cells in immunodeficient mice was suppressed by SAHA at concentrations that exerted no toxicity to the animals although histone hyperacetylation was observed in both normal and tumour cells *in vivo*. The selective effect on tumour cells makes SAHA an excellent candidate for therapy. Further, the ability of SAHA to suppress mammary and lung carcinogenesis makes it also a potential chemopreventive agent (Marks *et al*., 2000).

Peroxisome Proliferator–Activator Receptor Ligands

Peroxisome proliferator–activator receptors (PPARs) are nuclear receptors that function as ligand-dependent transcriptional regulators. The PPARs include three receptor subtypes encoded by separate genes: *PPAR-*α, *PPAR-*δ, and *PPAR-*γ. PPARs form heterodimers with the retinoid X receptors (RXRs), which bind to the consensus sequence of nucleotides in the regulatory regions of PPAR-regulated genes. Activation of PPAR-γ by the naturally occurring ligand 15-deoxy-$\Delta^{12,14}$-prostaglandin J2 (15d-PGJ2), has been linked to adipocyte differentiation, regulation of glucose homeostasis, inhibition of macrophage and monocyte activation and inhibition of tumour cell proliferation. PPARs and their ligands have also been implicated in the control of cell growth and differentiation (Roberts-Thomson, 2000). 15d-PGJ2 and other PPAR-γ activators (e.g. thiazolidinediones such as troglitazone and pioglitazone) were found to induce differentiation in a variety of cancer cell lines including liposarcoma, colon carcinoma, breast carcinoma, and prostate carcinoma. Treatment with pioglitazone induced terminal differentiation in primary human liposarcoma cells. Further, RXR-specific ligands were also potent adipogenic agents in cells expressing the PPAR-γ/RXR-α heterodimer, and simultaneous treatment of liposarcoma cells with both PPAR-γ- and RXR-specific ligands resulted in an additive stimulation of differentiation. These results suggested that PPAR-γ ligands and RXR-specific retinoids may be useful agents for the treatment of liposarcoma. Ligand activation of PPAR-γ in cultured breast cancer cells caused lipid accumulation, changes in breast epithelial gene expression associated with a more differentiated, less malignant state and a reduction in growth rate and clonogenic capacity

of the cells. PPAR-γ activation in colon cancer cells suppressed growth, increased expression of carcinoembryonic antigen and suppressed the expression of many genes associated with colon cancer. In addition, animal studies have shown that transplantable tumours derived from human colon cancer cells show a reduction in growth when mice are treated with troglitazone. These results indicate that the growth and differentiation of the above cancer cells can be modulated through PPAR-γ.

Phenylacetate, which is structurally similar to clofibrate, a PPAR ligand, was found to activate this receptor. In human prostate carcinoma, melanoma and glioblastoma cell lines there was a close correlation between drug-induced cytostasis, increased expression of the endogenous PPAR and PPAR activation. More recently, it was found using *in vitro* models that a close correlation exists between tumour growth arrest by phenylacetate and activation of PPAR-γ. The ability to bind and activate PPAR-γ was common to biologically active analogues of phenylacetate and corresponded to their potency as antitumour agents, whereas an inactive derivative had no effect on PPAR-γ. These results suggest that PPAR-γ may mediate tumour growth inhibition by aromatic fatty acids.

Planar–Polar Solvents

N,N′-Hexamethylenebisacetamide (HMBA) is a hybrid polar compound that was found to induce both the differentiation of murine erythroleukaemia cells and the differentiation of various other cell lines *in vitro* and in patients (Marks *et al.*, 1995). Detailed investigations using murine erythroleukaemia cells have delineated the early and late effects of HMBA (reviewed in Marks *et al.*, 1995). The induction of differentiation by HMBA required treatment at concentations of 3–10 mmol L^{-1} for 3–15 days. Several investigations have been carried out with human cancer cells. HMBA induced the differentiation of human teratocarcinoma, bladder carcinoma and glioma cells. In addition, HMBA suppressed cell growth and decreased the tumorigenicity of the cells. The effects of HMBA were associated with suppression of the expression of growth factors such as transforming growth factor alpha, keratinocyte growth factor and an autocrine factor teratocarcinoma-derived growth factor-1 that is related to epidermal growth factor. HMBA-induced cessation of proliferation was mediated, in part, by increased expression of the cyclin-dependent kinase inhibitor p27, enhanced association of p27 with cyclin E/cyclin-dependent kinase 2 (CDK2 complex) and suppression of kinase activity associated with cyclin E/CDK2. The formation of E2F complexes with pRB and the protein p130 has also been implicated in growth inhibition. Other effects of HMBA include enhancement of gap-junctional intercellular communication and induction of cell death, both of which can contribute to suppression of growth.

Vitamin D_3

The metabolically active form of vitamin D, 1α,25-dihydroxyvitamin D_3 (1α,25$(OH)_2D_3$) plays a key role in calcium homeostasis in the body. In addition, 1α,25$(OH)_2D_3$ can regulate cell growth and differentiation of normal and malignant cells including colon carcinoma cells, prostate cancer cells and neuroblastoma cells. Because the clinical use of 1α,25$(OH)_2D_3$ in differentiation therapy was hampered by its hypercalcaemic activity, various analogues have been synthesized with the hope of identifying some that are as potent as or more potent than vitamin D_3 in inducing tumour cell differentiation but less hypercalcaemic. Indeed, analogues such as 1,25-dihydroxy-23-ynecholecalciferol (23-D), 1,25-dihydroxy-Δ^{16}-23-yne-cholecalciferol (16-23-D) and 1,25-dihydroxy-22,24-diene-24,26,27-tribromovitamin D_3 (Seocalcitol EB 1089) have reduced action on calcium metabolism but high potency in cancer cell growth suppression and differentiation induction (Hansen *et al.*, 2000).

The analogue 19-nor-hexafluoride (1,25-dihydroxy-16-ene-23-yne-26,27-difluoro-19-nor-vitamin D_3) induced cell cycle arrest of prostate cancer cell lines and upregulated the cyclin-dependent kinase inhibitor (CDKI) p21^{Waf1}. Partial differentiation was evidenced by increased expression of PSA in LNCaP cells and E-cadherin in LNCaP and PC-3 cells. In mouse erythroleukaemia cells 1α,25$(OH)_2D_3$ induced haemoglobin and acetylcholinesterase activity. 1α,25$(OH)_2D_3$ and its analogues, 20-epi-22-oxa-24a,26a,27a-tribromo-1,25-dihydroxy vitamin D_3 (KH 1060); 20-epi-1,25$(OH)_2D_3$ 1,25$(OH)_2$-16-ene-D_3, and 1,25$(OH)_2$-16-ene-23-yne-D_3, especially KH 1060, were potent inducers of differentiation of breast cancer cell lines. Apoptosis was induced in four of six cells lines. Vitamin D_3 stimulated the differentiation of LA-N-5 neuroblastoma cells, which was associated with a decrease in N-myc expression and inhibition of cell growth. Two vitamin D_3 analogues, KH 1060 and EB 1089, can cause the same *in vitro* effects on LA-N-5 human neuroblastoma cells at 1% of the concentration required with vitamin D_3, thus making them more attractive candidates for clinical use.

Vitamin D_3 and many of its analogues exert their actions on cell growth and differentiation through the activation of nuclear vitamin D receptor (VDR), a ligand-activated transcription factor, which is a member of the superfamily of steroid hormone receptors. The ligand-activated VDR is found in complex with the retinoid X receptor (RXR) and enhances gene transcription from VD response elements (VDREs). The transcriptional activity can be enhanced by costimulation with vitamin D_3 and 9-*cis*-retinoic acid, the RXR ligand.

The vitamin D receptor has been detected in many types of cancer cell, including colon carcinoma, prostate, lung cancers, osteosarcomas and other types of cancer. Mutations and rearrangements do not appear to be associated with the development of these cancers.

Evidence that the antiproliferarive effects of 1α,25 $(OH)_2D_3$ were mediated by the nuclear receptor VDR was obtained from studies of transfection of VDR into receptorless prostate cancer cells thus restoring their response to the growth inhibitory effects of D_3. The downstream genes that may regulate the effects of D_3 on cell growth may include p21^{WAF1} and c-*fos*. In addition, vitamin D_3 and its analogues are potent inducers of transforming growth factor beta (TGF-β) in breast cancer cells and prostate cancer cells and it was suggested that TGF-β may contribute to the mechanism by which 1α,25$(OH)_2D_3$ promotes cellular differentiation.

U937 and THP-1 cell differentiation with 1α,25$(OH)_2$ D_3 correlated with gene transcription and functional expression of inducible nitric oxide synthase (iNOS). Inhibition of iNOS activity by N^{γ}-monomethyl-L-arginine significantly decreased *in vitro* cell differentiation with 1α,25$(OH)_2D_3$. Thus, it appears that NO plays a role in the growth arrest and terminal differentiation of promonocytic leukaemia cells.

Experiments utilizing 1α,25-$(OH)_2D_3$ analogues and kinase/phosphatase inhibitors suggested that tyrosine kinase and serine/threonine phosphorylation cascades, rather than vitamin D_3 receptor-mediated signals, were involved in some aspects of 1α,25-$(OH)_2D_3$'s actions. Both 1α,25-$(OH)_2D_3$ and the nongenomic analogue 1α,25-$(OH)_2D_3$ (HF) increased expression of PKC-α and PKC-δ and their translocation to the nucleus of the cell. The effects of HF were attenuated by the nongenomic antagonist 1β,25-$(OH)_2D_3$, suggesting that changes in PKC expression are mediated by a nongenomic signalling pathway. Enhanced phosphorylation of a variety of cellular proteins at serine and threonine residues was observed immediately after 1α,25-$(OH)_2D_3$ addition. It was proposed that 1α,25-$(OH)_2D_3$ primes acute promyelocytic leukaemia cell line NB4 cells for TPA-induced monocytic differentiation by increasing the expression of specific PKC isoforms and inducing the specific phosphorylation of key protein signalling intermediates. Indeed, 1α,25-$(OH)_2D_3$ and some of its conformationally locked (6-s-*cis* vs 6-s-*trans*) analogues, which bind poorly to VDR, increased p42MAPK phosphorylation in NB4 cells in a time- and dose-dependent manner, with the earliest response detectable at 30 s, which excludes a role for nuclear VDR in this effect.

Retinoids

Retinoids are naturally occurring and synthetic analogues of vitamin A. The physiological functions of naturally occurring retinoids include regulation of embryonal development and maintenance of the proper differentiation of many tissues in the adult. Retinoids also act pharmacologically to restore regulation of differentiation in certain malignant cells *in vitro*. The effects of retinoids on cell differentiation have been studied extensively in several cultured cell lines derived from embryonal carcinoma (EC), normal and malignant keratinocytes, premonocytic and myeloid leukaemias, neuroblastoma, and melanoma. In most of these cell types, retinoids enhance differentiation. However, in cultured keratinocytes and squamous cell carcinomas (SCCs), retinoids inhibit squamous differentiation. Because in many cases the squamous differentiation of normally nonkeratinizing epithelial cells is aberrant, the effect of retinoids can be viewed as restoration of the normal nonkeratinizing phenotype.

Retinoids appear to enhance predetermined programmes in cells that have the potential to undergo differentiation along one or more specific pathways. For example, in F9 EC cells, retinoids induce endodermal differentiation, whereas in human embryonal carcinoma cells, retinoids induce a neuronal differentiation. In P19 EC cells retinoids can induce both myogenic differentiation and neuronal differentiation depending on the concentration of retinoid used. In HL-60 myeloid leukaemia cells that have the potential to undergo either myeloid or monocytoid differentiation, retinoids can only induce the myeloid pathway. In contrast, all-*trans*-retinoic acid (ATRA) was able to induce three different pathways, ectodermal, mesodermal and endodermal, in a developmentally pluripotent germ cell tumour.

There are only limited reports on induction of differentiation of solid tumour cells *in vivo* and they are restricted to murine embryonal carcinoma cells injected into syngeneic mice. A significant degree of differentiation was observed in teratocarcinomas when RA was injected directly into the tumour (Speers and Altmann, 1984) or when several retinoids were administered in the diet (McCue *et al*., 1988).

The mechanism(s) underpinning the ability of retinoids to inhibit proliferation and clonogenicity of malignant cells and modulate their differentiation *in vitro* are thought to be related to their ability to modulate gene expression. This ability is mediated by retinoic acid receptors (RARs) and retinoid X receptors (RXRs), nuclear receptors which belong to the superfamily of steroid hormone receptors (reviewed in Chambon, 1996). RARs bind both natural retinoids ATRA and 9-*cis*-retinoic acid (9-*cis*-RA), whereas the RXRs bind only 9-*cis*-RA (Chambon, 1996). Retinoid receptors modulate the expression of their target genes by interacting as either homodimers or heterodimers with specific DNA response elements (Chambon, 1996). RXRs dimerize with and enhance the transcriptional activity not only of RARs but also of thyroid hormone receptor, vitamin D_3 receptor, PPARs and several orphan receptors (Chambon, 1996). The RA nuclear receptors may also interact antagonistically with components of other signal transduction pathway such as the AP-1 (jun–fos) transcription factor complex in stromelysin, collagenase promoters possibly by direct protein–protein interactions.

It appears that RARs may be necessary but not sufficient for mediating the effects of most retinoids on cell growth and differentiation. For example, RAR-αs

expressed by most human leukaemias (fresh cells and cell lines) regardless of their responsiveness to RA. Thus, gene regulation by retinoids may depend on the relative concentrations of particular RARs, RXRs and cofactors, the nature of the RAREs in that gene and the presence of a number of other transcription factors.

Many genes are regulated by retinoids. Some may be regulated directly by binding of receptors to their promoter region (e.g. RAR-β, cytochrome P-450RAI, homeobox genes) whereas others may be regulated indirectly by antagonism of the transcription factor activator protein 1 (e.g. collagenase). Different receptors may regulate the expression of distinct subsets of genes related to either growth or differentiation. Recently, a systematic study examined the expression patterns of genes in the cell line NB4 before and after ATRA treatment using complementary DNA array, suppression–subtractive hybridization and differential display polymerase chain reaction. A total of 100 genes were up-regulated 12–48 h after ATRA treatment, while the expression of 59 of 69 down-regulated genes was suppressed within 8 h. The transcriptional regulation of eight induced and 24 repressed genes was not blocked by cycloheximide, which suggests that these genes may be direct targets of the ATRA signalling pathway. Several cytosolic signalling pathways, including JAKs/STAT and MAPK, have been implicated in the effects of ATRA.

Tumour Necrosis Factor Alpha

Tumour necrosis factor alpha (TNF-α) is a 17-kDa cytokine which can induce differentiation, growth arrest or apoptosis. The effects of TNF on cellular differentiation have been demonstrated in malignant haematopoietic cells and cells derived from solid tumours. TNF treatment of a human rectal adenocarcinoma cell line induced features of early-stage differentiation, with goblet-like cell characteristics. The cells were growth-inhibited by TNF and exhibited enhanced expression of high molecular weight mucin glycoproteins. The induction of these differentiation characteristics correlated with reductions in epidermal growth factor receptor (EGF-R) levels and activity. TNF-α reduced proliferation and DNA synthesis in a human pancreatic adenocarcinoma cell line, without loss of viability. Parallel to these changes was an increase in carbonic anhydrase II mRNA, a marker for pancreatic cells of ductal origin. Likewise, TNF-α induced neuroblastoma cell lines to produce neurofilament proteins and adhesion molecules associated with differentiation. This induction was mediated by a calcium-independent inducible form of nitric oxide synthase and was accompanied by growth arrest. In cultured mammary carcinoma cells, TNF-α was shown to stimulate MUC1, isoactin and epithelial cell adhesion molecule expression. The various biological activities of TNF are signalled through two distinct receptors, p55 and p75. The differentiation-inducing activity of TNF-α was signalled through the TNF receptor, p55, via protein kinase C.

Interferons

Interferons (IFNs) are a unique class of cytokines in that they stimulate antiviral, antitumour and antigen presentation. They have been classified as interferon alpha (IFN-α), beta (IFN-β) and gamma (IFN-γ) according to their cellular origin (leukocytes, fibroblasts and lymphocytes, respectively). Because of their ability to inhibit malignant cell growth and phenotypic transformation, promote cellular differentiation and enhance apoptosis, they may be useful for cancer therapy.

Interferons inhibit *in vitro* the proliferation and colony formation in agar of malignant cells including myeloma, Burkitt lymphoma, erythroleukaemia, breast carcinoma, neuroblastoma and lung cancer. IFNs also modulated cell differentiation; in some cell types, IFNs stimulated differentiation and in others inhibited differentiation. IFN-β stimulated the differentiation of human melanoma cell lines as evidenced by increased pigmentation. In human HL-60 myeloid leukaemia cells, all three IFNs inhibited cell proliferation, but only IFN-γ induced differentiation. IFN-β suppressed the growth and enhanced squamous differentiation and apoptosis in cultured NSCLC cells. IFN-β enhanced squamous differentiation in cell lines with squamous features, whereas it induced apoptosis in cell lines with glandular features. IFN-β and IFN-γ modulated the growth and differentiation of head and neck squamous carcinoma in monolayer culture.

The interferons exert their multiple effects on cell proliferation, differentiation and possibly apoptosis by binding to cell-surface receptors through which they transmit a signal that results in the activation of transcription of numerous genes within minutes of receptor occupancy (Darnell *et al*., 1994). IFN-α and IFN-β share the same cell-surface receptor to transmit their signal, whereas IFN-γ has its own receptor. The signal transduction is initiated by the binding of interferon to its receptor. In the case of IFN-α, binding to the IFN-α/β receptor results in the activation of two types of tyrosine kinases in the cytoplasm: the Janus kinase 1 (Jak 1) and the tyrosine kinase 2. These kinases phosphorylate cytoplasmic proteins that contain Src homology (SH2 and SH3) domains called Stats (signal transducers and activators of transcription). Stat 1α is a 91-kDa protein, which can also appear as a spliced form of 84 kDa (Stat 1β), and Stat 2 is a 113-kDa protein. The Stat proteins undergo phosphorylation and form a complex called the ISGF3 (interferon-stimulated gene factor 3) with a cytoplasmic protein of 48 kDa. The complex is translocated into the cell nucleus and there the ISGF3 complex binds via the 48-kDA protein to a specific DNA sequence (IFN-stimulated response element or ISRE) in the promoter region of IFN-stimulated genes

(ISGs) and activates their transcription (Darnell *et al.*, 1994). The binding of IFN-γ to its receptor activates JAK1 and JAK2, which phosphorylate Stat 1α. The activated Stat 1α then migrates into the cell nucleus and binds directly to IFN-γ activated site (GAS) and stimulates gene transcription (Darnell *et al.*, 1994). Thus, all three IFNs share Stat 1 and JAK1 in their signalling. The STAT signalling pathway can play essential roles in cell differentiation, cell cycle control and development. In addition, it has been shown that activation of the STAT signalling pathway by IFN-γ in cervical and breast cancer cells can induce apoptosis through the induction of caspase 1 gene expression.

IFN-γ was found to inhibit cell proliferation by blocking progression in mid-G_1 phase associated with a block in Rb phosphorylation, which may be responsible for the down-regulation of cdk2–6, cyclin A and c-Myc in Daudi Burkitt lymphoma cells and in normal epidermal, mammary and tracheobronchial epithelial cells. (See the chapter *Signalling by Cytokines*.)

Combinations of Agents

The same rationale that has led to the successful application of combination of cytotoxic agents with nonoverlapping toxicities and distinct mechanisms of action can be applied to differentiation-inducing agents. Extensive studies were carried out with the myeloid leukaemia cell line HL-60 to define the efficacy of combinations of retinoids and other agents (Breitman and He, 1990). Such studies have demonstrated additive or synergistic effects of retinoids and the following agents: dimethyl sulfoxide, dimethylformamide, hexamethylenebisacetamide, butyrate, tiazofurin, IFNs, TNF-α, 6-thioguanine, 5-aza-2′-deoxycytidine, actinomycin, granulocyte colony-stimulating factor and interleukin-6. Studies with embryonal carcinoma have shown that a combination of ATRA and cyclic AMP and cAMP elevating agents induces a distinct pathway of endodermal differentiation compared with that induced by RA alone. The combination of RA and tamoxifen was found to be more effective in suppressing the growth of human breast carcinoma cells than each agent alone.

ATRA Plus IFN

The efficacy of the combination of IFN-α or IFN-γ and ATRA in induction of differentiation and growth inhibition was detected initially *in vitro* in established leukaemia cell lines (e.g. HL60, U937). The effects of IFNs and retinoids were either additive or synergistic, depending on the cell system evaluated, and distinct differentiation pathways could be stimulated in different cell types. Further, IFN-α restored responsiveness to ATRA in ATRA-resistant HL60 cells. Likewise, IFN-γ restored responsiveness to ATRA in ATRA-resistant v-myc expressing U937 cells. Further studies with fresh leukaemic cells from AML patients treated in short-term cultures with IFNs and ATRA also demonstrated synergistic growth inhibition and differentiation induction. In addition, increased inhibition of clonal growth and differentiation was observed after *in vitro* RA treatment of cells from patients treated with IFN-α *in vivo*. Additive or synergistic growth inhibition of various human tumour cell lines *in vitro* was reported for the combination of IFN-α or IFN-γ and ATRA or other retinoids. These effects were sometimes also associated with differentiation induction, particularly in neuroblastoma cells. Tumour cell types in which the combination of the two agents showed greater growth inhibition than each agent alone included breast carcinoma, osteosarcoma, ovarian carcinoma, squamous cell carcinoma, neuroblastoma, non-small cell lung carcinoma and cervical carcinoma. Furthermore, the growth of human neuroblastoma tumours in nude mice was inhibited synergistically by the combination of IFN-γ and ATRA.

In various cell lines, including those derived from APL, ATRA induces directly the expression of two transcription factors, Stat 1 and IRF-1 which play central roles in the IFN signal transduction. In addition, ATRA induces IFN-α synthesis and enhances the IFN-induced Stat activation and increased the binding of ISGF-3 and the transcription of ISGs in embryonal carcinoma and breast cancer cells.

Retinoids Plus 1,25-Dihydroxyvitamin D_3

Combinations of $1\alpha,25(OH)_2D_3$ analogues and ATRA or 9-*cis*-RA exhibit additive or synergistic effects on differentiation of leukaemia cell lines (e.g. HL-60, U937 and NB4). Furthermore, vitamin D_3 compounds augment apoptosis induced by 9-*cis*-RA in HL-60 cells and the combination down-regulates the expression of the anti-apoptotic gene product Bcl-2 while increasing the pro-apoptotic gene product Bax. The molecular mechanism underlying the effects of the combination of these agents involves the interactions of the nuclear receptors for vitamin D (VDR) and 9-*cis*-RA (RXR), which are able to form heterodimeric complexes and transcriptionally activate or repress target gene expression.

ATRA and Histone Deacetylase Inhibitors

TSA acted synergistically with ATRA to enhance the differentiation of the leukaemia cell lines U937, HL60 and NB4 cells. Further, the combined treatment of TSA with ATRA induced differentiation even in ATRA-resistant HL60 and NB4 cells. The mechanism of this interaction has been elucidated recently and it is related to the finding that transcriptional regulation by RARs involves modifications of chromatin by HDACs, which are recruited to RA-target genes by nuclear corepressors. The differentiation of APL cells is blocked by the PML–RAR-α fusion protein, which recruits the nuclear corepressor–HDAC complex. However, this block can be reversed by high doses of ATRA, through the release of HDAC activity from PML–RAR-α. Interestingly, inhibitors of histone

deacetylase such as TSA can potentiate retinoid-induced differentiation of ATRA-sensitive and restore the retinoid responses of RA-resistant APL cell lines (Lin *et al*., 1998). Further, TSA was shown recently to restore ATRA-dependent transcriptional activation and triggered terminal differentiation of primary blasts from acute myeloid leukaemia M2 and M4 in which the AML–ETO fusion protein blocks ATRA signalling (Ferrara *et al*., 2001). Likewise, TSA enhanced the response to ATRA in APL cells with t(11;17) translocation, which leads to the production of the fusion protein PLZF–RAR-α and a poor response to ATRA. In these cells, TSA inhibits the HDAC enzyme that is associated with PLZF–RAR-α corepressor complex but cannot be dissociated after the addition of high-dose ATRA alone.

ATRA and Arsenic Trioxide

Arsenic trioxide induces nonterminal differentiation of malignant promyelocytes and promotes apoptosis. In contrast, ATRA induces terminal differentiation that eventually leads to apoptosis. Both agents enhance the degradation of the leukaemogenic chimaeric protein PML–RAR-α resulting from the t(15;17) translocation characteristic of APL by different pathways, suggesting a possible therapeutic synergism. Indeed, arsenic trioxide synergized with ATRA to induce differentiation in ATRA-resistant APL cells but the dose and the sequence of their combination were important. Severe combined immunodeficient mice bearing APL–NB4 cells showed an additive survival effect after sequential treatment, but a toxic effect was observed after simultaneous treatment with ATRA and arsenic trioxide. These data suggest that combined arsenic trioxide and ATRA treatment may be more effective than single agents in ATRA-resistant patients (Jing *et al*., 2001).

IFN Plus Mezerein

Treatment of human melanoma cells with a combination of recombinant human IFN-β and the antileukaemic compound mezerein (MEZ) results in irreversible growth arrest, suppression of tumorigenic properties and terminal cell differentiation by increasing the expression of numerous genes.

TNF-α Plus 1α,25-dihydroxyvitamin D_3

The combination of TNF-α and 1α,25$(OH)_2D_3$ showed efficacy in enhancing the differentiation of chemically transformed human mammary epithelial cell lines as evidenced by increased expression of pan cytokeratin, mucin 1 and the adhesion molecules CEA, ICAM-1 and CD44v6.

CLINICAL ASPECTS

The potential of agents that stimulate cell differentiation to serve for cancer therapy has been studied extensively *in vitro* and in animal models. Such agents can suppress growth and enhance differentiation, which may also lead to apoptosis. Only a few of the numerous differentiation inducing agents shown in Table 1 have been examined in clinical trials and even for those that have been investigated, most trials were phase I or II. The only definitive demonstration of the efficacy of differentiation therapy is the treatment of acute promyelocytic leukaemia patients with ATRA.

HMBA

A few clinical studies explored the potential of using HMBA in cancer therapy. Young *et al*. (1988) treated 33 patients with different types of advanced cancer with HMBA by 10-day continuous i.v. infusion courses. Patients with no disease progression were given repeat courses of HMBA at 28-day intervals. Thrombocytopenia with haemorrhage and disorientation and confusion were the dose-limiting toxic effects and the maximal tolerated dose was 28 $g\,m^{-2}\,day^{-1}$ for 10 days. HMBA was cleared from plasma with a mean half-life of 2.5 h. Mean plasma steady-state HMBA concentrations of 1 $mmol\,L^{-1}$ could be maintained for 10 days with acceptable patient tolerance; however, HMBA concentrations in excess of 1.4 $mmol\ L^{-1}$ for 10 days were toxic. Nonetheless, objective antitumour effects were observed in five patients, with one partial remission in a patient with non-small cell lung cancer. Transient regression of cutaneous metastases was observed in three patients with breast carcinoma and one patient with colorectal carcinoma. Andreeff *et al*. (1992) conducted a phase II clinical trial of HMBA in 41 patients with myelodysplastic syndrome (MDS) or acute myelogenous leukaemia (AML). HMBA was administered by continuous infusion for 10 days and repeated after an interval of 18–75 days. HMBA induced a complete remission (CR) in three patients and a partial remission (PR) in six patients. The median duration of CR was 6.8 months (range 1.3–16 months) and that of PR was 3.7 months (range 1–7 months). The mean HMBA plasma levels were 0.86 ± 0.04 and $0.87 \pm 0.12\,mmol\,L^{-1}$ in responders and nonresponders, respectively. In certain patients HMBA induced differentiation of transformed haematopoietic precursors as indicated by morphological and chromosome analyses. The most prominent toxicity, thrombocytopenia, was reversible. Thus, it appears that it was not possible to achieve *in vivo* HMBA concentrations of 3–5 $mmol\,L^{-1}$ that are optimal for inducing differentiation of a variety of transformed cell lines *in vitro*. This has led to a search for more active compounds and a second generation of hybrid polar compounds were synthesized and characterized. Among these compounds was SAHA, which exhibited a far greater potency in inducing murine erythroleukaemia cell differentiation than HMBA. SAHA has been evaluated in animal models for antitumour efficacy and toxicity phase I human clinical trials are

ongoing in which analysis of histone acetylation serves as an intermediate marker of HDAC inhibitory activity (Marks *et al*., 2000).

Butyrate

Only very few clinical trials have been conducted with butyrate or its derivatives. A case report described the results of parenteral administration of butyrate ($500\,mg\,kg^{-1}\,day^{-1}$) for 10 days to a child with AML in relapse, who was resistant to conventional therapy. This treatment resulted in elimination of myeloblasts from the peripheral blood. An indication for differentiation has come from an analysis of the bone marrow, which showed an increase in mature myeloid cells and a reduction in myeloblasts from 80 to 20%. No impairment of liver or renal function and no coagulation abnormalities were observed during butyrate treatment at the above dose. Arginine butyrate was given in a phase I trial together with interleukin-2 to six patients with advanced metastatic colon cancer delivered via continuous intravenous infusion on days 1–6 with escalating doses starting at $2\,g\,kg^{-1}\,day^{-1}$. A daily ArgB dose of $2\,g\,kg^{-1}$ was delivered for nine cycles. No clinical responses were seen. The dose-limiting toxicities were fatigue and liver function abnormalities.

A clinical trial with the prodrug tributyrin compared the toxicities of escalating doses from 50 to $400\,mg\,kg^{-1}\,day^{-1}$ given p.o. after an overnight fast, once daily for 3 weeks, followed by a 1-week rest. Thirteen patients with solid tumours were treated and showed variable toxicities. Grade 1 and 2 toxicities included diarrhoea, headache, abdominal cramping, nausea, anaemia, constipation, azotaemia, lightheadedness, fatigue, rash, alopecia, odour, dysphoria and clumsiness. Grade 3 toxicities consisted of nausea, vomiting and myalgia. Peak plasma butyrate concentrations ranged from 0 to $0.45\,mmol\,L^{-1}$ (between 0.25 and 3 h after dose), but butyrate disappeared from plasma by 5 h after dose. Butyrate pharmacokinetics were not different on days 1 and 15. Because peak plasma concentrations near those effective *in vitro* ($0.5–1\,mmol\,L^{-1}$) were achieved, the authors considered pursuing dose escalation with dosing three times daily, beginning at a dose of $450\,mg\,kg^{-1}\,day^{-1}$ (Conley *et al*., 1998). Thus, there is only one case of differentiation *in vivo* by butyrate.

Aromatic Fatty Acids

In a phase I trial, phenylacetate was given to 17 patients with advanced solid tumours as a single i.v. bolus dose followed by a 14-day continuous i.v. infusion. Twenty-one cycles of therapy were administered at four dose levels. Stable PSA levels were maintained for more than 2 months in three of nine patients with metastatic, hormone-refractory prostate cancer. Another patient experienced less bone pain. One of six patients with glioblastoma multiforme had functional improvement for more than 9 months. Continuous i.v. infusion rates resulting in serum phenylacetate concentrations exceeding the K_m ($105.1 \pm 44.5\,\mu g\,mL^{-1}$) often resulted in rapid drug accumulation and dose-limiting toxicity (emesis and reversible central nervous system depression). Because the goal is to maintain serum drug concentrations greater than $250\,\mu g\,mL^{-1}$, which are required for *in vitro* activity, a subsequent trial was designed. In the second trial patients received phenylacetate as a 1-h infusion twice daily at two dose levels, 125 and $150\,mg\,kg^{-1}$ for a 2-week period. The intermittent exposure to drug concentrations exceeding $250\,\mu g\,mL^{-1}$ allowed time for drug elimination to occur between doses to minimize accumulation. Patients who did not experience dose-limiting toxicity or disease progression received additional cycles of treatment at 4-week intervals. Eighteen patients received 27 cycles of therapy. Dose-limiting toxicity, consisting of reversible central nervous system depression, was observed in three patients at the higher dose level. One patient with refractory malignant glioma had a partial response, and one with hormone-independent prostate cancer achieved a 50% decline in PSA level, which was maintained for 1 month. These phase I studies have indicated that phenylacetate at $125\,mg\,kg^{-1}$ twice daily for two consecutive weeks is well tolerated and that high-grade gliomas and advanced prostate cancer are plausible targets for phase II clinical trials (Thibault *et al*., 1995).

Recent phase I studies with phenylbutyrate given by i.v. or oral routes have shown that this drug is well tolerated clinically at concentrations which effect acetylation of histones *in vitro*. However, higher doses lead to reversible CNS depression. Although these studies do not allow an assessment of efficacy, the current development of phenylbutyrate is for combination with other agents based on indications from *in vitro* studies (Gore and Carducci, 2000).

PPAR Ligands

The finding that PPAR-γ agonists can induce terminal differentiation of normal preadipocytes and human liposarcoma cells *in vitro* suggested that such ligands may be useful clinically because the differentiation status of liposarcoma is predictive of clinical outcomes. Thus, enhancement of the differentiation status of a liposarcoma may have an impact on its clinical behaviour. With this rationale in mind, the PPAR-γ ligand troglitazone was administered to three patients with intermediate- to high-grade liposarcomas. Troglitazone induced histological and biochemical differentiation *in vivo* as evidenced by extensive lipid accumulation in tumour cells and increases in tumour triglycerides compared with pretreatment biopsies. In addition, differentiation markers in the adipocyte lineage were induced and the proliferation marker Ki-67 was decreased. These results indicate that differentiation

can be induced pharmacologically in a human solid tumour (Demetri *et al*., 1999).

A larger phase II study was conducted in 41 patients with histologically confirmed prostate cancer and no symptomatic metastatic disease. These patients were treated orally with troglitazone. Treated patients have shown prolonged stabilization of PSA. In addition, one patient had a dramatic decrease in serum PSA to nearly undetectable levels. These data suggest that PPAR-γ has the potential to be used for differentiation therapy of human prostate cancer and this potential should be explored further.

Vitamin D_3 Analogues

The clinical use of 1α,25$(OH)_2D_3$ in cancer prevention or differentiation therapy is hampered by its hypercalcaemic activity. To overcome this limitation, new vitamin D analogues have been synthesized and screened for exerting potent cell regulatory effects, but with weaker effects on the calcium metabolism than those of 1α,25$(OH)_2D_3$. Several such analogues have been identified including 23-D, 16-23-D and Seocalcitol (EB 1089) that have the potential to be used clinically owing to their reduced action on calcium metabolism.

Analogues of 1α,25$(OH)_2D_3$ have been synthesized which exhibited at least 10-fold higher potency than the parental 1α,25$(OH)_2D_3$ in inhibition of clonal growth of HL-60 myeloid leukaemia cells. (22*R*)-1α,25-$(OH)_2$-16,22,23-triene-D_3 had an ED_{50} of approximately $6\times10^{-11}\,mol\,L^{-1}$, whereas 1α,25$(OH)_2D_3$ gave an ED_{50} of approximately $10^{-8}\,mol\,L^{-1}$ on clonogenic cells from patients with AML. It was suggested that clinical trials, especially in a setting of minimal residual disease, may be warranted after assessment of *in vivo* toxicity. *Ex vivo* purging of leukaemic cells from normal human peripheral blood mononuclear cells for stem cell transplantation has also been proposed with these analogues because they inhibited the growth of leukaemia cells without affecting normal bone marrow CFU-GM cells and only mild inhibiton of clonogenic cells from peripheral blood.

EB 1089 was found to be 50–200 times more potent than 1α,25$(OH)_2D_3$ with respect to regulation of cell growth and differentiation both *in vitro* and *in vivo*, yet it displayed a reduced calcaemic activity *in vivo* compared with that of 1α,25$(OH)_2D_3$. Recent clinical evaluation of EB 1089, which was focused mainly on establishing a maximum tolerated dose in cancer patients, has demonstrated that the low calcaemic activity observed in animals can be reproduced in cancer patients. Furthermore, EB 1089 induced regression of tumours (e.g. hepatocellular carcinoma). Although these findings suggest that the development of EB 1089 as an anticancer drug is warranted, such a decision must await the completion of ongoing controlled clinical trials (Hansen *et al*., 2000).

Retinoic Acid

Acute promyelocytic leukaemia (APL), which is designated M3 in the FAB classification of acute myeloid leukaemias, was found to respond to orally administered ATRA ($45\,mg\,m^{-2}$) *in vivo* (Huang *et al*., 1988). In contrast to classical anthracycline–cytarabine chemotherapy, ATRA induced complete remission in about 85% of APL patients by inducing differentiation of blast cells to granulocytes without inducing aplasia of the bone marrow. Although complete remissions occur in most APL patients, the response is transient, possibly because ATRA induces P-450 enzyme that leads to a progressive decline in plasma drug concentrations. Consequently, resistance develops and all patients treated with ATRA alone eventually relapse.

In an attempt to overcome this problem, ATRA was used in several randomized and nonrandomized trials for remission induction followed by several cycles of consolidation chemotherapy, usually with idarubicin and cytosine arabinoside. The results of such studies have shown that ATRA significantly increased event-free survival and survival and decreased the incidence of relapse by comparison to chemotherapy alone in newly diagnosed APL. This approach yielded an approximately 2.5-fold increase in the proportion of long-term survivors who have presumably been cured of this disease (Soignet *et al*., 1997). A recently completed randomized long-term European APL group study has confirmed the superiority of the combination of ATRA followed by chemotherapy over chemotherapy alone in newly diagnosed APL, and concluded that ATRA should be incorporated in the frontline treatment of APL (Fenaux *et al*., 2000).

Recently, APL patients resistant to ATRA and conventional chemotherapy were found to respond to arsenic trioxide. This agent was shown to induce apoptosis in APL cells by down-regulating the antiapoptotic protein Bcl-2, increasing the activity of caspases and enhancing the degradation of PML–RAR-α (Chen *et al*., 1996; Soignet *et al*., 1998).

ATRA caused in some APL patients a potentially fatal retinoic acid syndrome characterized by fever, respiratory disease, hypotension and increased leukocyte count (Tallman *et al*., 2000).

The mechanism of differentiation induction by ATRA in APL cells is unique and fascinating. APL is associated with a specific t(15:17) translocation. The breakpoint on chromosome 17 reciprocally rearranges RAR-α with a putative transcription factor on chromosome 15 designated PML for promyelocytic leukaemia. Consequently, the APL cells produce a fusion protein called PML–RAR-α (de The *et al*., 1990), which retains the DNA binding domain of RAR-α and the ability to form homodimers. The formation of this fusion protein is thought to be the reason for the block in differentiation that drives the leukaemogenesis (Randolph, 2000). The fusion protein can

form homodimers and act as a dominant negative inhibitor of retinoid signalling by recruiting a corepressor complex, which includes an HDAC (Lin and Evans, 2000). Paradoxically, among myeloid leukaemias, APL (AML-M3) is the most sensitive to induction of differentiation by pharmacological levels of ATRA, despite the disruption of retinoid signalling. At the higher doses, ATRA causes the dissociation of corepressor from the PML–RAR-α and enhances the degradation of the fusion protein. Consequently, the normal RAR-α can function in the absence of a dominant negative inhibitor to regulate the expression of numerous genes associated with differentiation and growth (Zhang *et al*., 2000).

Combination of 13-*cis*-Retinoic acid and IFN-α

Several clinical trials using combination of retinoic acid and interferons were conducted in patients with skin cancer (Lippman *et al*., 1997), cervical carcinoma (Lippman *et al*., 1997), renal cell carcinoma and prostatic carcinoma. In a few of these, some efficacy has been demonstrated. However, there was no evidence that the treatment resulted in differentiation induction, and therefore, they are not included in this chapter.

CONCLUSIONS

The concept of differentiation therapy is a very attractive one in that it is based on understanding the block in normal differentiation and the mechanisms to overcome the block or induce alternative pathways to reach the mature phenotype. *In vitro* studies provided ample support for the concept and the elegant mechanistic and clinical studies with APL have demonstrated the proof of principle that differentiation therapy can be effective *in vivo*. Unfortunately, the success observed with APL in 1988 has not been reproduced with solid tumours. However, the recent preliminary studies with PPAR-γ ligands and histone deacetylase inhibitors suggest that these agents alone or in combination with other differentiation agents or with cytotoxic agents might show efficacy in clinical trials with various malignancies.

CARCINOGENESIS: THE BASIS OF RISK, THE TARGET OF PREVENTION

Cancer is a late, nonobligate stage of carcinogenesis, the long process during which cumulative alterations in DNA structure and function are expressed within and across all biological levels (e.g. RNA, protein, organelle, cell, tissue, organ, organism), as shown in **Figure 1**. Endogenous mechanisms, such as carcinogen detoxification, DNA repair, selective apoptosis, immunological surveillance and stromal responses, limit progression to dysregulated proliferation, clonal anarchy and cancer. Chemoprevention mimics or augments these natural defences with pharmacological agents that prevent, reverse or retard carcinogenesis during what is typically a decades-long latency to cancer (Sporn, 1976). For practical purposes, chemoprevention addresses carcinogenesis up to the point of invasion across the basement membrane, whereas clinically evident cancer is the domain of chemotherapeutics. In fact, the boundaries between cancer prevention and therapeutics are eroding – as are traditional notions of health and disease – with the advent of new technologies that allow us to detect and eradicate incipient disease long before it becomes clinically evident or lethal.

LEVELS OF PREVENTION

Terminology for cancer prevention derives from the more mature prevention sciences of cardiovascular and infectious diseases. As applied in preventive oncology, primary prevention refers to the identification and avoidance of carcinogens in unscreened, ostensibly healthy people presumed at average risk of cancer. Examples of primary prevention include tobacco cessation to lower the risk for lung cancer, dietary or lifestyle modifications to reduce the incidence of cardiovascular events and vaccination to reduce the incidence of hepatitis B infection (and also downstream consequences such as cirrhosis and hepatocellular carcinoma). Secondary prevention involves the identification of cohorts at greater than average risk of disease through screening for subclinical pathology followed by interventions to arrest disease progression (e.g. mammography followed by surgical resection, colonoscopy with adenomectomy). Analogies to secondary prevention in other fields of medicine include screening for persons with elevated serum lipid profiles followed by dietary modification and/or cholesterol-lowering drugs to reduce the incidence of cardiovascular events, and human immunodeficiency virus (HIV) testing of pregnant women followed by AZT administration to reduce viral infection of at-risk neonates. Finally, tertiary prevention involves patients with diagnosed disease in whom applied interventions may improve palliation and reduce complications. Examples of tertiary prevention include bisphosphonates to reduce the risk of skeletal fractures in breast cancer and multiple myeloma, aspirin to reduce cardiovascular events in patients with coronary artery disease, and glucose control to limit end-organ complications of diabetes.

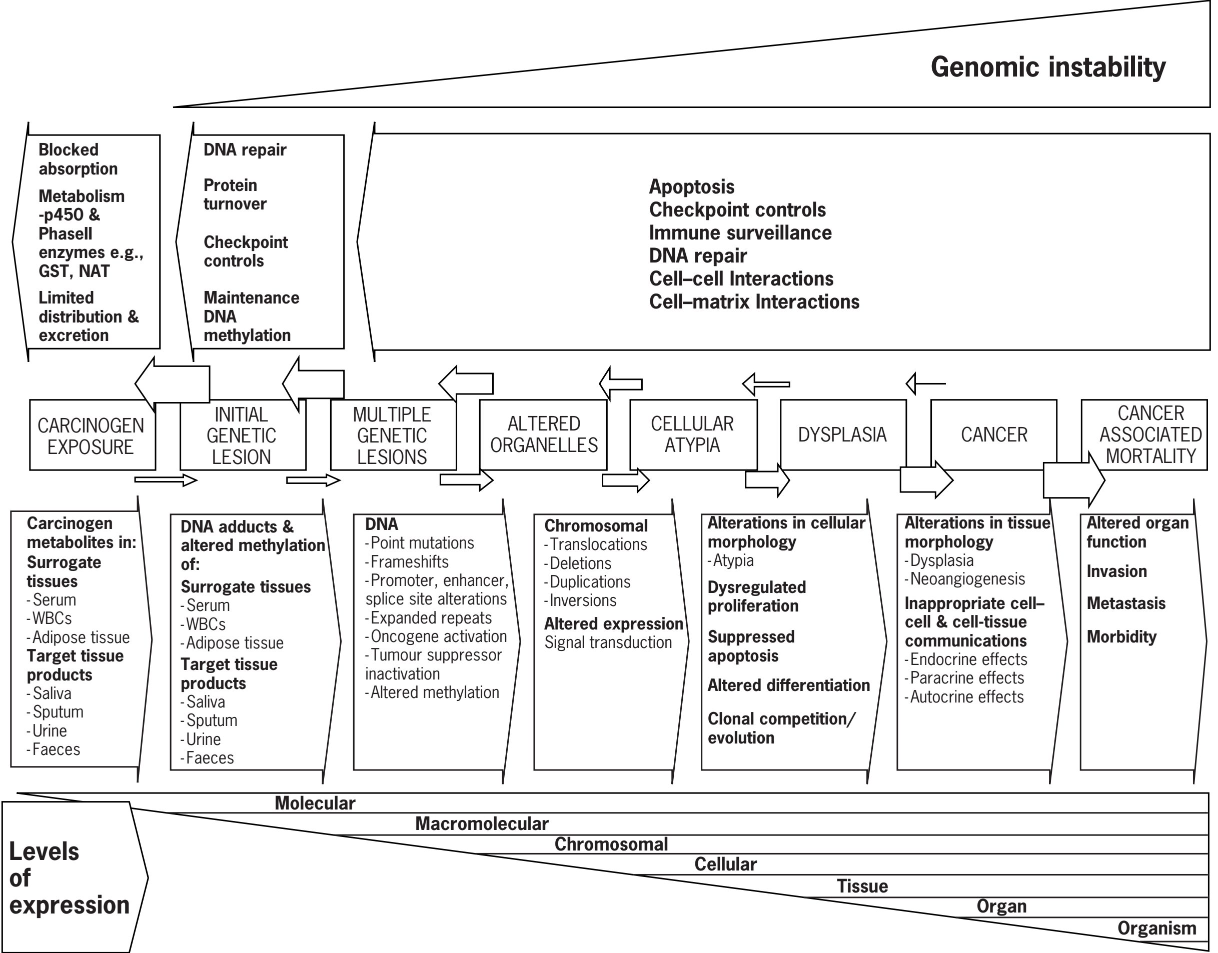

Figure 1 Mechanisms underlying carcinogenesis – a dynamic process. (Figure courtesy of Asad Umar, PhD, DVM.)

Context, rather than agent, dictates the grade of prevention. This context, however, is in flux owing to technological advances in biological imaging and molecular analyses that revolutionize our ability to visualize and characterize carcinogenesis (i.e. disease) at increasingly primitive levels of biological organisation. As a result, the demarcation between prevention and therapeutics is increasingly indistinct. Carcinogenesis is now recognized as a disease worthy of intervention, but it is a moving target.

BIOMARKERS

Progress in preventing cancer depends, in large measure, on the identification, development and validation of accurate, reliable and early biomarkers of carcinogenesis – events of structure or function on any level of biological organisation that convey insights into biology or pathology on a higher (and typically later) level, as shown in **Table 1**. Structural abnormalities are typically aberrations in number or component integrity within a biological level. Functional abnormalities may be quantitative or qualitative (i.e. inappropriate function relative to healthy biological need) and probably represent the more important criterion, but one that current technology measures with limited accuracy. As a result, functional dynamics are often deduced from structural abnormalities (e.g. loss of normal p53 activity inferred through overexpression of mutant p53). Biomarkers provide seminal insights into both the biological past and future. Molecular markers (e.g. DNA, RNA or protein) provide invaluable mechanistic insights into subclinical carcinogenesis, whereas tissue markers reflect imminent clinical pathology. Because of their proximity to clinical disease, tissue markers better justify the use of novel interventions in persons at risk of cancer.

Epithelial dysplasia (literally ‘disordered growth’) is architectural disarray at the tissue level spawned by clonal anarchy at lower biological levels, as described in **Table 2**. These neoplastic changes often occur adjacent to cancer foci, and are likely precursors to invasive disease. At a minimum, dysplasia reflects a biological milieu that is permissive for carcinogenesis. Although debate persists as to the absolute clinical risk associated with carcinogenesis identified at tissue (e.g. dysplasia), cellular (e.g. atypia) or even molecular (e.g. genetic mutation) levels, the potential reversibility of this process is the central premise of

Table 1 Hierarchy of biological aberrations (biomarkers) in carcinogenesis[a]

Level	Structural aberrations	Functional aberrations
DNA	Adducts Mutations Double minutes Translocations Hypo-/hypermethylation Hypo-/hyperploidy	Transcriptional over-/underexpression Transcriptional corruption Genomic instability
RNA	Inadequate copies Excessive copies Corrupted copies	Translational over-/underexpression Translational corruption
Protein	Inadequate Excessive Corrupted 1° structure 2° structure 3° structure 4° structure	Over-/ under-/ inactive Aberrant enzymatic function Impaired DNA repair Impaired DNA/ RNA replication Impaired post–translational modelling Impaired regulatory functions Impaired signal transduction Impaired maturation Impaired metabolism
Organelle	Aberrant nuclear morphology Enlarged nuclear–cytoplasmic ratio	Over-/ under-/ inactive
Cellular	Atypia	Over-/under-/inactive Functional immaturity Aberrant sensitivity to external growth stimuli
Tissue	Dysplasia Carcinoma *in situ* (CIS) Increased microvessel density Submucosal invasion Stromal reaction	Dysregulated population dynamics (increased proliferation and/or reduced apoptosis) Loss of intercellular adhesion Cell migration Neoangiogenesis Extracellular matrix degradation
Organ	Local invasion Metastasis	Functional compromise Mass effects

chemoprevention. In organs that are more biopsy accessible (e.g. skin, bladder, oral mucosa, oesophagus, stomach, colorectum, cervix), preinvasive neoplasia [e.g. actinic keratosis (AK), dysplasia, adenomas] has become an accepted target for intervention. The current standard of care is to intervene against dysplastic lesions, with incisional biopsy for diagnosis and risk reduction, followed by serial surveillance, focal resection or even organ extirpation, depending on the risk of the lesion(s) and of the patients.

In addition to clinical response criteria (e.g. adenoma, dysplasia or plaque regression), valuable mechanistic insights into the genesis of preinvasive neoplasia are often gleaned from prevention trials that integrate evaluations of multiple response biomarkers at different levels of biological organisation (i.e. molecular level (*APC* mutations, genomic expression, cyclooxygenase activity) and cellular/tissue levels (proliferation, apoptosis, aberrant crypt foci (ACF) number/morphology, adenoma regression/prevention). Such concomitant assessments are critical, because reliance upon any biomarker in isolation is likely

to result in incomplete or flawed interpretations of pathobiological mechanisms underlying risk and response.

Biomarker Identification and Development

Candidate biomarkers may arise out of mechanistic or correlative insights derived from a variety of research settings – *in vitro*, *in vivo*, observational or clinical. Biomarkers may be categorized according to the intended application as (1) risk markers that estimate the probability of some later event in the neoplastic process, also referred to as exposure, susceptibility, diagnostic or prognostic biomarkers, or (2) response markers that measure response to an intervention, also referred to as drug, surgical, radiological or dietary effect, or outcome biomarkers (see **Figure 2**).

Although all cells within an epithelial sheet inherit a common susceptibility to neoplasia, variable exposure to genetic and epigenetic insults (i.e. carcinogens, hormones, ultraviolet radiation, etc.) results in nonuniform distribution and rates of neoplastic progression, particularly at more complex biological levels. Not surprisingly, this patchy distribution leads to critical sampling errors. In order to ensure measurement accuracy and reliability, the first step in developing a candidate biomarker involves standardization of tissue acquisition and laboratory assays for specimen analysis. Noninvasive imaging technologies, such as optical coherence tomography (OCT) and light-scattering spectroscopy (LSS), have improved clinical sampling, and laser-capture microdissection has reduced the noise-to-signal ratio in laboratory-based analyses. In addition, expression microarrays now enable concomitant assessment of multiple molecular endpoints, streamlining what has until recently entailed immensely time- and tissue-consuming evaluations of lesions within the field at risk.

Once standardized, candidate biomarkers are assessed to establish their natural history, and also their association with cancer risk cross-sectionally and over time. Often, owing to low rates of certain cancers, these interrogations are initiated through retrospective studies that compare individuals with cancer to matched control populations. Alternatively, the natural history of a promising marker may be derived from prospective studies of risk cohorts, or from the placebo arm of intervention studies that incorporate biomarkers as secondary measures of response. Risk biomarkers that correlate with the development of invasive cancer may be applied to (1) estimate risk for incident neoplasia, (2) monitor disease progression, (3) adjust interventions to optimize the therapeutic index (TI) (i.e. the benefit-to-risk ratio), (4) prioritize interventions based on mechanistic insights or (5) stratify individuals entering prevention trials to balance significant covariates.

In addition, risk markers merit further inspection as possible markers of response in prospective clinical

Table 3 Surrogate endpoint biomarkers (SEB): ideal features[a]

Area	Features
Sampling	Standardized:
	Instruments
	Collection methods
	Preassay processing
	Sample transport
	Sample storage
Assay	Well-characterized neoplastic specimen as substrate
	Reproducible methods
	Limited inter-/intra-assay variance
	High sensitivity and specificity
	Inexpensive
	Adaptable to high-volume throughput
Tissue	Pathobiological context
	Differentially expressed in normal and neoplastic tissues
	Amenable to quantitative characterization
	Well-characterized natural history
	Easily measured with minimally invasive techniques
	Amenable to serial evaluations across time
	Validated as a marker of risk
	Response
	Modulable by preventive intervention of interest
	Specific for the effect of interest
	Short latency to invasive cancer
	Modulation correlates with reduction in invasive neoplasia
	Predictive validation
	Modulation predicts reduction in invasive neoplasia
	Relevant to a range of other interventions

[a]Adapted from Hawk *et al.*, 2000.

trials of investigational agents, as described in **Table 3**. Candidate response biomarkers with demonstrated biological relevance (often, established risk markers) are first evaluated in pilot studies to demonstrate their modulation following exposure to an intervention, then advanced into short- to intermediate-term trials that incorporate placebo controls. In these trials, the placebo arm confirms the marker's natural history and association with risk, whereas the active arm provides preliminary evidence of the agent's preventive efficacy. Once a response biomarker is established to be acceptably predictive of a later event of primary interest, such as cancer incidence or cancer-related mortality, it may be applied as a surrogate for the later event (i.e. surrogate endpoint biomarker (SEB)) with a reasonable measure of certainty (Temple, 1999; Hawk *et al.*, 2000). Technically, this credential is valid only with respect to the context in which it was tested; however, in a more liberal sense it might be generalized to other interventions and risk cohorts. The internal validity of the biomarker is based on its representativeness within a particular cohort. Relevance to a reference population and a broader range of interventions, in turn, affirms the biomarker's external validity. A conceptual algorithm for identifying, developing, and validating candidate SEBs is outlined in **Figure 3**.

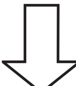
SEBs, Proven and Prospective

Validated SEBs, such as those presented in **Table 4**, facilitate preliminary efficacy testing of chemopreventive agents. This has been amply established with preinvasive lesions of the colorectum and breast. The 1993 National Polyp Study, for example, indirectly validated colorectal adenomas as SEBs for colorectal cancer in the context of surgical interventions, after showing up to 90% reductions in colorectal cancer incidence in subjects undergoing regular surveillance for adenomas, as compared with three historical control groups (Winawer *et al.*, 1993). Observational and experimental studies have also shown significant reductions in colorectal cancer mortality and, in some cases, incidence, in the context of colorectal cancer screening by stool blood-based tests or flexible sigmoidoscopy combined with colonoscopic adenomectomy. Finally, adenomas have achieved a measure of validation as SEBs in the context of medical interventions as well – over 20 observational studies confirm that nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the risk of colorectal adenomas, carcinomas and cancer-associated mortality (Smalley and DuBois, 1997).

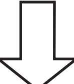
In breast cancer, preinvasive neoplastic lesions gained credibility as SEBs based on results from the National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 and B-24 trials (Fisher *et al.*, 1998, 1999). In these trials, women taking tamoxifen experienced reductions in ductal carcinoma *in situ* (DCIS) and/or invasive breast cancer. Proportional decreases in DCIS and invasive cancer provided a strong rationale for considering DCIS as an SEB for breast cancer. In response to data derived from the NSABP P-1 trial, the US Food and Drug Administration (FDA) approved the use of tamoxifen for risk reduction (i.e. prevention) in women at high risk of breast cancer. Although tamoxifen is the first agent specifically approved for cancer risk reduction, two other agents, intravesical Bacillus Calmette-Guerin (BCG) and topical fluorouracil, were approved years earlier to treat preinvasive neoplasia of the bladder and skin, respectively. Each of these approvals established dysplasia as an important target for medical interventions intended to control disease and ultimately prevent cancer. Given the brisk pace of biomarker research, dysplasia will likely achieve validation as a definitive, although probabilistic, SEB for cancer incidence in many other target organs over the next few years.

Select feasible/rational biomarkers
Based on mechanisms of disease and agent's hypothesized mechanism of action

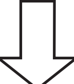
Standardize sampling
Establish target (neoplasia vs at-risk field), instruments and technique via standardized protocol



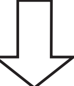
Standardize laboratory assay
Establish handling and processing methods for specimens including reagents, conditions and instruments; determine accuracy and reliability



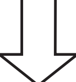
Establish status as cross-sectional risk marker for invasive neoplasia
Correlate cross-sectional risk within a population



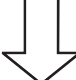
Establish status as a prospective risk marker for invasive neoplasia
Evaluate the natural history of the biomarker over times; correlate the marker with prospective risk either in a prospective study or via the placebo arm of a controlled intervention trial



Establish status as a modulable marker
Assess marker modulation between baseline and outcome in an intervention study (versus historical data on natural history or a concomitant placebo control)



Establish as a surrogate endpoint with one agent and in one model system
Correlate biomarker modulation at an intermediate time point with effects on clinical outcomes of interest (a clinical intervention, invasive cancer incidence, or another event)



Establish as a surrogate endpoint across agents and/or models
Test the predictiveness of biomarker modulation with different agents and/or in other model systems (against incident cancer or other clinical outcomes of interest); test the surrogate against combinations of agents

Figure 3 Development of tissue-based biomarkers as surrogate endpoints: a conceptual pathway. (Adapted from Hawk *et al.*, 2000.)

Table 4 Preinvasive neoplasia as markers of risk and surrogate efficacy[a]

Biomarker	Validated risk marker	Validated surrogate endpoint for surgical interventions[b]	Validated surrogate endpoint with medical interventions[c]
Ductal carcinoma *in situ* (DCIS)	✓	✓	Tamoxifen
Atypical ductal hyperplasia (ADH)	✓		Tamoxifen
Cervical intraepithelial neoplasia (CIN)	✓	✓	
Oral leukcoplakia	✓		
Oesophageal dysplasia (high grade)	✓	✓	
Colonic adenoma	✓	✓	Celecoxib
Bladder dysplasia	✓	✓	BCG, valrubicin
Prostatic intraepithelial neoplasia (PIN)	✓		
Actinic keratosis (AK)	✓	✓	5-Fluorouracil, diclofenac sodium, Aminolaevulinic acid with photodynamic therapy, masoprocol

[a]Adapted from Hawk *et al.*, 2000.
[b]Most of these dysplastic lesions are surgically removed upon identification, although only a few have been validated to demonstrate that doing so reduces the risk for subsequent cancers or cancer-associated mortality.
[c]Validation of these lesions as predictors of reduced cancer incidence is indirect in most instances, but the predictive association has been strong enough to justify approval for the treatment of a preinvasive neoplastic condition which may, therefore, reduce the risk of subsequent cancer incidence.

Table 5 Cohorts with an elevated cancer risk

Risk factor	Example
Endogenous	
Germ-line mutation	*APC* mutation (colorectal)
Genetic polymorphism	*GSTM1* −/− genotype (lung)
Family history	Two first-degree relatives with cancer and one with a precancer (colorectal, breast)
Exogenous	
Carcinogen exposure	
Chemical	Industrial benzene exposure (bladder)
Radiation	Therapeutic radiation exposure (breast)
Virus	Chronic hepatitis B infection (liver)
Somatic mutations	*p16* mutation, deletion or methylation (oesophagus)
Prevalent preinvasive neoplasia (dysplasia)	Actinic keratosis (skin) or adenoma (colorectal)
Personal history of past preinvasive neoplasia	Excised actinic keratosis (skin) or adenoma (colorectal)
Personal history of past cancer	Cancer survivor

Indeed, an expert advisory committee was recently convened under the auspices of the American Association for Cancer Research (AACR) to evaluate intraepithelial neoplasia as a target worthy of intervention.

The use of biomarkers to open up the ‘black box’ between early and late events of interest is not unique to cancer chemoprevention. Indeed, intermediate biomarkers are commonly applied in other areas of medical research and the management of chronic disease (e.g. diabetes, hypertension, HIV and cancer) to reduce morbidity and mortality through early diagnosis, and also to assess the necessity for, and responsiveness to, interventions applied with preventive or therapeutic intent. For example, serum lipid profiles and hypertension are biomarkers of risk and response that have expedited advances in cardiovascular disease research, and have had a profound impact on public health (Temple, 1999; Hawk *et al.*, 2000).

COHORTS

As noted above, carcinogenesis is fundamentally an unstable pathological process. However, even when it is expressed at the tissue level (i.e. as dysplasia), most disease regresses or remains stable, never advancing to invasive cancer. Certain populations and individuals are at increased risk of cancer due to carriage of highly penetrant susceptibility genes (e.g. *APC*, *MLH-1*, *MSH-2*, *BRCA1/2*), or environmental exposures (i.e. tobacco, radiation, exogenous hormones and hepatitis B, hepatitis C, Epstein–Barr and human papilloma viruses), as described in **Table 5**. These individuals not only have a greater likelihood of developing cancer than persons at average risk, but typically do so at an accelerated rate. As a result, trials conducted in high-risk populations may be sufficiently powered with relatively small cohorts followed for short

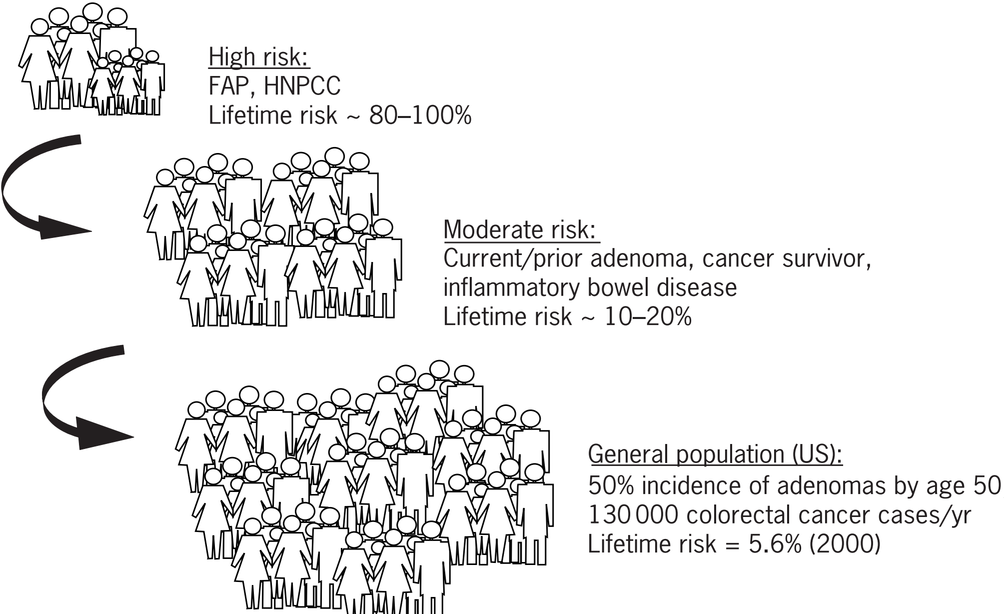


Figure 4 Agent testing along a risk gradient: colorectal neoplasia as a model.

periods of time. Agents confirmed as effective and safe in this context may then be tested for generalizability in progressively lower risk cohorts which collectively account for the overwhelming burden of cancer cases, provided that the diseases share a common aetiology (see **Figure 4**). Such strategies accelerate clinical agent development and the time to iterative testing in progressively lower risk cohorts, thereby conserving precious time and resources. Moreover, concerted testing along this risk gradient provides an ethical advantage – offsetting potential research risks with potential benefits for patients with the most to gain.

Table 6 Strategies to improve the therapeutic index (TI) (i.e. benefit:risk ratio) of chemopreventive agents

Reduce systemic exposure

Reduce dose
Reduce frequency
Reduce duration
Regional administration
Prophylax against or treat unintended toxicities
Improve mechanistic targeting
Combinatorial approaches/regimens

AGENTS

Toxicity and Safety Standards for Chemoprevention

In chemotherapeutics, iatrogenically induced toxicities may be tolerated in pursuit of cure. Cancer chemoprevention, however, may mandate long-term measures to prevent advanced disease that may not even develop. As a result, agents approved for preventive applications typically exceed safety and efficacy standards set for therapeutics. In an effort to improve the TI of promising chemopreventive agents, several strategies have been explored, including (1) enhanced mechanistic specificity (e.g. COX-2 selective vs COX nonselective inhibition), (2) agent combinations with additive or synergistic efficacy (e.g. COX + ODC inhibition; SERM + retinoid), (3) regional administration (i.e. topical formulations to maximize target:systemic exposure), (4) prophylaxis against worrisome toxicities (e.g. coadministration of antiulcer medication+NSAIDs) and (5) dose titration to biological efficacy, rather than maximally tolerated dose (see **Table 6**).

Enhanced mechanistic specificity has vast potential to improve the TI of promising agents, as demonstrated by the development of COX-2 selective inhibitors (derivatives of NSAIDs) for chemoprevention. Nonselective NSAIDs are a structurally diverse class of agents that have been shown to reduce cellular proliferation, slow cell cycle progression and stimulate apoptosis. These effects appear to be significantly linked to the inhibition of COX activity, which facilitates the conversion of arachidonic acid into bioactive lipids (e.g. prostaglandins, thromboxanes and prostacyclins) that are considered to be important promoters of carcinogenesis. The chemopreventive potential of NSAIDs as a class was established in a compelling body of

epidemiological, preclinical and clinical data accrued over the last two decades. However, safety concerns – largely due to gastrointestinal toxicities attributable to COX-1 inhibition – curbed enthusiasm for the development of NSAIDs as chemopreventives. COX-2 selective inhibitors have a markedly improved TI, as compared with nonselective COX inhibitors. Three complementary lines of research established COX-2 as a specific target for chemoprevention, based on the following: (1) COX inhibitors and *COX-2* gene deletions inhibit intestinal carcinogenesis in animal models; (2) nonselective COX inhibitors reduce the incidence of colorectal adenomas, cancer and cancer-associated mortality in human observational studies; and (3) COX inhibitors regress precancerous lesions (e.g. ACF and adenomas) in genetic and sporadic colorectal neoplasia cohorts. In 1999, the COX-2 selective inhibitor celecoxib was shown to reduce the number of colorectal adenomas in persons with the high-risk genetic condition known as familial adenomatous polyposis (FAP). This prompted the FDA to approve the provisional use of celecoxib in FAP patients, in conjunction with standard surveillance and surgical prophylaxis. Prospects for chemopreventive applications of NSAIDs have expanded markedly with the discovery of well-tolerated COX-2 selective derivatives such as celecoxib (Pharmacia) and rofecoxib (Merck). COX-2 inhibitors are now being aggressively developed as chemopreventives against an array of epithelial tumours, particularly those of the colorectum, oesophagus, skin and bladder.

Coadministration of several agents with chemopreventive activity may improve the TI by allowing downward dose adjustments of one or more of the applied agent(s). Additive/synergistic activity has been demonstrated with combinations of agents with different mechanisms of action, such as difluoromethylornithine (DFMO) or an epidermal growth factor receptor (EGFR) inhibitor plus NSAIDs in rat colonic tumours and retinoids plus anti-oestrogens in rat mammary cancer models. Combinatorial approaches are currently being tested in phase II clinical chemoprevention trials (e.g. DFMO plus sulindac in persons at risk of colorectal cancer, and fenretinide plus tamoxifen in women at risk of breast cancer).

Regional delivery systems are another promising area for agent development. Predictably, the most successful application of this strategy has been in skin cancer, where three topical agents have been approved by the FDA for regression of the nonmelanoma skin cancer precursor actinic keratosis (AK), i.e. 5-fluorouracil (5-FU), aminolaevulinic acid hydrochloride (Levulan Kerastick™), with photodynamic therapy, and sodium diclofenac (Solaraze™). Other effective or promising modes of direct delivery to target organs include aerosols to the lung, enemas or suppositories to the colorectum and instillations into the bladder.

Early neoplasia is characteristically more responsive and accessible to delivered agents than later stage disease, and therefore drugs may be titrated to a biologically active dose with negligible toxic potential. Such dose de-escalation models, although appropriate for population-based chemopreventive applications, may have less relevance to high-risk cohorts with limited medical prospects and viable options. Individuals with highly penetrant germ-line disease (FAP, hereditary non-polyposis colon cancer (HNPCC), basal cell naevus syndrome (BCNS), breast/ovarian syndromes, etc.), for example, may abide toxicity in order to improve the likelihood of disease control and/or organ preservation, increase surveillance intervals and latency to disease or alleviate concerns over developing cancer. Pharmacogenomics, the study of genetic polymorphisms that modulate drug metabolism, is one of many emerging fields that may advance cancer prevention by customizing agent and dose selection to individual patients, thereby enhancing the TI of chemopreventive agents.

Agent Development

Candidate chemopreventives are identified through scientific, medical and epidemiological literature review, preclinical drug screens and typically developed and tested through collaborations between academia, governmental agencies and the pharmaceutical industry. Chemoprevention research is intensely translational, and advances through bidirectional hypothesis generation and testing that swiftly applies laboratory findings in the clinic and vice versa. Lead compounds have been variously identified through (1) preclinical efficacy testing of promising agents with distinct molecular targets, (2) epidemiological data on drugs developed for other applications (e.g. oncological, endocrinological, rheumatological, gastroenterological) and (3) epidemiological data on dietary components. Once identified, mechanistic considerations prioritize agents for advancement into human trials. Although traditional testing is still required, this approach expedites agent development and conserves precious time and resources. Another strategy to shorten developmental timelines may be forthcoming. Owing to the polychronotopic (literally 'many times and places') nature of carcinogenesis, early pathological lesions (e.g. AKs, ACF) are a common incidental finding in persons diagnosed with more advanced disease (e.g. skin cancer or colorectal cancer). This phenomenon is consistent with a smouldering process (carcinogenesis) in which genetic and epigenetic events foster different rates and manifestations of neoplasia within the field at risk. Agent identification may be expedited by nesting 'preventive' clinical endpoints within compatible 'therapeutic' trials. This extraordinarily efficient strategy has potential to hasten the evaluation of promising agents with a chemopreventive potential based on their mechanism(s) of action, route of administration and safety profiles.

Preclinical Testing

Positive observational data and serendipitous results from nononcological clinical trials often prompt preclinical efficacy testing (e.g. in tissue culture and animal models) to define the mechanisms whereby agents inhibit carcinogenesis (e.g. inhibition of Ras farnesylation, EGFR, ornithine decarboxylase, matrix metalloproteinase, steroid aromatase and oncoproteins, or induction of antimutagenesis, apoptosis or antioxidation). Proven reductions in tumour incidence, multiplicity and/or overall burden in carcinogen-induced, transgenic or spontaneous animal cancer models may then justify human testing. Some of the most commonly used carcinogen-induced tumour models are azoxymethane (AOM)-induced rat colon tumours and ACF, dimethylbenz[*a*]anthracene (DMBA-) and *N*′-methyl-*N*-nitrosourea (MNU)-induced rat mammary tumours, benzo[*a*]pyrene (B(a)P)-induced rat lung tumours and *N*-butyl-*N*-(4-hydroxybutyl)nitrosamine (OH-BBN)-induced mouse urinary bladder tumours. Carcinogens and/or genetic lesions that reliably and reproducibly induce well-characterized tumours facilitate crude assessments of agent efficacy. Ideally, *in vivo* models approximate multistage genetic, cellular and histopathological changes that characterize human carcinogenesis; however, most models fall short of this ideal. In the case of carcinogen-induced tumour models, most commonly used toxins have no known role in human disease, severely limiting generalization to human carcinogenesis. Transgenic and gene knockout (i.e. gene-deleted) mice may mimic human disease more faithfully, although critical data are still falling into place. Among these, perhaps the most effectively applied model for chemoprevention is the multiple intestinal neoplasia (Min) mouse, that carries an *apc* mutation that predisposes them to intestinal adenomas. Min mice effectively simulate the clinical condition associated with *APC* mutations in human disease, FAP. The Min mouse model and similar ones based on mutations in the *APC* gene furnish dynamic systems in which modulation of colorectal adenoma formation by chemopreventive compounds may be tested. Another exciting model is the HPV-infected (K14-HPV16 heterozygote), oestradiol-treated mouse model, in which cervical intraepithelial neoplasia-like (CIN) lesions progress to squamous carcinoma of the cervix – potentially providing insights into another epithelial cancer. Technological advances arising out of ambitious international initiatives to develop mouse models for human cancers may generate and characterize robust new models for human carcinogenesis (http://www.nci.nih.gov/dcb/odhome.htm#MOUSE).

Several classes of pleiotropic agents (i.e. that target multiple signalling pathways) are under development for chemoprevention, including lipoxygenase (LOX) inhibitors, COX inhibitors, farnesyl-transferase inhibitors and corticosteroids. Agents such as antioestrogens (e.g. SERMs), anti-inflammatory drugs (e.g. aspirin, steroids and selective COX-2 inhibitors), polyamine synthesis inhibitors (e.g. DFMO), retinoid receptor selective ligands, agents that bind peroxisome proliferator-activated receptors (PPARs), and non-cytotoxic cancer chemotherapeutics (e.g. flutamide) are being comprehensively tested in clinical trials. Other promising prevention targets in the preliminary stages of investigation include cell cyclins, bile acids, telomerase and angiogenesis. Emerging structure–activity technologies may expedite the development of these and other promising leads.

Phased Clinical Testing of Agents for Chemoprevention

The efficacy and toxicity of candidate preventive agents are typically assessed in a series of clinical trials referred to as phase I, II or III studies, as summarized in **Table 7**.

Table 7 Common features of chemoprevention trials used in agent development

Phase	Agent dosing	Duration	Sample size and allocation	Control group	Goals
I	Escalation	Weeks–months	<25; nonrandomized or randomized	Occasionally	Pharmacokinetics; dose-finding based on short-term, mild to moderate toxicity
IIa	De-escalation	Months	<50; nonrandomized	Never	Dose-finding based on reliable biomarker modulation
IIb	Stable	Months–year	<100–200; randomized	Standard care[a]	Biomarker modulation (e.g. dysplasia regression) vs standard care[a]
III	Stable	Years	100–1000; randomized	Standard care[a]	Definitive efficacy to complement or replace standard care (e.g. reduce dysplasia/ cancer incidence)
IV	Stable	Unspecified	General marketing population	N/A	Long-term safety in target population

[a]In cancer chemoprevention, placebo may represent the standard of care.

Phase I trials quickly evaluate agent safety at several doses in a small number of subjects to establish an acceptable dose range. Phase II trials are larger and designed to assess preliminarily agent efficacy with regard to a specific precancerous condition (e.g. skin, breast or colorectal dysplasia). Compounds that have satisfied regulatory safety standards for other indications, such as NSAIDs for analgesia, obviate the need for phase I testing and may be ushered directly into phase II trials (referred to as phase IIa if no placebo group is included and phase IIb when one is). Phase III chemoprevention trials are usually randomized and placebo-controlled to test preventive agents or agent combinations against the standard of care for a specific condition. These studies typically involve hundreds to thousands of subjects observed for years, whereas phase II trials may be adequately powered with as few as 100 subjects observed over several months. Parenthetically, phase IV studies are postmarketing surveys conducted to assess agent side effects in the general population (Kelloff *et al*., 1995). (See the chapter *Translational Research*.)

GOALS OF CHEMOPREVENTION

Cardiovascular prevention research has shown that cholesterol-reducing statins effect 10–25% reductions in low-density lipoprotein (LDL) levels, yet account for 30–40% reductions in several major cardiovascular outcomes, clearly demonstrating the enormous public health implications of even small preventive effects. In terms of cancer prevention, Gaziano *et al*. estimated that an intervention that reduced all epithelial cancers by as little as 15% could conceivably prevent 73 000 cancer deaths annually in the USA, through reductions in cancer incidence, morbidity and mortality (Gaziano *et al*., 1996). Quality of life, latency to disease progression, frequency of screening and surveillance and organ preservation may also be improved by preventive interventions (see **Table 8**). In addition, although still controversial, diseases of ageing may share common initiating or promoting mechanisms, and certain classes of agents may prove beneficial in several chronic diseases (e.g. NSAIDs for arthritis/colorectal cancer, selective oestrogen receptor modulators (SERMs) such as tamoxifen or raloxifene for osteoporosis/breast cancer and statins for cardiovascular disease/colorectal cancer). As a specific example, NSAIDs exert analgesic, anti-inflammatory and cardiovascular effects; they may also inhibit cancer and neurodegenerative diseases, although these effects have not yet been confirmed in randomized trials.

Table 8 Goals of cancer chemoprevention

Short-range:
- Modulate validated mechanistic biomarkers
- Regress prevalent preinvasive neoplastic lesions
- Suppress recurrent preinvasive neoplastic lesions following definitive surgical resection
- Prevent incident preinvasive neoplastic lesions

Long-range:

Secondary prevention (i.e. screened cohorts at elevated risk)
- Improve efficacy of surveillance and its associated interventions
  - Address missed/complicated preinvasive neoplastic lesions
  - Preserve organs
- Reduce intensity of surveillance
- Improve safety of surveillance
- Reduce cancer risk of one (or multiple) organs
  - Reduce incidence
  - Delay onset

Primary prevention (i.e. general population)
- Provide an alternative/complement to broad-based cancer screening
- Reduce risk of several chronic diseases (e.g. cancer and cardiovascular disease)

CLINICAL TRIALS

Compelling mechanistic, observational and experimental evidence supports the development of several compounds for chemoprevention; however, many questions remain. As an example, for most chemopreventive applications, we do not know which agents are most effective or, more importantly, the optimal dose, duration, frequency or route of delivery. Nevertheless, the promise and feasibility of chemoprevention in persons at high risk of cancer has been amply demonstrated with tamoxifen for breast cancer and celecoxib for colorectal neoplasia (Fisher *et al*., 1998; Steinbach *et al*., 2000). These two trials provide a conceptual framework and set clinical standards for future studies. The following selected trials illustrate the accomplishments, challenges, and promise of clinical chemoprevention (summarized in **Tables 9–11**).

Upper Aerodigestive Tract Cancer

Head and neck cancer refers to a variety of cancers that develop in the mouth, throat, sinuses and nasal cavity. These tumours are most often associated with heavy smoking and/or alcohol consumption. The mucosa of the upper aerodigestive tract is readily visualized and biopsied, greatly facilitating identification of premalignant lesions, evaluation of agent efficacy and serial tissue sampling. Leucoplakia (literally 'white plaque') is a dysplastic precursor to oral cancer. With malignant transformation rates up to 36% depending on the degree of dysplasia, oral leucoplakia provides a clinical target for cancer chemoprevention trials. Retinoids are the most extensively studied chemopreventive agents for regression of oral leucoplakia and treatment of the field at risk. The first positive chemoprevention trial proved that 13-*cis*-retinoic acid (13*c*RA) administered to subjects over 3 months

Table 9 Chemoprevention clinical trials demonstrating prevention efficacy

Organ system	Endpoints	Cohort	Sample size	Control[a]	Intervention × Duration	Author, year
Upper aerodigestive tract (UADT)	Second primary incidence	Prior squamous cell carcinoma of the head and neck	103	✓	Isotretinoin (low dose) × 12 mo	Hong, 1990
	Leucoplakia incidence	Symptomatic oral mucosal hyperplasia/dysplasia	70 (59)[b]		Isotretinoin responders (× 3 mos) randomized to low-dose isotretinoin[e] vs. β-carotene × 9 mo	Lippman, 1993
	Leucoplakia incidence	Symptomatic oral mucosal hyperplasia/dysplasia	43		α-Tocopherol × 24 mo	Benner, 1993
	Leucoplakia regression	Prevalent oral leucoplakia	44	✓	Isotretinoin × 3 mo	Hong, 1986
Lung	Second primary incidence	Postresection of stage I non-small cell cancer	307	✓	Retinol palmitate × 12 mo	Pastorino, 1993
	Cancer incidence	History of skin cancer	974	✓	Selenium × 4.5 yr	Clark, 1998
	Metaplasia incidence	Current smokers	70		Etretinate × 6 mo	Gouveia, 1982
	Metaplasia incidence	Current smokers	40		Etretinate × 6 mo	Misset, 1986
	Metaplasia incidence	Cytologically abnormal sputum	26		13-*cis*-Retinoic acid × 6 mo	Saccomanno, 1982
	Cytological improvement	Current smokers with metaplasia	73	✓	Folate + hydroxycobalamin × 4 mo	Heimburger, 1988
	Cytological improvement	Heavy smokers with metaplasia	52		Aromatic retinoid (Et_1) × 6 mo	Mathe, 1982
Stomach	Precancerous lesion regression	Narino, Columbia residents with precancerous lesions	852	✓	Antibiotics[e], ascorbic acid[e], β-carotene[e] × 6 yr	Correa, 2000
Colon	Cancer incidence[c]	History of skin cancer	1312	✓	Selenium × 4.5 yr	Clark, 1998
	Adenoma recurrence	Resected sporadic adenoma	913	✓	Calcium carbonate × 4 yr	Baron, 1999
	Adenoma number and size	Familial adenomatous polyposis	22	✓	Sulindac × 9 mo	Giardello, 1993
	Adenoma number and size	Familial adenomatous polyposis	77	✓	Celecoxib × 6 mo	Steinbach, 2000
Liver	Cancer incidence	Hepatitis C-related cirrhosis	90	✓	Interferon-α × 12 wk	Nishiguchi, 1995
	Cancer incidence	Hepatitis B infection	101	✓	Interferon × 12 wk	Lin, 1999

Breast	Cancer incidence	Women at increased risk of breast cancer (Gail model)	13 388	✓	Tamoxifen × 5 yr	Fisher, 1998
Prostate	Cancer incidence[c]	Male smokers	29 133	✓	3 arms: α-Tocopherol[e] β-Carotene α-Tocopherol + β-carotene × 5–8 yr	ATBC, 1994
	Cancer incidence[c]	History of skin cancer	974	✓	Selenium × 4.5 yr	Clark, 1998
Bladder	Cancer incidence	Superficial transitional cell carcinoma following BCG	65		Megadose vitamins[e] vs RDA multivitamins × 10 mo	Lamm, 1994
	Tumour progression	Superficial transitional cell carcinoma	660	✓	Intravesical and percutaneous BCG – induction and maintenance over 3 yr	Lamm, 2000
Cervix	CIN[d] regression	CIN[d] II and III	301	✓	Cervical caps with β-*trans*-RA – periodically over 6 mo	Meyskens, 1994
Skin	AK regression	Moderate to severe actinic keratoses	48	✓	Topical DFMO × 6 mo	Alberts, 2000
	Time to cancer incidence	Prior actinic keratoses and/or skin cancers	2297	✓	Retinol × $\leq$5 yr	Moon, 1997
All sites	Cancer incidence and mortality	Linxian, China residents at high risk of gastro-oesophageal cancers	29 584	✓	4 arms: Retinol, zinc Riboflavin, niacin Vitamin C, molybdenum β-Carotene, vitamin E, selenium[e] × 1–5 yr	Blot, 1993

[a]Controlled trials include those with a placebo arm, no treatment control or standard of care.
[b]Responders were randomized.
[c]A secondary endpoint.
[d]CIN: cervical intraepithelial neoplasia.
[e]Agent with a significant preventive effect in a multi–arm trial.

Table 10 Cancer chemoprevention clinical trials demonstrating a null effect

System	Primary endpoint	Cohort	Size	Control[a]	Intervention × duration	Author, year
Upper aerodigestive tract	Second primary incidence (head and neck, or lung cancer) and overall survival	Past head and neck or lung cancer	2592	✓	Retinyl palmitate, *N*-acetylcysteine, both × 2 yr	van Zandwijk, 2000
	Second primary incidence	Resected head and neck cancer	316	✓	Etretinate × 24 mo	Bolla, 1994
Lung	Cancer incidence	Male US physicians	22 071	✓	Aspirin + β-carotene Aspirin β-Carotene × 12 yr	Hennekens, 1996
	Metaplasia incidence	Chronic smokers with prevalent metaplasia or dysplasia	152	✓	Isotretinoin × 6 mo	Lee, 1994
	Cytological atypia incidence	Former asbestos workers	755	✓	β-Carotene + retinol	McLarty, 1995
	Cytological atypia incidence	Current smokers	150	✓	Etretinate × 6 mo	Arnold, 1992
Oesophagus	Oesophageal/gastric cancer incidence	Residents of Linxian, China with oesophageal dysplasia	3318	✓	Supplementation with 14 vitamins and 12 minerals × 5.25 yr	Li, 1993
	Precancerous lesion incidence	Residents of Huixian, China	610	✓	Retinol, riboflavin, zinc × 13.5 mo	Munoz, 1985
	Chronic oesophagitis or oral leukoplakia regression	Uzbekistan males with oral leucoplakia and/or chronic oesophagitis	532	✓	Riboflavin Vitamins A and E + riboflavin β-carotene Vitamins A and E + β-carotene × 20 mo	Zaridze, 1993
Colon	Cancer incidence	US male physicians	22 071	✓	Low-dose aspirin vs β-carotene × 5 yr	Gann, 1993
	Adenoma incidence	Recent adenoma history	864	✓	β-Carotene, vitamins C and E vs β-carotene and vitamins C and E × 1 yr	Greenberg, 1994
	Adenoma incidence	Recent adenoma history	1429	✓	Wheat bran fibre × 5 yr	Alberts, 2000
	Adenoma incidence	Recent adenoma history	2079	✓	Intensive for low-fat, high-fibre, fruit and vegetable diet × 4 yr	Schatzkin, 2000
	Adenoma incidence	Recent adenoma history	665	✓	Calcium, fibre × 3 yr	Faivre, 2000
Liver	Cancer incidence	Hepatitis C-related cirrhosis	99	✓	Interferon-α2b × 48 wk	Valla, 1999
Breast	Cancer incidence	Stage I cancer or DCIS	2972	✓	Fenretinide × 5 yr	Veronesi, 1995
	Cancer incidence	Family history of breast cancer	2471	✓	Tamoxifen × 5.8 yr	Powles, 1998
Cervix	CIN I and II regression	Prevalent koilocytic atypia, CIN I or II	331	✓	Folic acid × 6 mo	Childers, 1995
Skin	Cancer incidence	History of nonmelanoma skin cancer	1805	✓	β-carotene × 5 yr	Greenberg, 1990
	Cancer incidence	Prior basal cell cancers	981	✓	Isotretinoin × 3 yr	Tangrea, 1993
	Cancer incidence	Prior basal or squamous cell cancers	525	✓	Retinol, isotretinoin × 3 yr	Levine, 1997

[a]Controlled trials include those with a placebo arm, no treatment control, or standard of care.

Table 11 Chemoprevention clinical trials demonstrating a harmful effect

System	Endpoint	Cohort	Size	Control	Intervention × duration	Author, year
Lung	Cancer incidence	Male smokers	29 133	✓	α-Tocopherol + β-carotene × 5–8 yr	ATBC, 1994
	Cancer incidence	Smokers, former smokers, and workers exposed to asbestos	18 314	✓	β-Carotene and retinol × 5 yr	Omenn, 1996
Colon	Adenoma incidence	Sporadic adenoma history	665	✓	Fibre × 3 yr	Faivre, 2000

dramatically transforms leucoplakia lesions into normal-appearing oral mucosa (Hong *et al*., 1986). However, these responses were neither durable nor complete. Although several retinoid doses, schedules and formulations have been evaluated, the TI remains dose limiting. Other candidate chemopreventives of considerable interest for this condition include NSAIDs, EGFR inhibitors and a pro-apoptotic adenovirus (ONYX-015).

Head and neck cancer is associated with a high rate of new primary cancers (up to 40%), many of which develop within apparently normal mucosa in the vicinity of the original cancer. It is postulated that chemopreventive interventions may reduce the rate of these 'second primary' cancers. Placebo-controlled secondary prevention trials of retinoids in patients with completely excised primary squamous cell carcinoma of the head and neck have shown reduced rates of second primaries in the treatment group, although tumour recurrence rates remain unchanged. The EUROSCAN Study, for example, was a randomized placebo-controlled trial designed to assess the chemopreventive efficacy of a retinoid (vitamin A) or an antioxidant (*N*-acetylcysteine) administered for 2 years to 2592 subjects with head and neck or lung cancers, almost all of whom were former (and many current) smokers. No statistically significant difference in second primary rates was observed with either agent. In aggregate, the data suggest a role for retinoids as secondary chemopreventives only in the context of early neoplasia. Because of their potential as a class, retinoids are being further explored in phase III trials.

Lung Cancer

Lung cancer is the leading cause of cancer death in both men and women. Smoking is the major preventable risk factor and accounts for up to 90% of all lung cancers. The lung presents formidable obstacles to observation and acquisition of tissue, thus hampering molecular characterization and mutational sequencing of early lesions. For this reason, manifestations of preinvasive lung neoplasia have traditionally been detected through random sampling of the bronchial tree (for metaplasia or dysplasia) or sputa (for cytological atypia). These screening methods, however, are inexact and inefficient. In one study, only 50% of heavy smokers screened by bronchoscopy met entry criteria for bronchial metaplasia, severely slowing study progress. Correlations between cigarette consumption and the risk of bronchial metaplasia may simplify selection criteria for future studies. A preliminary effort in this regard was a 6-month trial of the retinoid etretinate in persons with bronchial metaplasia, which showed a significant improvement in the metaplasia index. A less invasive approach to the detection of premalignant changes of the lung involves evaluation of sputum cytology. In one study, qualitative cytological changes in sputa correlated well with the use of another retinoid (13cRA). A slightly different efficacy assessment follows changes in sputum cytology serially collected from high-risk patients. In the course of these investigations, several potential confounders have come to light. For example, in a study of active smokers with bronchoscopic dysplasia or metaplasia treated with etretinate versus placebo, high rates of spontaneous regression (20%) and significant reductions in metaplasia upon smoking cessation were noted in the placebo group. As a result, dysplasia is now regarded as the more robust endpoint for prevention research. New directions in early phase lung cancer chemoprevention include the use of light-induced fluorescent (LIFE) bronchoscopy to detect prevalent dysplastic lesions with greater sensitivity and aerosolized agents to deliver agents directly to the respiratory epithelium.

An early trial of high-dose vitamin A in patients with resected stage I lung cancer showed preliminary efficacy in preventing the emergence of second primary cancers and recurrence of the original tumour. Although vitamin A significantly reduced new cancers, tumour recurrences were unaffected. The phase III EUROSCAN Study, however, did not confirm these positive results. NSAIDs, LOX inhibitors and the micronutrient selenium may have protective effects against lung cancer, and are currently being evaluated in clinical chemoprevention trials.

It is sobering to note that two large lung cancer prevention trials have conclusively demonstrated the harmful effects of β-carotene supplementation. The first reported trial was the Alpha-Tocopherol, Beta Carotene (ATBC) Prevention Study of 29 133 Finnish male smokers randomized to α-tocopherol (vitamin E), β-carotene, α-tocopherol plus β-carotene or placebo for 5–8 years (Alpha-Tocopherol, Beta Carotone Cancer Prevention Study Group, 1994). Surprisingly, men receiving β-carotene

experienced higher rates of lung cancer and lung-cancer associated mortality. These disturbing results were confirmed by the Carotene and Retinol Efficacy Trial (CARET) of 18 314 smokers and asbestos workers randomized to a combination of β-carotene and retinyl palmitate versus placebo for a median of 4 years. An interim analysis of CARET was conducted in the wake of the ATBC results, and showed a 28% increase in lung cancer incidence and a 17% increase in mortality rates in the β-carotene arm, forcing early termination of the trial.

Gastro-oesophageal Cancer

Gastric cancer is recognized as a major cause of cancer-associated mortality worldwide. Aetiological factors identified through observational studies include diets high in fats, pickled vegetables and salted or smoked fish, diets low in fruits and vegetables and gastric mucosal infection with *Helicobacter pylori*. The potential benefits of antioxidant supplements and/or *H. pylori* eradication are being evaluated in high-risk populations with prevalent precursor lesions. One study recently reported a marked histopathological improvement with ascorbic acid, β-carotene or antibiotic therapy administered over 6 years. Observational and laboratory data suggest that NSAIDs may also have preventive efficacy in this context.

Squamous oesophageal cancer is relatively infrequent in Western populations, but a major concern in Asia and Africa. In contrast, Barrett-associated adenocarcinoma is quickly rising in prevalence in the USA. Risk factors for the disease include tobacco, alcohol and dietary deficiencies in the case of squamous cell and gastro-oesophageal reflux in adenocarcinoma. Both cancers are characterized by dysplastic precursor lesions that can be identified by cytological or histopathological analyses.

Most work on oesophageal cancer chemoprevention has been conducted in areas with an extremely high prevalence of cancer, such as Northern China. Most of the trials have not reported improvements in the status of dysplasia with antioxidant vitamins or calcium supplementation. However, the largest trial to date demonstrated that treatment with β-carotene, α-tocopherol and selenium reduced all cancer-associated and overall mortality. Observational data suggest that NSAIDs may reduce the risk of cancer by 40–70%, though this hypothesis has yet to be tested in randomized clinical trials. Trials evaluating the merits of DFMO, COX-2 inhibitors, selenium, acid suppression, photodynamic therapy or combinations of these interventions in persons with prevalent dysplasia are currently under way.

Colon Cancer

Colorectal cancer is a leading cause of cancer morbidity and mortality worldwide. Despite continuing advances in therapy, long-term survival has not improved significantly over the last four decades. As a result of insights into the biologic potential of preinvasive neoplasia and effective early detection and interventional technologies, colorectal cancer has become a preventable disease. Because of these successes, colorectal cancer has become the model for chemopreventive agent development.

The most definitive NSAID chemoprevention trial to date was the Physicians' Health Study (PHS), in which 22 071 subjects were randomized to aspirin (325 mg QOD) versus placebo for an average of 5 years (Gann *et al*., 1993). No significant difference was seen between groups in the self-reported frequency of new large bowel malignancies. This surprising null effect has been variously attributed to the rarified cohort (all subjects were male physicians), the lack of uniform colorectal surveillance guidelines and the limited dose and duration of aspirin use. In the wake of the PHS, other large trials are testing the efficacy of the same or higher doses of aspirin for chemoprevention against colorectal adenoma/cancer in more heterogeneous cohorts.

Selective COX-2 inhibitors (e.g. celecoxib, rofecoxib) are under investigation in clinical trials of persons at elevated risk of colorectal cancer due to germ-line mutations or prior sporadic neoplasia. COX-2 is overexpressed in nearly 50% of adenomas and 80–85% of adenocarcinomas, whereas it is rarely expressed in normal colorectal epithelium. This overexpression appears to be functionally important for neoplastic progression, as evidenced by the lower incidence of intestinal polyps in mice without a functional *COX-2* gene. A phase II/III randomized, placebo-controlled trial administered celecoxib for 6 months to 83 FAP subjects and showed significant reductions in colorectal adenoma number and size, with a side effect profile comparable to placebo (Steinbach *et al*., 2000). These data served as the premise for a landmark FDA approval of celecoxib to complement standard care (i.e. surveillance and prophylactic surgery) for patients with FAP, a genetic condition which, in the absence of interventions, assures the development of colorectal cancer. Whether celecoxib as a single agent, or in combination with other drugs, can reduce the extraordinarily high cancer risk of this cohort will be established in future clinical trials.

Calcium has been studied in five adenoma recurrence trials. The most definitive of these studies randomized nearly 1000 persons with prior adenomas to calcium versus placebo and demonstrated a statistically significant 19% reduction in adenoma recurrence (Baron *et al*., 1999). The Women's Health Initiative (WHI) is currently randomizing 45 000 postmenopausal women to calcium and vitamin D versus placebo (among other agents) for a mean of 9 years and will assess incidence of diseases such as osteoporosis and colorectal cancer. Given its size and duration, the WHI is likely to generate authoritative data on the utility of

calcium supplementation for the prevention of colorectal cancer.

Two clinical trials have failed to demonstrate that dietary fibre modulates adenoma recurrence. One randomized trial of wheat bran fibre in 1429 subjects with prior adenomas showed no significant reduction in colorectal adenomas attributable to fibre. Another trial of persons who adopted a low-fat, high-fibre, fruit and vegetable diet also reported null results (Alberts *et al*., 2000; Schatzkin *et al*., 2000).

Clinical trials have shown that DFMO given over 12 months significantly suppresses rectal polyamine levels in patients at risk of colorectal neoplasia, and is well tolerated despite reports of mild gastrointestinal and audiological toxicities (Meyskens *et al*., 1998). Exciting data show that DFMO and NSAIDs in combination synergistically reduce intestinal neoplasia compared with placebo, even when the doses are reduced by 50%. Two clinical trials are testing this hypothesis, one in subjects with prior sporadic adenomas and the other in persons with FAP.

Liver Cancer

Hepatocellular carcinoma (HCC) (also referred to as hepatoma) is the most common type of liver cancer and one of the most common cancers (and causes of cancer death) globally, creating a strong impetus for cancer prevention. HCC aetiological risk factors include chronic infection with hepatitis B or C viruses (HBV, HCV) and cirrhosis, which may be considered a preneoplastic condition. Carcinogens such as aflatoxin and alcohol further potentiate risk.

Prevention of HCC has been accomplished with hepatitis B vaccine. For HCV-induced HCC, however, interventions are still being developed. The most promising chemopreventive agent for HCV-induced HCC is interferon, an immune modulator, that induces sustained virological responses (undetectable HCV RNA) and histological improvements in a limited number of patients. Interestingly, more than 10 observational studies suggest that interferon also reduces the risk of liver cancer. In addition, two of three small, randomized controlled trials conducted in persons harbouring HBV chronic infection or HCV-induced cirrhosis have reported significant reductions in liver cancer incidence in patients receiving interferon for limited periods. Clinical trials to confirm the preventive efficacy of interferon are ongoing.

Other promising approaches may involve induction of phase 2 enzymes to bolster aflatoxin detoxification, and retinoids for their antineoplastic activity. A trial of an acyclic retinoid (polyprenoic acid) reported significant reductions in the incidence of second primary HCCs, although no effect against tumour recurrence. COX-2 inhibitors or SERMs may be evaluated in future trials.

Breast Cancer

Breast cancer is the most common form of cancer among women in the USA. The incidence of breast cancer has been rising for the past two decades, although mortality has remained relatively stable. Much of the increase in incidence is associated with increased screening by physical examination and mammography. There are several well-established factors for breast cancer, including family history, nulliparity, early menarche, advanced age and a personal history of breast cancer.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 Trial, completed in 1998, is the largest breast cancer chemoprevention study conducted to date (Fisher *et al*., 1998). A total of 13 388 women who met specific criteria for high risk of breast cancer (based on the Gail predictive model) were randomized to tamoxifen versus placebo (Gail *et al*., 1989). The rationale for this study evolved out of studies that showed a reduced rate of contralateral second primary cancers in women treated adjuvantly with tamoxifen. The study was prematurely terminated when an interim analysis showed a 49% reduced risk of breast cancer in women receiving tamoxifen. Importantly, risk reductions were noted with tamoxifen in all subsets.

The P-1 Trial demonstrated the protective potential of tamoxifen, but also exposed its profound limitations. Most striking was the finding that despite reductions in oestrogen receptor positive (ER +) disease, tamoxifen evidently has no impact on oestrogen receptor negative (ER−) breast cancer. In addition, two smaller trials of women at lower risk for breast cancer did not confirm P-1 Trial results. One of these studies, the Italian Tamoxifen Prevention Study, randomized 5408 hysterectomized women to tamoxifen versus placebo (Veronesi *et al*., 1998). Unlike the P-1 Trial, patient selection was not based on breast cancer risk. In fact, nearly half of the accrued cohort had prior ovarian ablation and was consequently at reduced risk of breast cancer, owing to low circulating oestrogen levels. Complicating interpretations further, the trial prematurely stopped accrual owing to concerns over a high drop-out rate. Under these circumstances, no difference in breast cancer incidence was observed between study groups. Even so, subset analysis suggested that women using hormone replacement therapy may have derived some preventive benefit from tamoxifen. In a separate study based at the Royal Marsden Hospital in the UK, 2494 women aged 30–70 years with a family history of breast cancer were randomized to tamoxifen versus placebo (Powles *et al*., 1998). As in the Italian trial, the premature drop-out rate was high and tamoxifen did not alter the incidence of breast cancer. Divergent outcomes between the European and American trials may relate, in part, to baseline differences between the study populations.

Tamoxifen was also tested as a secondary chemopreventive against breast cancer in the NSABP B-24 trial (Fisher *et al*., 1999); 1804 women with a prior diagnosis of DCIS were randomized to tamoxifen versus placebo for 5 years, and tamoxifen was shown to reduce the incidence of ipsilateral and contralateral breast cancers. Moreover, because effects of tamoxifen on DCIS were comparable to its effects on invasive breast cancer, DCIS is now regarded as a plausible SEB for breast cancer chemoprevention.

Despite FDA regulatory approval, tamoxifen has not been universally adopted as the standard of care for secondary prevention of breast cancer in the USA. Qualms over use of tamoxifen for this indication chiefly relate to the toxicity profile, which includes endometrial cancer, venous thromboembolism, hot flushes, cataracts and vaginal dryness. Negative reports from the European trials may also have dissuaded physicians from prescribing tamoxifen for chemoprevention. A follow-up study of 22 000 women at high risk of breast cancer, the Study of Tamoxifen and Raloxifene (STAR), will assess the relative efficacy and safety profiles of tamoxifen and a closely related compound, raloxifene.

Although premalignant breast lesions have long been associated with invasive cancer, prospective assessment of chemopreventive effects has been hampered by surgical removal of early breast neoplasia. Moreover, the organ's architecture limits options for reliably identifying early markers that may serve as SEBs. To determine tissue-based risk biomarkers, Fabian *et al*. recently published the results of 10 years of biomarker data derived from fine-needle breast aspirations performed in women with family histories of breast cancer, prior precancerous biopsies or invasive breast cancer (Fabian *et al*., 2000). Random peri-areolar fine-needle aspirations (up to 10 per breast) were obtained at baseline and after 6 months and evaluated for cytological and molecular markers (e.g. EGFR, p53, ER, HER2/NEU). At 45 months of follow-up, hyperplasia with atypia was associated with an increased cancer risk. Furthermore, although no single molecular marker was informative, overexpression of multiple molecular markers was associated with an increased cancer risk. This study establishes markers of risk in would-be candidates for chemoprevention, and provides an important clinical model for testing chemopreventive agents. A different investigational strategy assesses biomarkers in ductal carcinoma *in situ* (DCIS) specimens and adjacent, apparently unaffected epithelium. This 'presurgical model' exploits the interval between the time of diagnostic biopsy and definitive surgery in order to test whether test agents modulate biomarkers.

Prostate Cancer

Prostate cancer is the most common nondermatological malignancy worldwide. Risk factors include age, family history and black race. The only screening test for the detection of early prostate cancer is serum prostate-specific antigen (PSA), which may reduce cancer mortality in the context of surgical and/or radiation therapy directed at early disease. PSA biology, function, age-related expression and its various molecular forms are under intense investigation to determine whether PSA might be an SEB for prostate cancer. Two precursor lesions for prostate cancer (atypical adenomatous hyperplasia and prostatic intraepithelial neoplasia (PIN)) are also under investigation as candidate biomarkers for prostate cancer.

There are no mature data on agents for the prevention of prostate cancer, but several trials are under way. Finasteride (5α-reductase inhibitor), selenium and α-tocopherol (vitamin E) are undergoing clinical testing. The hypothesis to test the last two agents (selenium and α-tocopherol) arose from observations of reduced incidences of prostate cancer by secondary analysis in chemoprevention trials of other target organs.

Bladder Cancer

Bladder cancer is a common cause of cancer morbidity and mortality worldwide. In industrialized countries cigarette smoking is the greatest risk factor for bladder cancer, most of which are transitional cell carcinomas. In developing areas of the Middle East and parts of Africa, infection with schistosomiasis accounts for a high incidence of bladder cancer, the majority of which are squamous cell carcinomas.

Patients with newly diagnosed bladder cancer typically present with premalignant bladder lesions, most of which are curable. Management of these lesions, also referred to as superficial bladder cancer, includes surgical and non-surgical interventions. Superficial bladder cancer is associated with the highest annual rate of second primary tumours of any site. Although most of these new tumours are noninvasive, a significant percentage of patients have multiple recurrences, some of which will progress to invasive disease. Intravesical therapy with BCG vaccine after surgical resection decreases recurrence rates by 45%. Oral retinoids, NSAIDs and megadose vitamins are undergoing phase III clinical testing to prove efficacy as secondary preventives against superficial bladder cancer. The data from these studies will mature over the next several years.

Cervical Cancer

Cervical cancer, one of the most common cancers in women, is a promising area for chemoprevention because of the accessibility of the cervix to evaluation (i.e. Pap tests) and the relatively slow progression to cervical cancer from recognized precursor lesions, termed cervical intraepithelial neoplasia (CIN). High-grade CIN is usually treated by removing the abnormal tissue to reduce the risk of progression to invasive cancer. In fact, broad application of screening programmes to detect and treat preinvasive neoplasia have greatly reduced cervical cancer incidence

and mortality. As a result, CIN has achieved a high degree of validation as an SEB for cervical cancer incidence and mortality, at least in the context of screening coupled with surgery. To date, no medical intervention for cervical cancer has demonstrated an acceptable TI, however several agents are under investigation. Retinoids in particular have shown promise, although their associated toxicities may hinder compliance.

The major risk factor for cervical cancer is infection with human papillomavirus (HPV). Vaccines that eradicate or prophylax against the most common oncogenic viruses (primarily HPV-16 and -18) or their related proteins (E6 and E7) may prove valuable as chemopreventives against cervical cancer. Most cervical cancers (95%) contain HPV, and worldwide the most common type is HPV-16. A 6000 woman placebo-controlled trial of an HPV-16 vaccine will soon be initiated in Costa Rica, where the prevalence of HPV positivity in women with CIN approaches 89%. This vaccine is one of several under development that uses virus-like particles (VLPs) that resemble the authentic virus, but do not pose an infectious risk, to produce high titres of neutralizing antibodies. In the Costa Rica study, virological and pathological endpoints will be used to assess vaccine efficacy.

Skin Cancer

Skin cancer is classified as either nonmelanoma or melanoma, depending on the cell of origin. The incidence of non-melanoma skin cancer (NMSC) (i.e., basal and squamous cell carcinomas (BCC, SCC)) nearly equals that of all other cancers combined. Moreover, NMSC rates are increasing, which is consistent with dose-dependent effects of photocarcinogenesis on ageing populations. NMSC may arise from actinic keratoses (AKs), lesions that are associated with cumulative exposure to UV irradiation, immunosuppression and certain chemicals. AKs are typically cured by destructive techniques (cryotherapy, chemical peels, carbon dioxide laser, shave excision or dermabrasion) or the application of topical agents (5-FU, trichloroacetic acid, phenol or retinoids). However, the malignant potential of AKs, coupled with the cost and cosmetic deformity of standard management, mandate the identification of well-tolerated agents that eradicate AKs, and potentially reverse or retard progression to NMSC. Certain cohorts are at exceptionally high risk of developing NMSC and provide accelerated models for skin carcinogenesis due to chronic immune-suppression (as with solid organ transplant recipients), ultraviolet hypersensitivity syndromes or certain rare genetic syndromes. Several agents have been tested experimentally for the chemoprevention of NMSC, including retinoids, NSAIDs, DFMO and green tea compounds (e.g. polyphenols and epigallocatechin-3-gallate (EGCG)).

Chemoprevention trials of oral vitamin A (retinol) for nonmelanoma skin cancer have shown mixed results. One phase III study showed efficacy against moderate to severe AKs and associated reductions in SCC. However, in another study of subjects with higher risk disease (i.e. a history of skin cancer), the results were unremarkable. Topical formulations of DFMO and colchicine have shown preliminary efficacy in the regression of AKs. Recent US regulatory approvals for regression of AKs include aminolaevulinic acid hydrochloride (Levulan Kerastick™) with photodynamic therapy (PDT) and sodium diclofenac (Solaraze™) for AKs (http://www.fda.gov/cder/approval/index.htm).

Melanoma skin cancer accounts for a much smaller fraction of skin cancers than does NMSC, but it is a substantially more lethal disease with few good therapeutic options. Despite a robust melanocyte progression model with well-characterized intermediate lesions, clinical experience in the chemoprevention of melanoma is minimal. Topical retinoids have been preliminarily tested in subjects with dysplastic naevi (DN), precursor lesions with a high rate of malignant transformation to melanoma. Although clinical and histological improvements were observed in DN treated with topical tretinoin, the responses were not durable. In addition, the degree of skin irritation prompted concerns over compliance with the regimen. A follow-up study will assess whether improved efficacy is achieved through coadministration of systemic retinoids with a lower dose of the topical formulation.

Melanoma is an immunogenic tumour, and may be a good target for vaccine-based prevention. Typically the response to immunization correlates inversely with disease stage and tumour burden, thus vaccines are likely to have a greater impact on subclinical disease (i.e. prevention) than advanced cancer (i.e. therapeutics). This provides a strong rationale for testing promising melanoma vaccines in a preventive context. (See the chapter *Genetic and Cellular Vaccines*.)

THE FUTURE OF CANCER CHEMOPREVENTION

As recently as 1990, there were no accepted SEBs or approved agents for cancer prevention. Since then, preinvasive neoplastic lesions have come to be regarded as excellent markers of risk and chemopreventive response, and several preventive agents have been approved. Our ability to characterize neoplasia on the molecular level is likely to accelerate advances over the next decade (see **Table 12**).

Worldwide, carcinogenesis and atherogenesis impart heavy societal burdens. Reductions in competing cardiovascular deaths – achieved through prevention – ensure that cancer will become the dominant public health issue for ageing populations. With this recognition comes increased responsibility for professional and public implementation of prevention as the foundation of clinical care and health policy. Indeed, we have already witnessed the emergence of a new cancer paradigm. Formerly the

Table 12 Promising directions in cancer chemoprevention

Interventions with improved mechanistic targeting
Genomics, proteomics, etc., to define molecular targets better
Combinatorial screening to identify agents with greater specificity
Broader consideration of agents with preventive potential
Antibiotics
Antiviral agents
Biologics/vaccines
Gene-directed interventions
Nutraceuticals
Cytostatic cancer 'chemotherapeutics' – optimized for risk cohorts
Improved agent administration
Biologically active dose
Targeted agent delivery – topical/regional
Optimized dosing schedules – frequency, duration
Agent combinations
Improved agent development pathways
New *in vitro/in vivo* models with high throughput and greater biological relevance
Better defined risk cohorts
Better validated biomarkers and animal models
Cross-sectional, multiplex efficacy evaluations, e.g. expression arrays
Sensitive and specific superficial imaging, e.g. high-resolution/magnifying endoscopy, 'optical biopsies,' functional imaging technologies
Nested prevention evaluations in therapeutic trials

simultaneous declaration of illness, disability and death, cancer is now regarded as one late stage in a prolonged disease process that affords both time and targets for intervention. As a result, our focus must shift from downstream events (cancer) to midstream processes (carcinogenesis). The challenges that this presents, and how we respond to them, will determine the pace of our success, although not success itself, which is inevitable.

- New Uses for Antisense and Ribozymes in Cancer
- Conclusion

INTRODUCTION

The fundamental advances in molecular genetics in the last two decades have introduced a number of new tools in our armamentarium for the manipulation of gene expression. Chief among these are the use of antisense molecules initially, and ribozymes subsequently, for the manipulation of mammalian gene expression. Not surprisingly, some of the most important demonstrations of the utility of antisense and ribozyme targeting have occurred in the realm of cancer. Moreover, recent advances in understanding the molecular basis of cancer have defined a plethora of new targets for antisense and ribozyme-based inhibition. More recently, the maturation of this technology to the clinical oncological arena is being achieved with the completion of a number of clinical trials using a broad array of targets in cancer. In short, the biological and therapeutic potential of antisense and ribozyme technology is being explored. We therefore take the opportunity in this chapter to review the scientific basis for this technology and discuss its broad utility in cancer-related applications, including the progress made and problems encountered in this field in its march toward the clinical arena.

SCIENTIFIC BACKGROUND

Antisense

The principal appeal of antisense therapy is its inherent simplicity. With the knowledge that a particular stretch of DNA encodes an mRNA molecule which is then the template for protein synthesis, it was hypothesized that an antisense DNA or RNA strand would hybridize to the mRNA in complementary Watson–Crick fashion, thereby resulting in blockage of translation and sequence-specific inhibition of expression. Antisense molecules are commonly composed of single-stranded DNA, where they are termed antisense oligodeoxynucleotides (ODNs). Alternatively, DNA encoding the antisense can be expressed as antisense RNA by an expression cassette. With antisense ODNs, the presumed mechanisms of action include blockage of translation, RNA transport and splicing. Most importantly, perhaps, the RNA–DNA hybrid can be recognized and cleaved by RNase H, yielding an additional mechanism of repression of gene expression. Finally, antisense RNA generated by expression cassettes or viral vectors can also block target gene expression through activation of double-stranded RNase. The first demonstration of the ability of antisense molecules to inhibit target gene expression (Zamecnik and Stephenson, 1978) raised considerable interest in the potential of antisense molecules not just as a molecular tool in biomedical research, but also as a novel class of therapeutic agent.

With the further testing of antisense oligonucleotides in preclinical models, a number of problems surfaced which threatened the theoretical appeal and presumed scientific mechanisms of action of these compounds. Over time, however, a clearer picture has emerged regarding the practical realities of antisense targeting. Moreover, the issues of nonsequence-specific and/or non-antisense activity need to be fully addressed before a particular antisense molecule is to enter the clinical arena in order to maximize the potential of antisense compounds.

Ribozymes

Catalytic RNAs (known as RNA enzymes or ribozymes) were discovered initially as self-cleaving entities in two disparate systems, the ribonuclease P of *Escherichia coli* (Guerrier-Takada *et al*., 1983), and the intervening sequence of *Tetrahymena thermophila* (Zaug and Cech, 1986). The hammerhead ribozyme was identified in the virusoid from lucerne transient streak virus, and the hairpin ribozyme from the 'minus' strand of satellite RNA of tobacco ringspot virus. The initial demonstration of *trans*-acting catalytic activity and *in vitro* mutagenesis studies of the hammerhead ribozyme (Haseloff and Gerlach, 1988) paved the way for use of ribozymes as tools to manipulate the expression of potentially any gene. The therapeutic potential of hammerhead ribozymes was subsequently examined in the setting of human immunodeficiency virus (HIV) infection (Sarver *et al*., 1990) and cancer (Scanlon *et al*., 1991). **Figure 1** depicts the secondary structure of the hammerhead ribozyme, including conserved sequences required for catalytic activity, as well as the proposed interaction with its target mRNA. The hammerhead ribozyme is composed of two regions: (1) the catalytic core, effecting the cleavage reaction, and (2) three hybridizing regions. Stems I and III represent the hammerhead flanking sequences that hybridize to the target RNA in complementary fashion. Hammerhead ribozymes have been shown to recognize and cleave target sequences containing XUN, with X being any nucleotide and N being A, C or U. In general, targets containing GUC, GUA, GUU, CUC and UUC sequences are favoured. Modifications in the hammerhead have been shown to yield the ability to cleave AUA sequences in *trans*. Recently, *in vitro* selection techniques were utilized to expand further the range of cleavable triplets by the hammerhead ribozyme to include AUG and even AAG, rendering the central U nonessential. Therefore, it is likely that further advances will continue to increase the range of targets amenable to hammerhead ribozyme cleavage.

The hairpin ribozyme has also undergone a similar path of development and progress. The hairpin ribozyme (depicted in **Figure 2**) consists of 50 bases and cleaves corresponding 14-base RNA substrates. The ribozyme consists of four helices separated by two internal loop sequences. The hairpin binds to the substrate through helices 1 and 2 and cleaves 5′ to a guanosine within loop A separating helices 1 and 2. Mutagenesis studies have defined the B^4, N^5, G^6, U^7, C^8 sequence in the target RNA as optimal for recognition and cleavage by the hairpin ribozyme. In this scheme, cleavage occurs between N^5 G^6, and B represents C, U or G, whereas N represents C, U, A or G. Following the identification of transacting activity by hairpin ribozymes, their potential therapeutic utility

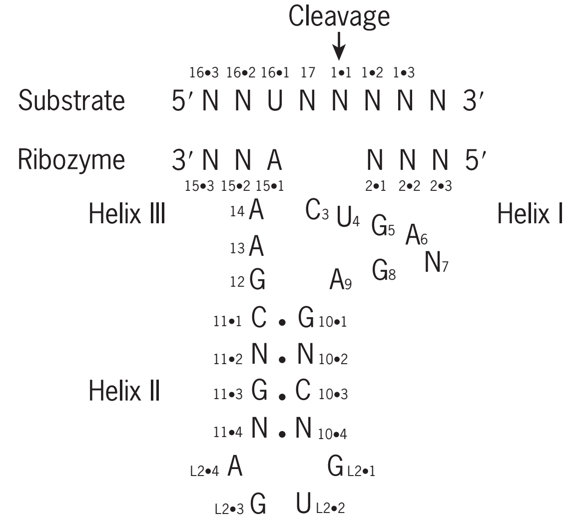

Figure 1 Conserved sequences of the hammerhead ribozyme and position relative to its target RNA.

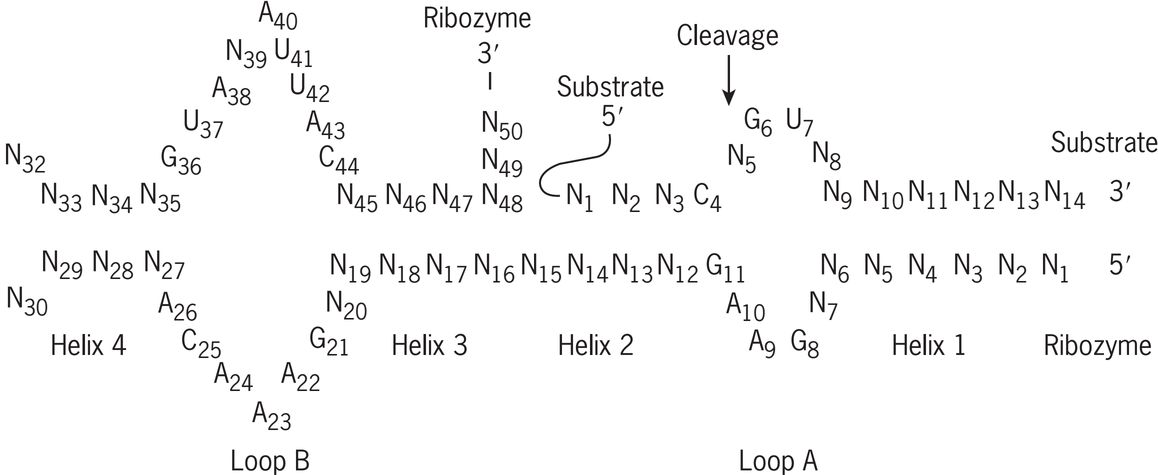

Figure 2 Consensus sequences of the hairpin ribozyme and position relative to its substrate.

was examined initially in the setting of HIV (Ojwang *et al.*, 1992).

Finally, in addition to cleavage activity, ribozymes can result in inhibition of target gene expression through antisense mechanisms, namely blockage of translational machinery or through activation of RNase recognizing double-stranded RNA.

DESIGN, FORMULATION AND DELIVERY OF ANTISENSE ODNs AND RIBOZYMES

Since the initial reports demonstrating the utility of antisense and ribozymes in suppressing gene expression, a number of issues have emerged which deserve further attention in the optimization of antigene strategies. These issues relate to (1) optimal design, (2) optimal formulation and (3) optimal delivery of antisense ODNs and ribozymes.

Design of Antisense ODNs and Ribozymes

Although numerous studies have demonstrated the successful implementation of antisense- and ribozyme-based strategies, with certain exceptions the optimal design of such molecules still remains largely empirical. Thus, proof of target gene inhibition, catalytic activity (in the case of ribozymes), sequence-specific effects (in the case of ODNs), biological activity and the inclusion of convincing control sequences is required for each new molecule that is being examined. Nevertheless, certain patterns have emerged, attention to which will probably increase the possibility of a successful endeavour. In the design of antigene strategies, issues regarding both the target and the antigene must be considered.

With respect to the target gene to be inhibited, several factors are of paramount importance. First, selection of a target that plays a key role in a cellular pathway, or in a biological phenotype, is crucial. In short, the more important the target gene, the more likely it is that antigene strategies will be successful (see the next section on optimal targets tested thus far in cancer). Moreover, the half-life of the target RNA and protein may play a key role in the kinetics of the desired inhibition, especially in studies that allow for transient inhibition of the target gene. Therefore, targeting an immediate–early gene (with a short protein half-life) such as c-*fos* was shown to reverse drug resistance more rapidly than targeting the *mdr*-1 gene, whose protein is more stable. Thus, the stability of the target protein may dictate the relative utility of transient studies with ODNs as opposed to achieving prolonged inhibition with the use of stable transformants.

The next critical issue concerns the selection of the appropriate stretch of mRNA within the target gene. This issue differs from target to target and must be tested with the design of each new molecule. Both antisense and ribozyme strategies have been shown to be successful whether they target the 5′ end of the mRNA, the 3′ untranslated region or regions in between. More important than the actual site is the accessibility of the target RNA region to antigene sequences. In this regard, the formation of stem-loops or lariats within the target mRNA as well as protein–RNA interactions may severely limit the accessibility of the target RNA to antisense ODNs or ribozymes. In fact, double-stranded regions of folded single-stranded RNA and sites of interaction with RNA-binding proteins have been shown to be less accessible to ribozymes. In one study, a ribozyme expression library demonstrated that effective target sites for ribozymes were limited to single-stranded gaps of mRNA. As an illustration, screening the human acetylcholinesterase transcript for GUC and CUC triplets revealed that only five of the 55 potential sites were accessible to hammerhead ribozyme-mediated cleavage. To address this concern, several groups have utilized RNA folding predictions prior to the selection of sites for ribozyme cleavage. In the case of ribozymes, several groups have utilized *in vitro* cleavage of target RNAs to screen ribozymes recognizing different areas of the same gene. However, the kinetics observed with *in vitro* studies is not always predictive of ribozyme activity *in vivo*, thus underscoring the need for empirical testing.

With respect to the design of the antisense or ribozyme molecule itself, several additional factors must be considered. The first is the optimal length of antigene sequences. Again, as with the selection of the inhibition site, no universal rule can be stated. In general, most studies have used ODNs (or flanking sequences in the case of ribozymes) as small as 12–20 bases in length. However, longer antisense molecules, in certain cases including the entire gene, have been shown to retain activity. This issue may be especially important in the case of ribozymes where the trade-off between specificity (necessitating longer sequences) and rapid dissociation that allows multiple turnover (favoured by shorter sequences) may help determine success. A more recent study examining this issue found a minimum length of 51 nucleotides in the 3′ antisense arm to be necessary for inhibition of HIV replication. Conversely, short-chain ribozymes were superior when microinjected into the cytoplasm or when transcribed *in vitro*. Therefore, there may be different requirements for ribozyme length dependent on the site of inhibition (nucleus vs cytoplasm).

In the case of antisense ODNs, recent studies have shed light on additional considerations in the inclusion of specific sequences within the antisense moiety. The most troubling initial finding was the observation of biological activity by nonantisense mechanisms with the use of phosphorothioate ODNs. First, ODNs with four contiguous guanine residues (also known as G quartets) were shown to display a high affinity for proteins (Krieg *et al.*, 1995) and

to be capable of mediating anti-proliferative effects through a nonantisense mechanism (Burgess *et al*., 1995). Subsequently, several reports indicated significant interactions between antisense ODNs and heparin-binding proteins. Mac-1, also known as CD11b/CD18, a member of the integrin family, was shown to act as a cell-surface receptor for ODNs, capable of mediating their internalization (Benimetskaya *et al*., 1997). Moreover, ODNs were shown to interact nonsequence specifically with two other heparin-binding proteins, the vascular endothelial growth factor (VEGF) receptor known as flk-1 and the epidermal growth factor receptor. In the case of flk-1, ODN binding resulted in perturbations of ligand-induced activation and receptor phosphorylation. To address these concerns, guidelines for the appropriate testing and development of specific antisense ODNs have been established (Stein and Krieg, 1994).

More recently, so-called 'second generation' antisense ODNs have been developed in order to improve activity and reduce toxicity. These have included modifications in the base, the sugar or the phosphate backbone. A prominent example is the 2′-alkyl substitution in the ribose moiety. Therefore, the prototypical ODN has been defined to consist of a 20-mer with 2′-alkyl-modified bases and phosphorothioate linkages on the 5′ and 3′ ends of the ODN with a phosphodiester backbone.

Formulation of Antisense/Ribozymes

Given the inherent instability of RNA and the susceptibility of DNA to serum nucleases, the utility of several modifications has been examined in order to optimize the half-life of antigene molecules. In general, these have fallen into two major categories: (1) chemical modifications of oligonucleotides for exogenous delivery and (2) use of expression cassettes to generate antisense or ribozyme RNA.

The most commonly used modification to the phosphodiester ODN is the phosphorothioate ODN, in which a single sulphur substitutes for oxygen at a nonbridging position at each phosphorus atom. This resulted in improved serum half-life but was compounded by the nonantisense effects discussed in the preceding section. In the case of ribozymes, several other modifications have been examined to improve exogenous delivery studies. Briefly, these include 2′-fluoro, 2′-amino, 2′-*O*-allyl and 2′-*O*-methyl substitutions. Another modification is the so-called chimaeric ribozyme, which includes both DNA and RNA moieties. Despite encouraging results *in vitro*, extensive *in vivo* testing of these modifications has been lacking in appropriate model systems. Therefore, for *in vivo* ribozyme studies, expression of the ribozyme by plasmid DNA or viral vector still represents the best-tested method.

In *in vitro* systems, long-term expression of ribozymes has been achieved by stably transfecting ribozyme DNA into the desired cell line. In this manner, transformant clones can be selected with high-level ribozyme expression, thereby increasing the chances of observing an altered phenotype (reduced cell growth, angiogenesis or resistance to chemotherapeutic agents). One of the major factors in modulating ribozyme expression is the selection of an appropriate promoter. As is common for many gene therapy applications, viral promoters represent a popular approach for use in expression cassettes. Ribozyme expression has been achieved using several viral promoters, including the dexamethasone-inducible mouse mammary tumour virus promoter, the SV40 promoter, the herpes simplex virus thymidine kinase promoter, the HIV and Rous sarcoma virus long terminal repeats and the cytomegalovirus (CMV) promoter–enhancer. Cellular promoters utilized to drive ribozyme expression have included the β-actin promoter and the melanocyte-specific tyrosinase promoter. Ribozymes have also been incorporated into tRNA genes to take advantage of RNA polymerase III-mediated transcription. Finally, ribozymes have been embedded in the 3′ untranslated region of other genes. Interestingly, even though the ribozyme RNA sequences transcribed intracellularly are typically enhanced by the addition of poly(A) tails, these noncomplementary sequences do not appear to alter significantly substrate cleavage *in vivo*. Nevertheless, a common approach to circumvent this potential problem is the use of *cis*-acting ribozymes to cleave and liberate the desired *trans*-acting ribozyme upon transcription.

Delivery of Antisense ODNs and Ribozymes

The development of appropriate delivery vehicles represents the single largest impediment to the successful application of gene therapy. Not surprisingly, limitations in vector technology have also slowed the progress of antisense and ribozyme approaches to the clinic. While a detailed overview of gene therapy vectors currently in use is beyond the scope of this chapter and is undertaken elsewhere, this section will discuss the strategies used to date to deliver potential antisense and ribozyme therapeutics.

With respect to antisense ODNs, given that the oligonucleotide is the active moiety itself (without a requirement for gene expression), there may not be a formal requirement for a delivery vector. Thus, these compounds have been more actively studied and have matured most rapidly to the clinical arena (see Clinical Trials section). Antisense ODNs are usually tested either alone or complexed with cationic liposomes. Optimizing antisense ODN delivery both to the appropriate tissues and in order to facilitate efficient intracellular (and intranuclear) uptake is of paramount importance. Uptake in nonspecific tissues can lead to increased toxicity, whereas poor cellular uptake

will result in diminished activity. Given that antisense ODNs are polyanionic structures, they diffuse poorly across lipophilic cellular membranes. Therefore, their cellular uptake occurs mainly through absorptive and fluid-phase endocytosis. Following internalization, ODNs enter the endosomal compartment, where they are susceptible to enzymatic degradation.

Several strategies have been tested to circumvent these potential obstacles. To improve intracellular delivery, multiple cations have been utilized to balance the net negative charge of ODNs. These have included cationic lipids, polylysine, polyethylenime and transferrin polylysine complexes. A recent report suggested that a new transfection reagent, cytofectin, was capable of destabilizing the endosomal compartment, thereby facilitating ODN release to the cytoplasm. Second, specific cell or tissue targeting has been attempted to direct ODN uptake. These approaches have included the use of receptors such as folate or transferrin. More recently, immunoliposomes were developed by coupling monoclonal antibodies directed against the disialoganglioside GD_2 to cationic liposomes. Phosphorothioate antisense ODNs targeting the c-*myb* oncogene were shown to bind selectively to neuroblastoma cells when complexed to these immunoliposomes, resulting in antiproliferative effects *in vitro* (Pagnan *et al*., 2000). In the case of ribozymes, when used as oligonucleotides, similar strategies have been employed as described for antisense ODNs. In addition, a recent report demonstrated efficient *in vitro* transport of ribozymes to the cytoplasm and nucleus when complexed to liposomes fused with haemagglutinating virus of Japan.

In the case of ribozymes expressed intracellularly, however, other delivery techniques have been examined. These have largely included the use of viral vectors. Paralleling the progress in the gene therapy field, early studies utilized retroviral vectors for ribozyme delivery. However, given the inability to transduce non-dividing cells efficiently and to generate high-titre virus particles, the ribozyme field has quickly moved to second-generation vectors. These have largely included recombinant adenoviruses and, more recently, adeno-associated viruses. Examples of viral targeting of ribozymes will be provided in the following section. Finally, in recent studies, cationic liposome–DNA complexes have been utilized to deliver ribozymes to tumour-bearing animals.

PRECLINICAL MODELS AND RESULTS

Antisense

It is beyond the scope of this chapter to discuss every study utilizing antisense technology with potential utility to cancer. Therefore, we will limit the discussion to those targets that have been shown to have significant therapeutic promise through vigorous *in vitro* and/or *in vivo* testing and thus may be closest to clinical application. In general, the type of cellular genes targeted can be categorized into the following: (1) oncogenes; (2) cell cycle regulatory genes; (3) drug-resistance genes; (4) angiogenic genes; (5) growth factor receptor genes; and (6) genes in cell signalling pathways. The targets representing these groups are summarized in **Table 1**.

With respect to oncogenes, some of the earliest studies utilizing antisense technology targeted oncogenes with known defects in particular tumours, thus potentially representing tumour-specific agents. A prominent example of this approach included antisense targeting the *BCR-ABL* gene formed by the chromosome 9 to 22 translocation (the Philadelphia chromosome) in chronic myelogenous leukaemia (CML). Several studies have examined the utility of targeting *BCR-ABL* with antisense ODN (Szczylik *et al*., 1991), such that this approach has reached the clinic (see the following section). A second targeted approach to specific tumour types is the use of antisense targeting of the mutant *ras* gene family. Specifically, antisense RNA against the entire K-*ras* gene was delivered by a retroviral vector to nude mice bearing human lung carcinoma cells, resulting in inhibition of tumour growth (Georges *et al*., 1993). Antisense ODNs have also been used to target mutated H-*ras*, a strategy which is under clinical investigation.

A second strategy for selecting oncogenes for antisense targeting concerns those that are activated by virtue of overexpression in multiple cancers without translocation or mutation. The most prominent examples of this approach have included antisense ODNs targeting c-*myb* in CML (Calabretta *et al*., 1991) and melanoma and targeting the c-*raf*-1 kinase in human bladder and breast carcinoma xenograft models (Monia *et al*., 1996).

A somewhat related strategy has concerned the use of antisense approaches to inhibit expression of growth factor receptors in different tumours. Examples of targets have included the insulin-like growth factor I receptor, the EGFR and the HER-2/*neu* receptor overexpressed in breast cancers (see **Table 1**).

More recently, the identification of cyclins and their role in normal and neoplastic cell growth has generated a new array of targets for cancer. Antisense targeting of cyclin D1 has been extensively studied in different preclinical models of carcinomas, and has been shown to enhance cytotoxicity to cisplatin. A recent study utilizing antisense to $p21^{WAF1/CIP1}$ showed increased sensitivity of colon cancer cell lines to radiation therapy.

Finally, other studies have examined and demonstrated the utility of targeting signalling molecules such as Nuclear Factor *Kappa* B and protein kinase Cα (Dean and McKay, 1994). More recent uses of antisense technology have targeted VEGF to inhibit angiogenesis and growth of melanoma cells *in vivo* and *bcl-2* to chemosensitize melanomas in SCID mice (Jansen *et al*., 1998).

Table 1 Use of antisense therapy in preclinical models of human cancer

Target gene	Sequence	Results	Reference
BCR-ABL	ODN	Inhibition of leukaemic but not normal haematopoietic colonies *in vitro* and *in vivo*	Szczylik *et al.* (1991)
K-*ras*	Retrovirus; antisense RNA	Intratracheal installation decreases lung carcinoma growth in nude mice	Georges *et al.* (1993)
NF-κB	ODN	Regression of HTLV-1 Tax-transformed fibrosarcomas in mice	
c-*myb*	ODN; immunoliposomes	Reduced growth of CML and neuroblastoma *in vitro* and of melanoma *in vivo*	Calabretta *et al.* (1991) Pagnan *et al.* (2000)
c-*raf*	ODN	Reduced growth of human bladder and breast tumour xenografts	Monia *et al.* (1996)
ILGF-R	Stable transformant	Inhibition of tumorigenicity of He La cells	
EGF-R	ODN; folate–PEG liposomes	Inhibition of keratinocyte proliferation *in vitro*	
HER-2/*neu*	ODN	Inhibition of breast cancer cell growth; induction of apoptosis	
Cyclin D1	Stable transformant	Decreased cell growth and tumorigenicity; sensitization to cisplatin	
VEGF	Stable transformant	Diminished melanoma cell growth, angiogenesis and metastasis	
Protein kinase A, Cα	ODN	Reduced tumour cell growth *in vivo*; synergy with chemotherapeutic agents	Dean and McKay (1994)
bcl-2	ODN	Reduced growth of lymphomas in SCID mice; improved response of melanoma to dacarbazine *in vivo*	Jansen *et al.* (1998)

Table 2 Use of ribozyme therapy in preclinical models of human cancer

Target gene	Ribozyme/delivery method	Results	Reference
c-*fos*	HH; stable transformant; inducible promoter	Reversal of cisplatin resistance; elucidation of downstream DNA repair pathway	Scanlon *et al.* (1991)
H-*ras*/N-*ras*	HH; transformants, retroviral and adenoviral delivery	Decreased *ras* gene expression in tumours; reversed invasive phenotype; decreased growth of xenografts, melanoma and transformed 3T3 cells	Kashani-Sabet *et al.* (1994)
BCR-ABL	HH; exogenous delivery	Diminished expression and *in vitro* cell growth	Snyder *et al.* (1993)
Mdr-1	HH; stable transformant	Reversal of MDR phenotype	
HER-2/*neu*	HH; adenoviral delivery; stable transformant	Reduced protein, *in vitro* and *in vivo* cell growth	Suzuki *et al.* (2000)
CAPL/mts 1	HH; stable transformant	Proliferation-independent inhibition of metastatic activity	
EGFR	HH; stable transformant	Targeting splice site mutation reduces tumour growth in nude mice	
FGFBP	HH; stable transformant	Reduced angiogenesis and growth of xenograft tumours	
Pleiotrophin	HH; stable transformant	Reduced angiogenesis and metastasis in nude mice	Czubayko *et al.* (1996)
MMP-9	HH; stable transformant	Decreased lung metastasis; cell growth unaffected	
α6 integrin	HH; stable transformant	Reduced adherance, invasion and metastasis	
EBNA	HH; adenoviral	Blocked virus-induced B cell proliferation	

HH: hammerhead.

Ribozymes

Ribozyme targeting of genes associated with cancer shares some common features with antisense, but interesting differences also exist (see **Table 2**). The most obvious area of overlap is the use of ribozymes targeting oncogenes. The most extensively studied system includes ribozymes targeting the activated H-*ras* gene at codon 12, in which the GUC sequence in the tumour (encoding valine) is recognized by ribozyme cleavage, whereas the wild-type GGC sequence (encoding glycine) is not. Ribozymes targeting mutated *ras* genes have been investigated in a number of

preclinical model systems (Kashani-Sabet *et al.*, 1994). Delivery of anti-*ras* ribozymes has been accomplished by both retroviruses and adenoviruses.

BCR-ABL is another gene that has been extensively analysed in ribozyme studies. Several investigators have examined the exogenous delivery of modified ribozymes targeting *BCR-ABL* for CML (Snyder *et al.*, 1993). Finally, other oncogenes targeted by ribozymes are listed in **Table 2**.

The second area of overlap with antisense and ribozyme targeting is in reversal of drug resistance, although the targets utilized have differed. The first demonstration of ribozyme targeting in cancer showed the reversal of resistance to cisplatin in ovarian carcinoma cells (Scanlon *et al.*, 1991). The use of the anti-*fos* ribozyme was subsequently broadened to cover the multidrug-resistant (MDR) phenotype also. Along these lines, several investigators demonstrated the utility of hammerhead ribozymes targeting the *mdr-1* gene to reverse resistance to a variety of chemotherapeutic agents associated with the MDR phenotype.

The third common category concerns targeting angiogenic genes. Once again, the genes selected for ribozyme targeting differ from those discussed in the antisense section. Hammerhead ribozymes have been shown to reduce angiogenesis by targeting the pleiotrophin gene (Czubayko *et al.*, 1996) and the gene encoding the basic fibroblast growth factor-binding protein. In the case of pleiotrophin, melanoma cell lines expressing the ribozyme had a reduced capacity for metastasis. Recently, continuous infusion of a synthetic hammerhead ribozyme oligonucleotide targeting the VEGF receptor flt-1 (termed ANGIOZYME), was shown to produce anti-metastatic effects in murine models (Pavco *et al.*, 2000).

Antimetastatic activity is another well-documented use of hammerhead ribozymes. This potential has been amply demonstrated in studies using ribozymes to target the *CAPL/Mts 1* gene, the integrin gene $\alpha 6$ and the matrix metalloproteinase *MMP-9* gene.

Finally, two additional targets of ribozyme therapy not previously discussed with antisense include cancer-associated viral genes and telomerase. Ribozymes have been shown to suppress the transformed phenotype associated with the human papillomavirus *E6* and *E7* genes and the Epstein–Barr virus nuclear antigen-1. Finally, several groups have reported on the use of ribozymes targeting telomerase sequences. However, to date, no effects on the neoplastic phenotype have been reported.

CLINICAL TRIALS OF ANTISENSE AND RIBOZYMES

As alluded to in the preceding section, with the completion of preclinical studies using antisense ODNs and ribozymes in a number of model systems, the stage was set for these compounds to enter the clinical arena. In fact, a number of studies using antisense ODNs in cancer have been completed, and many others are currently under way (see **Table 3**). Intravitreal administration of an antisense ODN targeting the cytomegalovirus genome (CMV) has been approved by the US Food and Drug Administration for CMV-induced retinitis associated with HIV infection. Ribozymes are also entering the clinical arena, as a clinical trial of hairpin ribozyme is under way in the treatment of HIV infection. In this section, the results of antisense studies described thus far will be reviewed, and the potential of ribozymes as anticancer therapeutics will be further explored.

The first report of a clinical trial of antisense therapy in cancer involved the use of an antisense ODN targeting *p53* (Bishop *et al.*, 1996). In this phase I trial, 16 patients with advanced haematological malignancies (either refractory acute myelogenous leukaemia or advanced myelodysplastic syndrome) were treated by continuous intravenous infusion of a 20-mer phosphorothioate oligonucleotide complementary to *p53* mRNA for 10 days. Five dose levels, ranging from 0.05 to $0.25\,\mathrm{mg\,kg^{-1}\,h^{-1}}$ were examined. No specific toxicity was found to be directly related to the administration of the antisense ODN. Pharmacokinetic studies revealed that plasma drug concentrations increased with dose, and that 36% of the administered dose was recovered in the urine. While there was diminished *in vitro* expansion of leukaemic cells following ODN therapy, no clinical complete responses were observed. A second study examined the pharmacokinetic profile

Table 3 Antisense ribozyme compounds in clinical trials of cancer

Target gene	Target cancer	Phase	Reference/status
c-*raf*	Multiple	I; II	Stevenson *et al.* (1999)
p53	Haematological malignancies	I	Bishop *et al.* (1996)
bcl-2	Non-Hodgkin lymphoma; prostate cancer; melanoma	I; II	Webb *et al.* (1997) Ongoing
c-*myb*	CML	I	
PKC-α	Multiple	I	Ongoing
	Ovarian	II	
H-*ras*	Solid tumours	I	Ongoing
flt-1	Breast cancer, melanoma	II	Ongoing

of an antisense ODN targeting intercellular adhesion molecule-1. A phase I dose escalation study was conducted in volunteers with single or multiple intravenous infusions of ISIS 2302. Laboratory abnormalities included dose-related increases in activated partial thromboplastin time and insignificant increases in C3a. The plasma half-life was found to be 53–54 min for intact drug and 67–74 min for total oligonucleotide. No adverse effects were related to drug treatment.

Subsequently, the results of two phase I trials of antisense ODNs targeting *bcl-2* and c-*raf*-1 have been published at the time of this writing. The preliminary results of several other trials have been reported in abstract form. In the case of *bcl-2* antisense ODN, a phase I study examining daily subcutaneous infusion of an 18-mer phosphorothioate oligonucleotide for 2 weeks was performed in five patients with bcl-2-positive non-Hodgkin lymphoma (Webb *et al*., 1997). This dose escalation study investigated doses ranging from 4.6 to 73.6 mg/m^2 . With the exception of local inflammation at the injection sites, no treatment-related adverse events were noted. One patient had a complete response of nodal disease lasting 4 months. Another patient had improved tumour burden that did not qualify as a partial response. Two patients had improvements in their constitutional symptoms with antisense ODN treatment, and several patients had a reduction in the number of circulating lymphoma cells or serum concentration of lactate dehydrogenase. Importantly, Bcl-2 expression was assayed using flow cytometry, and was reduced in the peripheral blood and bone marrow aspirates of one patient and in the lymph node aspirates of another patient (Webb *et al*., 1997).

More recently, the results of a phase I clinical, pharmacokinetic and pharmacodynamic trial of ISIS 5132 targeting c-*raf*-1 kinase have been reported (Stevenson *et al*., 1999). Thirty-one patients with advanced malignancies underwent a dose-escalation trial of a 20-base phosphorothioate antisense ODN complementary to 3′ untranslated sequences of c-*raf*-1 mRNA with nine dose levels ranging from 0.5–6.0 $mg\,kg^{-1}$ as a 2-h intravenous infusion three times weekly for three consecutive weeks. In this study, a maximum tolerated dose was not achieved, and toxicities included fever and fatigue. Laboratory toxicities included elevations in the activated partial thromboplastin time and levels of C3a. The potential for complement activation resulted in closure of the study at a dose of 6.0 $mg\,kg^{-1}$. One patient with metastatic colorectal carcinoma was observed to have minor response in a liver metastasis. Another patient with metastatic renal cell carcinoma had stable disease during 10 courses of treatment prior to progressive disease.

Pharmacokinetic studies, similar to prior studies, revealed a linear increase in mean plasma concentrations with increasing dose. The mean half-life of ISIS 5132 was 59.8 min. In this study, patients' circulating peripheral blood mononuclear cells were used as a surrogate to study expression of c-*raf*-1 during ISIS 5132 administration. Reductions of c-*raf*-1 expression were noted in 13 of 14 patients by day three of treatment, with a median decrease of 42% of initial values. Interestingly, higher doses of antisense ODN did not result in more prolonged gene expression. In the two patients with possible clinical benefit noted previously, c-*raf*-1 mRNA levels were reduced during the period of disease stability, but became elevated with disease progression.

A few reports have described the preliminary experience with antisense ODNs in other oncological settings. A study of antisense c-*myb* ODN in 18 patients with refractory leukaemia showed minimal toxicity and one response in a patient with CML in blast crisis who reverted to chronic phase. Two trials of antisense ODN targeting protein kinase Cα to patients with refractory cancer have been performed. Early analysis of these trials shows tolerability of the antisense therapy, and clinical responses were observed in ovarian cancer patients. This has resulted in a phase II trial in ovarian carcinoma. More recently, a trial of G3139, an antisense ODN targeting *bcl-2* mRNA combined with dacarbazine in patients with metastatic melanoma showed responses in three of 14 evaluable patients. Study treatment was associated with transient fever, flushing, rash and liver function abnormalities. Reduction of Bcl-2 protein in tumour biopsy samples and induction of apoptosis of melanoma cells was observed.

Taken together, the studies performed to date allow a number of conclusions to be drawn. First, antisense ODN therapy appears to be remarkably safe, even in the setting of advanced malignancies. Several dosing and administration schedules have been analysed, and further optimization is required. Antisense ODN therapy appears to have a short half-life and a fairly predictable pharmacokinetic profile. Demonstration of inhibition of gene expression has been provided in a few instances, but needs to be examined more closely. To date, the presence of nonantisense effects in humans is unknown. Transient clinical benefits and/or responses have been observed. These studies suggest the readiness of antisense ODNs for phase II trials, in which a more accurate assessment of clinical response is possible. Moreover, no conclusions can yet be drawn regarding the specific genes targeted. Furthermore, the exact nature of the malignancies that would represent the most suitable targets for antisense therapy has yet to be defined. Nevertheless, the results amassed to date are encouraging to permit the continued clinical maturation of antisense technology.

With respect to ribozymes, further optimizations in gene delivery techniques will probably be required prior to initiation of widespread clinical testing. Recent studies using systemic delivery and expression of ribozymes using cationic lipid–DNA complexes with vectors that permit sustained transgene expression to tumour-bearing animals offer a possible improvement to currently existing ribozyme therapeutics for cancer.

NEW USES FOR ANTISENSE AND RIBOZYMES IN CANCER

In addition to the use of antisense/ribozymes to down-regulate gene expression for therapeutic purposes, novel uses of these compounds are emerging, with potential applications to human cancer. One intriguing use of these compounds is in the functional genomics of cancer. With the completion of the human genome project, a myriad of candidate genes will emerge with possible roles in the initiation, progression, prevention, and/or treatment of human cancer. The use of antisense and/or ribozymes to suppress a target gene of interest in tumour cell lines or in tumour-bearing animals may represent a powerful strategy to define the role of previously uncharacterized genes in cancer. Second, antisense/ribozyme technology has been adapted to achieve repair of mutated genes. While this represents an evolving technology at the present time, the theoretical appeal to the treatment of the primary genetic defects of human disease (including cancer) are obvious.

CONCLUSION

In this chapter we have reviewed the evolution of antisense and ribozymes from tools in molecular biology to tools in the clinical management of cancer. It is clear that there is enormous potential in antisense/ribozyme therapy, but also that there are significant pitfalls and obstacles yet to be overcome. However, these technologies are being increasingly tested in clinical trials of human cancer. The coming decade is sure to see the continued progress and development of antisense and ribozymes as therapeutics.

- Inhibition of Oestrogen Synthesis
- Blocking Oestrogen Action
- Selective Oestrogen Receptor Modulation
- Conclusions

INTRODUCTION

Remarkable advances have been made during the past 40 years in the treatment of childhood leukaemia. However, the application of combination chemotherapy for the treatment of solid tumours has met with only modest success. The one exception is the treatment of breast and prostate cancer. These diseases are major killers of women and men, respectively.

Advances in the treatment of breast and prostate cancer have occurred primarily because of changes in the way treatment strategies have evolved. The treatment of both diseases depends on surgery, staging, radiation therapy and combination chemotherapy. Nevertheless, unlike other solid tumours in humans, breast and prostate cancer are dependent upon oestrogens or androgens, respectively for growth. The tumour cells contain the relevant steroid hormone receptor that can harness circulating steroids to cause uncontrolled cell replication and tumour growth. As a result of knowledge of the link between steroid hormones and breast and prostate tumour growth, treatment strategies to deny access of steroids to the tumour have been investigated and shown to provide benefits for the patient. In 1966, Professor Charles B. Huggins received the Nobel Prize for Medicine for his work on the hormone therapy of prostate cancer.

In its simplest form, hormonal therapy initially was the removal of the ovaries or the testes. Endocrine ablation caused tumour regression or stabilization of disease progression in a majority of patients. However, the discovery and understanding of steroid hormone receptor mechanisms provided an invaluable target for drug discovery and rational therapeutics. Although the principles for the treatment of breast and prostate cancer are similar, breast cancer research has led the way with discoveries and innovative therapeutic strategies. In this chapter, we will consider breast cancer treatment as the model for hormonal therapy for two major reasons. First, the application of the antioestrogenic drug tamoxifen has been shown to benefit millions of women with all stages of breast cancer, and it is calculated that 400 000 women are alive today because of the use of the drug following surgery. Second, tamoxifen is a pioneering medicine as it is the first drug to be available to prevent breast cancer in high-risk women. There is no other therapeutic intervention that is approved to prevent any other cancer in people at risk.

BREAST CANCER: AN INTRODUCTION

Breast cancer is diagnosed in approximately 176 000 patients in the USA each year. Even more striking is the prevalence of breast cancer in the population, which exceeds other solid tumours such as lung cancer, colon cancer and prostate cancer. Not only are there a large number of new diagnoses of breast cancer each year, but there are also an enormous number of breast cancer survivors who remain at risk for recurrence of the disease or the development of a new primary breast cancer.

Breast cancer can be broadly divided into various stages. Advanced disease presents with clearly identified metastases at distant sites. In node-positive breast cancer,

tumour is identified by the pathologist in the axial lymph nodes sampled during surgery. A patient who is node negative at presentation has a good prognosis with a $>80\%$ chance of survival depending on the size of the original primary tumour. However, the routine use of regular mammography has resulted in an increased diagnosis of ductal carcinoma *in situ* (DCIS). This is non-invasive breast cancer that is currently treated with surgery, radiation and the antiestrogen tamoxifen (Fisher *et al.*, 1999).

During the past 30 years, breast cancer therapy has evolved from the treatment of advanced disease to the administration of adjuvant therapy for the eradication of microscopic disease. Systemic treatment options that are available to breast cancer patients include chemotherapy, hormonal therapy and biological therapy. However, results from chemoprevention studies now offer risk reductions for women with elevated risk factors for the disease (Fisher *et al.*, 1998). Indeed, the widespread availability of agents with the potential to prevent disease (e.g. chemoprevention) has introduced a new dimension into women's health care. (See the chapters on *Breast* and *Chemoprevention*.)

HORMONES AND BREAST CANCER

The relationship between endocrine manipulation and breast cancer was first established over 100 years ago. In 1896, it was first shown that the removal of the ovaries from a premenopausal woman with advanced breast cancer resulted in tumour regression. However, surgical oophorectomy was not found to be beneficial for all premenopausal patients. Only about one-third of premenopausal women with metastatic breast cancer showed objective evidence of tumour regression, and these women gained approximately 1 year of additional life. A similar effect on breast cancer was found to occur by irradiating the ovaries. It was later found that the effect of radiation on ovarian function correlated with decreases in oestrogen production that reached basal levels several months following treatment.

Once synthetic corticosteroids became available in the 1950s, other forms of endocrine ablation became feasible, including surgical adrenalectomy and hypophysectomy. Tumour responses were reported in 30–40% of patients undergoing these procedures, but the associated morbidity and mortality were unacceptably high. Eventually, medical therapies for inducing an adrenalectomy were identified with drugs such as aminoglutethimide (see later under Aromatase Inhibitors). Although much of the early work focused on ways of achieving oestrogen deprivation, paradoxically high-dose oestrogen therapy resulted in tumour regression in postmenopausal women with advanced breast cancer. This became the treatment of choice for postmenopausal women during the 1950s and early 1970s before the antioestrogen tamoxifen became available (see later under Tamoxifen for Treatment). The link between ovarian hormones and breast cancer growth was established in the first half of the twentieth century, but only one patient in three with advanced breast cancer responded. The problem was to determine prospectively who would benefit from endocrine ablation.

Through a series of elegant experiments, Jensen and Jacobsen hypothesized that an oestrogen receptor (ER) must be present in oestrogen-target tissues, such as the uterus, vagina and pituitary (Jensen and Jacobsen, 1962) that would control the response of the tissue selectively. Ultimately, the ER was isolated and characterized as an extractable protein from oestrogen-target tissues (**Figure 1**). These findings led to the development of ER assays that could be used to predict which of the patients with metastatic breast cancer would respond to endocrine manipulation. In a random population of patients with metastatic breast cancer, 30–35% will respond to endocrine manipulation, whereas 55–60% of patients with tumours known to be ER-positive respond to endocrine manipulation. Several studies have shown that older patients diagnosed with breast cancer are more likely than younger patients to express ER. About 44% of breast cancer patients in the age group 40–49 years express ER, whereas 69% of patients 70 years or older express ER.These data suggest that most patients with metastatic

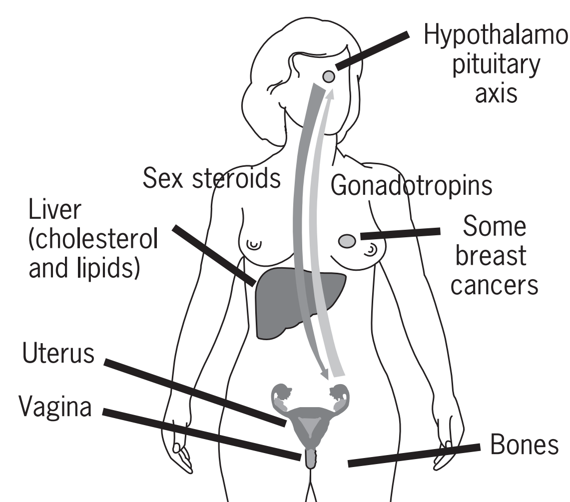

Figure 1 The oestrogen target tissues identified around a woman's body. The menstrual cycle is controlled by the negative feedback system that operates between ovarian steroid synthesis and gonadotropin release through the hypothalamopituitary axis. The pulsatile release of luteinizing hormone-releasing hormone (LHRH) from the hypothalamus causes the release of gonadotropins from the pituitary gland. Oestrogen receptors are found in a majority of breast cancers.

Mer 25

Tamoxifen

breast cancer are eligible for endocrine manipulation at some point in the course of the disease.

In 1958, MER-25 (**Figure 2**), the first nonsteroidal antioestrogen, was discovered, but because of toxicity in the central nervous system and relatively low potency, further development was discontinued. This class of drugs, however, block the binding of oestradiol to the ER so they had potential in treatment for breast cancer. Tamoxifen, the antioestrogenic, pure *trans* isomer of a substituted triphenylethylene, was initially developed as a potential postcoital contraceptive, but was eventually shown to induce ovulation in subfertile women. Fortunately, preliminary clinical studies of tamoxifen in patients with metastatic breast cancer showed antitumour activity, leading to its development as a treatment of breast cancer (Lerne and Jordan, 1990).

ERSα AND -β AS TARGETS FOR THERAPY

The biological effects of oestrogen are now known to be mediated by two receptors, referred to as ERα and ERβ. ERα was first identified and isolated in the mid-1960s. The cloning of ERα in 1986 focused research efforts on the existence of only one ER protein (ERα) identical in all target tissues. However, almost three decades after the initial discovery of ERα, ERβ was identified in the rat, human and mouse. The discovery of ERβ has already advanced our understanding of oestrogen signalling and may explain the responses to oestrogen in tissues in which ERα was not detectable. The role of ERα and -β in physiology is currently being deciphered through the use of 'knockout' transgenic mice that have ERα, ERβ or both receptors knocked out (Couse and Korach, 1999).

The two ERs share functionally conserved structure (A–F domains) (**Figure 3**) with a variable N-terminal region involved in transactivation function (A/B), a centrally located, well conserved DNA-binding domain (C) and C-terminal region involved in dimerization and in binding to heat shock protein (HSP) 90 (D), ligand-binding domain (LBD) (E) with transactivation functions and F region. Region F appears to play a role in modulating transcriptional activation by ERα. ERβ is homologous to ERα, at the ligand-binding (58%) and DNA-binding (96%) domains, whereas the A/B region, hinge domain and F region are not well conserved.

ERα contains two activation functions (AFs) which contribute to the ER's transcriptional activity. ERα contains an activating function only in the ligand-binding domain but has an AF-1 site that is functionally very different to ERα. AF-1 of ERα is located in the N-terminal region within the A/B region and was originally believed to be constitutively active and ligand independent. It has been demonstrated that ligand-independent activation of ER via the AF-1 domain is closely related to the phosphorylation status of the receptor. In particular, Ser118 in the AB region of ERα is important for the activation through the Ras-MAP kinase (MAPK) signalling cascade and Ser106 and Ser124 are two phosphorylation sites in the A/B region of ERβ which are essential for ligand-independent activation of the ERβ via the MAPK cascade. In addition, both receptors contain a second activation domain, AF-2, which is present at the C-terminus and is ligand dependent. Mutational analyses demonstrate the importance of this region for ER transactivation because AF-2 can interact with a number of putative transcriptional coactivators in a ligand-dependent manner.

AF-1 and AF-2 can activate transcription independently but in most cases they synergize with one another in a promoter- and cell context-specific manner. It is believed that ER activates gene expression by binding to oestrogen response elements (EREs) in responsive genes through the synergistic action of AF-1 and AF-2. ERβ was also shown to activate transcription of target genes through EREs, but there is evidence that ERβ may reduce the actions of low levels of oestrogen. However, it has been demonstrated recently that although oestrogen can induce an AP-1 site in a reporter construct through ERα, it is inactive via ERβ. Interestingly, ER antagonists activate ERβ to induce activity through an AP-1 site and through the human retinoic acid receptor α-1 promoter.

The two receptors ERα and ERβ may form functional heterodimers on DNA that could bind the steroid receptor coactivator SRC-1 and stimulate transcription of a target gene. The ability of ERα and ERβ to form heterodimers suggests that ER may function through different dimeric states, and it is possible that the dimers could be activated by selective ligands.

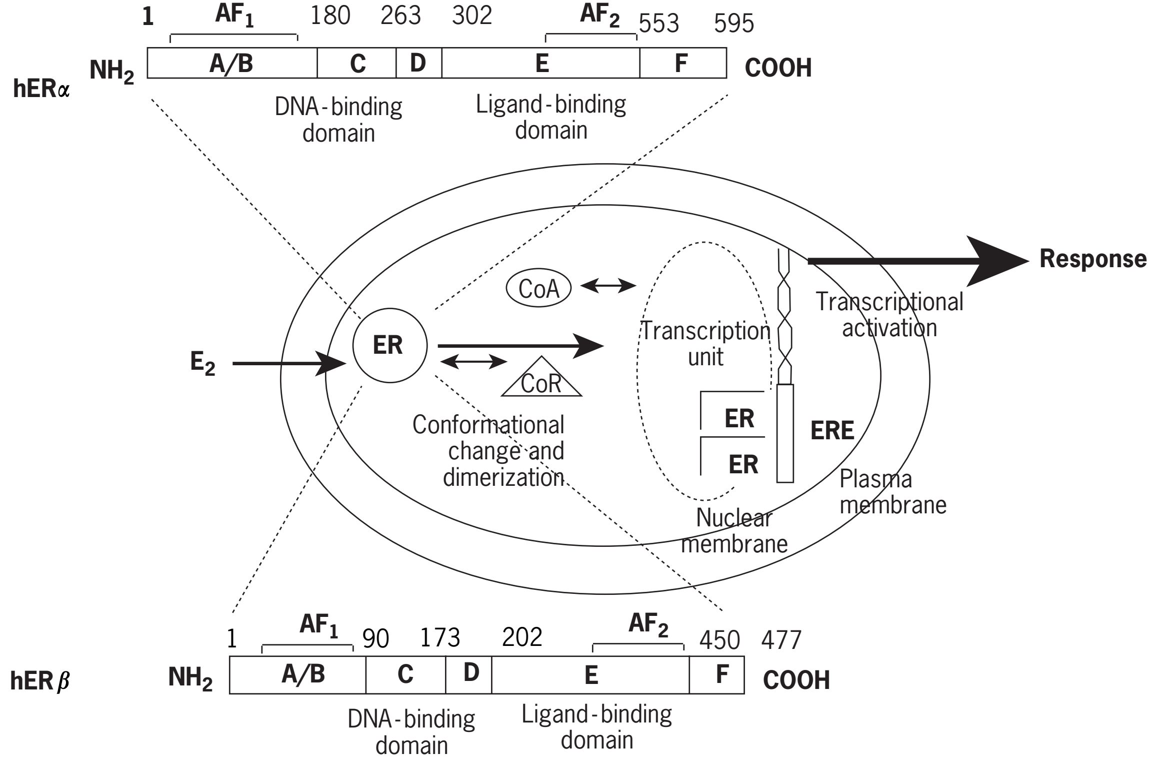

Figure 3 The subcellular mechanism of action of oestrogen in a target tissue, i.e. ER-positive breast cancer. Oestrogen action is regulated by two oestrogen receptors: the classical ER now referred to as ERα and the newly described oestrogen receptor ERβ. Once oestrogen binds to the receptor, the complex changes shape and dimerizes before binding to oestrogen-response elements (EREs) in the promoter region of an oestrogen responsive gene. Gene translation occurs by the binding of coactivator (CoA) molecules to the ER complex that contribute to the transcription complex. RNA polymerase and DNA unwinding enzymes are recruited to ensure gene transcription. Antioestrogen ER complexes could incorporate novel corepressor (CoR) molecules to block gene transcription. (From Levenson and Jordan, 1999, *European Journal of Cancer*, **35**, 1628–1629.)

A Molecular Mechanism for Oestrogen Action

The existence of two rather than one ER indicates that the mechanism of action of oestrogen and antioestrogens is even more complex than previously thought. Oestrogen, upon binding to its high-affinity receptor (or receptors), triggers the expression of multiple genes involved in the regulation of cell proliferation and differentiation. The binding to the agonist allows the ER to dissociate from heat-shock protein (HSP 90), dimerize, bind to specific DNA sequences and stimulate transcription of responsive genes. Now it is well known that ER itself is far from being the direct controller of transcription: it requires an interaction with a complex of coregulatory proteins (coactivators or corepressors), which act as signalling intermediates between the ER and the general transcriptional machinery (**Figure 3**). Recently, the crystal structure of the LBD of ERα was determined with oestradiol and the synthetic nonsteroidal oestrogen diethylstilboestrol (Brzozowsky *et al*., 1997; Shiau *et al*., 1998). Both high-affinity ligands interact with the same amino acids to locate the oestrogens correctly (**Figure 4**). A key feature of an oestrogen is the ability to be enveloped in an hydrophobic pocket that is closed by helix 12 (an essential site for AF-2 activation) in the ligand-binding site of ERα (**Figure 4**). Apparently, helix 12 is critical for the recruitment of coactivators to the AF-2 site and subsequent initiation of RNA polymerase activity. The repositioning of the helix 12 after ligand binding has been proposed as an important mechanism for full oestrogen action at ERα (Brzozowsky *et al*., 1997; Shiau *et al*., 1998).

Coactivators

There is considerable evidence that nuclear steroid receptors must associate with other nuclear proteins to form a transcription complex. For example, it has been shown that the AF-1 and AF-2 domains of ERα bind to TATA-binding protein (TBP) *in vitro*. Moreover, ER can interact with components of the transcription factor IID (TFIID) complex and TFIIB. Interactions between ER and

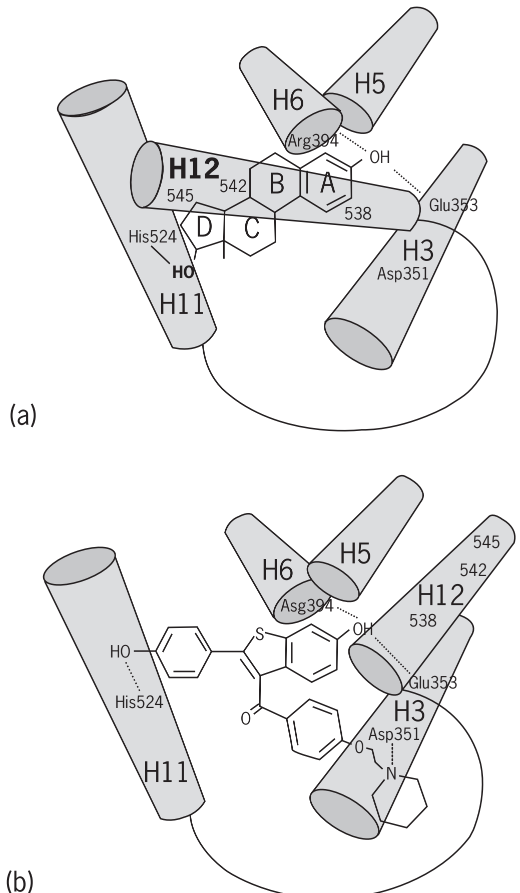

Figure 4 (a) The locking of oestradiol in the ligand-binding domain of ERα. Helix 12 seals the steroid into hydrophobic pocket and exposes sites on the complex that can bind to coactivators. (b) The wedging of raloxifene in the ligand binding domain of ERα. Helix 12 cannot seal the SERM into the hydrophobic pocket because the antioestrogenic side chain interacts with AA 351, which acts as a pivot for the helix. Helix 12 blocks the binding sites so coactivators cannot bind. (From Jordan and Morrow, 1999, *Endocrine Reviews*, **20**, 253–278.)

TFIID-associated factor (TAF), $TAF_{II}30$, have also been described. However, although all these interactions are necessary, they are not sufficient to mediate transcription. The multiprotein complex must not only provide the machinery to transcribe the appropriate gene but also facilitate a mechanism for exposing the quiescent gene. This process must destabilize the DNA–histone complex to allow RNA polymerase access to complete transcription.

Several coactivators have been described for ER based upon their ability to interact with agonist-bound receptor but not with an antagonist-bound receptor. ERAP 160 and RIP 140 were identified using the LBD of ER as bait. Interestingly, RIP 140 does not interact with basal factors of the transcription machinery, suggesting a mechanism other than a bridging function for a coactivator. SRC-1, on the other hand, was isolated from a human cDNA library using the LBD of hPgR as bait. However, studies indicate that SRC-1 and ERAP 160 are variants of the same family of proteins. The majority of receptor-interacting factors have been identified by using LBD of nuclear receptor as a bait. This, therefore, explains why the AF-2 site is believed to be the most important site for coactivators recruitment. However, It has been demonstrated that SRC family members are not only transcriptional mediators for the ligand-dependent AF-2 and AF-1 of ERα but are also involved in ligand-independent interaction with ERβ through phosphorylation of AF-1 via MAP-kinase cascade. Functional interaction of ER and SRC-1 occurs in the absence of exogenous ligand through cyclin D bridging. In addition, SRA (steroid receptor RNA activator), which is part of the SRC-1 complex, mediates transactivation via AF-1. Moreover, ERα/ERβ heterodimers were able to bind the SRC-1 and stimulate transcription of a reporter gene.

TIF2 belongs to the family of transcriptional intermediary factors (TIFs) which mediate AF activity to the transcription machinery. The SRC-1-related TIF2 also efficiently stimulates AF-2 activity of ER *in vivo*. Another protein involved in coactivator complex with SRC-1 is p300/CBP, a 300-kDa protein related to the cAMP response element-binding protein, CBP. It has been demonstrated that SRC-1 and p300/CBP contain intrinsic acetyltransferase activity and can interact with other histone acetyltransferases (HATs). Acetylation by SRC-1 of histones bound at specific promoters could be a mechanism by which the AFs of ER and associated coactivators activate transcription of specific genes by enhancing formation of a stable preinitiation complex.

A Molecular Mechanism for Antioestrogen Action

Antioestrogens are competitive inhibitors of oestrogen action. The shape of the ligand, with a strategically placed alkylaminoethoxy side chain, is essential to convert an oestrogenic complex to an antioestrogenic complex with reduced oestrogenic efficacy. Earlier models of antioestrogen action (proposed before the ER was cloned and sequenced) suggested that the antioestrogenic side chain prevents the receptor from closing so that the activation of the complex would be incomplete. The partial agonism of receptor complexes would occur because of an equilibrium mixture of activated and unactivated receptor complexes.

There is now convincing evidence that the shapes of different antioestrogen–ER complexes are not all the same. A mutated ER assay methodology in human liver cancer cells was used to classify new drugs based on their interaction with an engineered C_3 promoter target. However, it is the realization that a third component of the signal transduction system is involved that has provided the most excitement for understanding why some antioestrogens are

more oestrogen-like than others. Coactivators and possibly corepressors are key components that can modulate gene activation. Clearly, the shape of an antioestrogenic ER complex will dictate how or if any other protein in a transcription unit will bind.

The crystallization of the LBD of the ER with oestrogens and antioestrogens has provided enormous insight into the change in protein shape that prevents antioestrogens from building a transcription complex at AF-2. It is known that 4-hydroxytamoxifen silences AF-2 whereas AF-1 remains constitutively activated.

Both raloxifene and 4-hydroxytamoxifen fit into the hydrophobic pocket of the ligand-binding domain but the antioestrogenic side chain prevents the reorientation of helix 12 that must seal the ligand into the receptor before coactivators can bind and produce a transcription complex (Brzozowsky *et al*., 1997; Shiau *et al*., 1998). The high affinity ligands both interact, through phenolic hydroxyls, with Glu353 and Arg394 to locate the ligands correctly in the binding domain (**Figure 4**). However, the tertiary nitrogen side chain with a bulky phenyl group is critical for antioestrogenic activity because of an interaction with Asp351. This interaction is the key to oestrogen-like properties of the ER complex which may or may not subsequently bind coactivators (MacGregor Schafer *et al*., 2000). Although the X-ray crystallography of the raloxifene–and tamoxifen–ER complexes are similar (Brzozowsky *et al*., 1997; Shiau *et al*., 1998), there are significant differences in the interaction of the antioestrogenic side chains of raloxifene and 4-hydroxytamoxifen with amino acid 351. These differences have the potential to alter the degree of oestrogenic activity of the different antiestrogen–ER complexes (MacGregor and Jordan, 1998).

Corepressors

Although the experimental evidence suggests that activating functions can be prevented in the antioestrogen–ER complex by stopping coactivators from binding, an alternative hypothesis is an increased binding of proteins that interact only with the antiestrogen–ER complex. Corepressors would therefore neutralize an antiestrogen–ER complex.

CURRENT STRATEGIES FOR THE ENDOCRINE TREATMENT OF BREAST CANCER

The description of the target site specificity of oestrogen and the regulation of steroidogenesis by the hypothalamopituitary axis have been fundamental to devise current strategies that restrict the access of oestrogens to the tumour. It is now appropriate to summarize the principal therapeutic strategies that have proved to be successful endocrine approaches to control tumour growth.

Most of the work was originally focused on postmenopausal patients with metastatic breast cancer (**Figure 5**). Antioestrogens bind specifically to the ER in the breast tumour so the action of the group was a direct application of the emerging knowledge of oestrogen action in its target tissue during the 1960s (Jenson and Jacobson, 1962). In contrast, aminoglutethimide restricted the availability of circulating oestrogen in postmenopausal women. Aminoglutethimide blocks the biosynthesis of steroids in the adrenal glands and blocks the conversion of androstenedione to oestrone by aromatase enzymes in peripheral body fat (**Figure 5**). Although the approach of using aminoglutethimide was clinically successful, the incidence of side effects focused efforts to design more specific agents. The result is a variety of aromatase inhibitors that are specific for the enzyme at peripheral sites.

The antioestrogen tamoxifen has been proved to be effective in premenopausal patients (**Figure 6**) despite increases in circulatory oestrogen caused by interruption of the hypothalamopituitary axis feedback system. The sensitivity of the hypothalamopituitary axis to an *apparent* reduction in circulating oestrogen levels from the ovary causes a reflex rise in gonadotrophins. This is also the reason why aromatase inhibitors are not used in premenopausal women because the powerful action of

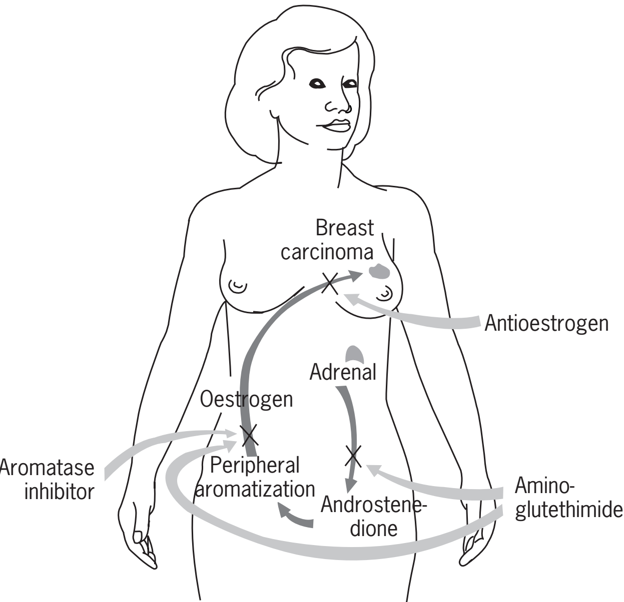

Figure 5 The evolution of strategies for the endocrine treatment of advanced breast cancer in postmenopausal patients. Antioestrogens block oestrogen action in the tumour. Aminoglutethimide blocks steroidogenesis in the adrenal glands and the conversion of androstenedione by aromatase enzymes in peripheral body fat. Aromatase inhibitors are now available that block the peripheral enzyme specifically.

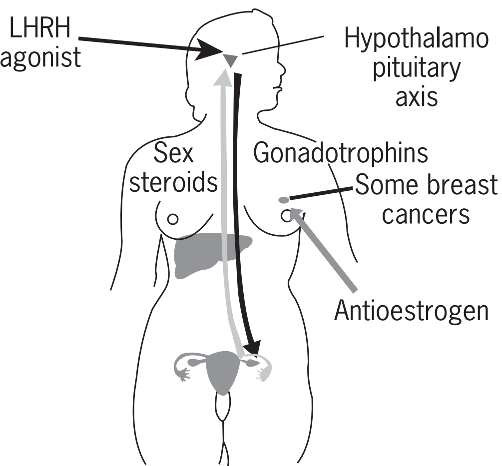

Figure 6 Premenopausal women with advanced breast cancer can be successfully treated with luteinizing hormone-releasing hormone (LHRH) agonists that causes a chemical oophorectomy by desensitizing the pituitary gland, thereby blocking gonadotrophin release. Additionally, tamoxifen blocks oestrogen binding to tumour ER. Combination therapy of the antihormones is proving to be a valuable new treatment strategy.

gonadotrophins would reverse ovarian aromatase blockade. Another strategy, that is proving to be successful in premenopausal patients, is the use of sustained release preparations of luteinizing hormone-releasing hormone (LHRH) to cause desensitization of the pituitary gland. As a result, the reduction in gonadotrophins causes a chemical oophorectomy. A combination of a sustained release preparation of an LHRH agonist and an antioestrogen will effectively decrease the availability of oestrogen to the tumour. This treatment approach is being evaluated at present.

INHIBITION OF OESTROGEN SYNTHESIS

Premenopausal Women – Luteinizing Hormone-Releasing Hormone (LHRH) Agonists

Castration was first reported as an effective therapy for metastatic breast cancer over 100 years ago, at a time when hormones had not been characterized. Several different means of causing ovarian ablation have been studied in the interim: surgical oophorectomy, radiation-induced ablation of the ovaries and, more recently, medical therapy using LHRH agonists.

LHRH is produced by the hypothalamus and stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary, which in turn stimulate the ovaries to synthesize oestrogen and progesterone. Under normal conditions, LHRH is released in a pulsatile manner, resulting in pulsatile release of LH and FSH. The continuous administration of an LHRH agonist overstimulates the LHRH receptors, causing an initial rise in LH and FSH. However, after 1–2 weeks the LHRH receptors become desensitized, leading to decreased release of FSH and LH. The ovaries respond by decreasing the synthesis of oestrogen and within 4 weeks of starting therapy with an LHRH agonist, circulating oestrogen levels are at a postmenopausal level. Unlike other ways of causing castration, serum oestradiol levels return to normal within 4 weeks of discontinuing the LHRH agonist.

Goserelin acetate (Zoladex®) is the only LHRH agonist approved by the US Food and Drug Administration (FDA) for the treatment of metastatic breast cancer in pre- and perimenopausal women. It is administered as a monthly, subcutaneous injectable implant (3.6 mg) that provides continuous release of the drug. Response rates ranging from 28 to 60% have been reported from phase II clinical trials of goserelin acetate in premenopausal women with metastatic breast cancer. In a randomized trial of premenopausal women with metastatic disease comparing goserelin acetate with surgical oophorectomy, with or without tamoxifen, no significant differences in response rates or survival were detected between treatment arms. Toxicities reported in women receiving goserelin acetate are those consistent with a menopausal state including hot flushes, loss of libido, vaginal dryness and decreased bone mineral density. Other LHRH agonists under investigation include buserelin and tryptorelin. The role of LHRH agonists as an adjuvant therapy for early-stage breast cancer is the subject of ongoing clinical trials.

Postmenopausal Women – Aromatase Inhibitors

The aromatase enzyme is the rate-limiting step in the conversion of androgens to oestrogens. Aromatase is an enzyme complex containing a cytochrome P-450 haemoprotein and a flavoprotein, nicotinamide adenine dinucleotide phosphate (NADPH) P-450 reductase. The cytochrome P-450 catalyses a series of three hydroxylations of the androgen substrates, androstenedione and testosterone. Since the aromatase cytochrome P-450 has little homology to other P-450 enzymes, it has been assigned to a separate gene family designated CYP19.

The major substrates for the aromatase enzyme are androstenedione (**Figure 7**) and testosterone, both produced principally in the adrenal glands, and to a lesser degree in the ovaries. Aromatase expression has also been demonstrated in the stromal compartment of some human breast tumours. This finding suggests that some breast tumours may have an innate ability to synthesize oestrogen, thereby stimulating growth locally. Whether this finding is clinically relevant is unknown. Figure 7 Classification of aromatase inhibitors.

enzyme selectively catalyses only the production of oestrogens, whereas other similar enzymes govern the production of other steroid hormones including glucocorticoids, androgens or mineralocorticoids. The optimum way of decreasing oestrogen production is to target *selectively* the aromatase enzyme without inhibiting the activity of the other enzyme systems.

Aromatase inhibitors are of two general types, competitive inhibitors and suicide inhibitors (**Figure 7**). Once a suicide inhibitor binds the aromatase enzyme, the sequence of hydroxylations is initiated, but the hydroxylations produce a covalent bond between the enzyme and inhibitor that irreversibly blocks the activity of the enzyme. Following exposure to a suicide inhibitor, the aromatase enzyme activity can only be restored with new enzyme synthesis. Suicide inhibitors include formestane and exemestane. Competitive inhibitors *reversibly* bind to the active enzyme site and either no enzyme activity is triggered or it has no effect. The inhibitor can dissociate from the binding site, allowing renewed competition between the inhibitor and substrate (i.e. androstenedione) for binding to the active binding site. For the effect of a competitive inhibitor to persist, a constant concentration of the inhibitor, in excess of the substrate, must be present. Competitive inhibitors include aminoglutethimide (nonselective), anastrazole and letrozole.

Competitive Aromatase Inhibitors

Aminoglutethimide

Aminoglutethimide (**Figure 7**) was the first widely used aromatase inhibitor for the treatment of advanced breast cancer. It caused a 'medical adrenalectomy' by blocking cholesterol side-chain cleavage, leading to a decrease in adrenal steroid synthesis. In addition, aminoglutethimide inhibits the peripheral aromatase system, resulting in decreased conversion of androstenedione to oestrogens. Adrenal synthesis of cortisol is inhibited by the action of aminoglutethimide, which can lead to clinical features of Addison disease including skin rash, fatigue, lethargy, ataxia and orthostatic hypotension. As a result, aminoglutethimide is usually administered with a supplemental corticosteroid, such as hydrocortisone.

The results from numerous clinical trials involving the combination of aminoglutethimide and replacement steroids show response rates of 20–56% in previously untreated patients with advanced breast cancer. The median duration of response is 11–12 months. Although described as previously untreated, many of the patients in these trials had received prior androgens, oestrogens or oophorectomy. Patients with ER–positive tumours have higher response rates (56%) compared with patients with ER-negative tumours (12%). Additionally, patients with sites of disease predominantly in the skin, soft tissues and bone were most likely to respond to aminoglutethimide.

Anastrazole

Anastrazole (Arimidex®) (**Figure 7**) is a potent, oral selective aromatase inhibitor that is approved as treatment for metastatic breast cancer in postmenopausal women who have failed tamoxifen. In animal studies, anastrazole was selective for the aromatase enzyme, while not inhibiting enzymes in the adrenal gland that control other

pathways such as mineralocorticoid or glucocorticoid synthesis. For all doses of anastrazole evaluated in phase I studies, the drug is well tolerated and does not effect cortisol or aldosterone secretion, at baseline or in response to ACTH. Consequently, glucocorticoid or mineralocorticoid replacement therapy is not required with anastrazole treatment.

The results from two mature phase III clinical trials have been reported. Anastrazole (1 or 10 mg per day) was compared to oral megesterol acetate (160 mg per day) in 764 postmenopausal patients with metastatic breast cancer that developed progressive disease following treatment with tamoxifen. Patients who received the 1 mg dose of anastrazole had a statistically significant survival advantage over patients receiving megestrol acetate (22% relative reduction in mortality). Patients receiving 1-mg of anastrazole had a longer median time to death (26.7 months) than patients receiving megesterol acetate (22.5 months). A nonsignificant survival advantage was observed for patients receiving the 10-mg dose of anastrazole compared with patients receiving megesterol acetate. Anastrazole was well tolerated at both dose levels and was not associated with the weight gain or dyspnoea observed in patients treated with megesterol acetate. The recommended daily dose of anastrazole is 1 mg. Anastrazole is as good as, if not better than, tamoxifen as a first-line therapy for metastatic breast cancer and is also under investigation as an adjuvant therapy.

Letrozole

Letrozole (Femara®) (**Figure 7**) is a potent, oral selective aromatase inhibitor, recently approved for the treatment of tamoxifen-resistant, advanced breast cancer in postmenopausal women. Phase I/II clinical trials showed that both 0.5- and 2.5-mg doses of letrozole suppressed circulating levels of oestrogen by over 90% and both doses were clinically effective. In a randomized, phase III clinical trial comparing letrozole (0.5 or 2.5 mg per day) with megesterol acetate (160 mg per day), 551 patients were evaluated. Patients treated with 2.5 mg of letrozole attained a 24% overall response rate compared with 16 and 13% in patients treated with megesterol acetate and 0.5 mg of letrozole, respectively. Patients treated with 2.5 mg per day of letrozole also had a longer time to treatment failure than patients in the other two treatment groups, but there was not a statistically significant survival advantage for any treatment group. Similarly to the anastrazole trials, letrozole was well tolerated and was associated with less weight gain and dyspnea compared with megesterol acetate.

In a large trial, 555 postmenopausal women with tamoxifen-resistant, advanced breast cancer were randomized to letrozole (0.5 mg or 2.5 mg per day) or aminoglutethimide (250 mg twice daily). Patients treated with letrozole achieved a higher response rate than patients treated with aminoglutethimide: letrozole (2.5 mg per day) 19.5%, letrozole (0.5 mg per day) 16.7% and aminoglutethimide 12.4%. Patients treated with the higher dose of letrozole attained a small, but statistically significant improvement in time to disease progression and overall survival (28 versus 20 months) compared with patients treated with aminoglutethimide. The recommended daily dose of letrozole is 2.5 mg.

In the USA, only anastrazole and letrozole are FDA approved for second-line therapy of metastatic breast cancer in postmenopausal women following treatment with antioestrogens. Ongoing clinical trials are evaluating the efficacy of selective aromatase inhibitors as first-line therapy in postmenopausal patients with ER-positive, metastatic breast cancer. In addition, these agents are being evaluated in the adjuvant setting, either as primary therapy versus tamoxifen or following 5 years of treatment with tamoxifen.

Suicide Aromatase Inhibitors

Formestane

Formestane (Lentaron®) or 4-hydroxyandrostenedione (**Figure 7**) is a steroidal inhibitor that is approved outside the USA for the treatment of advanced breast cancer in postmenopausal women. Formestane has poor oral bioavailability and is generally administered as an intramuscular (IM) injection. A schedule of 250 mg, IM, every 2 weeks inhibits peripheral aromatization by 85% and suppresses oestradiol levels by 65%. Several reports indicate that this administration schedule results in objective tumour responses of up to 40% and stable disease status in an additional 14–29% of patients. Formestane has been compared with tamoxifen as first-line therapy of metastatic disease in postmenopausal patients who have received prior adjuvant therapy. Objective response rates were similar for the two agents. IM administration of the drug can be associated with injection abscesses and inadvertent intravenous injection has been associated with anaphylactoid reactions.

Exemestane

Exemestane (Aromasin®) (**Figure 7**) is a steroidal aromatase inhibitor developed for oral use. Following a 25 mg per day oral dose of exemestane, plasma levels of oestrone, oestradiol and oestrone sulphate were found to be suppressed by 94.5, 92.2 and 93.2%, respectively. A large phase II, multicentre trial evaluated exemestane (25 mg per day) in patients with progressive metastatic disease following treatment with nonsteroidal aromatase inhibitors. A total of 241 patients were enrolled and an objective response rate of 7% was observed and an additional 25% of patients maintained stable disease for >6 months. Nonvisceral sites of disease were most likely to respond. Exemestane produced an overall response rate of 40% (CR + PR + SD) in 78 patients who were refractory to, or who developed progressive disease while receiving aminoglutethimide. An objective response rate of 9% was

observed in 87 patients who developed progressive disease following treatment with megesterol acetate and tamoxifen. An additional 20% of patients maintained stable disease for >6 months. Patients who had become refractory to exemestane, 25 mg per day, did not respond to 100 mg per day. A large, international trial, comparing exemestane with megesterol acetate in tamoxifen-refractory metastatic disease has just been completed. In general, these clinical trials have shown exemestane to be well tolerated. Nausea, fatigue and hot flushes are the most commonly reported toxicities.

BLOCKING OESTROGEN ACTION

Tamoxifen for Treatment in Pre- or Postmenopausal Patients

The antitumour effect of tamoxifen (Nolvadex®) (**Figure 2**) is mediated primarily through the ER. Tamoxifen is considered the first-line endocrine therapy for all stages of breast cancer and was recently reported to reduce the risk of developing breast cancer in high-risk populations of women. Tamoxifen is currently approved for the treatment of metastatic breast cancer in postmenopausal women, ER-positive, metastatic breast cancer in premenopausal women and metastatic breast cancer in men. Tamoxifen is also approved as an adjuvant therapy, either alone or following chemotherapy for early-stage, hormone receptor-positive, breast cancer in pre- and postmenopausal women.

Clinical trials evaluating tamoxifen in postmenopausal women with advanced breast cancer have reported response rates of 15–53%, with a median duration of response of 20 months. The patient characteristics that predict a response to tamoxifen are similar to other endocrine therapies. Tumours expressing ER have a 50% probability of responding to tamoxifen compared with $<10\%$ in patients with ER-negative tumours. Tamoxifen has been shown to be equally effective in inducing tumour responses compared with other forms of endocrine therapy; however, tamoxifen is associated with less toxicity. The few published phase II clinical trials of tamoxifen treatment in premenopausal women with ER-positive, metastatic breast cancer report response rates between 20 and 45% with a median duration of response of 2.5–36 months. Small, randomized clinical trials comparing tamoxifen with oophorectomy in premenopausal patients with metastatic disease show no statistically significant difference in overall response rate between the two treatments.

The Oxford Overview Analysis of systemic adjuvant therapy for early-stage breast cancer confirmed that tamoxifen reduced the odds of breast cancer recurrence by 25% and the risk of death due to breast cancer by 16%, compared with patients not treated with tamoxifen (EBCTCG, 1998). The benefit produced by tamoxifen was more significant in postmenopausal women, in whom the annual odds of breast cancer recurrence and death were reduced by 29 and 20%, respectively. The relative benefit of tamoxifen was the same whether patients were axillary node positive or negative, but the absolute benefit was of greater magnitude in patients with the greatest risk of recurrence (e.g. axillary node positive). The magnitude of benefit derived from adjuvant tamoxifen therapy also depended on whether a tumour was ER positive or negative. The annual odds of recurrence were reduced by 13% in patients with ER-poor tumours and by 32% in patients with ER-positive tumours. Similarly, the reduction in the annual odds of death was 11 and 21% in patients with ER-poor and ER-positive tumours, respectively. In postmenopausal women with ER-positive tumours, tamoxifen reduced the annual odds of recurrence and death by 36 and 23%, respectively, compared with patients with ER-negative tumours, in whom the annual odds of recurrence and death were reduced by only 16%. Reanalysis of the data in the Oxford Overview Analysis 5 years later demonstrated little or no benefit for patients with ER-negative tumours taking tamoxifen (EBCTCG, 1998). In ER-positive patients under the age of 50 years treated with adjuvant tamoxifen, there is a significant reduction in the odds of death that is comparable to patients over the age of 50 years, treated with adjuvant tamoxifen, and similar to the reduction in the annual odds of death detected in patients under the age of 50 years who are treated with adjuvant chemotherapy.

It is important to point out that the Oxford Overview Analysis (EBCTCG, 1998) of breast cancer adjuvant clinical trials confirmed several principles defined in the laboratory: (1) tamoxifen blocks oestrogen binding to the ER so a patient with an ER-positive tumour is more likely to respond; (2) long-term early treatment in animal models produces a more complete antitumour effect than short-term treatment, thus long-term adjuvant therapy should be superior to short-term adjuvant therapy; and (3) tamoxifen prevents rat mammary carcinogenesis so the drug should reduce primary breast cancer incidence. It is now established that tamoxifen is effective in pre- and postmenopausal women, 5 years of adjuvant treatment is superior to 1–2 years of treatment and 5 years of adjuvant treatment reduces the incidence of contralateral breast cancer by 47%.

The optimum duration of tamoxifen therapy in the adjuvant setting has been addressed by several clinical trials and considered in the Oxford Overview Analysis. The Oxford Overview Analysis stratified patients based on tamoxifen therapy administered for <2, 2 and >2 years. Although the Oxford Overview Analysis does not answer the question regarding the optimum duration of tamoxifen treatment, the greatest reduction in the risk of recurrence and death was seen in patients treated with tamoxifen for >2 years. It is now clear that 5 years of therapy is superior

to shorter durations of therapy in terms of reducing the risk of recurrence and death (**Figure 8**). This is also true for the reductions in incidence of contralateral breast cancer (**Figure 9**).

The benefit of tamoxifen therapy for longer than 5 years has been addressed in three studies, comparing 5 years of tamoxifen therapy with 10 years or indefinite therapy. The results from these trials do not show additional clinical benefit from adjuvant tamoxifen treatment with durations of therapy longer than 5 years. The National Cancer Institute (NCI) recently recommended that tamoxifen should be discontinued after 5 years of adjuvant treatment in patients with node-negative disease (Fisher *et al*., 1996). An important observation, bearing on the duration of treatment, is the fact that patients who stop tamoxifen at 5 years continue to accrue survival benefit (EBCTCG, 1998). Obviously, the long-term effects of tamoxifen merit continued investigation. Indeed, there is a possibility that the duration (i.e. 5 years) of tamoxifen currently used for chemoprevention is not the optimum. Only additional clinical trials of longer duration can address this issue, but decades of patient follow-up will be necessary before sufficient data are available. The major problem is that long-term therapy tends to increase the possibility of developing drug resistance. In the case of tamoxifen, drug resistance can manifest itself in the selection of ER-positive tumours that grow in response to tamoxifen (Gottardis and Jordan, 1988). As a result, an antioestrogen that is devoid of oestrogen-like properties would be an advance for the treatment of breast cancer.

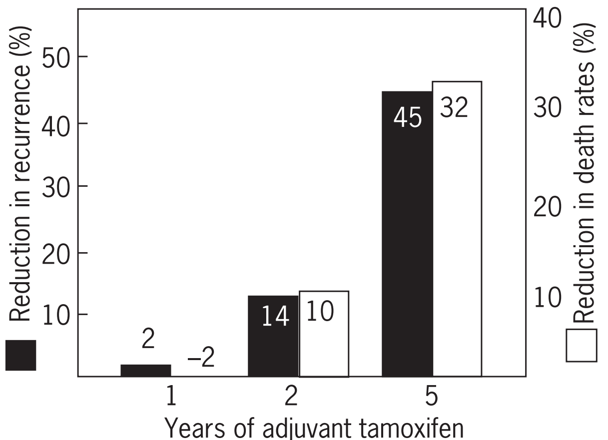

Figure 8 The relationship between the duration of adjuvant tamoxifen therapy in ER-positive premenopausal patients and the reduction in recurrence and death rate. A longer duration of treatment has a dramatic effective on patient survival. (From Jordan and Morrow, 1999, *Endocrine Reviews*, **20**, 253–278.)

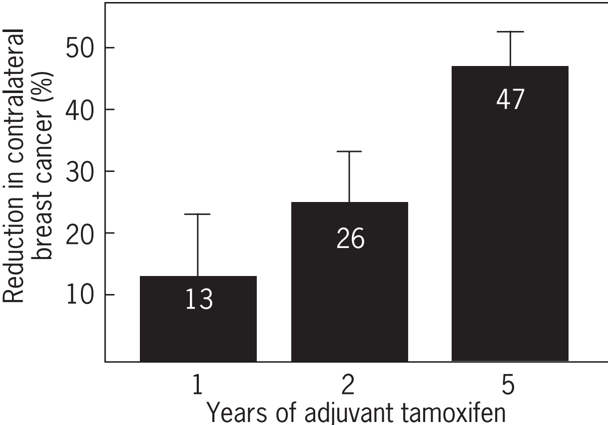

Figure 9 The relationship between the duration of adjuvant tamoxifen and the reduction in contralateral breast cancer. A longer duration is clearly superior, and the 5-year result that produces a 47% reduction in contralateral breast cancer is equivalent to the result observed in the NSABP tamoxifen prevention trial (see **Figure 11**). (From Jordan and Morrow, 1999, *Endocrine Reviews*, **20**, 253–278.)

Pure Antioestrogens for Treatment in Postmenopausal Patients

Pure antioestrogens, such as ICI 182,780 (Faslodex®) (**Figure 10**) are being developed to avoid the weak oestrogen-like effects of tamoxifen that are associated with drug resistance and changes in the uterus. Pure

antioestrogens, unlike mixed agonist–antagonist compounds such as tamoxifen, have a different molecular mode of action. ICI 182,780 binds to the ER with affinity similar to oestrogen, but it causes destabilization of the ER dimer and enhanced ER degradation. The drug has proved effective against tamoxifen-resistant and tamoxifen-stimulated tumours *in vitro* and *in vivo*. Animal experiments also show that ICI 182,780 causes complete block of endometrial and myometrial proliferation. The potential advantages for complete oestrogen blockade in patients include more complete and/or longer lasting clinical responses, activity in tumours that have become resistant to tamoxifen therapy and lack of uterine complications. The potential disadvantages of complete oestrogen blockade include exacerbation of menopausal symptoms, reduced bone mineral density, vaginal dryness and lipid changes. Large randomized clinical trials are now under way that compare pure antioestrogens with selective aromatase inhibitors as second-line therapy for metastatic breast cancer. Clinical trials are also evaluating the effect of pure antioestrogens compared with antioestrogens as first-line therapy for metastatic breast cancer (Howell *et al*., 2000).

Tamoxifen for Prevention in Pre- or Postmenopausal Women

Tamoxifen has 30 years of experience in clinical trials and is used to treat all stages of breast cancer. Naturally, since tamoxifen prevents mammary carcinogenesis in the laboratory, it was a reasonable extension of the use of tamoxifen to test its worth in women at high risk. The National Surgical Adjuvant Breast and Bowel Project (NSABP) Tamoxifen Prevention Trial (P-1) recruited a total of 13 388 women of ≥ 35 years of age who were at increased risk of developing breast cancer to be randomized to receive tamoxifen or placebo for 5 years. All women with a history of lobular carcinoma *in situ* (LCIS) or who were over 60 years of age were eligible to participate in the trial. For all other women, a modified Gail algorithm was used to estimate their risk over time and those women with a 5-year risk of breast cancer of at least 1.67% were eligible to participate. The Gail model (Gail *et al*., 1989) incorporated the following variables: number of affected first degree relatives, number of previous breast biopsies, atypical hyperplasia in a biopsy, age at menarche, nulliparity or age at first live birth and race. The Gail model is available from the NCI as a Risk Disc.

With a median follow-up of 54.6 months, a 49% reduction in the risk of invasive breast cancer and a 50% reduction in the risk of noninvasive breast cancer were detected in women receiving tamoxifen. The reduction in risk was observed in women of all ages and at all levels of breast cancer risk (e.g. LCIS, atypical hyperplasia, etc.). Tamoxifen reduced the occurrence of ER-positive tumours by 69%, but there was no difference in the occurrence of ER-negative tumours. The number of vascular events (e.g. pulmonary embolism, deep venous thrombosis and stroke) was higher in the tamoxifen group than the placebo group. Furthermore, these events tended to occur in women over the age of 50 years. In the tamoxifen-treated women there was also a 45% reduction in hip fractures, a 39% reduction in Colles wrist fractures and a 26% reduction in spine fractures compared with the placebo group. This last finding with an 'antioestrogen' was not unexpected as tamoxifen maintains bone density in the ovariectomized rat and postmenopausal women. Two other chemoprevention studies have been published, but they are too small to be classified as chemoprevention trials. However, the results are valuable to assess the toxicity in well women. The results of the studies are compared in **Figure 11**.

Side Effects of Tamoxifen in Pre- or Postmenopausal Women

The widespread use of tamoxifen as a treatment and now as a chemopreventive has focused attention on its side effects. The most common adverse effect reported in relation to tamoxifen therapy is vasomotor instability, manifested by hot flushes, facial flushing, tachycardia and sweating. These symptoms are reported in 15–20% of pre- and postmenopausal patients and typically decrease in intensity and frequency over time. Amenorrhoea can occur in up to 40% of premenopausal women. Visual disturbances caused by cataract formation, optic neuritis, retinopathy or macular oedema rarely occur. Thromboembolic events can occur in 1–2% of patients treated with tamoxifen (Fisher *et al*., 1998).

During the past 10 years, a number of case reports and clinical trial results have associated tamoxifen therapy with an increased incidence of endometrial carcinoma. Several analyses of the data have concluded that there is a modest increase in the incidence of endometrial carcinoma as a result of receiving tamoxifen (4/1000 tamoxifen-treated women per year versus 1/1000 women per year for the normal postmenopausal population). Premenopausal women do not have an elevation of their risk of endometrial cancer (Fisher *et al*., 1998). This potential toxicity is more relevant to patients receiving tamoxifen as a chemopreventive agent.

SELECTIVE OESTROGEN RECEPTOR MODULATION

Nonsteroidal antioestrogens were originally defined as compounds that would inhibit oestradiol-stimulated rat uterine weight. The nonsteroidal antioestrogens are partial oestrogen agonists in the uterus, but also inhibit carcinogen-induced rat mammary tumour growth and the growth

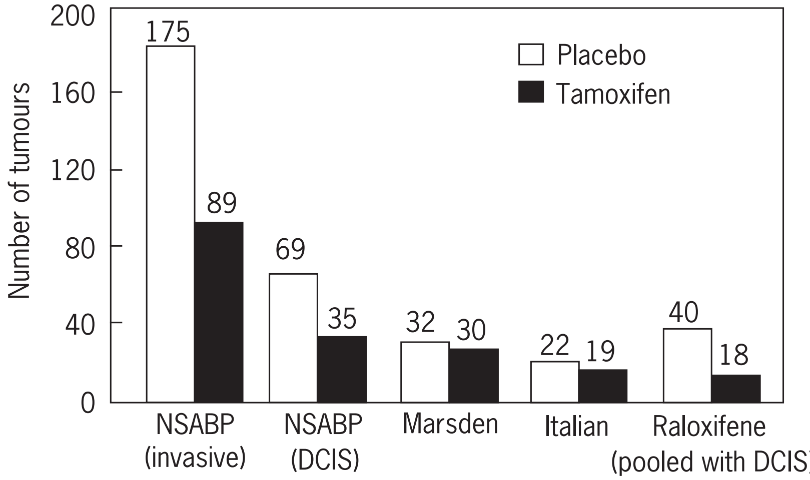

Figure 11 A comparison of the able-to-be evaluated events observed in the studies to reduce the incidence of breast cancer in well women. The National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 trial is the only completed prospective clinical trial designed to test the worth of an antioestrogen to prevent breast cancer in 13 388 high-risk women, who were selected on a validated mathematical risk model. The figure illustrates the effect of tamoxifen on both invasive and noninvasive ductal carcinoma *in situ* (DCIS) breast cancer. By contrast, the Royal Marsden study is a pilot project, and stated to be a toxicity evaluation in 2471 women at lower risk than the NSABP study. These women were selected based on first-degree relatives with breast cancer. The Italian study is from 3984 normal-risk women, half of whom had already had an oophorectomy. Finally, the raloxifene result is estimated from published abstracts and is a secondary endpoint from 10 553 postmenopausal women around 70 years of age who were participating in osteoporosis trials. The results for raloxifene are for both invasive and noninvasive breast cancer, but an effect of raloxifene on reducing DCIS alone has not been found because the events are too few. (From Jordan and Morrow, 1999, *Endocrine Reviews*, **20**, 253–278.)

of ER-positive breast cancer cells *in vitro*. The finding that the compounds expressed increased oestrogenic properties, i.e. increased uterine weight in the mouse, raised questions about the reasons for the species specificity and created a new dimension for study which ultimately led to the recognition of the target site-specific actions of antioestrogens. However, the finding that tamoxifen would increase immune-deficient mouse uterine weight but prevent the growth of a transplanted ER-positive breast tumour suggested that the tamoxifen–ER complexes were being interpreted differently, i.e. as an oestrogenic or antioestrogenic signal, respectively, at different target sites (Jordan and Morrow, 1999). Additionally, tamoxifen and raloxifene maintained bone density in ovariectomized rats at doses that prevent mammary cancer (Delmas *et al*., 1997). This concept was subsequently referred to as selective oestrogen receptor modulation (SERM) to describe the target site-specific effects of tamoxifen around a women's body (**Figure 12**) and to justify the use of raloxifene as a preventive for osteoporosis. The whole class of drugs is now known as SERMs.

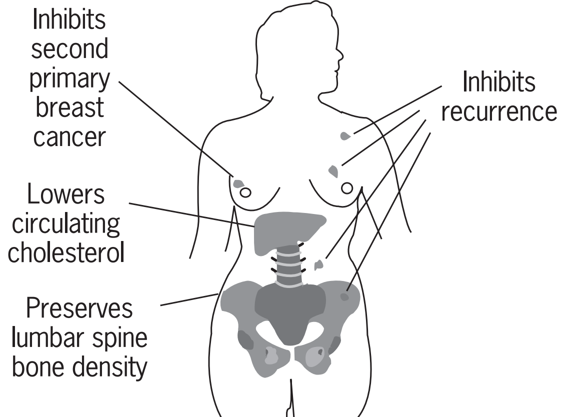

Figure 12 The selective ER modulation observed clinically with tamoxifen in postmenopausal women. Tamoxifen is an antioestrogen in breast cancer but has oestrogen-like actions in bone and causes a decrease in circulating cholesterol.

During the past decade, there has been intense interest in identifying the reason for the target site-specific effects of antioestrogens. One possible mechanism is the presence of two ERs, ERα and ERβ, but, there are no definitive studies that indicate that tamoxifen or raloxifene interact differently with either receptor. Although the precise mechanisms have not, as yet, been discovered, the incentive to achieve success is high. This knowledge will not only permit a rational application of tamoxifen and raloxifene in patients, but also the discovery of new

mechanisms for drug selectivity will open the door for new innovations in drug discovery.

An ideal antioestrogen would exhibit the target site-specific effects that SERMs do but they would be more refined. For example, the use of tamoxifen carries an increased risk of endometrial cancer and has been shown to cause DNA adduct formation in the rat liver (White, 1999). Clearly, a compound that does not cause the negative side effects and that possesses all of the benefits of tamoxifen would be an attractive option. Several different compounds are currently under investigation. In general they are structurally related to the compound raloxifene (**Figure 13**).

The rationale for the use of raloxifene as a breast cancer preventive is based on a hypothesis that was formulated when selective oestrogen receptor modulation was first recognized. The concept was simply stated.

We have obtained valuable clinical information about this group of drugs that can be applied in other disease states. Research does not travel in straight lines and observations in one field of science often become major discoveries in another. Important clues have been garnered about the effects of tamoxifen on bone and lipids (**Figure 12**) so it is possible that derivatives could find targeted applications to retard osteoporosis or atherosclerosis. The ubiquitous application of novel compounds to prevent diseases associated with the progressive changes after menopause may, as a side effect, significantly retard the development of breast cancer. The target population would be postmenopausal women in general, thereby avoiding the requirement to select a high-risk group to prevent breast cancer (Lerner and Jordan, 1990).

This concept, and the supporting laboratory data, subsequently led to the development of raloxifene for osteoporosis, but with the possibility of breast and uterine safety. This would be distinct from the use of oestrogen replacement therapy to prevent osteoporosis because oestrogen causes an increased risk of breast and endometrial cancer.

Figure 13 SERMs currently under investigation as treatments or preventives for osteoporosis, coronary heart disease or breast cancer.

Raloxifene

Raloxifene (Evista®) (**Figure 13**) was originally under development as a breast cancer therapy, but results from an early clinical trial with raloxifene in patients with advanced disease were disappointing. As a result, the development of raloxifene was redirected in the 1990s towards osteoporosis because of encouraging laboratory data on bone density (Jordan *et al*., 1987). Raloxifene is approved for the prevention of osteoporosis in postmenopausal women (Delmas *et al*., 1997; Ettinger *et al*., 1999). The current incentive to test raloxifene further in multiple diseases comes from trials to prevent osteoporosis The Multiple Outcomes of Raloxifene Evaluation (MORE) Trial involved over 7700 women and an additional 2800 women participating in other clinical trials designed to examine the risk of fracture in postmenopausal women who received either placebo or raloxifene were also analysed. The trials were not designed to assess the efficacy of raloxifene as a breast cancer-preventive agent, but based on the hypothesis that a tamoxifen-like drug can reduce breast cancer and maintain bone density, analysis of the data at 40 months of follow-up showed a 65% decrease in the incidence of invasive breast cancer in raloxifene-treated patients compared with patients receiving placebo. Similar to the findings from the NSABP Tamoxifen Prevention Trial (P-1) (Fisher *et al*., 1998), the effect of raloxifene was most striking in reducing the occurrence of ER-positive tumours (74%). Raloxifene appeared to have no effect on the incidence of ER-negative tumours (Cummings *et al*., 1999). An analysis of breast cancer incidence from all randomized osteoporosis trials involving raloxifene is shown in **Figure 11**. This preliminary observation encouraged the NCI to support a second prevention trial that is comparing raloxifene with tamoxifen in postmenopausal women determined to be at high risk of developing breast cancer. The trial, Study of Tamoxifen and Raloxifene (STAR), is recruiting 22 000 volunteers.

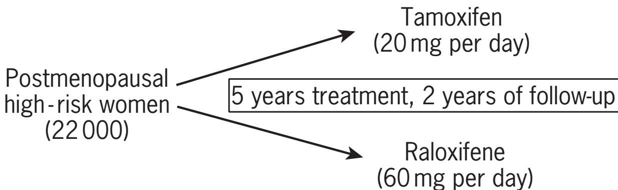

Figure 14 The study of tamoxifen and raloxifene (STAR) is recruiting 22 000 high-risk postmenopausal women to be randomized to tamoxifen (20 mg per day) or raloxifene (60 mg per day). Compounds will be given for 5 years with a 2-year wash out period. Endometrial biopsies are not required, but symptoms of spotting and bleeding will be followed up to determine whether endometrial cancer is present. The primary endpoint is breast cancer incidence, but secondary endpoints of fractures, coronary heart disease and symptoms will be collected.

Results will be available in 2006 (**Figure 14**) (Jordan and Morrow, 1999).

CONCLUSIONS

The development of endocrine therapy for the treatment and prevention of breast cancer has evolved dramatically over the last 100 years. Most patients with an established diagnosis of breast cancer will receive some form of endocrine therapy during the clinical course of their disease. One of the most attractive aspects of the endocrine therapies currently available is the ease with which most patients tolerate the medications.

As laboratory observations have been translated to the clinic, antioestrogens have been shown to reduce the incidence of breast cancer in high-risk populations. One of the intriguing observations from the NSABP Tamoxifen Prevention Trial is that tamoxifen appears to reduce the occurrence of ER-positive breast cancer exclusively (Fisher *et al*., 1998). However, the fact raloxifene is widely used as a preventive for osteoporosis and is being tested in high-risk populations for the prevention of coronary heart disease points to a broader future application for SERMs. As novel SERMs are developed and targeted for different diseases, it is possible to speculate that the incidence of breast cancer will decrease. Nevertheless, with an ageing population, the absolute number of breast cancer cases may remain the same. These tumours may be refractory to traditional endocrine therapy because of antioestrogen drug resistance or the tumour is already ER negative. This will be among the challenges of cancer pharmacology in the twenty-first century.

At present there are no therapeutic interventions that can reduce the risk of prostate cancer. However, measurement of prostate-specific antigen (PSA) can provide guidance for the physician when monitoring elderly men over the age of 70 years.

Prostate cancer is age related and appears to be more hormone responsive than breast cancer, i.e. more men respond initially to endocrine therapy. The treatment of prostate cancer has followed the successful path established for breast cancer. Men no longer have to have their testes removed to reduce circulating androgen levels. LHRH agonists are used routinely to cause a chemical hypophysectomy and reduce gonadotropin levels. Based on advances with nonsteroidal antioestrogens, i.e. drugs for breast cancer treatment, nonsteroidal antiandrogens have been developed to block the androgen receptor in the tumour. Today the treatment of prostate cancer mirrors the treatment of breast cancer. For the future, an effort is being made to study the chemoprevention of prostate cancer by interrupting the prostate-specific metabolic activation of androgens to the steroid dihydrotestosterone that binds to the androgen receptor. Similarly, there are attempts to develop a new class of drugs, the selective androgen receptor modulators (SARMs), that might have multiple applications in men's health.

Chapter 93

Antiangiogenic Therapy

Kevin J. Turner and Adrian L. Harris

Imperial Cancer Research Fund, Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK

CONTENTS

- Why is Angiogenesis an Attractive Therapeutic Target?
- Principles of Antiangiogenic Therapy
- Potential Problems in Antiangiogenic Therapy
- The Future of Antiangiogenic Therapy

WHY IS ANGIOGENESIS AN ATTRACTIVE THERAPEUTIC TARGET?

Tumours depend upon angiogenesis for growth and the development of metastases. This observation has prompted efforts to exploit this dependence in the development of antitumour strategies. This approach has become known as 'antiangiogenesis.' Antiangiogenesis has several theoretical advantages over conventional therapy. Firstly, endothelial cells (ECs) are genetically stable. Unlike tumour cells, the ECs of the neovasculature are normal, unmutated host cells. Spontaneous mutation in tumour cells underlies drug resistance. The relative genetic stability of the endothelium means that the development of drug resistance is less likely. Second, drugs have easy access to their therapeutic target. One of the problems with anticancer therapy is that access of intravenous agents to solid tumours is poor. In antiangiogenic therapy the target cells are those which constitute vessel walls; intravenous antiangiogenic agents contact these cells directly. Third, antiangiogenic therapy has an inherent 'amplification' mechanism. In conventional therapy, cells unaffected by the therapeutic intervention may continue to proliferate. This proliferation of a subpopulation of the tumour leads to tumour regrowth and enhanced drug resistance. In antiangiogenic therapy, successful interference with only a few ECs may lead to disruption of a whole vessel. Loss of a single vessel may deprive a significant number of tumour cells of essential nutrients, leading to cell death. Fourth, ECs active in angiogenesis are distinguishable from host ECs unassociated with the tumour vasculature. Were this not the case, antiangiogenic therapy might affect normal endothelium throughout the body which would markedly restrict its utility. Tumour-associated ECs are distinguished by their rate of proliferation; in human breast cancer, tumour-associated endothelial cells may proliferate up to 50 times more than normal vessels (Fox *et al.*, 1993). Angiogenic ECs also differ from normal endothelium in the antigens that they express. For example, the vascular endothelial growth factor (VEGF) receptor is more abundant on tumour endothelium compared with normal and VEGF also stimulates production and expression of the urokinase receptor on tumour ECs. Similarly, the cell adhesion molecule E-selectin and the integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$ are known to be unregulated in tumour endothelium (Brooks, 1996). Exploitation of these and other differences may lead to antiangiogenic therapy that has no effect on ECs other than those in the tumour neovasculature. Fifth, whilst tumour-associated endothelium differs from normal host endothelium, the ECs in different tumours are relatively similar. It may be that a single antiangiogenic strategy is effective against disparate tumour types. Conversely, there is some heterogeneity between the ECs in different tumours. Exploitation of these differences may allow organ-specific antiangiogenic approaches. (See also the chapter *Angiogenesis*.)

PRINCIPLES OF ANTIANGIOGENIC THERAPY

Antiangiogenic therapy can be targeted at different points in the angiogenesis cascade (**Figure 1**). A study of angiogenic factors in primary tumours has shown that most tumours express at least six different factors (Relf *et al.*, 1997). Despite this multiplicity of factors, inhibitors of individual factors are effective, possibly because of synergy between factors or because some factors are more potent or important than others. Approaches that target ECs directly (vascular targeting) also constitute an important strategy and may bypass problems associated with targeting one of several mediators. The current state of trials involving antiangiogenic agents is summarized in **Tables 1–3**.

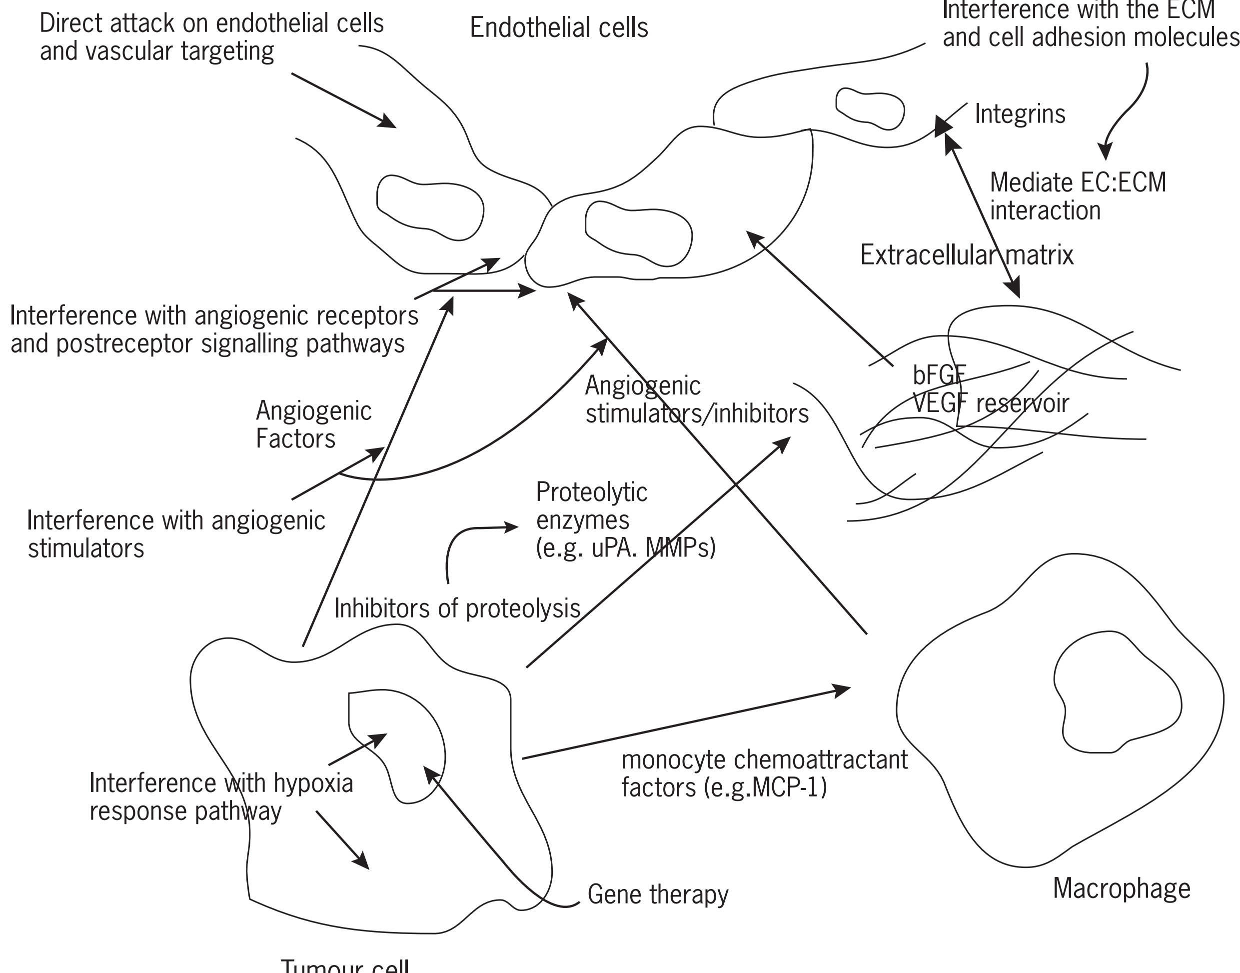

Figure 1 Diagram showing the points at which different classes of antiangiogenic agents may act. (Adapted from Jones and Fujiyama, 1999.)

Interference with Angiogenic Stimulators

VEGF

Monoclonal antibodies to VEGF have reduced both angiogenesis and tumour growth in a number of xenograft animal models. Humanized anti-VEGF monoclonal antibody for the treatment of solid tumours has been used with some success in phase I clinical trials with disease stabilization achieved in 13/25 patients. Phase II trials are currently under way for metastatic renal cancer.

Our understanding of the effects of VEGF antibodies has been enhanced by the use of intravital videomicroscopy techniques that provide 'real-time' information. Treatment with VEGF antibodies results in reductions in the diameter and tortuosity of vessels, and eventually to vessel regression. These data suggest that VEGF is not only needed for angiogenesis, but is also required for the survival of tumour-associated endothelium (Yuan *et al.*, 1996).

An exciting approach is the coupling of toxins to VEGF itself. A fusion molecule consisting of VEGF and the active region of the diphtheria toxin (DT390) demonstrates highly selective toxicity on ECs. This construct slows tumour growth in a murine model of Kaposi sarcoma (KS) (Arora *et al.*, 1999).

FGFs

Interferons are frequently used in the treatment of patients with advanced renal cancer. Exposure of carcinoma cells to interferon-α (IFN-α) *in vitro* and *in vivo* can down-regulate the gene expression and protein production of basic fibroblast growth factor (bFGF) and inhibit growth of human bladder cancer xenografts in nude mice (Dinney *et al.*, 1998). IFN-2α has also been used successfully in the treatment of life-threatening airway haemangiomas in infancy and in the treatment of a giant cell tumour of the mandible. Interferon-α is currently in phase II/III trials.

Table 1 Angiogenesis inhibitors in phase I clinical trials or currently under development (see text for full details)

Name	Class/mechanism of action	Status
VEGF conjugated to diphtheria toxin	Selective targeting of ECs	Under development
Platelet factor 4	Binds to VEGF/bFGF and inhibits binding to receptors	Under development
Dominant mutant VEGFR-2	Binds VEGF and prevents postreceptor triggering	Under development
Soluble mutant VEGFR-1	Binds VEGF and prevents binding to receptor	Under development
SU6668	Inhibits signalling via VEGFR-2 and PDGFR	Phase I
ZD4190	Blocks signalling via VEGFR-2	Under development
Accutin	Disintegrin, blocks binding of ECs to ECM by blocking integrin $\alpha_v\beta_3$	Under development
Endostatin	Mechanism uncertain, but may induce apoptosis	Phase I
Restin	Fragment of collagen XV, mechanism uncertain	Under development
Vasostatin	Fragment of calreticulin, mechanism uncertain	Under development
TSP-1	ECM glycoprotein, mechanism uncertain	Under development
Ang-2	Ang-1 antagonist	Under development
Tie-2 extracellular domain	Reduces binding to endogenous Tie-2	Under development
Gene therapy	Variety of mechanisms	Under development
CM 101	Group B haemolytic streptococcus exotoxin	Phase I

Table 2 Antiangiogenic agents in phase II clinical trials (see text for full details)

Name	Class/mechanism of action	Status
Humanized monoclonal antibody against VEGF	Inhibits VEGF	Phase II, renal cancer
Thalidomide	Inhibits bFGF, precise mechanism unknown	Phase II, against AIDS-KS, breast and prostate cancers
Suramin	Binds VEGF/bFGF	Phase I/II, prostate cancer
Vitaxin	Humanized mouse anti-integrin $\alpha_v\beta_3$ antibody	Phase I/II
Neovastat	MMP inhibitor	Phase I/II
Squalamine	Blocks EC activation and migration	Phase II (in conjunction with other agents)
Combrestatin A4	Induces apoptosis of proliferating endothelial cells	Phase I/II
IL-12	Upregulates IFN-γ and stimulates NK cells	Phase II (AIDS-KS)

Table 3 Antiangiogenic agents in phase III clinical trials (see text for full details)

Name	Class/mechanism of action	Status
Interferon-α	Down-regulation of bFGF	Phase II/III
CAI	Inhibition of calcium-mediated signalling	Phase II/III, ovarian, lung and renal cancers
SU5416	Blocks tyrosine kinase activity of VEGFR-1	Phase I/II/III, in conjunction with conventional chemotherapeutic agents
Marimastat	MMP inhibitor	Phase III
Bay 12-9566	MMP inhibitor	Phase III
AGM 1470	Inhibits methionine aminopeptidase type 2	Phase III
IM-862	Synthetic dipeptide that upregulates IL-12	Phase III (KS)

Thalidomide was originally marketed as a sedative hypnotic in the 1950s. It is now infamous for its potent teratogenic activity causing hypoplastic and aplastic defects in the limbs when ingested during the first 2 months of pregnancy. Thalidomide potently inhibits bFGF-induced angiogenesis *in vivo*. It seems likely that the developmental effects of thalidomide are mediated via this antiangiogenic activity. Thalidomide is currently in stage II trials for the treatment of breast and prostate cancer, gliomas, AIDS related Kaposi sarcoma (AIDS-KS) and diabetic retinopathy. Partial responses have been achieved in hormone-refractory prostate cancer, gliomas and multiple myeloma (Singhal *et al.*, 1999).

Suramin is a polysulfonated naphthylurea that mimics heparin and has been used for 80 years to treat parasitic infections. Virtually all endothelial growth factors

including bFGF and VEGF are heparin binding. Angiogenesis induced by bFGF and VEGF is inhibited in animal models. Most of the clinical experience with suramin is in the treatment of hormone-refractory prostatic carcinoma where it has been evaluated in phase I and II clinical trials with a response rate of approximately 20%. Suramin use is complicated by its long but variable half-life (44–54 days) and its narrow therapeutic index. The most common side effects are haematological and neurological toxicity and adrenal suppression. Analogues with a more favourable therapeutic ratio are under investigation. Some of the problems with use of suramin may be avoided if it is administered locally; some success has been achieved with bladder instillation in the treatment of superficial transitional cell carcinoma.

The anticoagulants fragmin and heparin both have antiangiogenic activity. Analogues to specific regions of the heparin molecule have been shown to inhibit bFGF-induced proliferation in some tumour cell lines. Pentosan polysulfate (PPS) is a synthetic heparin-like compound that is in phase I/II trials for the treatment of AIDS-KS. Disease stabilization has been observed in a small subgroup.

Platelet factor 4 (PF-4) is stored in the α granules of platelets. It is released during platelet aggregation but its physiological role remains unclear. Its use as an experimental control led to the serendipitous observation that it inhibits angiogenesis in animal models. In this context, PF-4 probably works by binding heparin binding proteins such as bFGF and VEGF thus reducing their binding to their receptors. Initial clinical results with PF-4 are disappointing with no beneficial effect observed in the treatment of a variety of tumour types. The short circulating half-life of the currently available forms of PF-4 may underlie this lack of response. Direct injection into KS lesions has resulted in some encouraging results.

Interference with Angiogenic Receptors and Post-receptor Signalling Pathways

The importance of the VEGF–VEGFR-2 receptor–ligand system was investigated in experiments involving the infection of glioblastoma multiforme cells with a retrovirus encoding a dominant mutant of VEGFR-2 which lacks the kinase domain. The mutant receptor dimerized with the wild-type receptor and prevented triggering of the postreceptor pathway after VEGF binding. Glioblastoma multiforme cells infected in this way demonstrated reduced growth *in vitro* (Millauer *et al.*, 1994).

By alternative splicing, the mRNA for VEGFR-1 can also encode a truncated soluble form of the receptor that consists of the extracellular VEGF binding domain but not the intracellular signal transduction moiety. VEGF binds to both species of VEGFR-1 with equal affinity. The role of the soluble receptor variant and the mechanisms that control its expression are unclear. In animal experiments, expression of the soluble form of the receptor was associated with inhibition of tumour growth and metastases and resulted in reduced mortality (Goldman *et al.*, 1998).

Carboxyaminotriazole (CAI) is a low molecular weight synthetic peptide that inhibits proliferation and invasion of a variety of tumour cell types. It works by blocking calcium channels and thus inhibiting the tyrosine kinases associated with a number of angiogenic factor receptors. In *in vitro* angiogenesis assays and in tumour xenograft animal models, CAI has been shown to be antiangiogenic. CAI has been evaluated in phase I and II clinical trials. Encouragingly, CAI resulted in disease stabilization in a number of refractory tumours. Gastrointestinal side effects were the most common but cerebellar ataxia was dose limiting. Phase II/III trials are under way against ovarian, lung and renal cancers.

A number of low molecular weight synthetic peptides have recently been evaluated for their ability to inhibit angiogenesis: Lefluonomide (SU101), SU6668 and SU5416. Lefluonomide is an inhibitor of receptor tyrosine kinases that blocks platelet-derived growth factor (PDGF) signalling. Trials are underway in prostatic, ovarian, lung and brain tumours. SU5416 blocks the tyrosine kinase activity of the VEGFR-1 receptor. Disease stabilization was observed in phase I trials for a number of tumour types and phase I, II and III trials using SU5416 in combination with conventional chemotherapeutic modalities are under way. SU6668 inhibits signalling mediated by both VEGFR-1 and the PDGF receptor. Phase I trials are under way.

ZD4190 is an anilinoquinazoline derivative that inhibits specifically the tyrosine kinase activity of the VEGFR-2 receptor. Significant antitumour activity has been demonstrated following oral administration in animal models.

Signalling by FGFs is mediated by transmembrane receptor tyrosine kinases. Encouraging results in the specific inhibition of this kinase activity have been achieved with pyrimidine-based compounds.

Interference with the Extracellular Matrix (ECM) and Cell Adhesion Molecules

The integrins are a family of transmembrane receptors that mediate cell–cell and cell–ECM interaction. The integrin $\alpha_v\beta_3$ is expressed highly by angiogenic ECs and antibodies to $\alpha_v\beta_3$ can block bFGF-induced angiogenesis. The disintegrins, a family of low molecular weight peptides derived from snake venom, block the binding of human umbilical vein ECs (HUVEC) to the ECM by blockade of $\alpha_v\beta_3$. Accutin is a recently purified disintegrin that has been shown to have *in vivo* antiangiogenic activity in the chick chorioallantoic membrane model of angiogenesis. This effect was mediated by blockade of endothelial $\alpha_v\beta_3$

and induction of apoptosis. A humanized version of a mouse anti-$\alpha_v\beta_3$ antibody named Vitaxin is currently under evaluation in phase I and II clinical trials.

The chemotherapeutic agent doxorubicin has been linked to an α_v integrin-binding motif in an attempt to target drug delivery. The construct enhanced the efficacy and reduced the toxicity of doxorubicin given to nude mice with breast cancer xenografts. (See the chapter *Targeting the Extracellular Matrix*.)

Endogenous Inhibitors of Angiogenesis

The switch to the angiogenic phenotype that is necessary for tumour growth probably results from not only induction of angiogenic stimulators but also the down-regulation of angiogenic inhibitors. Angiostatin and endostatin are angiogenesis inhibitors that show great potential from animal experiments. Angiostatin was initially purified from the urine and blood of mice bearing Lewis lung carcinoma primary xenografts (O'Reilly *et al.*, 1994). Upon removal of the primary tumour (the source of angiostatin), there was marked growth and vascularization of metastases. If purified angiostatin was given intraperitoneally coincident with the removal of the primary tumour, inhibition of metastases was maintained. Furthermore, exogenous angiostatin also reduced the growth of the primary tumour xenografts. Similar results were obtained when the same group subsequently identified endostatin, an endogenous inhibitor of angiogenesis from haemangioendotheliomas. In a dramatic series of experiments, Boehm *et al.* then demonstrated that repeated courses of endostatin caused tumour regression without the emergence of drug resistance (Boehm *et al.*, 1997). Endostatin is currently under evaluation in phase I trials.

The precise mechanisms of action of angiostatin and endostatin are unclear. Angiostatin appears to bind to the α/β-subunits of ATP synthase and thus inhibits matrix-enhanced plasminogen activation with a consequent reduction in invasive activity (Stack *et al.*, 1999). Endostatin is believed to induce endothelial cell apoptosis by the down-regulation of antiapoptotic proteins such as Bcl-2 (Dhanabal *et al.*, 1999).

Angiostatin and endostatin are derived from the proteolytic processing of plasminogen and collagen XVIII, respectively, which are not themselves antiangiogenic. Similarly, Restin is a 22-kDa fragment of human collagen XV that suppresses the growth of renal carcinoma xenografts and Vasostatin is a 180 amino acid fragment of calreticulin that also suppresses human tumour growth in a murine model. Other examples of inhibitory molecules encrypted within larger inactive molecules include a 16-kDa fragment of prolactin which inactivates urokinase by inducing the urokinase inhibitor PAI-1 (plasminogen activator inhibitor), a fragment of prothrombin (prothrombin kringle 2 domain) which inhibited bFGF-induced growth of ECs and the cleaved conformation of the serpin antithrombin. Thrombospondin-1 (TSP-1), another potent inhibitory factor, is an ECM glycoprotein that is also derived from an internal fragment of the whole molecule. Success in determining precisely which residues within TSP-1 are responsible for its inhibitory activity has enhanced the potential of TSP-1 as an antiangiogenic agent. Regulation of the proteolytic processing that produces these endogenous inhibitors is a potential antiangiogenic strategy.

Blood vessel maturation is regulated by angiopoetin-1 (Ang-1), which binds to the tyrosine kinase receptors Tie-1 and Tie-2. Tumours produce a related factor, Ang-2, which binds to Tie-2 but does not activate it. The use of Ang-2 as an antiangiogenic Ang-1 antagonist is under investigation. Similarly, when mice are injected with the extracellular domain of the Tie-2 receptor, tumour growth can be reduced by more than 75% (Lin *et al.*, 1997).

Oncogene Stimulation of Angiogenesis and the Role of Hypoxia

Activation of oncogenes is associated with gain of function and inactivation of tumour-suppressor genes with loss of function. Changes in gene expression of this type may underlie the switch to an angiogenic phenotype and thus provide a further strategy for antiangiogenic intervention. A number of recent observations link oncogenes/tumour-suppressor genes with mediators of angiogenesis.

The tumour-suppressor gene *p53* positively regulates TSP-1 and thus mutations of the *p53* gene result in reduced TSP-1 expression (Dameron *et al.*, 1994). *p53* mutations are associated with many other aspects of tumorigenesis including increased cell proliferation and reduced apoptosis. Similarly, the proangiogenic molecules bFGF, TFG-α and TGF-β are upregulated in cells where there is a mutation in the *ras* oncogene.

The transforming nature of oncogenes might be manifested, at least in part, through angiogenesis. In an elegant series of experiments, Rak *et al.* measured the level of VEGF expression in cultured rat intestinal epithelial cells that had been transfected with a mutant human H-*ras* oncogene (Rak *et al.*, 1995). They demonstrated that transfected cells strongly expressed VEGF mRNA whereas VEGF was undetectable in nontransformed cells. Similar associations have been demonstrated for oncogenes that encode transcription factors such as c-Fos and translation initiation factors such as eukaryotic initiation factor-4e (EIF-4e). EIF-4e may enhance the efficiency of use of VEGF mRNA allowing an increase in protein without increased RNA synthesis (Scott *et al.*, 1998; Crew *et al.*, 2000). Thus, whilst oncogenes might predominantly promote tumour growth via alterations in control of the cell cycle, a secondary and indirect mechanism might be mediated via angiogenesis.

Physiological stresses such as hypoxia and hypoglycaemia are potent mediators of gene expression. Hypoxia induces VEGF gene expression by upregulation of the transcription factors hypoxia inducible factor-1α and -2α (HIF-1α and HIF-2α). These transcription factors are expressed constitutively, but in the presence of oxygen are targeted for degradation by the ubiquitin–proteasome pathway. (The proteasome is an intracellular multiprotein complex that is responsible for the degradation of many cellular proteins. Proteins are targeted for destruction by the proteasome after being tagged with ubiquitin. The ubiquitin–proteasome pathway has a critical role in cell-cycle progression, gene expression and modulating the response to anticancer drugs). In hypoxia, HIF-1α and -2α are not destroyed and they translocate to the nucleus where they up-regulate the expression of a number of genes, including VEGF. Von Hippel–Lindau (VHL) disease is a rare inherited disorder characterized by the development of multiple bilateral tumours (renal cancer, cerebellar haemangioblastomas, pancreatic tumours, phaeochromocytomas and retinal angiomas) (Turner, 2000). The product of the *VHL* tumour-suppressor gene has a pivotal role in modulating the upregulation of VEGF. In RCC cells that are mutant for *VHL*, HIF-1α and -2α are expressed in both normoxia and hypoxia. Transfection with wild-type *VHL* restores hypoxic regulation of HIF-1α/2α expression. Recent work suggests that VHL is necessary for the oxygen-dependent degradation of HIF. VHL appears to bind to HIF and to 'tag' it for destruction by the proteasome (Maxwell *et al.*, 1999).

The hypoxia response pathway is an attractive therapeutic target. Hypoxic cells are resistant to conventional radiotherapy and chemotherapy. This problem might be overcome if drugs could be targeted specifically against hypoxic cells. Conversion of the prodrug 5-fluorocytosine to its active metabolite, 5-fluorouracil, is promoted by the bacterial enzyme cytosine deaminase. Increased expression of this enzyme has been induced *in vitro* using hypoxic induction of modified promoters and this has resulted in enhanced cell death (Dachs *et al.*, 1997).

Gene Therapy

Gene therapy is an attractive means of delivering antiangiogenic factors for a number of reasons (Lau and Bicknell, 1999). First, it is likely that most antiangiogenic compounds would need to be administered for prolonged periods if tumour dormancy is to be maintained. Gene therapy might allow a one-off administration of a vector that results in long-term production of the antiangiogenic peptide. Second, if gene therapy could be targeted preferentially at angiogenic regions of the tumour vasculature then therapeutic levels of an antiangiogenic factor could be achieved at the tumour site with minimal risk to physiological angiogenesis elsewhere. The use of gene therapy as a means to modulate angiogenesis is at an early stage but some success has been achieved in inhibiting the expression of proangiogenic mediators, in interference with signalling processes and in up-regulating inhibitors of angiogenesis. For example, transfection of glioblastoma cells with an antisense construct against VEGF results in reduced VEGF expression and reduced tumorigenicity in nude mice xenografts. Smaller and less aggressive tumours result when DNA encoding the antiangiogenic factors thrombospondin-1 (TSP-1) is transfected into breast carcinoma xenografts in comparison with untransfected cells (Kong and Crystal, 1998). Adenovirus-mediated transfer of angiostatin inhibits angiogenesis and growth of glioblastoma xenografts (Tanaka *et al.*, 1998). It has also been demonstrated that the KDR and E-selectin promoters are selectively expressed in ECs and therefore could be used for targeting the vasculature (Jagger *et al.*, 1997). Development of suitable vectors remains a major obstacle to gene therapy and the problems of efficient gene transduction and prolonged expression of the transgene have been difficult to overcome. Furthermore, the redundancy that exists in the angiogenic cascade means that inhibition of a single or limited number of factors may be of limited use. Future developments in antiangiogenic gene therapy may target the ECs directly.

Inhibitors of Proteolysis

Degradation of the ECM by proteolytic enzymes is essential for EC migration and tumour invasion. Many of these proteases are upregulated by VEGF and bFGF. The matrix metalloproteinases (MMPs) are an important group of degradative proteases that collectively are capable of degrading all the components of the ECM. Both synthetic and naturally occurring inhibitors of MMPs are in clinical trials. Marimastat, a zinc chelator, is a general MMP inhibitor. In initial studies, administration of marimastat achieved favourable reductions in the serum markers of a variety of cancers (prostate, colon, ovary and pancreatic) although this was not associated with tumour regression (Gore *et al.*, 1996). In a phase III study of 400 patients with advanced pancreatic cancer, marimastat was no more effective than gemcitabine, the 'drug of choice.' Further trials involving marimastat are under way. Better tolerated than marimastat is the MMP inhibitor Bay 12-9566, which is orally active and inhibits MMP-2 and MMP-9. Bay 12-9566 is the subject of several international phase III trials. A naturally occurring MMP inhibitor, Neovastat, has been derived from shark cartilage and appears to have antiangiogenic and anti-inflammatory activity. Results of phase I/II trials are awaited. The immunosuppressant cyclosporine inhibits both MMP-2 and MMP-9 in addition to inhibiting EC function, although its clinical role in antiangiogenesis has not yet been assessed.

Urokinase plasminogen activator (uPA) is another important ECM protease. Antibodies to the uPA receptor

suppress bFGF-induced angiogenesis and tumour growth in mice. Transfection of prostate cancer cells with mutant uPA resulted in smaller, less vascular tumours and fewer metastases in a rat xenograft model.

AGM 1470 is an antiangiogenic agent currently being assessed by phase III clinical trials. Most success so far has been achieved in the treatment of AIDS-KS, where partial responses have been achieved and the treatment well tolerated; a phase III trial is under way. Complete remission has also been reported in a patient with metastatic cervical cancer who underwent 22 months of treatment. The mechanism of action of AGM 1470 remains uncertain, although recently it was found to bind irreversibly to, and thus inhibit, the peptidase methionine aminopeptidase type 2 (metAP-2).

It has been demonstrated recently that new vessel formation *in vivo* requires transmembrane MMPs on the EC surface, which function as pericellular fibrinolysins. These EC-bound proteinases are a potential therapeutic target.

Direct Attack on Endothelial Cells and Vascular Targeting

Antiangiogenesis should be distinguished from vascular targeting. Antiangiogenesis involves therapy directed against biochemical targets aiming to inhibit new blood vessel formation and proliferation. In vascular targeting the established tumour vasculature is the therapeutic target; the aim is acute destruction of the tumour vasculature and tumour necrosis.

Transforming growth factor β (TGF-β) induces proliferation in angiogenic but not in nonangiogenic ECs. Part of the TGF-β receptor known as endoglin is recognized by TEC-11, a mouse monoclonal antibody. Staining of tissue sections has demonstrated that TEC-11 binds to ECs in a number of tumour types but not to the ECs in normal tissue. Some success has been achieved in targeting proliferating ECs *in vitro* by linking TEC-11 to the cytotoxic ricin A chain (Derbyshire and Thorpe, 1997).

A bispecific antibody has been developed where one arm is linked to inactive tissue factor and the other arm targets an experimentally induced marker on tumour vasculature ECs (Huang *et al.*, 1997). When the latter arm binds to tumour endothelium the inactive tissue factor is activated by exposure to cell-surface phospholipids. The coagulation cascade is initiated and tumour vessels thrombose. When this antibody was given intravenously to mice with subcutaneous neuroblastomas a third of the mice had complete tumour regression and no thrombi were seen in other organs.

Vascular targeting has been used in the treatment of soft tissue sarcomas of the extremities using TNFα. In this example, an isolated limb perfusion system was used to target TNFα to tumour-associated ECs, causing destruction of the microcirculation of the sarcoma.

CM 101 is a group b haemolytic streptococcus exotoxin that binds preferentially to tumour endothelium. It activates complement C3 and the resulting inflammatory reaction causes vessel disruption and tumour necrosis. Partial responses have been observed in phase I clinical trials (Harris, 1997).

Squalamine is an aminosteroid antibiotic first extracted from dogfish shark liver. It inhibits a sodium–hydrogen exchanger and has antiangiogenic and anti-infective activity. It may work by blocking EC activation and migration and by inhibiting growth factor expression. Phase I trials in brain and breast tumours are under way and a phase II study of squalamine in combination with taxol and carboplatin in the treatment of non-small cell lung cancer began in June 1999.

The cytoskeleton has an essential role in EC proliferation. The tubulin inhibitor Combretastin A4 causes proliferating ECs to apoptose, resulting in vessel shutdown. It is in phase I/II trials.

Other Compounds and Approaches

The interleukins have a variety of anti- and proangiogenic effects. Interleukin-10 (IL-10) inhibits *in vitro* angiogenesis by up-regulating TIMP-1 and by down-regulating MMP-2 and MMP-9 (Stearns *et al.*, 1999). Interleukin-12 (IL-12) induces interferon-γ (IFN-γ) and stimulates proliferation of natural killer (NK) cells. Both IFN-γ and NK cells demonstrate antiangiogenic activity and IL-12 is currently in phase II trials for AIDS-KS and other solid tumours. IM-862 is synthetic dipeptide that up-regulates IL-12 and which has been shown to be efficacious in a phase III trial against KS.

Paclitaxel is an anticancer agent licensed in the treatment of AIDS-KS and recurrent ovarian and metastatic brain tumours. It works by stabilizing microtubules. It may also have antiangiogenic activity and is currently under evaluation in this regard, although toxicity may restrict its usefulness.

Circulating levels of prostate-specific antigen (PSA) are used to screen for prostate cancer and to evaluate response to intervention. Despite its name, PSA is not prostate specific, having been detected in breast, lung and uterine cancers. Intriguingly, elevated PSA levels have been associated with better prognosis in breast cancer. A recent study has suggested that PSA has antiangiogenic activity (Fortier *et al.*, 1999). PSA inhibited EC migration, proliferation and invasion and impaired EC response to stimulation by FGF and VEGF. PSA also inhibited the development of melanoma metastases in a mouse xenograft model.

Recent work on non-small cell lung cancer has assessed the ratio of mature to immature vessels (the vessel maturation index, VMI) using a monoclonal antibody, LH39, which recognizes selectively an epitope unique to

mature vessels. A high VMI was associated with low angiogenesis, an absence of lymph node involvement and low levels of the angiogenic factor thymidine phosphorylase (Kakolyris *et al.*, 1999). This study highlights immature, although not necessarily proliferating, vessels as a future target in antiangiogenesis.

Antiangiogenesis and the Immune Response

Cells of the immune system are able to recognize and destroy tumour cells. There is significant interplay between angiogenesis and the immune response: leucocyte-derived cytokines are angiogenic stimulators, and the adhesion molecules expressed by tumour-associated ECs influences which leucocytes contribute to a localized inflammatory infiltrate. The expression of EC adhesion molecules such as ICAM-1, VCAM and E-selectin is induced by leucocyte derived chemokines such as TNFα, IL-1 and IFN-γ. By contrast, leucocyte adhesion to ECs is inhibited by TGF-β. Tumour microvessels are characterized by diminished adhesion of leucocytes to ECs (Griffioen *et al.*, 1998). It is likely that this reduced adhesion occurs because angiogenic factors down-regulate EC adhesion molecules. This reduced leucocyte adhesion might be advantageous to a tumour since it would impede the antitumour immune response. It has therefore been suggested that the antiangiogenic mediators might promote tumour cell destruction by the immune system by facilitating leucocyte adhesion to tumour-associated ECs (Griffioen *et al.*, 1998). Stimulation of cultured ECs by bFGF resulted in marked down-regulation of ICAM-1; the presence of the antiangiogenic peptide PF4 completely abrogated this effect. It may be that antiangiogenic factors that both inhibit new vessel formation and facilitate leucocyte–EC interaction will be particularly efficacious.

POTENTIAL PROBLEMS IN ANTIANGIOGENIC THERAPY

Whilst tumours cannot grow larger than 2–3 mm^3 without a new blood supply, they remain viable. Antiangiogenic therapy cannot therefore be ultimately cytotoxic. Hence, it is vital that antiangiogenic therapies are well tolerated since they are likely to be given repeatedly or continuously over prolonged periods. For the same reasons, it is important that drug resistance does not emerge. Since antiangiogenic therapies may only be cytostatic, lack of regression must not be equated with lack of effect, and novel ways of assessing response may be required. The utility of noninvasive means of determining tumour blood flow such as colour-flow Doppler and PET (positron emission tomography) scanning is under evaluation in the assessment of antiangiogenic therapies.

Interference with physiological angiogenesis is a concern. Treatment may have to be delayed postoperatively to allow for adequate wound healing, and disturbance of the menstrual cycle may occur.

There is a multitude of factors and pathways involved in angiogenesis and there is likely to be a degree of intrinsic redundancy. Blocked pathways may be circumvented and down-regulation of one factor may be compensated for by up-regulation of another. Some tumours may be able to divorce themselves entirely from angiogenesis-dependent growth. Human lung secondary tumours and some lung primaries may grow by a nonangiogenic-dependent mechanism by the invasion of pre-existing alveolar vessels (Pezzella *et al.*, 1997). There is a need to focus research effort on critical steps and identification of final common pathways. Multiple antiangiogenic treatments may be required synchronously for adequate clinical effect.

Care should be exercised in translating data from mouse xenograft experiments when planning clinical trials. The growth dynamics of experimental tumours may differ substantially from their human counterparts. Few human tumours grow as fast as typical mouse models and thus can be expected to demonstrate less intense angiogenic activity (Augustin, 1998).

THE FUTURE OF ANTIANGIOGENIC THERAPY

It is likely that antiangiogenic treatments will be used in conjunction with more established modalities that target the tumour cells and that are intended to be cytotoxic. Encouraging results have been achieved in preclinical studies (Teicher, 1996) and of particular note is the use of angiostatin in combination with radiotherapy (Mauceri *et al.*, 1998). The toxicity of this combination was selective for the tumour vasculature but did not result in increased toxicity toward normal tissue. Improved identification of markers specific to proliferating ECs will facilitate targeting of antiangiogenic therapy, particularly gene therapy. It may be that certain angiogenic mechanisms predominate in certain patients or tumours. Furthermore, different stages of the same tumour vary in their susceptibility to antiangiogenic agents. Recently, four different antiangiogenic factors were tested at three distinct stages of disease progression in a transgenic mouse model of pancreatic islet cell carcinogenesis (Bergers *et al.*, 1999). The four inhibitors tested showed distinct efficacy profiles depending on the stage of disease being treated. As understanding of angiogenesis grows it may be possible to tailor therapy toward the particular angiogenic profile of a patient or tumour. The results of antiangiogenic therapy to date are encouraging but the most recent preclinical data on angiogenesis inhibitors are particularly exciting. Antiangiogenic treatments, in combination with

other approaches, have great potential in the management of malignant disease and may be used in combination therapy and for maintenance therapy with all tumour types.

Chapter 94

Targeting the Extracellular Matrix

Raffaella Giavazzi and Giulia Taraboletti
Mario Negri Institute for Pharmacological Research, Bergamo, Italy

CONTENTS

- Targeting the Extracellular Matrix of Tumours
- Therapeutic Strategies Exploiting the Extracellular Matrix of Tumours
- Use of Matrix-related Molecules for Selective Delivery of Therapeutic Agents
- Matrix-targeted Agents can Act with Multiple Mechanisms of Action
- Conclusion

TARGETING THE EXTRACELLULAR MATRIX OF TUMOURS

The extracellular matrix (ECM), a complex mesh of collagens, proteoglycans and glycoproteins, is a vital supporting scaffold of tissues, as it contributes to their architecture, isolates tissue compartments and acts as a selective macromolecular filter. An important role for the ECM in regulating cell adhesion, motility, differentiation, proliferation and survival is now well recognized (for details, see the chapters *Extracellular Matrix: The Networking Solution* and *Invasion and Metastasis*). The rationale of selectively targeting the tumour ECM is based on the fact that it differs from that of normal tissues in terms of:

- composition: the tumour matrix presents either a different proportion of matrix components or molecules usually not found in the ECM of normal tissues;
- molecular organisation (architecture): the tumour matrix is usually poorly organized;
- turnover: a high matrix-degrading proteolytic activity is a hallmark of tumour malignancy and is necessary for tumour invasion and metastatic dissemination.

Three main molecular players act in the interaction between tumour cells and the ECM:

- matrix molecules: besides acting as a substrate for cell adhesion and tissue organisation, the ECM regulates important cell functions, many of which are related to tumour progression (such as motility, proliferation, invasiveness); therefore, the differences in matrix composition and architecture found in tumours may have profound effects on the behaviour of tumour cells;
- receptors: tumour cells often express an altered pattern of receptors for matrix molecules (mainly integrins), therefore determining a different response/interaction to matrix;
- matrix-degrading enzymes: these enzymes, produced by tumour or stromal cells, greatly affect cell interaction with the extracellular environment.

Although these molecules are ‘normal’ host structures, their association with the transformed tissues makes them quantitatively or qualitatively different from their counterparts in normal tissues, and therefore recognizable by an appropriate treatment. Agents that affect the complex, coordinated interplay between matrix molecules, receptors and proteases can alter the tumour homeostasis, hence affecting tumour progression.

Therapeutic strategies include (**Table 1**):

- agents affecting tumour cell interaction with the ECM, including peptides or recombinant fragments of the active sequences of matrix components, integrin antagonists and ligands of matrix components;
- molecules that modulate the deposition of matrix components;
- inhibitors of matrix degradation.

THERAPEUTIC STRATEGIES EXPLOITING THE EXTRACELLULAR MATRIX OF TUMOURS

Functional Domains of ECM Molecules

The concept of using small matrix-derived molecules for treatment purposes has emerged from studies in the last two decades, showing that synthetic peptides corresponding to minimal active sequences of cell adhesion molecules, such as laminin and fibronectin, where able to prevent metastasis in experimental models (Humphries *et al*., 1986). Since then, a great amount of experimental evidence has accumulated, which confirmed that isolated

Table 1 Examples of therapeutic strategies exploiting tumour-associated extracellular matrix

Analogues of the functional site of matrix components
- Synthetic peptides or recombinant fragments (*endostatin, tumstatin*)
- Molecules that mimic functional regions (*heparin-like agents, laminarin, suramin*)

Integrin antagonists
- Synthetic peptides, recombinant domains containing integrin recognition sequences (*RGD, NGR*)
- Disintegrins
- Nonpeptide integrin antagonists
- Anti-integrin antibodies (*vitaxin*)
- Agents modifying integrin expression (*cytokines*)
- Inhibitors of integrin signalling (*genistein, CAI*)

Molecules that modulate the deposition of matrix components
- Cytokines (*IL-1, TNF-α, IFNs*)
- Differentiating agents (*retinoids*)
- Other (*halofuginone*)

Inhibitors of matrix degradation
- Inhibitors of the serine-, cysteine- and matrix metalloproteases (see **Table 2**)
- Inhibitors of protease synthesis (*cytokines, glucocorticoids, retinoids, halofuginone*)
- Bisphosphonates (*clodronate*)
- Inhibitors of heparanases (*nonanticoagulant heparins, PI-88*)

domains of matrix molecules – usually synthetic peptides or recombinant fragments – could be used as the basis for developing therapeutic agents. Depending on the biological activity of the original molecule, isolated domains could be employed either to mimic an antineoplastic activity of the intact molecule or to act as competitors of its pro-malignant activity.

Recombinant Domains

Given the presence of cryptic sites in matrix components – regions usually not exposed in the native molecule – the activity of isolated domains can be totally unrelated to that of the original, intact molecule (Davis *et al.*, 2000). Examples of this have recently been provided by the identification of fragments of collagen or fibronectin endowed with antineoplastic activity.

Collagen Fragments

Fragments from different collagen molecules have been described to have antiangiogenic and antineoplastic activity. Examples are a noncollagenous fragment of type XVIII collagen (known as endostatin) (O'Reilly *et al.*, 1997), the NC10 domain of type XV collagen (restin, homologous to endostatin) and the NC1 domains of different α-chains of type IV collagen: $\alpha 1$ (also named arresten), $\alpha 2$ (canstatin), $\alpha 3$ (tumstatin) and $\alpha 6$. Although these isolated domains have antineoplastic activity, native collagens type IV, type XVIII and type XV are devoid of such activity. All these compounds have antiangiogenic activity, and endostatin is currently in clinical trials (see the chapter *Antiangiogenic Therapy*). Fragments of type IV collagen could also act by blocking the interaction of tumour cells with the basement membranes, or, since the NC1 domain is thought to be involved in collagen assembly, they could affect matrix organisation. In addition, at least for one of them, tumstatin, a sequence – distinct from the antiangiogenic one – has been shown to have a direct antiproliferative activity for melanoma cells (Maeshima *et al.*, 2000).

Fibronectin Fragments

An example is Anastellin, a III1-C fibronectin fragment, derived from the first type III repeat of fibronectin, has been described to inhibit growth of experimental tumours, mainly acting through an antiangiogenic mechanism. Anastellin is thought to act by altering matrix assembly or interfering with the avβ3 receptor on endothelial cells (Yi and Ruoslahti, 2001).

Synthetic Peptides

Synthetic peptides corresponding to active sequences of matrix molecules, such as fibronectin (RGD, PHSRN, LDV, REDV), laminin (YIGSR, IKVAV) and thrombospondin-1 (GSVTCG, WSPW), have been studied in experimental models (Yamada, 1991). They have shown high potential in inhibiting cell functions associated with the malignant behaviour of tumour cells, including angiogenesis and metastatic dissemination of experimental tumours.

It has been a general experience that small peptides are poor therapeutic agents since, *in vivo*, they diffuse rapidly, are often susceptible to proteolytic degradation and are subjected to a rapid clearance. Chemical modifications of the peptides have been introduced to improve their pharmacological characteristics, including the preparation of multimeric or cyclic peptides (see also Integrin Antagonists, below), use of D-amino acids, synthesis of *retro–inverso* peptidomimetics, conjugation with molecules (polyvinylpyrrolidone, polyethylene glycol or the heparin-like 6-*O*-carboxymethylchitin) or addition of chemical groups and spacers. These modifications improve the therapeutic index of the peptides by increasing their resistance to enzymatic degradation and hence stability in biological fluids, and by altering the peptide clearance. Modified peptides can be radiolabelled for diagnostic use and for radionucleotide therapy.

Molecules Similar to Functional Domains

Natural or synthetic molecules acts as competitive inhibitors of matrix components, thanks to their structural similarity.

Heparin-like Molecules

Low molecular weight heparins, modified heparins lacking the anticoagulant activity, and heparin-like agents, such as laminarin (a sulphated polysaccharide) and suramin (a polysulphonated naphthylurea) which are structural mimics of heparan sulphates, have a potential therapeutic effect. Preclinical and clinical observations suggest that the antineoplastic effect of these molecules is not necessarily related to their anticoagulant activity. Heparin-like molecules have been reported to inhibit cell proliferation by preventing the binding of growth factors to their cell surface low affinity receptors. In addition, many of these compounds have the ability to block heparanase, a heparan sulphate-degrading enzyme associated with the metastatic potential of tumours (see Inhibitors of Heparanases, below). These compounds have been shown to prevent metastasis formation and angiogenesis in preclinical models. Information from early phases clinical trials with low molecular weight heparins indicate an improved cancer outcome and a favourable pharmacological profile (Zacharski *et al.*, 2000).

Integrin Antagonists

Among the great variety of receptors that mediate tumour cell interaction with matrix components, integrins appear to play a major role in tumour progression (Albelda, 1993). The pattern of integrin expression is known to change during cell transformation, and such alterations profoundly affects malignant tumour behaviour. The modulation of integrin expression or the selective block of integrin functions can suppress tumorigenicity and/or metastatic potential in experimental tumour models. This led to the development of specific inhibitors for this class of receptors. An integrin currently drawing great interest in terms of therapeutic applications is $\alpha v\beta 3$, implicated in the progression of human melanoma, in angiogenesis and in the process of cell survival. In addition, $\alpha v\beta 3$ is involved in the proteolytic activity of both tumour and endothelial cells, through binding to MMP-2.

Strategies to block the activity of these receptors include peptide and non-peptide integrin antagonists, disintegrins, anti-integrin antibodies, agents modifying integrin expression on tumour cells and inhibitors of integrin signalling.

RGD-related Peptides

The antineoplastic activity of peptides designed on the integrin-recognition sequence RGD is due to various mechanisms, including a direct antimetastatic activity on tumour cells (Humphries *et al.*, 1986) and inhibition of endothelial cell functions. A cyclic RGD peptide (EMD 121974) is currently undergoing clinical trials as an anti-angiogenic compound. In addition to the integrin antagonist activity, a recent report indicates that RGD-containing peptides induce apoptosis in an integrin-independent way, through direct intracellular activation of caspase 3, a proapoptotic protein.

Non-peptide Integrin Antagonists

They have been identified, taking advantage of chemical libraries generated by combinatorial organic synthesis. These compounds could represent an alternative to the use of peptides that, as mentioned above, are usually poor pharmacological agents. This approach has led to the identification of nonpeptide inhibitors of integrins. One of them (TSRI265), has recently been shown to block collagen degradation by tumour cells as well as angiogenesis, by preventing the RGD-independent interaction of $\alpha v\beta 3$ with MMP-2 (Silletti *et al.*, 2001).

Disintegrins

These molecules, thanks to the presence of an RGD sequence, have the potential to block integrins, hence their name. Several disintegrins (i.e. salmosin, albolabrin, rhodostomin, accutin), have been described to inhibit tumour cell adhesion, invasion, proliferation, extravasation and experimental metastasis. Moreover, as they also interact with integrins on endothelial cells, disintegrins have been reported to inhibit angiogenesis. The therapeutic potential of these compounds is still to be defined.

Anti-integrin Antibodies

Based on the selectivity of $\alpha v\beta 3$ as a marker of angiogenic blood vessels, antibodies against $\alpha v\beta 3$ have been developed as antiangiogenic therapy (Eliceiri and Cheresh, 1999). Vitaxin is a humanized version of the LM609 monoclonal antibody, which blocks the binding of $\alpha v\beta 3$ to adhesion proteins and disrupts ECM-induced signalling, leading to the activation of p53 and to apoptosis of endothelial cells. Vitaxin is currently in early clinical trials as an inhibitor of angiogenesis.

Agents Modifying Integrin Expression

Factors that modulate the expression of integrins on the surface of both tumour and endothelial cells can affect tumour progression. It has been proposed that cytokines, i.e. TNF and IFNγ, suppress $\alpha v\beta 3$ activation, causing detachment and apoptosis of endothelial cells (Rüegg *et al.*, 1998).

Integrin Signalling

Signalling transduction pathways represent another potential target to block tumour cell interaction with the ECM. Different steps of the signalling cascade have been targeted for therapeutic intervention. Inhibitors of tyrosine kinases (such as genistein), of PKC (staurosporine, sphingosine) and of calcium influx (carboxyaminotriazole) have also

been reported to affect matrix-driven tumour cell behaviour. Some of these compounds are currently being subjected to clinical trials.

Molecules that Modulate the Deposition of Matrix Components

Since the ECM composition can profoundly influence the behaviour of tumour cells, agents that affect matrix synthesis–deposition have been studied in tumour progression. Given the critical role of the matrix in angiogenesis, many of these compounds have also been found to have antiangiogenic activity. Several cytokines (such as interleukin-1β and tumour necrosis factor α) and agents that control cell differentiation have been shown to affect matrix synthesis and deposition.

Retinoids

Retinoids, natural and synthetic analogues of vitamin A, are currently being subjected to clinical trials in cancer prevention and therapy. Their antineoplastic activity is the result of several different effects on tumour cell differentiation and interaction with the ECM. Indeed, they have been described as inhibiting the production of proteases and their inhibitors, reducing cell migration and invasion, altering cell adhesion to the matrix and modulating the expression of integrins by tumour cells.

Halofuginone

This low molecular weight quinazoline alkaloid, originally approved for use as an antiparasitic for farm animals, is currently attracting great interest as a pharmacological inhibitor of matrix synthesis and deposition. Halofuginone inhibits gene expression of the $\alpha 1$ chain of type I collagen. In addition, it also acts as an inhibitor of proteases, since it cause a transcriptional suppression of MMP-2 synthesis. The antineoplastic activity of halofuginone, observed in preclinical models, is attributed to a combined antimetastatic activity on tumour cells (reduced ability to invade and extravasate) and antiangiogenic activity (Elkin *et al*., 2000). This compound is under development for treating solid tumours and other diseases associated with fibrosis.

Inhibitors of Matrix Degradation

Tumour-associated lytic enzymes, produced by tumour cells and the adjacent stroma-infiltrating cells, are responsible for the remodelling of the matrix typically found in tumours. Furthermore, matrix-degrading enzymes exert functions that go beyond the physical destruction of connective tissue barriers, including activation of receptors and cell surface molecules, release of growth and angiogenic factors stored in the matrix and generation of active fragments from matrix components. Altogether this makes the proteolytic system highly involved in the process of tumour progression, metastasis and angiogenesis and thus a relevant target for therapeutic interventions. Inhibitors of metalloproteinases (MMPs), serine proteinases (the plasminogen activator system) and cysteine proteinases (cathepsins), as well as inhibitors of heparanases are under extensive investigation in cancer. Owing to their double role in tumour cell invasion and in angiogenesis (see the chapter *Invasion and Metastasis*), they are under development as both antimetastatic and antiangiogenic agents. The blockade of matrix degradation has shown efficacy in inhibiting cell invasion, tumour growth, angiogenesis and metastasis in a variety of *in vitro* systems and animal models. The promising results of the preclinical studies have rapidly led to clinical trials for several of these inhibitors. It is worth noting that the different proteolytic systems interact with each other, through a complex cross-regulation of protease activation among the members of all families. Therefore, the combination of these inhibitors is now foreseen as the optimal treatment in blocking tumour progression.

Matrix Metalloproteinase Inhibitors (MMPIs)

MMPIs are the proteinase inhibitors most advanced in clinical trials (Hidalgo and Eckhardt, 2001). The great interest in these molecules has been generated by earlier studies showing that the addition of exogenous TIMPs or the transfection with TIMP–cDNA reduced tumorigenicity, local invasiveness, metastasis as well as angiogenesis in several experimental models. TIMPs are not pharmacologically suitable for clinical use. Therefore, several companies have focused their efforts on the development of synthetic MMPIs (Giavazzi and Taraboletti, 2001). They differ in origin, MMP inhibitory profile and zinc-binding group (**Table 2**).

Table 2 Matrix metalloproteinase inhibitors entered in clinical trials

Compound	Origin	Status[b]
Batimastat (BB94)	Hydroxamic[a]	Phase I
Marimastat (BB-2516)	Hydroxamic[a]	Phase II–III
Prinomastat (AG-3340)	Hydroxamic[a]	Phase II–III
Metastat (COL-3)	Tetracycline derivative	Phase I
BAY 12–9566	Carboxylic[a]	Phase II–III
Neovastat (Æ-941)	Cartilage derivative	Phase I–IIa
BMS-275291	Sulfhydryl[a]	Phase I
CGS 27023A	Hydroxamic[a]	Phase I

[a]The zinc-binding group is indicated.
[b]As of May 2001.

A key structural feature of MMP inhibitors is the presence of a metal-binding group that is capable of chelating the zinc ion at the active site of the MMP. The first compounds to be tested in cancer patients – batimastat, CGS27023A, prinomastat and marimastat – all have a hydroxamate binding group. Nonhydroxamic acid inhibitors were synthesized later. Recently, approaches based on the screening of compound libraries have successfully identified novel compounds with MMP inhibitory activity. The rational design of inhibitors has received a great input by the recent advent of high-resolution X-ray and NMR analysis of the structures of the MMP–inhibitor complex.

The inhibition profiles of the different MMPIs vary substantially across the MMP family, the main targets being MMP-2 and MMP-9, that are associated with tumour malignancy in many types of cancers. The significance of the inhibitory profile of the different MMPIs in clinical development is the subject of debate. From the early clinical trials with broad-spectrum MMPIs (e.g. marimastat), the observation of adverse effects suggested that the use of more selective inhibitors (e.g. BAY 12-9566) should provide greater specificity, and hence limit side effects. On the other hand, it is now clear that more than one MMP family member is involved in the course of the disease, this being in favour of a broad-spectrum inhibitor. Requisites for suitable MMP inhibitors are also acceptable pharmacokinetics and high oral bioavailability.

Batimastat (BB-94)

The best studied MMPI in preclinical models is batimastat, a synthetic hydroxamate, with a broad spectrum of activity on MMPs including on MMP-1, -2, -3, -7 and -9. Batimastat was tested as a suspension administered by intracavity injection to patients with malignant ascites and pleural effusion. Its clinical development was suspended owing to its poor solubility and poor local tolerability.

Marimastat (BB-2516)

Related to batimastat, this compound is orally available and is currently under investigation in several phase II–III clinical trials. Phase I studies in healthy volunteers showed plasma levels exceeding the concentrations required to inhibit MMP-2. Phase II studies have been conducted on patients with advanced ovarian, colorectal, pancreatic and prostatic cancers, all tumour types for which high expression of MMP-2 and MMP-9 has been described. In these studies the combined analysis of the modulation of serum tumour markers and of drug-related toxicity has been proposed to select the dose range for long-term studies. The main reported drug-related adverse event is a reversible musculoskeletal syndrome. Marimastat is the first MMPI to have completed phase III studies (Brown, 2000). In the first phase III study, on patients with advanced pancreatic cancer, the survival of patients receiving marimastat was not superior to that of patients receiving gemcitabine. In a second phase III trial, on patients with gastric cancer, there was a modest, but nonsignificant, improvement in survival in the marimastat-treated arm compared with placebo. Two marimastat SCLC studies are due to report very soon.

Prinomastat (AG-3340)

Another synthetic hydroxamate, prinomastat, inhibits MMP-2, -3, -9 and -13, but it is poorly active on MMP-1. It was selected among a series of structurally related inhibitors of MMPs, synthesized using a protein structure-based drug design. In patients with advanced cancer, phase I studies with AG-3340 given orally twice daily showed no dose-limiting toxicity. However, also for this hydroxamate, at higher doses reversible joint-related complaints were reported. Phase III trials in combination with chemotherapy in hormone-refractory prostate cancer and advanced non-small-cell lung cancer (NSCLC) did not meet primary efficacy objectives.

CGS 27023A

Designed as a stromelysin (MMP-3) inhibitor, this compound has a broad-spectrum activity. Phase I clinical studies indicate that the drug is generally well tolerated; the major toxicity was cutaneous rash. It is believed that this is one of the factors that prevented the progression of the compound to advanced clinical trials.

BMS-275291

This compound has completed phase I dose escalation in normal volunteers and is expected to enter phase II–III trials on advanced cancer. BMS-275291, structurally different from and more selective than the first generation of MMPIs, is expected to have an improved safety profile.

BAY 12-9566

This nonpeptidic, noncollagen-mimicking, biphenyl MMPI with a carboxylic zinc binding group is an example of an MMPI that claims a selective spectrum of activity mainly against MMP-2 but not MMP-1. Phase I clinical studies indicated that the compound is generally well tolerated. Drug-related adverse effects were transient, with asymptomatic transaminase elevation and mild thrombocytopenia; no musculoskeletal pain has been reported. However, the main phase III trials of BAY 12-9566 in small-cell lung and pancreatic cancers have been stopped because of negative findings and the development of BAY 12-9566 has been halted.

Neovastat (Æ-941)

This complex, derived from shark cartilage, has multiple mechanisms of action that include the inhibition of MMPs and interaction with the VEGF receptor. The lack of a clear identification of the MMPI activity in the extract makes its development difficult. Phase I–II trials are being conducted with Æ-941 in refractory lung, prostate and breast cancer. No serious drug-related adverse events have been reported and a reduction in PSA levels has been observed

in prostate cancer. Phase III trials in patients with renal cell carcinoma and NSCLC are planned.

Tetracycline derivatives

A variety of nonpeptidic natural product MMP inhibitors have been discovered by screening. These include the tetracyclines minocycline and doxocycline and the newer tetracycline analogues that have been chemically modified to eliminate the antibiotic activity. Metastat (COL-3) is a representative compound of this class currently in early clinical trials.

So far, the results from clinical trials with MMPIs have been rather disappointing (Hidalgo and Eckhardt, 2001). As indicated by the results on animal cancer models, MMPIs are intended to prevent tumour growth and spread, but are unable to control heavy tumour burden. Clinical benefit with MMPIs in cancer is therefore likely to be confined to patients with early stage or low burden cancer. By contrast, the majority of the clinical studies with MMPIs are placebo-controlled advanced-stage cancer. This was pointed out by Brown (2000) in the analysis of the results on gastric cancer studies with marimastat. Another observation from the preclinical studies is that tumours regrow after suspension of the administration of the inhibitor. Given the nature of their mechanism of action, MMPIs are not expected to interfere with cell proliferation and, therefore, these compounds are not intended to affect tumour cells as cytotoxic agents do. These observations have led to investigations of the antitumour activity of MMPIs in combination with conventional cytotoxic drugs. Several experimental studies have shown that the combination of MMPI with cytotoxic agents improves tumour response in both drug-sensitive and -resistant tumours and increases animal survival. These findings strongly suggest the use of MMPIs to potentiate the activity of cytotoxic drugs or to maintain the response after reductive therapy with a cytotoxic drug. Finally, another difficulty in the clinical evaluation of the activity of MMPIs has been the absence of valid surrogate endpoints to determine the optimum dose and to identify responsive tumours.

Additional preclinical studies are now needed in order to investigate the possibility that other MMPs (rather than those targeted so far) could be more efficacious targets for therapeutic block of the proteolytic activity of tumours. In this respect, the recently demonstrated important role for MT1-MMP could indicate this protease as one of the new targets. In addition, it is crucial to understand at which stage of the disease a patient would be more likely to benefit from therapy with protease inhibitors (Bergers *et al*., 1999).

Inhibitors of the Plasminogen Activation System

Generation of the serine proteinase plasmin from the plasminogen activation system, which includes the urokinase- and tissue-type plasminogen activators uPA and tPA, the serpins PAI-1 and PAI-2 and the uPA receptor (uPAR), represents a promising target for anti-invasive therapy (Mignatti and Rifkin, 2000). This is proved by the documented role of uPA-catalysed plasmin generation in cancer cell invasion through the extracellular matrix. Moreover, recent findings indicate an additional role for this system in inducing cell migration and invasion through plasmin-independent mechanisms, due to interactions among uPA, uPAR, PAI-1, ECM proteins, receptors and growth factors. The most promising results in cancer therapy have been obtained with the uPAR blockade. Antibodies, antisense oligonucleotides and uPAR antagonists, including small molecular weight peptide inhibitors, affect tumour invasion, metastasis, angiogenesis and tumour growth in animal models.

Inhibitors of Cathepsins

The abnormal extracellular location of these lysosomal aspartyl or cysteine proteases in tumours makes these enzymes potential targets to block tumour-associated matrix degradation. The levels of cathepsins and their endogenous inhibitors have been proposed as prognostic markers in cancer. Pharmacological inhibitors still have to be developed.

Bisphosphonates

These osteoprotective compounds have been shown to be effective in preventing osteolytic metastases. Analogues of pyrophosphate, they bind to hydroxyapatite on bone surface, preventing bone resorption. In addition, they also inhibit tumour cell adhesion to mineralized matrices, reduce the expression of MT1-MMP and are cytotoxic for macrophages and osteoclasts. Clinical trials (with clodronate and pamidronate) have indicated that bisphosphonates have low toxicity and, albeit with some contradictory results, suggest the effectiveness of these compounds in adjuvant therapy in patients at high risk of developing metastases to bone (Diel and Mundy, 2000). Unexpectedly, adjuvant clodronate has been reported to decrease visceral metastasis in women with breast cancer at high risk of distant metastasis. This finding confirms the preclinical evidence that, apart from the known osteoprotective effects, bisphosphonates also have a direct effect on the adhesion and invasiveness of tumour cells.

Inhibitors of Heparanase

Heparanases are heparan sulphate-degrading endoglycosidases, the expression of which correlates with the metastatic potential of tumour cells. Heparanases are also involved in angiogenesis, both directly (by stimulating endothelial cell invasion) and indirectly (by releasing and promoting the activity of matrix-bound angiogenic

factors) (Vlodavski *et al*., 1999). Heparanase inhibitors, non-anticoagulant heparin species or sulphated oligosaccharides (which are structural mimics of heparan sulphate), decrease the primary tumour growth, metastasis and vascularity of experimental tumours. The heparanases inhibitor PI-88 has been shown to be a potent inhibitor of metastasis and angiogenesis. It has received approval for trials in cancer patients.

USE OF MATRIX-RELATED MOLECULES FOR SELECTIVE DELIVERY OF THERAPEUTIC AGENTS

Molecules targeting the matrix or receptors can be employed to improve the delivery of therapeutic agents, such as cytotoxic drugs and vectors for gene therapy. The use of vehicles that have a high affinity for molecules specifically expressed at the tumour site allows the selective delivery of an effective dose of therapeutic agent to the neoplastic tissue with the advantage of reduced general toxicity and dose-limiting side effects.

Anti-integrin Antibodies

Cytotoxic drugs have been conjugated to anti-integrin antibodies, in order to achieve more efficient targeting of the integrin-expressing tumour cells. Coupling a doxorubicin derivative to the LM609 antibody, which recognizes the $\alpha v\beta 3$ on melanoma cells, improved the antineoplastic effect of the drug in mice.

RGD-related Peptides and Matrix Binding Sequences

Peptides recognizing adhesive receptors of tumour cells have been used as vehicles to improve the targeting of cytotoxic drugs to the neoplastic tissues. The RGD-related NGR peptide has been selected for high tumour-homing '*in vivo*' using a phage-displayed peptide library. This peptide, which binds to aminopeptidase N (CD13) on the tumour vasculature, when coupled to doxorubicin has been shown to increase the antitumour properties of the cytotoxic drug in an experimental model (Arap *et al*., 1998).

Receptor-recognizing sequences of matrix components can control tissue tropism of gene therapy. Integrin-binding peptides synthesized with a polylysine chain to form an electrostatic complex with DNA can function as a DNA vector. This has been found useful in the design of nonviral vectors for gene therapy; the presence of specific peptides directs gene delivery to selected cell types.

Incorporation of peptides or matrix-binding sequences by molecular engineering of envelope 'escort' proteins has been used to improve tissue tropism of viral vectors. Incorporation of NGR peptides in envelope proteins has been used to improve the specific targeting of retroviral vectors to the tumour vasculature, in experimental models. Similarly, retroviral vectors bearing the collagen-binding sequences of von Willebrand factor have been shown to accumulate at the tumour site (where collagen matrix is exposed), strongly enhancing the therapeutic effect of the gene therapy.

Antibodies Recognizing the ECM of Tumour Vessels

Antibodies recognizing tumour matrix molecules selectively expressed in tumours have been proposed for diagnostic imaging or as selective vehicles for treatment, coupled to toxic agents. The technology of antibody phage display libraries has led to the development of recombinant antibody fragments to be used as tumour-targeting agents. Potential targets include fibronectin and tenascin isoforms. A human antibody fragment that recognizes the spliced repeat C of tenascin has been shown to localize *in vivo* around vessels and proliferating cells in malignant tumours (high-grade astrocytoma). A high-affinity human antibody fragment (L19) that recognizes the fibronectin isoform containing the ED-B oncofoetal domain has been shown to localize selectively to newly formed blood vessels in tumour tissues. Recently, L19 antibody fused to tissue factor has been shown to induce the selective infarction and eradication of solid tumours in mice (Nilsson *et al*., 2001).

Tumour-associated Proteases

As mentioned above, high production of proteolytic enzymes is a hallmark of aggressive tumours. The possibility has therefore been explored of using these tumour-associated enzymes as local activators of prodrugs. Peptide prodrugs activated by MMPs, plasmin and γ-glutamyl-transpeptidases have been shown to have a protease-dependent cytotoxic effect in preclinical studies.

Fibronectin

A fragment of fibronectin greatly increases the efficiency of retroviral-mediated gene transfer into human haematopoietic cells, *ex vivo*, through a mechanism probably involving colocalization of retroviral particles and target cells. A protocol using a recombinant fibronectin fragment used to assist in *ex vivo* retroviral transduction is currently being subjected to clinical trials.

MATRIX-TARGETED AGENTS CAN ACT WITH MULTIPLE MECHANISMS OF ACTION

An important concept that emerges from the above description of matrix-targeting compounds is that many of them act through multiple mechanisms. Therefore, they can be proposed for different therapeutic approaches.

In some cases, the same compound can act on different molecular targets. Halofuginone inhibits the synthesis of collagen $\alpha 1$(I) and of the protease MMP-2 (see the section Molecules that Modulate the Deposition of Matrix Components, above). Heparin-like molecules can affect coagulation, block the binding of growth factors to cells and act as inhibitors of heparanase (see the sections Molecules that Mimic Functional Domains of ECM Components and Inhibitors of Heparanase, above). The differentiating agents retinoids also modulate the expression of integrins and the production of proteases and matrix components (see the section Molecules that Modulate the Deposition of Matrix Components, above).

The complexity of activities can also occur at the level of cellular targets. Since similar molecular mechanisms govern the invasive processes of tumour and endothelial cells, compounds acting on these common mechanisms can affect both tumour invasion and angiogenesis. The final antineoplastic activity of collagen fragments, integrin antagonists, halofuginone and inhibitors of matrix-degrading enzymes (see the section Inhibitors of Matrix Degradation, above) is ascribable to a combined anti-metastatic and antiangiogenic activity.

Naturally occurring examples of functional complex molecules are provided by the ADAMTS. As indicated by the acronym (*A Disintegrin And Metalloproteases with ThromboSpondin* motifs), these molecules include different active sequences and consequently exert multiple activities. Two of them, METH-1/ADAMTS1 and METH-2/ADAMTS8, have been reported to inhibit angiogenesis (Vazquez *et al*., 1999).

A large family of dietary constituents that, on the basis of epidemiological studies, are suggested to exert a cancer chemopreventive effect, have been described as acting through multiple mechanisms. Among these, epigallocatechin-3-gallate, the major flavonoid of green tea, has been reported to inhibit proteases involved in tumour cell invasion and angiogenesis.

CONCLUSION

Targeting tumour matrix-associated molecules and, more in general, tumour stroma is a relatively new way of thinking in cancer treatment. Interactions between ECM and tumour cells on the one hand and between ECM and host cells on the other play a pivotal role in tumour progression. Metastasis formation, the angiogenic process and the host response to tumour transformation are affected by the environment, of which ECM is a major component. This has stimulated the development of a range of antagonists of matrix receptors and their ligands and inhibitors of ECM-associated functions. The complexity of the underlying molecular mechanisms (multiple classes of molecules interact with each other) and the involvement of distinct pathways at different stages of tumour progression make the development of successful therapy difficult. The identification of selective tumour-associated ECM targets, the development of compounds with suitable pharmacological characteristics and their use in the correct combinations will constitute the main focus of future research efforts.

Although at this time the development of successful drugs is clearly more arduous than suggested by preclinical studies, agents targeting the tumour environment can be considered good candidates to potentiate, rather than replace, conventional antitumour therapies.

- Growth Factor Receptor Blockade Therapy
- Conclusions

INTRODUCTION

Cancer is the second leading cause of death in the United States today. Its development is a complex process in which malignant cells proliferate to form a tumour or a large progeny of transformed cells. This involves multiple genetic alterations resulting in phenotypic changes to the cell characteristic of the malignant process such as increased survival, proliferation and invasion. Although the individual steps in tumorigenesis are not completely understood, the fundamental process involves cells undergoing a series of successive genetic changes, each of which alters the cell genome in a way that confers a selective growth advantage to a specific cellular clone. These genetic changes lead to altered cellular signalling or to an imbalance of proteins that stimulate the cell cycle. The identification and characterization of oncogenes and tumour-suppressor genes have enhanced our understanding of the biochemical pathways associated with the tumour progression.

A major limitation of current cancer therapy is the ability of cancer cells to metastasize. Metastasis, the spread of cells from a primary neoplasm to a distant site, is not a random process. This process involves a number of highly regulated steps, which are influenced by both host factors and the intrinsic properties of the tumour cells (reviewed by Radinsky, 1995). The essential steps in the formation of a metastatic lesion include: (1) growth of neoplastic cells after the initial transforming event(s) that is first supported with nutrients supplied from the local microenvironment; (2) neovascularization must occur next for a tumour mass to exceed approximately $2\,mm^3$ in volume; the regulation, synthesis and secretion of tumour angiogenesis factors play a vital role in this process; (3) local tumour cell invasion of the surrounding host stroma occurs next via blood and lymphatic vessels and is enhanced by the production of lytic enzymes such as matrix metalloproteinases (MMPs) and urokinase from either tumour cells or host inflammatory cells; (4) once the tumour breaches the stroma of the circulatory system, detachment and embolization of small tumour cell aggregates occur, with the majority of tumour cells being rapidly destroyed; for most tumours, fewer than 0.1% of tumour cells that enter the circulation survive to form metastases owing to blood turbulence and the trauma associated with arrest, transcapillary passage and lysis by lymphocytes, monocytes and natural killer (NK) cells; (5) the tumour cells must arrest in the capillary beds of distant organs, either by adhering to capillary endothelial cells or by adhering to the exposed subendothelial basement membrane; (6) extravasation occurs next, by mechanisms similar to those that influence initial invasion; (7) tumour cell survival and proliferation within the organ parenchyma complete the metastatic cascade. To grow in the organ parenchyma, the metastases must develop a vascular network and evade the host immune system. For production of clinically relevant metastases, each of the outlined steps must be completed. Failure to complete one or more steps (e.g. inability to invade host stroma, a high degree of antigenicity, inability to grow in a distant organ's parenchyma) eliminates the cells.

Numerous examples exist in which malignant tumours metastasize to specific organs (Fidler, 1990). In 1889, Paget proposed that the growth of metastases is influenced by the interaction of particular tumour cells (the 'seed') with the unique organ's environment (the 'soil') and that metastases resulted only when the seed and soil were compatible (Paget, 1999). Common regional metastatic involvements have been attributed to anatomical or mechanical

considerations such as efferent venous circulation or lymphatic drainage to regional lymph nodes but distant organ metastases represent a unique pattern of organ specificity. Experimental and clinical confirmation of these observations advocates that the microenvironment of each organ influences the implantation, invasion, survival and growth of distinct tumour cells (Fidler, 1990; Radinsky, 1995). The mechanistic basis of this interaction remains under intense investigation. What influences a tumour cell's response to specific organ environments? What enables one tumour cell to survive and ultimately proliferate as a metastatic lesion and another to lie dormant in some cases for years? The properties of the tumour cell and host factors play a key role in this process. For example, during the metastatic cell's interactions with a number of host cells and systems, biochemical signals from endocrine, paracrine or autocrine pathways, alone and in combination, stimulate or inhibit tumour cell survival and proliferation, with the eventual outcome dependent on the net balance of positive and negative regulators. Hence the successful metastatic cell, referred to three decades ago as the 'decathlon champion' (Fidler, 1990), must also be viewed as a cell receptive to its environment (Radinsky, 1995).

Membrane-bound receptor tyrosine kinases (RTKs) and their corresponding growth factor ligands participate in this process in multiple solid tumour types and their metastases. This chapter focuses on current and novel therapeutic strategies targeting RTKs and/or their corresponding growth factor ligands in the therapy of primary solid tumours and their resulting metastases. Emphasis is given to strategies using monoclonal antibody and small molecule kinase inhibitor approaches targeting specific members of the ErbB family of RTKs including the epidermal growth factor (EGF) and the ErbB2/HER2 receptors. Use of the RTK targeting agents alone and in combination with cytotoxic compounds or radiation is discussed in the context of antitumour effects in terms of mechanisms affecting tumour cell survival, proliferation, invasion and angiogenesis in preclinical animal tumour models and in human clinical trials. (See also chapter on *Signalling by Tyrosine Kinases*.)

GROWTH FACTOR RECEPTOR TYROSINE KINASES

Cell surface molecules carry information from the microenvironment to the cell. Cells communicate by way of cell surface receptors that recognize and respond to signals from the environment. One major family of cell surface molecules is composed of transmembrane proteins with intrinsic tyrosine kinase activity. The superfamily of RTKs is organized into subfamilies depending on structural and sequence similarities (Blume-Jensen and Hunter, 2001). These include the epidermal growth factor receptor (EGFR) family, the platelet-derived growth factor receptor (PDGFR) family, the insulin receptor (IR) family, the fibroblast growth factor receptor (FGFR) family, the hepatocyte growth factor receptor (c-Met) family and the neurotrophin growth factor receptor family (**Table 1**). These RTKs contain several discrete domains, including an extracellular ligand-binding domain, a transmembrane domain, a tyrosine kinase catalytic domain and a C-terminal domain. Interaction of a growth factor with its receptor at the cell surface leads to a tight association enabling growth factors to mediate their activities at nanomolar concentrations.

Receptor tyrosine kinases have activity against tyrosine residues present both within the receptor itself and in downstream adaptor molecules. RTKs bind to specific ligands triggering a conformational change resulting in dimerization of the receptors. Receptor dimerization brings together the tyrosine kinase catalytic domains (intracellular domains), which phosphorylate each other on tyrosine residues, and activate intracellular signal transduction pathways (Blume-Jensen and Hunter, 2001). The mitogenic pathway is mediated through the growth factor receptor binding protein (Grb2) and activation of the Ras and the mitogen-activated protein kinase (MAPK) signalling pathways. Some growth factors, particularly insulin-like growth factor I (IGF-I), can promote cell survival by activating the phosphatidylinositide-3-OH kinase (PI3′K) and its downstream target, the serine–threonine kinase Akt, also known as PKB (protein kinase B), thus promoting cell survival through the activation of anti-apoptotic pathways.

BIOLOGICAL PROPERTIES OF EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR)

The epidermal growth factor receptor (EGFR; also known as HER, human epidermal growth factor receptor, and c-erbB1) is a representative member of the tyrosine kinase family of receptors. EGFR was the first receptor described to have tyrosine kinase activity and the first member of the receptor tyrosine kinase family to be sequenced (Mendelsohn, 1997; Wells, 1999). The EGFR responds to multiple factors from the EGF family of ligands. Each ligand can elicit a different activating or deactivating response that is dependent on ligand and cell type. The overactivation of EGFR can have dramatic effects on a cell's normal functions, leading to uncontrolled migration, survival and proliferation. *Egfr* gene knockout mice usually die in the blastocyst stage or *in utero*, but may live to 20 days post-birth depending on the genetic background of the mice (Wells, 1999). EGFR has a variety of ligands with redundant signalling pathways. EGF is well characterized and can be a potent activator of epithelial cells. Transforming growth factor α (TGF-α) is a potent

Table 1 Growth factor receptor families and their properties in malignancy

Receptor family	Family members	Action
Epidermal growth factor receptor (EGFR)	EGFR HER2/neu/c-erbB2 HER3/c-erbB3 c-erbB4 Xmrk	Epithelial cell growth
Hepatocyte growth factor receptor (c-Met)	c-Met	Mesenchymal cell growth Proangiogenic

	trkB	

For a review, see Blume-Jensen and Hunter (2001).

activator during liver regeneration and normal epithelial growth and is often expressed in an autocrine manner by different tumour cells (Radinsky, 1995). Mice deficient in TGF-α or EGFR do not die early in development, indicating redundancy in the EGFR/TGF-α signalling pathways that can compensate for the loss of either protein. Other members of the EGF family of ligands include amphiregulin (AR), heparin-binding EGF-related growth factor (HB-EGF) and betacellulin (BTC).

Following stimulation by ligand, the EGFR (ErbB1) is able to heterodimerize with other members of the EGF/c-erbB family of receptors, namely ErbB2 (Her2/neu), ErbB3 and ErbB4 (Blume-Jensen and Hunter, 2001). This heterodimerization allows EGFR to respond to another family of growth factor ligands, the neuregulins (Wells, 1999; Kirschbaum and Yarden, 2000). Activation of intracellular signalling pathways occurs when the RTK binds to one or a few intracellular proteins with Src homology 2 (SH2) domains via typical docking sites containing phosphotyrosine residues (Blume-Jensen and Hunter, 2001). These effector molecules include the adaptor proteins Grb2, Shc, Crk, Vav and Nck and proteins that regulate second messengers such as PI3-kinase, PI-4,5-kinase and PLC-γ (**Table 2**).

THE ROLE OF RTKs AND EGFR IN HUMAN CANCER

The most common cellular lesions found in human cancers involve the overexpression of RTKs in combination with autocrine stimulation of the receptor by ligand. These include TGF-α, PDGF A and B, acidic fibroblast growth factor (aFGF), basic fibroblast growth factor (bFGF) and their specific receptors (**Tables 1** and **2**). Epidermal growth factor receptors are present on many normal and tumour cells (Wells, 1999; Ciardiello *et al*., 2001). Elevated levels and/or amplification of the EGFR has been found in many human tumours and cell lines, including breast cancer, gliomas, lung cancer, bladder cancer (Dinney *et al*., 1997; Perotte *et al*., 1999; Inoue *et al*., 2000), tumours of the female genital tract, the A431 epidermoid carcinoma, prostate carcinoma, pancreatic carcinoma and colon carcinoma (Radinsky, 1995). These results suggest the physiological significance of inappropriate expression of members of the RTK family including EGFR in abnormal cell growth control, making it and other receptor tyrosine kinases prime targets for anticancer therapy.

EGFR Signal Transduction and Bladder Cancer Progression

Transitional cell carcinoma (TCC) of the bladder is the fourth most common malignancy in the United States. Clinical studies evaluating the significance of EGFR expression in human TCC have shown that >50% of human TCCs overexpress EGFR, and that the level of expression directly correlates with tumour grade, stage and survival (Dinney *et al*., 1997; Perrotte *et al*., 1999; Inoue *et al*., 2000; Brons *et al*., 2000). In patients with superficial bladder cancer, EGFR expression correlates with multiplicity, time to disease recurrence and overall recurrence rates. EGFR expression also predicted disease progression to muscle invasive or metastatic TCC and was an independent prognostic factor for death in a multivariate analysis. EGFR expression also has prognostic significance for patients with advanced TCC. Patients with muscle-invasive TCC which overexpress EGFR have a 20% probability of long term cancer-specific survival which is significantly worse than the survival of those whose tumours did not express EGFR. These studies establish the importance of EGFR overexpression in the development and progression of human TCC of the bladder.

EGFR Signal Transduction and Pancreatic Carcinoma Progression

The EGFR and its ligands (including EGF, AR and TGF-α) are also commonly overexpressed in pancreatic cancer and their expression is associated with a worse prognosis (Evans *et al*., 1997). This coexpression of both receptor and ligand and the fact that EGF, AR and TGF-α are mitogens for pancreatic cancer cell lines have led to the hypothesis that an EGFR-dependent loop contributes to the malignant phenotype of this disease. Its importance in the biology of pancreatic cancer is supported by experiments targeting either EGFR or its ligands (see below) (Bruns *et al*., 2000a,b). Immunohistochemical analysis of 87 pancreatic tumours for EGFR, TGF-α and EGF found that coexpression of these proteins correlated with a more rapidly progressive pancreatic cancer in comparison with tumours that failed to express the receptor and its ligands. Similarly, a statistically significant decrease in the survival of patients overexpressing the EGFR and at least one of its ligands was observed. No correlation between survival and the presence of Ki-*ras* or the *p53* tumour-suppressor gene mutations was observed. In addition, a longer median survival in unresectable pancreatic cancer patients treated with the anti-EGFR Mab 425 was reported and one complete response was observed in a patient who remained in an unmaintained remission for 3 years (Evans *et al*., 1997). These studies establish the importance of EGFR overexpression in the development and progression of human pancreatic carcinoma and collectively implicate the EGFR as a potential target in the therapy of carcinomas from multiple origins.

GROWTH FACTOR RECEPTOR BLOCKADE THERAPY

There are several methods of RTK blockade therapy designed to interrupt signal transduction selectively. These therapeutic approaches targeting RTKs include strategies using monoclonal antibodies (MAbs) targeted to the extracellular domain, tyrosine kinase inhibitors that are preferential for individual RTKs, bispecific and single-chain antibodies, overexpression of dominant negative mutant receptors, ligands conjugated to toxins, inhibitors of receptor dimerization or antisense RNA. Each of these approaches will be outlined below in the context of specific therapeutic effects alone and in combination with cytotoxic drug therapy or radiation in preclinical experiments and in some cases clinical trials.

Monoclonal Antibody Therapy of Human Cancers

Directing monoclonal antibodies (MAbs) towards a specific RTK represents a promising anticancer therapeutic strategy. By selectively targeting the extracellular portion of a receptor, ligand binding and subsequent intracellular signalling can be prevented. Also, some antibodies subsequent to receptor binding evoke a host immune response

to the tumour. Several MAbs are currently in clinical trials or in use in the clinic, including Rituximab (anti-CD20), Trastuzumab (anti-ErbB2/Her2) and C225 (anti-EGFR). In 1997, the US Food and Drug Administration (FDA) approved the first MAb for the treatment of human cancer. This was anti-CD20 mouse/human chimaeric antibody, Rituximab/Rituxan^{TM}, used to treat human B cell lymphomas. Clinical trials using this MAb showed a 15–60% objective response rate when administered as a signal agent and a 95–100% response rate when combined with chemotherapy (Coiffer *et al.*, 1998).

In 1998, the FDA approved the second MAb for the treatment of human cancer. Trastuzumab, commonly known as Herceptin^{TM}, is a chimaeric mouse/human anti-ErbB2/HER2/neu receptor monoclonal antibody. This was the first antibody approved to treat solid tumours. ErbB2/HER-2/neu regulates normal epithelial cell growth. Amplification and/or overexpression result in increased receptor activity and increased tumour growth. Clinically, ErbB2/HER-2 overexpression is associated with a more rapid rate of tumour growth, increased rates of metastasis and decreased patient survival. However, overexpression of ErbB2/HER-2 is seen in approximately 20–30% of breast cancer patients and a small number of patients with other solid tumours such as lung, bladder, ovary and pancreas (Slamon *et al.*, 1989).

Binding of the Herceptin MAb antibody to the HER-2 receptor results in competitive inhibition of ligand binding to the receptor. *In vitro*, anti-ErbB2/HER-2 antibodies have been shown to downregulate the kinase activity of the receptor, decrease cell proliferation and increase chemosensitivity in HER-2 overexpressing cells (Benz and Tripathy, 2000). As a single agent in phase II clinical trials, 17% of patients with metastatic breast cancer achieved a 50% or greater reduction in tumour size. In phase III trials when Herceptin was given with paclitaxel or doxorubicin/cyclophosphamide, objective response rates increased to 44 and 53%, respectively (Burris, 2000; Benz and Tripathy, 2000).

Monoclonal antibodies have also been developed to the EGFR. An example is anti-EGFR humanized MAb C225, which is currently in multiple clinical trials (Mendelsohn, 1997). C225 binds to the extracellular domain of EGFR, blocking ligand binding and resulting in blockade of receptor activation (and in some cases increased internalization of the nonactivated receptor) (**Figure 1; see colour plate section**), decreased proliferation and cell-cycle arrest. C225 also exhibits additive to synergistic effects when given in combination with chemotherapy or radiation versus either agent alone. Recent preclinical studies in our laboratory have shown that the treatment of human bladder and pancreatic cancer with C225 results in significantly decreased primary tumour growth and incidence of lung, liver and lymph node metastases (Perotte *et al.*, 1999; Bruns *et al.*, 2000; Inoue *et al.*, 2000).

Anti-EGFR Therapy of Human Pancreatic Cancer in Preclinical Models

Cancer of the exocrine pancreas is characterized by extensive local invasion and early development of metastasis (Evans *et al.*, 1997). At the time of diagnosis, more than 80% of the patients present with either locally advanced or metastatic disease. The inability to detect pancreatic cancer at an early stage, its aggressiveness and the lack of effective systemic therapy are responsible for rapid death from this disease. In fact, only 4% of all patients with adenocarcinoma of the pancreas will survive 5 years after diagnosis. For patients with advanced pancreatic cancer, even the recent introduction of the deoxycytidine analogue gemcitabine does not extend median survival beyond 6–9 months. Therefore, new therapeutic modalities such as RTK blockade therapy are needed for this disease.

As described above, an association exists between pancreatic tumour progression and the expression and function of the EGFR. The pancreas is one of the richest sources for expression of prepro-EGF, thereby raising the question of autocrine growth stimulation of pancreatic cancer by EGF production (Bruns *et al.*, 2000a,b). EGF has been shown to promote pancreatic carcinogenesis in hamsters and the *in vitro* growth of human pancreatic cancer cells (Evans *et al.*, 1997). In addition to EGF, several cultured human pancreatic cancer cell lines produce TGF-α. TGF-α has been shown to be 10–100 times more potent than EGF in stimulating anchorage independent growth of these cell lines; 3-, 15- and 10-fold increases in the mRNA levels of EGFR, EGF and TGF-α, respectively, have been reported in pancreatic carcinomas as compared with normal pancreatic tissue. These data suggest that overexpression of the EGFR and its ligands may contribute to the malignant phenotype in human pancreatic cancer (Yamanaka *et al.*, 1993).

We recently reported that therapy with the anti-EGFR humanized MAb C225 inhibited the growth of established human pancreatic carcinomas growing in the pancreas of athymic nude mice (Bruns *et al.*, 2000a) (**Table 3**). These data show that targeting the EGFR in established disease with anti-EGFR MAbs alone or in combination with gemcitabine results in significant antitumour effects (**Table 3**). The abrogation of tumour growth and distant lymph node and liver metastases was due in part to blockade of EGFR tyrosine kinase activation (**Figure 1**) and reduction of tumour-induced neovascularization (**Figure 2; see colour plate section**) secondary to the downregulation of tumour cell expression of the angiogenic factors VEGF and IL-8 (Parker *et al.*, 1998; Dinney *et al.*, 1997) (**Figure 3; see colour plate section**). These studies confirm that systemic administration of the chimaeric anti-EGFR MAb C225 inhibits growth and metastasis of human pancreatic cancer established in the pancreas of athymic nude mice. Therapy with MAb C225 has a significant antitumour effect

Table 3 Therapy of human pancreatic tumours in nude mice with anti-EGFR MAb C225 and gemcitabine. (Adapted from Bruns *et al.*, 2000a.)

Therapy[a]	Incidence of macroscopic tumours[b]			Total pancreas weight (mg) (range)[e]	Median tumour volume (mm^3) (range)[f]	Median body weight (g) (range)
	Pancreas tumour	Liver metastasis[c]	Regional LN metastasis[d]			
Control	10/10	5/10	10/10	923 (660–1371)	539 (254–860)	22 (16–24)
Gemcitabine	10/10	3/10	6/10	297 (205–485)	152 (59–365)	22 (18–29)
C225	5/10	2/10	8/10	119 (97–157)	0.3 (0–13)	25 (21–28)

[a] 1×10^6 L3.6pl cells were implanted into the pancreas. Therapy began on day 7 when the median tumour size was 18 mm^3. Anti-EGFR MAb C225 (1 mg); gemcitabine (250 mg/kg) alone or in combination was injected i.p. biweekly for 4 weeks. Control mice received saline. Tumour volume, weight and extent of metastases were evaluated at necropsy on day 32

[b] Number of tumour-positive mice per number of injected mice

[c] Number of mice with visible nodules (>1 mm in diameter) per number of injected mice

[d] Number of mice with enlarged regional lymph nodes per number of injected mice

[e] $p < 0.0001$ (unpaired Student's *t*-test) control versus all three therapy groups

[f] Tumour volume was calculated using the equation $v = ab^2/2$, where a is the longest diameter and b is the shortest diameter of the tumour. $p < 0.0001$ control versus all three therapy groups and anti-EGFR MAb C225 versus anti-EGFR MAb C225 plus gemcitabine therapy group.

mediated by direct effects on the tumour cells with respect to inhibition of proliferation, and by inhibition of angiogenesis mediated by downregulation of tumour cell produced angiogenic factors, which are potentiated when used in combination with gemcitabine.

EGFR Signalling and Regulation of Angiogenesis

The downregulation of angiogenic factors produced by the tumour restores the balance between stimulating and inhibitory factors that keeps angiogenesis dormant under normal conditions. The observation that downregulation of the angiogenic stimulus of the tumour cells inhibits the host angiogenic response emphasizes the complexity of tumour–host interactions. The experiments outlined above demonstrate that inhibition of angiogenesis characterizes, in part, the antitumour effect of therapy directed at inhibiting EGFR signalling pathways in human pancreatic tumour cells. This observation was first reported by Petit *et al.* (1997) and later confirmed by several groups, including our own in multiple tumour systems (Perrotte *et al.*, 1999; Bruns *et al.*, 2000a,b; Ciardiello *et al.*, 2001). Both EGF and TGF-α, which are ligands for EGFR, induce angiogenesis. Therefore, downregulation of EGFR signalling pathways could inhibit tumour growth by inhibiting tumour-mediated angiogenesis, independent of any direct cytostatic effect on tumour growth. Preclinical data suggest that EGFR blockade therapies alone and in combination with cytotoxic therapies (e.g. gemcitabine, paclitaxol) inhibit the growth of established human carcinomas growing orthotopically in immunodeficient mice (**Table 3**). The abrogation of tumour growth and distant metastasis was due, in part, to a reduction in tumour-induced neovascularization secondary to the downregulation of tumour cell expression of the angiogenic factors vascular endothelial growth factor (VEGF), bFGF and interleukin-8 (IL-8), leading to endothelial and tumour cell apoptosis and ultimately to regression of established tumours (**Figures 2 and 3**). Thus, the presence of the proangiogenic factors VEGF, bFGF and IL-8 were necessary to maintain a viable microcirculation and maintain tumour growth. The withdrawal of the angiogenic stimulus by EGFR blockade therapy resulted in regression of the tumour's neovasculature and ultimately tumour cell death.

The mechanisms by which EGFR signalling pathways regulate VEGF and IL-8 are unclear, but it is established that upregulation of these factors follows activation of the EGFR signalling pathways by EGF or TGF-α. Transcription of VEGF is potentiated by activation of the four AP-1 transcription factor binding sites within its promoter; the IL-8 promoter has one AP-1 site (Petit *et al.*, 1997). After activation of EGFR signalling pathways, *ras* and *raf* are activated, resulting in phosphorylation of c-Fos and c-Jun, leading to increased AP-1 activity (Petit *et al.*, 1997). This increase in AP-1 transcription factor activity leads to transcription of genes with AP-1 sites in their promoter. Since VEGF and IL-8 all share AP-1 binding sites, they are potential targets for therapies that downregulate EGFR signalling pathways and reduce AP-1 activity. EGFR activation has also been shown to stimulate VEGF expression in multiple tumour cells (Ciardiello *et al.*, 2001). Petit *et al.* (1997) reported that *in vitro* treatment of the human epidermoid carcinoma cell line A431 with MAb C225 downregulated VEGF and that after *in vivo* therapy tumours showed a reduction in microvessel density counts (Petit *et al.*, 1997). Similar observations have now been reported in multiple tumour models (Ciardiello *et al.*, 2001).

Alternative Mechanisms for the Tumoricidal Effect of EGFR Blockade

A cooperative growth inhibitory and cytotoxic effect of C225 in combination with several chemotherapeutic agents and radiation has recently been shown to augment antitumour activity in several mouse xenograft models and in human clinical trails (Wells, 1999). Anti-EGFR MAb C225 substantially enhanced the cytotoxic effects of doxorubicin, *cis*-diammine-dichloroplatinum, gemcitabine and paclitaxol on well-established xenografts (Baselga *et al.*, 1993; Mendelsohn, 1997). Furthermore, clinical trials with squamous cell carcinoma of the lung have demonstrated the capacity of the anti-EGFR MAb C225 to localize in such tumours and to achieve saturating concentrations in the blood for >3 days without toxicity. The molecular pathways for this effect are unclear, but those affecting DNA repair, multidrug resistance, cell cycle checkpoint control or as discussed above angiogenesis, may be involved. For example, treatment with C225, but not EGF, triggered a specific physical interaction between the internalized EGFR and DNA-dependent protein kinase (DNA-PK) implicated in the repair of DNA double-strand breaks (Mendelsohn, 1997). This significantly reduced the level and activity of DNA-PK in the nucleus with a concomitant increase in DNA-PK levels in the cytosol, suggesting that EGFR blockade and downregulation by C225 may impair DNA repair by reducing the nuclear level of DNA-PK. The capacity of C225 to modulate tumour cell cycle distribution may also play a central role regulating the increased sensitivity to chemotherapeutic agents (e.g. gemcitabine, paclitaxol) and radiation. This may involve cell cycle checkpoint control as an activator of cell death (Wells, 1999). EGFR blockade results in cellular arrest at the G_1 restriction point, and cells damaged by chemotherapy or radiation typically arrest in G_2-M to repair DNA alterations. Mendelsohn (1997) hypothesized that when tumour cells simultaneously ignore two checkpoint signals (e.g. activated by EGFR blockade and cytotoxic drug or radiation treatment), cell death occurs. Nonmalignant epithelial cells, which obey checkpoint control signals, may be less susceptible to the cytotoxic effects of these combination treatments. These data indicate that inhibition of EGFR signalling probably acts through several potential mechanisms to sensitize tumour cells to cytotoxic agents or radiation and provides possible mechanisms for enhanced effects of therapy of human carcinomas with EGFR blockade agents in combination with cytotoxic agents or radiation.

Receptor Tyrosine Kinase Inhibitors

RTK-specific inhibitors are small molecules that directly inhibit RTK activity and hence phosphorylation by physically interacting with the kinase domain and blocking ATP binding or inhibiting tyrosine phosphorylation. Newer generation compounds compete at the ATP-binding site and prevent phosphorylation by blocking the phosphate source, ATP. These compounds are also very receptor specific. Most RTK inhibitors are targeted against the EGFR family (Noonberg and Benz, 2000).

In an attempt to block selectively EGFR signalling, Buchdunger *et al.* (1995) synthesized a new class of dianilinophthalimide (DAPH) tyrosine kinase inhibitors. DAPH2,4,5-bis(4-fluoroanilino)phthalimide, is a potent and selective inhibitor of the EGFR tyrosine kinase and the PKC $\beta 2$ enzyme. *In vivo*, DAPH2 significantly reduced the growth, in a dose-dependent manner, of human A431 and 253J B-V bladder carcinoma xenografts growing in immunodeficient mice (Dinney *et al.*, 1997; Parker *et al.*, 1998).

Bos *et al.* (1997) found that PD153035, an RTK inhibitor, suppresses the growth of a number of EGFR-overexpressing human cancer cell lines. Administration of the RTK inhibitor in combination with MAb C225 further increased the antitumour activity of PD153035. The effects of ethyl 2,5-dihydroxycinnamate (EtDHC), a novel EGFR TK inhibitor, were tested on human glioblastoma cell lines expressing different EGFR mutants. They found that EtDHC was more potent in inhibiting EGFR tyrosine kinase activity in cell lines overexpressing the wild-type *EGFR* gene, resulting in decreased cell growth and DNA synthesis. In cell lines expressing truncated EGFR, a higher dose of EtDHC was required to achieve similar effects. This finding was in contrast to work with another EGFR TK inhibitor, tyrophostin AG 1478, that preferentially inhibited glioblastoma cells expressing truncated EGFR (Han *et al.*, 1996).

A new class of irreversible RTK inhibitors were recently engineered against EGFR and ErbB2/HER-2 (Fry, 2000). The inhibitor PD168393 inactivates the EGFR tyrosine kinase by covalently modifying a cysteine residue in the ATP binding pocket. It was also found that the irreversible inhibitor was nine times more effective than a similar reversible compound (PD174265) in a human A431 epidermoid carcinoma xenograft model. An even greater difference (30-fold) was seen against HER-2 phosphorylation in MDA-MB-453 human breast carcinoma cells.

The efficacy of RTK inhibitors has recently been described. Faust *et al.* (1999) found that PD153035, an RTK inhibitor against the EGFR TK, caused apoptosis and growth inhibition *in vitro* of human squamous cell carcinoma of the head and neck (SCCHN). Murakami *et al.* (1999) described the activity of Sporostatin, a novel and specific inhibitor of the EGFR tyrosine kinase. Sporostatin was isolated from a fungus of *Sporomiella* sp. M5032 and is noncompetitive with either substrate or ATP. They also reported that sporostatin inhibits the autophosphorylation of the EGFR in A431 cells. More recent reports describe similar results with RTK inhibitors of the EGFR and ErbB2/HER-2 receptor. To date, multiple EGFR-preferential RTK inhibitors from a number of companies including AstraZeneca, OSI, Novartis and

Pfizer are in human clinical trials (Cassinelli *et al*., 2000); Fry, 2000; Kirschbaum *et al*., 2000 and Vincent *et al*., 2000).

Bruns *et al*. (2000b) recently published a study of a novel EGFR RTK inhibitor, PKI166, from Novartis Pharma. They found that administration of PKI166 significantly inhibited the growth and liver and lymph node metastases of human pancreatic cells growing in the pancreas of nude mice. As a single agent, PKI166 reduced the growth of pancreatic tumours by 45%. Primary tumour growth was further reduced when PKI166 was combined with gemcitabine (85% versus control). Combination therapy also resulted in a decreased incidence of liver and lymph node metastases and prolonged survival. These results are similar to those seen with anti-EGFR MAb C225 administered in combination with gemcitabine (see above). The observed decrease in tumour growth was due, in part, to a decrease in tumour microvessel density that was attributed to increased endothelial cell death following therapy with PKI166 alone and in combination with gemcitabine.

Bispecific and Single-chain Antibodies

Bispecific antibodies (BsAb) are recombinant proteins that contain one bivalent variable region (Fv) arm targeting an epitope on the surface of a tumour cell and another targeting an immune effector cell, such as a T lymphocyte. BsAb recruit immune effector cells to the tumour target and generate an increased host–tumour interaction, leading to tumour-cell death.

Negri *et al*. (1995) tested the antitumour effect of the anti-EGFR/anti-CD3 BsAb M26.1 with the constant region removed. They found that the BsAb M26.1 targeted human T lymphocytes to the EGFR in an ovarian cancer xenograft immunotherapy model (IGROV1) and increased the survival of the treated animals. Valone *et al*. (1995) used BsAb MDX-210 in a phase Ia/Ib clinical trial in patients with advanced breast or ovarian cancer that overexpresses ErbB2/HER-2/neu receptor. MDX-210 binds to type I Fc receptors for immunoglobulin G (IgG) (Fc gammaRI) and to the HER-2/neu receptor. MDX-210 targets Fc gammaRI-positive immune effector cells such as monocytes and macrophages to tumour cells that overexpress HER-2. In the phase I clinical trial, one partial and one mixed tumour response were observed among 10 assessable patients receiving MDX-210. Goldstein *et al*. (1997) developed a similar antibody that targets the EGFR and Fc gammaRI-positive immune cells. This BsAb, H22-EGF, inhibited the growth of EGFR-overexpressing cells and mediated the cytotoxicity of these cells in the presence of Fc gammaRI-positive cells. Similar results have been seen with single-chain antibody therapy.

Single-chain antibodies (scFv) are recombinant proteins composed only of immunoglobulin heavy- and light-chain variable regions linked by a short, flexible polypeptide. Single-chain antibodies have rapid tumour penetration *in vivo* owing to their small size. These antibodies can be exogenously administered or generated within a tumour cell. ScFv are able to inhibit ligand binding and kinase activity or prevent receptor maturation and cell surface expression. The development of scFv is still in an immature stage as problems with delivery, stability and gene transfer are considered.

Beerli *et al*. (1994) developed a secreted form of an scFv that competes with EGF binding to the EGFR. This antibody was expressed in EGFR-transformed cells and was shown to inhibit receptor activation in an autocrine manner. This group also developed scFv against the extracellular domain of the ErbB2/HER-2 receptor using a different approach from above. The single-chain antibodies were expressed intracellularly and targeted to the lumen of the endoplasmic reticulum (ER). By binding the extracellular domain of the newly synthesized ErbB2/HER-2 receptor, the scFvs prevented the transit of the receptors through the ER to the cell surface, thus inactivating the receptors. Similar approaches have been utilized to inactivate HER-2 in T47D human mammary carcinoma cells. EGF and neu differentiation factor (NDF) induced the activation of mitogen-activated protein kinase (MAPK) and growth stimulation by NDF was inhibited in cells devoid of cell surface ErbB2/HER-2 receptors.

Dominant-negative Mutant Receptors

Previous work has provided evidence that structurally defective receptors can suppress the action of wild-type receptors, thus behaving as dominant-negative mutations. This causes various decreased receptor responses resulting in decreased cell proliferation, cell migration, etc. Wells (1999) found that the kinase-negative mutant EGFR K721A was internalized following ligand binding but was then recycled to the cell surface. Wild-type receptors, however, were degraded following internalization. Based on this information they determined that intracellular trafficking of the EGFR was determined by a sorting mechanism that recognizes EGFR molecules based on their kinase activity. Therefore, the mutant receptors were causing the suppression of the wild-type receptors. In culture, EGF stimulated the dimerization of both types of receptors in cultured NIH/3T3 cells that coexpressed human wild-type EGFR and a mutant EGFR that was lacking most of its cytoplasmic domain. However, only homodimers of wild-type receptors were activated by tyrosine autophosphorylation following ligand binding. Heterodimerization with mutant receptors resulted in the inactivation of the wild-type receptors, resulting in decreased kinase activity (Kashles *et al*., 1991).

More recent studies have shown that NIH/3T3 cells transformed with the activated *HER-2* oncogene could

be phenotypically reverted by a dominant-negative mutant HER-2 receptor (Messerle *et al*., 1994). These variants were mutated in the transmembrane region and the ATP-binding site of the kinase domain. The authors also found a significant decrease of mutant growth in soft agar (80–90%) compared with the transformed cells. Qian *et al*. (1994) showed that a kinase-deficient HER-2 could suppress the function of wild-type EGFR in transformed mouse fibroblast cells. EGFR normally heterodimerizes with HER-2 following ligand activation and becomes cross-phosphorylated. However, heterodimers formed by HER-2 mutants and wild-type EGFR resulted in a lack of kinase activity. The kinase-deficient ErbB2/HER-2 receptor protein behaves as an anti-oncogene factor and causes reversion of the transformed phenotype.

CONCLUSIONS

A primary goal of cancer research is an increased understanding of the molecular mechanisms mediating the process of tumour progression and metastasis. Experimental analysis of the interaction between cancer cells and the microenvironment has increased our understanding of the biological mechanisms mediating tumour formation and organ-specific metastasis. Insight into the molecular mechanisms regulating these processes has produced a foundation for new therapeutic approaches. As reviewed here, RTKs and their corresponding ligands act to influence tumour cell growth, differentiation, invasion, metastasis and angiogenesis. Taken together, the abundance of growth-promoting factors, the disturbance of growth-inhibitory pathways, tumour-induced angiogenesis and the presence of gene mutations combine to give cancer cells a distinct growth advantage which clinically contributes to rapid tumour progression, metastasis and poor survival. The analyses presented here of new and novel RTK blockade therapies add new evidence to support the concept that tumour progression and metastasis are not a random process; they constitute a regulated process that can be analysed at the molecular level in the context of the relevant organ environment. This new knowledge will lead to the further design and implementation of more effective RTK blockade therapies alone and in combination with cytotoxic compounds or radiation for this dreaded disease.

Chapter 96

Signal Transduction Pathway Targeting

Stanley B. Kaye and Paul Workman

Institute of Cancer Research and Royal Marsden Hospital, Sutton, Surrey, UK

CONTENTS

- Introduction
- Farnesyl Transferase Inhibitors (FTIs)
- Cyclin-dependent Kinase Inhibitors (CDKIs)
- Receptor Tyrosine Kinase Inhibitors (RTKIs)
- Protein Kinase C Inhibitors (PKCIs)
- Other Targets
- Future Perspectives
- Acknowledgement

INTRODUCTION

The term signal transduction is used to describe the molecular processes involved in the communication between the cell and its environment, and in the regulation of cell fate (Downward, 2001). The rationale for developing signal transduction inhibitors as anticancer agents is clear. New anticancer agents are targeted increasingly to the specific abnormalities in the sequence and level of expression of a series of key genes that combine together to drive the progression of human cancer (Hanahan and Weinberg, 2000; Evan and Vousden, 2001). Many of the genetic abnormalities in cancer cells lead to the activation of proliferative signal transduction pathways, deregulation of cell cycle control and the activation of antiapoptotic and cell survival pathways (Hanahan and Weinberg, 2000). In addition, pathways leading to angiogenesis, invasion and metastasis are upregulated (Hanahan and Weinberg, 2000).

The new generation of molecular therapeutics targeted specifically to these deregulated pathways should be more effective and less toxic than the broadly antiproliferative cytotoxic drugs which dominate current therapy (Garrett and Workman, 1999; Workman, 2000). This promise has still to be fully evaluated in hypothesis-testing clinical trials, but progress with the anti-erbB2 monclonal antibody Herceptin (trastuzumab), the Bcr-Abl inhibitor Glivec (imitanib, STI571; CGP57148B) and the epidermal growth factor receptor tyrosine kinase inhibitor Iressa (ZD1839) has very clearly exemplified the clinical potential of molecular therapeutics targeted to deregulated signal transduction pathways (Garrett and Workman, 1999; Workman, 2000, 2001a).

Although most cancers are likely to be driven by the combinatorial effects of several different oncogenes and tumour-suppressor genes, it is possible that therapeutic modulation of any one deregulated target or pathway may be sufficient to give a therapeutic effect (Workman, 2000, 2001a). Such effects are likely to be cytostatic rather than cytotoxic. Hence clinical trials will have to be planned very carefully in order to identify therapeutic activity (Gelmon *et al.*, 1999). In addition, pharmacodynamic endpoints will be required to confirm the intended molecular mode of action and to guide dose selection (Garrett and Workman, 1999; Gelmon *et al.*, 1999; Workman, 2000, 2001a). It is essential to bear in mind that signal transduction inhibitors may have multiple actions, not only in terms of molecular locus, but also with respect to the biological effects achieved, e.g. cell cycle arrest, induction of apoptosis or inhibition of angiogenesis. Although single agent activity may be seen, it seems more likely that optimal use of the new molecular therapeutics will be in combination. Such combinations may involve multiple agents targeted to various signal transduction pathways.

However, in considering the introduction of signal transduction inhibitors into clinical practice, it should be emphasized that it will certainly be the case that conventional cytotoxics will continue to provide a large proportion of the available therapy for the next 5–10 years. Hence an important challenge will be to develop more effective ways of using cytotoxic agents, in particular to overcome the key clinical problem of drug resistance. Here signal transduction inhibitors may play a key role. It is well understood that the response of cancer cells to chemotherapy or radiotherapy represents a balance between cell death (usually by apoptosis) and cell survival (generally following damage repair during cell cycle arrest) and that this balance can be altered by increasing or decreasing the activity of those cell signals leading either to apoptosis or damage repair. Thus it is evident that signal transduction inhibitors can fundamentally alter the chemo- and radiosensitivity of cancer cells (Dent and Grant, 2001). Their clinical development must therefore recognize this

considerable opportunity as part of a combined therapeutic approach. This is not to dismiss their potential as single agents, which already is becoming evident in clinical trials, but it serves to remind those involved in their development of the importance of pursuing both avenues.

Previous reviews have described progress with the development of signal transduction inhibitors (e.g. Gibbs, 2000; Workman, 2000, 2001b). The emphasis of the present review will be on the progress made and challenges ahead with the introduction of these agents into clinical trials and routine practice. The current clinical status of the various candidate signal transduction inhibitors will be summarized briefly according to the target, with reference made in each case to both single agent and combination studies. Particular attention will be focused on:

- farnesyl transferase inhibitors;
- cyclin-dependent kinase inhibitors;
- receptor tyrosine kinase inhibitors;
- protein kinase C inhibitors.

This chapter will concentrate mainly on small molecule enzyme inhibitors, although other approaches to signal inhibition are also in clinical development. Selected antibodies acting on signal transduction will be discussed. Antisense inhibitors based around phosphorothioate oligonucleotides have been shown to retain biological activity following continuous intravenous administration. Targets for these agents include the H-*ras* oncogene, c-*Raf*-1 kinase (and hence the MAP kinase signalling cascade), *protein kinase C*α and also the antiapoptotic oncogene *bcl-2*. In each case, only modest toxicity has been noted; pharmacodynamic studies have indicated the potential for reduced target expression in peripheral blood mononuclear cells and hints of activity in phase I trials in various tumours have been sufficient to justify further development of antisense drugs, both as single agents and in combination with conventional chemotherapy (Cunningham *et al*., 2000).

FARNESYL TRANSFERASE INHIBITORS (FTIs)

The receptor tyrosine kinase→Ras→MAP kinase pathway is frequently activated in tumours by mutation or overexpression of *ras* oncogenes, growth factors or growth factor receptors (Workman, 2001b). This stimulated the discovery of FTIs, on the basis that inhibition of the post-translational modification and membrane localisation of Ras would block proliferative signal transduction. At least five FTIs have entered clinical trials in humans and data are available on four, R115777 (Janssen), SCH6636 (Schering-Plough), L778123 (Merck) and BMS 214662. Clinical experience has recently been summarized (Johnston, 2000). In all cases, prolonged exposure schedules have been investigated in phase I trials. R115777 and SCH6636 have used oral formulations, L778123 and BMS 214662 are administered intravenously.

R115777 has been administered over 21 days, and the dose-limiting toxicity (at 400 mg b.d.) is a combination of myelosuppression, fatigue and peripheral neuropathy. Higher doses, up to 1300 mg b.d. for 5 days every 2 weeks, are feasible, but not on a continuous basis (Zujewski *et al*., 2000). Hints of clinical activity were seen in the initial studies in patients with pancreatic, colon and non-small-cell lung cancer and plasma levels of R115777 at the MTD exceeded those which were clearly active *in vitro*. More recently, two disease-specific studies with R115777 have indicated significant antitumour efficacy, in six of 20 patients with refractory acute leukaemia (Lancet *et al*., 2000), and three of 27 patients with advanced breast cancer (Johnston *et al*., 2000). In the leukaemia study, *ex vivo* inhibition of FT enzyme activity and MAP kinase phosphorylation inhibition was confirmed in sequential bone marrow samples. Combination schedules involving R115777 together with gemcitabine and 5-fluorouracil (5FU)–leucovorin have also been completed, and toxicity has been predictable and manageable.

SCH6636 was administered in various oral regimes, and in addition to myelosuppression, other aspects of dose-limiting toxicity included diarrhoea, vomiting and nephrotoxicity. Regimes have included oral dosing for 1 week followed by a 3-week rest period (Adjei *et al*., 2000), a 2-week on/2-week off schedule and continuous oral dosing (Hurwitz *et al*., 1999). Using the first of these, at the MTD of 400 mg b.d., a biological surrogate marker of activity, i.e. inhibition of prelamin A farnesylation in buccal mucosa, was assessed, and effective inhibition was noted. With this schedule a patient with non-small-cell lung cancer obtained a partial response, while stable disease was noted in a number of other patients, with treatment duration ranging up to 9 months. Combination regimens have included SCH6636 together with paclitaxel and gemcitabine.

For L778123, an intravenous formulation was used with a 7-day administration in a 3-week cycle. At the maximum tolerated dose (MTD) of 560 mg/m^2 day^{-1}, dose-limiting toxicity comprised myelosuppression and nausea (Britten *et al*., 1999). A second study, with a 14- or 28-day continuous infusion, reached an MTD of 840 mg/m^2, with dose-limiting toxicity comprising myelosuppression and cardiac conduction changes (Rubin *et al*., 2000a). At a half of this dose, a surrogate tissue assay – inhibition of farnesylation of hDJ2 in peripheral blood mononuclear cells – showed effective inhibition. L778123 has been given together with paclitaxel, and also radiotherapy (based on preclinical evidence of enhanced radiation-induced apoptosis).

For BMS 214662, three phase I trials (using single 1 h, daily ×5, and weekly intravenous infusions) are ongoing. Nausea, vomiting and diarrhoea have been noted as the major toxicities, and clinical activity has been seen in patients with breast, colorectal and non-small-cell lung

cancer. Dose-related inhibition of farnesylation was noted in peripheral blood cells (Ryan *et al*., 2000). Further trials, combining the drug with conventional chemotherapy, are also planned.

It should be emphasized that the precise molecular mechanism responsible for the antitumour activity of FTIs is not at all clear and remains controversial (Workman, 2001b). A number of cellular proteins are farnesylated and inhibition of any of these, in addition to Ras, may contribute to the therapeutic activity. One potentially important consequence of treatment with FTIs is the switch from farnesylation to geranylgeranylation of RhoB, leading to apoptosis.

In summary, whatever their precise mode of action, FTIs showed a range of manageable antiproliferative and other side effects, and inhibition of the target enzyme in surrogate tissues has been confirmed. However, no molecular studies have yet been reported using solid tumour biopsies from treated patients. Interesting antitumour activity for single agent therapy has been seen, particularly with R115777. Major challenges for the future include the choice of dose and schedule, with the balance appearing to lie between continuous exposure and normal tissue toxicity. An additional question will be the choice of tumours to test, since a large number either have mutated or deregulated Ras; however, the relevance of this is now unclear. Finally, these agents have also demonstrated synergy with a range of cytotoxic agents, perhaps because RhoB, which is probably an important intracellular target, is involved in apoptosis and DNA repair. Combination trials, using FTIs with chemotherapy will thus be viewed with particular interest.

CYCLIN-DEPENDENT KINASE INHIBITORS (CDKIs)

Cyclin-dependent kinases are frequently deregulated in cancer by a variety of means, including overexpression of the cyclin and kinase components, together with mutation or loss of negative regulators such as p16 (Garrett and Workman, 1999). The first CDKI to be tested clinically was flavopiridol. This inhibits CDK1, -2 and -4 (and at higher doses it also inhibits other protein kinases including EGF receptor tyrosine kinase). Flavopiridol has antitumour activity in its own right and has also shown schedule-dependent synergy *in vitro* with paclitaxel. In the first phase I trial using a 72-h intravenous infusion every 2 weeks, dose-limiting toxicity initially comprised secretory diarrhoea (at $62.5\,\mathrm{mg/m^2\,day^{-1}}$). With antidiarrhoeal prophylaxis a higher dose ($98\,\mathrm{mg/m^2\,day^{-1}}$) was achievable, before dose-limiting hypotension was also noted (Senderowicz *et al*., 1998). In addition a characteristic ‘proinflammatory syndrome’ comprising ’flu-like symptoms and local tumour pain occurred at the higher dose levels. Pharmacokinetic analyses indicated that concentrations which inhibited all three CDKs were achievable, and one patient with renal cancer achieved a partial response, with minor responses in patients with colon cancer and lymphoma. However, a subsequent phase II trial in renal cancer, using the same schedule, has shown minimal activity (Stadler *et al*., 2000).

Of greater interest is a second phase I trial which involved a 24-h infusion of flavopiridol, either preceded or followed by a 24-h infusion of paclitaxel (Schwartz *et al*., 1998). Apoptosis was measured in peripheral blood lymphocytes, and a clear difference was noted with respect to drug sequencing. The sequence of paclitaxel followed by flavopiridol led to a marked increase in apoptosis, whereas an actual reduction was noted with the reverse sequence. These observations, although preliminary and not involving tumour cells, may have important implications for future combination regimes, since on theoretical grounds the interaction between a cell cycle inhibitor and conventional chemo- or radiotherapy may be either synergistic or antagonistic, and scheduling could be a key determinant.

Another cell cycle inhibitor which directly inhibits CDK1 and -2 is staurosporine. The benzoyl derivative UCN-01 has other actions, and at lower concentrations it inhibits the G2/M checkpoint kinase Chk1. This would be expected to potentiate the effects of chemotherapy in tumour cells. A phase I trial of UCN-01 also involved a 72-h i.v. infusion, and dose-limiting side effects included vomiting, hyperglycaemia and pulmonary toxicity (Senderowicz, 2000). Antitumour activity was seen in patients with melanoma and anaplastic lymphoma. Measurements on saliva of free drug levels indicated that concentrations compatible with modulation of the cellular response to a DNA-damaging agent were clinically achievable. An extremely long half-life was also noted, thought to be due to extensive binding of UCN-01 to α-acidic glycoprotein. Shorter infusion phase I protocols are planned. However, at this stage, the drug’s toxicity will probably preclude extensive further investigation in combination schedules. Nevertheless, the preclinical data would argue persuasively for further studies of compounds of a similar type in combination with drugs such as 5FU or platinum, or alternatively with radiation.

A third CDKI in clinical development (within the EORTC) is E7070, a novel chloroindolylsulfonamide which inhibits CDK2 and cyclin E in cancer cells at concentrations ranging from 1.4 to $131.4\,\mu\mathrm{g\,mL^{-1}}$ *in vitro*. Phase I clinical trials have employed a daily $\times 5$ (1 h), 5-day continuous infusion, and weekly infusion (1 h) schedules (Raymond *et al*., 2000a). Myelosuppression is dose-limiting, clinical responses have been seen in patients with breast and uterine cancer and pharmacodynamic studies are ongoing.

A range of new CDKIs are now emerging with the potential for selectivity against particular CDKs. It might be envisaged that a CDK4 inhibitor could mimic the effects of restoring p16 function. A CDK2 inhibitor could

induce apoptosis in tumour cells with deregulated E2F expression. However, the biological and clinical effects of selective CDK inhibition are likely to be more complex.

RECEPTOR TYROSINE KINASE INHIBITORS (RTKIs)

An alternative approach to signal transduction inhibition is to target at the level of cell membrane receptors, rather than further downstream. There are numerous examples of overexpression of growth factors and/or RTKs in cancer, leading to the potential for autocrine growth stimulation, and in some cases mutations are also seen (Garrett and Workman, 1999). A range of targets have been identified, and inhibitors of varying specificity have been tested clinically. These include inhibitors of EGF (or ErbB-1), PDGF and VEGF RTKs.

There are at least five molecules in clinical development as EGF RTKs: ZD1839 (Iressa; AstraZeneca), CP358774 (Pfizer), CI-1033 (Parke-Davis), EKB 1869 (Wyeth) and PKI 166 (Novartis). In addition a human-to-murine chimaeric monoclonal antibody, C225 (Imclone) has been developed for the purpose of direct inhibition of EGFR, while a second humanized monoclonal antibody (Herceptin) directed against another member of the ErbB family of receptors, the erbB2 or Her-2/neu receptor, has attracted the most attention because of clear evidence of clinical benefit in randomized trials in breast cancer.

ZD1839 is completing phase I clinical trials, using an oral preparation, delivered over 14 or 28 days. At the highest doses given, dose-limiting toxicity includes diarrhoea and skin rash; indeed, a skin rash first visible on the face has been seen at all doses above 250 mg and appears to be characteristic of agents targeting EGF RTK, presumably because of the high level of receptor expression in normal skin (Baselga *et al*., 2000a). Objective tumour responses to ZD1839 given as a single agent have been noted in patients with non-small-cell lung and prostate cancer, with hints of activity in ovarian and head and neck cancer. Phase II single-agent studies are therefore planned, and phase III trials in non-small-cell lung cancer, combining ZD1839 with platinum-based chemotherapy, are also under way. The potential for significant augmentation of cytotoxic chemotherapy, and perhaps circumvention of clinical drug resistance, is particularly intriguing because of the persuasive laboratory data pointing to the role of EGF as a survival signal in cells exposed to DNA-damaging agents. In due course, the clinical schedules used in combination trials may need to take account of these interesting possibilities.

There are fewer clinical data available on the other compounds in development, but experience to date indicates a similar pattern of toxicity. Skin rash has been seen with CP358774 (now renamed OSI-774) and the agent is proceeding to phase II trials, hints of activity having already been detected in non-small-cell lung, head and neck, ovarian and renal cancer (Karp *et al*., 1999). CI-1033 is interesting in that it is in fact an inhibitor of all four members of the ErbB family of receptors and is currently in phase I trials.

As regards CI-225, clinical data on both single-agent and combination regimes are available. Antibody was given either as a single intravenous dose or weekly. As with ZD1839, a characteristic skin rash was noted, otherwise toxicity was minimal. A dose of 200 mg/m^2 was considered optimal, based on pharmacokinetic data, indicating saturation of systemic clearance at that level (Baselga *et al*., 2000b). Moreover, an earlier clinical trial with a murine anti-EGF receptor monoclonal antibody indicated more than 50% receptor saturation of tumour biopsies following treatment of patients at that dose.

Combination trials with chemotherapy and radiation therapy have been particularly interesting. Head and neck and colorectal cancer patients with disease progressive on prior cisplatin-containing or CPT-11 containing treatment were retreated with the same dose of cisplatin (or CPT-11) and weekly injections of CI-225. Seven of eight patients demonstrated a partial response (Rubin *et al*., 2000b). In a separate trial, 15 patients were treated with weekly CI-225 during a course of radiation therapy for locally advanced disease; the overall response rate was 93% (Ezekiel *et al*., 1999).

For Herceptin, initial clinical trials using a weekly intravenous schedule showed that it was well tolerated, and a modest 15% response rate was noted in patients with Her-2/neu positive breast cancer (Baselga *et al*., 1996). Following evidence of synergy in xenograft studies, a randomized trial of chemotherapy (paclitaxel or doxorubicin–cyclophosphamide) with or without Herceptin was conducted in patients with advanced breast cancer, and both response and overall survival were significantly improved (Slamon *et al*., 2001). Herceptin is rapidly finding its way into adjuvant clinical trials in HER-2/neu-positive breast cancer and is also being evaluated in combination with other drugs, particularly platinum, in other cancers. The regulatory approval of Herceptin for use in a genomically defined subgroup of patients represents an important landmark in the evolution of the new molecular therapeutics acting on signal transduction pathways and other cancer genome targets.

There are two PDGF RTKIs which have undergone clinical development, SU101 (Sugen) and CGP57148, now renamed STI571 or Glivec/Gleevec (Novartis). Both are given in continuous oral regimes, and the data with Glivec are particularly intriguing. In addition to its property as an inhibitor of PDGF RTK with an IC_{50} of 300 $nmol\,L^{-1}$, Glivec also has been found to have remarkable potency (IC_{50} 38 $nmol\,L^{-1}$) as an inhibitor of the tyrosine kinase associated with the Bcr/Abl fusion protein present in patients with chronic myeloid leukaemia (CML). This led to a modification of the phase I development plan, with the focus

switching to patients with refractory CML. A remarkable level of clinical activity has been noted, with 96% of patients demonstrating a clinical response at doses of Glivec above 300 mg daily for up to 5 months (Druker and Lydon, 2000). It is too soon to evaluate fully the contribution that the drug will make in the management of this disease, particularly in those with lymphoid blast crisis, but already it is evident that it will have an important clinical role, especially as toxicity so far has been minimal. Indeed the drug has recently obtained rapid regulation for the treatment of CML. For the field in general, this experience illustrates the potential for a new signal transduction inhibitor to make an impact, when a susceptible target can be identified for a specific inhibitor. The potential for drug resistance has been noted and combinations of Glivec with cytotoxic chemotherapy will now be examined. Clinical evaluation of STI571 is now continuing in patients with solid tumours known to express PDGF. These include glioma, prostate and small-cell lung cancer. In this last tumour the inhibition of c-kit-associated tyrosine kinase may also be of importance. Indeed, recent reports of remarkable responses in the rare subtype of c-kit positive sarcoma – the gastrointestinal stromal sarcoma (GIST) – are of great interest.

A second PDGF RTKI SU101 has also had fairly extensive clinical assessment. This is in fact a new formulation of an old agent, leflunomide, originally developed as an immunomodulatory agent in 1982. It does have immunosuppressive properties; these may possibly to relate to its potency as a PDGF RTKI and consequent regulation of B and T cell activity, in addition to its antimetabolite properties. The precise role of inhibition of PDGF receptor signalling versus the more conventional antimetabolite effects is not clear. Preclinical studies confirmed specificity of receptor inhibition, and indicated activity in a range of PDGF receptor expressing tumours *in vitro* and *in vivo*. Clinical trials mostly used weekly intravenous 24-h infusions of SU101. Fatigue, nausea and myelosuppression were noted at the highest doses. Tumour regressions were noted in the first trials in patients with recurrent glioma, and a level of significant clinical benefit as high as 43% was claimed in nonrandomized phase II trials (Norman, 2000). However, CNS toxicity proved to be problematic, and after two treatment-induced deaths occurred, the clinical development of the agent was discontinued.

The clinical development of specific VEGF RTKIs has taken a slightly different route, since here the main target is the endothelial cell–tumour cell interaction, the focus being inhibition of angiogenesis. An example of an agent studied in some detail clinically is SU5416 (Sugen). This primarily blocks VEGF-mediated Flk-1 receptor signalling, but does not inhibit tumour cell growth directly. Phase I trials have involved twice weekly intravenous infusions, and toxicity at the highest dose has included vomiting and headache, but at lower doses the drug is well tolerated. Dose-related changes in vascular permeability have been noted, using gadolinium-enhanced magnetic resonance imaging (MRI) scans, and phase II trials of the agent are under way (O'Donell *et al.*, 2000). In addition, further clinical trials of SU5416 in combination with chemotherapy are proceeding because of additive/synergistic effects noted in human tumour xenografts (Cropp and Hannah, 2000). In particular, the combination of SU5416 and 5FU–leucovorin in patients with colorectal cancer is being actively pursued; preliminary clinical data suggest that significant tumour control can be achieved. In addition, a more potent VEGF RTK inhibitor, SU6668, is also being studied in phase I trials. This has the potential advantage of inhibiting signalling via VEGF, PDGF and also FGF, all of which appear to have a role in tumour angiogenesis.

Alternative approaches to VEGF signalling are being taken with a number of other agents; perhaps the agent with the longest history is thalidomide, which is a potent down-regulator of several peptide signalling molecules, including TNFα and VEGF. Interestingly, thalidomide has demonstrated single-agent antitumour activity in a number of diseases, including renal cancer (Eisen *et al.*, 2000), Kaposi sarcoma and glioma, and insight into the contribution which VEGF antagonism makes would clearly be of value in developing this approach.

One further example of a signalling agent in the clinic is the natural flavonoid quercetin. This is a rather nonspecific protein kinase inhibitor, with antitumour activity in human tumour xenografts. A phase I trial using an intermittent i.v. schedule showed that reversible nephrotoxicity was dose-limiting, and tyrosine kinase inhibition was noted in peripheral blood cells (Ferry *et al.*, 1996). A subsequent phase I trial examined the combination of quercetin with carboplatin, because of hints of activity in ovarian cancer, and this approach is certainly of interest, particularly with agents of better defined specificity.

A key issue for the future will be the extent to which specificity towards a single receptor is or is not desirable. It could be argued that well-defined agents, with the ability to inhibit two or three receptors, may find broader application. Examples which will be studied in the clinic in the near future include SU5418, which inhibits VEGF, PDG and FGF receptors. (See also chapter *Growth Factor Receptor Blockade*.)

PROTEIN KINASE C INHIBITORS (PKCIs)

Protein kinase C is one of the most ubiquitous of intracellular signal transduction targets for inhibition (Caponigro *et al.*, 1997) At least 12 isoforms exist, and these are intimately involved in cell signals leading to proliferation and differentiation. PKC isoenzymes consist of a single-polypeptide chain divided into a regulatory and a catalytic domain, and a number of modulators acting mainly at one or other domain have been tested clinically. Single-agent antitumour activity is clearly possible, the best example being tamoxifen, which is both a PKC inhibitor (IC_{50} 40–100 μmol L^{-1}) and

an oestrogen receptor blocker (Couldwell *et al*., 1996). However, there is probably greater potential for these agents as modulators of currently available cytotoxic drugs. This may occur through a number of mechanisms. Staurosporine is one of the most potent PKC inhibitors, but is poorly selective. Among several analogues with greater specificity for certain PKC isoenzymes, CGP 41251 (Midostaurin, Novartis) has been most extensively tested. It is an *N*-benzoyl derivative, most effectively inhibiting cytosolic PKC (IC_{50} 0.5 $\mu mol\,L^{-1}$). It has modest activity in its own right in a range of xenografts, and can reverse P-glycoprotein-mediated drug resistance, restoring doxorubicin sensitivity in a number of models (Crosios, 2000).

A phase I trial of CGP 41251 involving daily oral dosing of 28 days, used a novel surrogate endpoint to test for target (PKC) inhibition. This comprised a measurement of TNF and IL-6 production in response to mitogen stimulation of white blood cells taken from treated patients, the response being significantly lowered as a consequence of (reversible) PKC inhibition. Toxicity comprised nausea and lethargy, but the trial was concluded when the number of daily tablets reached 12, rather than through confirmation of a maximum tolerated dose (Propper *et al*., 2001). Preliminary reports of clinical improvement have been described in a phase II study of CGP41251 in patients with low-grade lymphoma, and clinical trials of combination treatment with chemotherapy and radiotherapy are ongoing.

A second PKC antagonist, bryostatin, has also entered clinical trials in recent years. This is a macrocyclic lactone, derived from a marine bryozoan, and in different conditions it is in fact capable of both PKC antagonist and agonist activity. Clinical trials have involved intravenous infusions of various durations, and the dose-limiting toxicity of myalgia may relate to the drug's ability to stimulate cytokine production (Jayson *et al*., 1995). Responses were seen in patients with ovarian cancer and lymphoma, and phase II trials are ongoing, while combination regimes are also being planned.

OTHER TARGETS

Clearly the range of cell signals which could represent targets for new drug development in cancer is considerable, and likely to expand further as the sequencing of the human genome is finalized (International Genome Consortium, 2001; Venter *et al*., 2001). Complete sequencing of the genomes of cancer cells is likely to identify new cancer gene targets (Futreal *et al*., 2001; Workman, 2001a). **Table 1** lists some of the main targets for which drugs are in preclinical and clinical development for cancer treatment. These include p70S6 kinase, phosphorylation and activation of which is inhibited by a novel rapamycin analogue CCI-779 (Wyeth). This compound is actually an inhibitor of mTOR and is proving to be of considerable interest, not least because of modest toxicity in phase I, associated with clinical activity in renal and breast cancer (Raymond *et al*., 2000b). mTOR inhibitors may have particular utility in tumours which have lost the function of the *PTEN* tumour-suppressor gene, leading to activation of the PI3 kinase pathway, although this is by no means clear. Also of potential interest in view of the role of PI3 kinase in proliferation and apoptosis would be the development of PI3 kinase inhibitors.

Table 1 Current genomic targets for drugs in preclinical and clinical development

EGF receptor tyrosine kinase	Farnesyl transferase
ErbB2 receptor tyrosine kinase	Protein kinase C
VEGF receptor tyrosine kinase	Hsp90
PDGF receptor tyrosine kinase	Histone deacetylases
FGF receptor tyrosine kinase	Histone acetylases
Src tyrosine kinase	p53-mdm2 interaction
Raf-1 kinase	Integrins
MEK kinase	Proteases
Bcr/Abl kinase	Telomerase
Cyclin-dependent kinase	HIF-1α
mTOR	Poly-ADP ribose polymerase
p70S6 kinase	DNA protein kinase
PI3 kinase	Chk 1 kinase
Aurora kinase	Wnt signalling pathway

The degradation of intracellular proteins, including those responsible for signalling apoptosis (including p27, p21, p53 and NF-kappa B), is now known to be a primary function of the ubiquitin–proteasome pathway (Garrett and Workman, 1999). This could be a crucially important cell signalling regulation pathway to target for inhibition, and a potent molecule, PS-341, has now been developed for this purpose. As with other signalling inhibitors, a rationale could be developed both for an antitumour affect on its own, and for an anticipated enhancement of the affect of conventional chemotherapy. Both predictions have been borne out in laboratory studies, and the first phase I trials with an oral dose schedule of twice-weekly PS-341 indicate the feasibility of this approach. Effective inhibition of the 20S-proteasome has been demonstrated in lymphocytes with minimal toxicity seen so far, and hints of antitumour activity have been noted in a patient with melanoma (Hamilton *et al*., 2000). Further clinical trials (single agent and chemotherapy combinations) are awaited with interest.

The molecular chaperone protein HSP90 is also proving to be a target of considerable interest, because of its central role in the intracellular processing of key signalling proteins (Kelland *et al*., 1999). Inhibition of HSP90 and its close homologue GRP94 leads to proteasomal degradation of a range of important oncogenic client proteins, including c-Raf-1, CDK4, Akt/PKB, erbB2 and also mutant p53, leading to cell cycle arrest and apoptosis (Hostein *et al*., 2001). A phase I trial of the geldanamycin analogue,

17AAG, which targets the HS90 chaperone is now under way, with proof of principle studies focusing on measurement of elevated HSP70 levels in peripheral blood lymphocytes and tumour biopsies (Clarke *et al*., 2000), as well as changes in client proteins such as c-Raf-1 (Banerji *et al*., 2000).

Modulators of histone acetylation, and hence of gene transcription, also have exciting potential (Kouzarides, 2000; Workman, 2001c).

FUTURE PERSPECTIVES

The preclinical development and clinical testing of signal transduction inhibitors is a rapidly evolving field. However, two issues of particular note are:

1. phase I trials require to be designed carefully as 'proof-of-principle' hypothesis-testing studies, with extensive use of pharmacodynamic endpoints (Gelmon *et al.*, 1999);
2. the combination of these novel cytostatic agents with conventional chemotherapy must be an essential part of their clinical evaluation, because of the complex potential nature of these interactions at the level of the tumour cell (Dent and Grant, 2001; Waldeman *et al.*, 1997).

The next 5 years will be very stimulating as a range of mechanism-based signal transduction inhibitors undergo clinical evaluation as part of an overall strategy of individualized, genome-based cancer therapy.

DNA DAMAGE AND REPAIR

General Aspects

The genetic information specifying the phenotypes, functional activities and the adaptive and reparative capacity of our cells is stored in the linear sequence of approximately 3×10^9 copies of the four bases guanine, cytosine, adenine and thymine, aligned in the DNA macromolecule. This central molecular blueprint needs to be preserved intact and must be reproduced by DNA replication with utmost fidelity whenever cells prepare for division.

During the lifetime of cells and organisms, the structural and functional integrity of the genome is constantly compromised by various forms of DNA damage that either occurs 'spontaneously' or is caused by exogenous and endogenous DNA-reactive agents. On the one hand, DNA damage that accumulates in cells can be cytotoxic, i.e. cause programmed cell death (apoptosis) or other forms of cell breakdown. However, DNA lesions can also result in the mutation of genes whose inactivation or functional alteration subverts regular cell type-specific properties and may enhance cancer risk.

In recent years it has become evident that the recognition and processing of cellular DNA damage is tightly interconnected with the transcriptional status of target genes, the regulation of DNA repair gene transcription and the control of cell cycle progression and apoptosis via so-called DNA damage checkpoints. The efficacy of distinct modes of DNA repair differs interindividually, with age and among different cell types (most likely also depending on their state of differentiation).

Human cancer cells very often exhibit defects in 'checkpoint' and cell cycle regulation – notably in the p16^{INK4a}–cyclin D1–pRb pathway (see The Mammalian Cell Cycle below) – and even among histologically similar tumours there is wide variability with respect to DNA repair capacity. The latter is a reflection of the genetic and phenotypic heterogeneity and instability of cancer cells, which also explains the frequent generation of variant cell subpopulations within tumours. Together, these properties strongly influence the sensitivity of malignant cells toward DNA-reactive therapeutic agents and represent potential targets for modulation to achieve more effective therapy.

Spontaneous and Induced DNA Damage

In spite of the extraordinary precision of the molecular machinery for DNA replication (notably of the DNA polymerases), replication errors resulting in mismatched bases in the DNA double helix do occur, albeit at relatively low frequency. This is not surprising given the fact that about 10^{10} bases need to be paired correctly with their complementary bases in a diploid human cell per round of cell division, corresponding to about 10^{25} bases during the average human lifetime (assuming a total of 10^{15} cell divisions). Other forms of spontaneous (i.e. unpreventable) structural DNA alterations include noninstructional abasic sites in the DNA molecule, resulting from the loss (via hydrolytic cleavage of *N*-glycosylic bonds) of purine or, less frequently, pyrimidine bases; the conversion of cytosine or 5-methylcytosine to uracil or thymine, respectively, via deamination; a broad spectrum of DNA lesions caused by reactive oxygen species (ROS) that are produced, e.g., in the course of cellular metabolic processes; and alkylated bases formed in DNA by reaction with *S*-adenosylmethionine or with alkylating compounds generated by bacterially catalysed nitrosation of endogenous amides or amines.

To a large extent, however, potentially mutagenic and cytotoxic DNA lesions result from exposure to exogenous DNA-reactive agents, including chemicals of environmental or nutritional origin, solar ultraviolet (UV) light, ionizing radiation and cancer chemotherapeutic drugs. The respective DNA lesions are 'agent-specific,' i.e. they reflect the chemical nature and DNA reactivity of a given compound. The molecular structures of such DNA lesions are therefore highly diverse, and in many cases remain to be clarified because an unknown, but undoubtedly large, number of exogenous DNA reactants still await identification and new chemicals, including cancer therapeutic drugs, continue to be synthesized.

Nevertheless, a considerable number of specific DNA lesions have already been structurally characterized, notably the DNA reaction products of various mono- and bifunctional alkylating *N*-nitroso compounds, some polycyclic hydrocarbons and heterocyclic amines, aflatoxin B_1, UV light, ionizing radiation and ROS. Exogenous DNA alterations have been operationally classified into 'bulky,' helix-distorting lesions that include large-sized base monoadducts or the intra- and interstrand DNA cross-links typically induced by bifunctional anticancer agents (e.g. chloroethylnitrosoureas, platinum derivatives; see later sections) versus small, essentially nondistorting base adducts. (See also the chapters *Mechanisms of Chemical Carcinogenesis* and *The Formation of DNA Adducts*.)

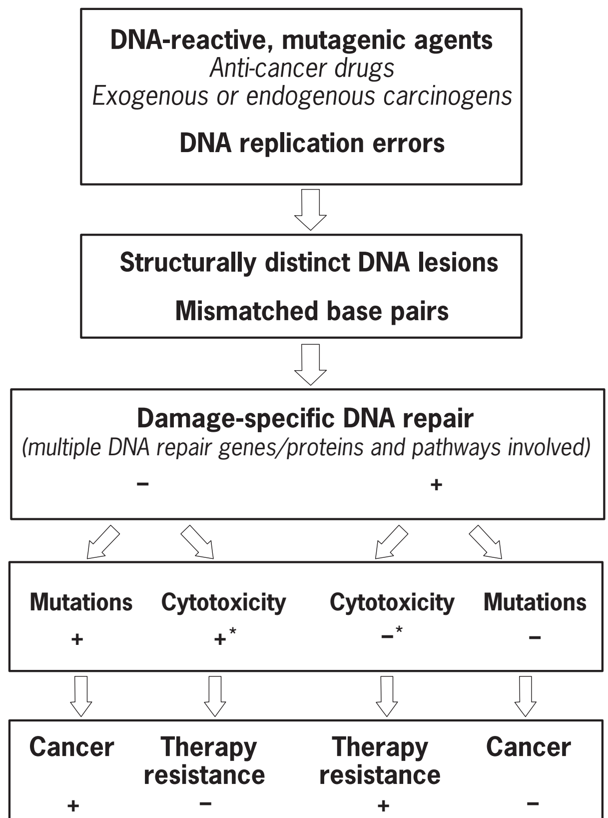

Figure 1 DNA repair: counteragent in mutagenesis and carcinogenesis, accomplice in cancer therapy resistance.

DNA Repair Mechanisms and Molecular Pathways Involved

Timely and error-free repair is the key protective mechanism counteracting the generation of mutations from premutational DNA alterations, thereby holding cancer risk in check. However, because the DNA machinery of the cell can process both potentially mutagenic and cytotoxic DNA lesions, DNA repair also enables cells to cope with an otherwise deleterious load of DNA damage (**Figure 1**).

A large number of genes and proteins have been, and continue to be, identified as being directly or indirectly involved in DNA repair. Not unlike the immune system with its surveillance functions at the cellular level, the DNA repair machinery of our cells represents a modular system with multiple recognition and effector mechanisms, built-in redundancies and 'backup pathways,' allowing the subtle distinction between specific types and sites of DNA damage (Friedberg *et al*., 1995; Wood, 1996; Rajewsky *et al*., 1998).

Human examples of defects in DNA repair genes associated with a dramatically increased risk of skin cancer or colorectal cancer, are the familial genetic disorders Xeroderma pigmentosum (XP) and hereditary nonpolyposis colorectal cancer (HNPCC) respectively.

To enhance the power of the cells' response to DNA damage, the DNA repair machinery joins forces with the molecular controls of cell cycle progression and DNA replication under the surveillance of checkpoint proteins and pathways (Weinert, 1998). In addition to being involved in the control of the transcriptional activity of DNA repair genes, checkpoint proteins signal the arrest of proliferating cells in the G_1 phase of the cell cycle, thus providing more time for DNA repair to avoid the replication of damaged DNA in S phase. Cells may become arrested in mid-G_1 or just prior to the transition of cells from G_1 to S phase. Arrest may also occur in G_2, presumably to avoid the segregation of damaged chromosomes in mitosis (M). In kinetic terms, G_1 arrest in response to DNA damage is at least two-componential (Agami and Bernards, 2000). An initial rapid induction phase is mediated by the proteolytic degradation of cyclin D1, a very important regulatory protein responsible for cell cycle progression through G_1 and often overexpressed in malignant cells. Thereafter, G_1 arrest is maintained through increased stability of the transcription factor p53, the tumour-suppressor protein most frequently inactivated in human cancers.

The p53 protein also promotes DNA repair through the transcriptional induction of target genes such as *p53R2*, which encodes a ribonucleotide reductase catalysing the

conversion of ribonucleoside diphosphates to the deoxyribonucleotides required in major DNA repair reactions (Tanaka *et al*., 2000). Unprotecting cells through inactivation of p53 therefore increases their sensitivity toward DNA-reactive drugs (see Cancer Therapy Resistance). If the extent of DNA damage surpasses a critical, not yet well-specified level, checkpoint proteins such as p53 direct cells into a suicidal apoptotic pathway rather than attempting to accomplish recovery by DNA repair in vain.

A simple scheme of major DNA repair pathways is shown in **Figure 2**. Two principal modes of DNA repair are distinguished: (1) one-step repair (OSR) (i.e. the direct reversal of DNA damage) and (2) excision repair, including nucleotide excision repair (NER), base excision repair (BER) and mismatch repair (MMR) (see Jiricny, 1998, and the next section). Not included in this scheme are (1) the repair of DNA double-strand breaks (induced, e.g., by ionizing radiation, ROS or anticancer agents) by homologous recombination or nonhomologous DNA end joining, and (2) the bypass of DNA lesions by low-fidelity DNA polymerases, a potentially very important error-prone (i.e. mutagenic) repair process, the molecular mechanisms of which have not yet been fully clarified. In a recent model of mutagenic lesion bypass, polymerase ι first misincorporates a deoxynucleotide opposite a helix-distorting lesion or abasic site in DNA, and polymerase ζ then extends from the mispair to complete the bypass (Johnson *et al*., 2000).

OSR is performed, for example, by the repair protein O^6-alkylguanine-DNA alkyltransferase (MGMT) through direct removal of an alkyl group from the O^6-atom of guanine in the DNA of cells exposed to alkylating agents (Pegg, 1990). With increasing size of the alkyl group ($\geq$ethyl), the relative contribution of MGMT to the repair of O^6-alkylguanines in DNA decreases and excision repair steps in as a backup modality.

NER, BER and MMR are multistep pathways involving different proteins and protein complexes. Acting upon a

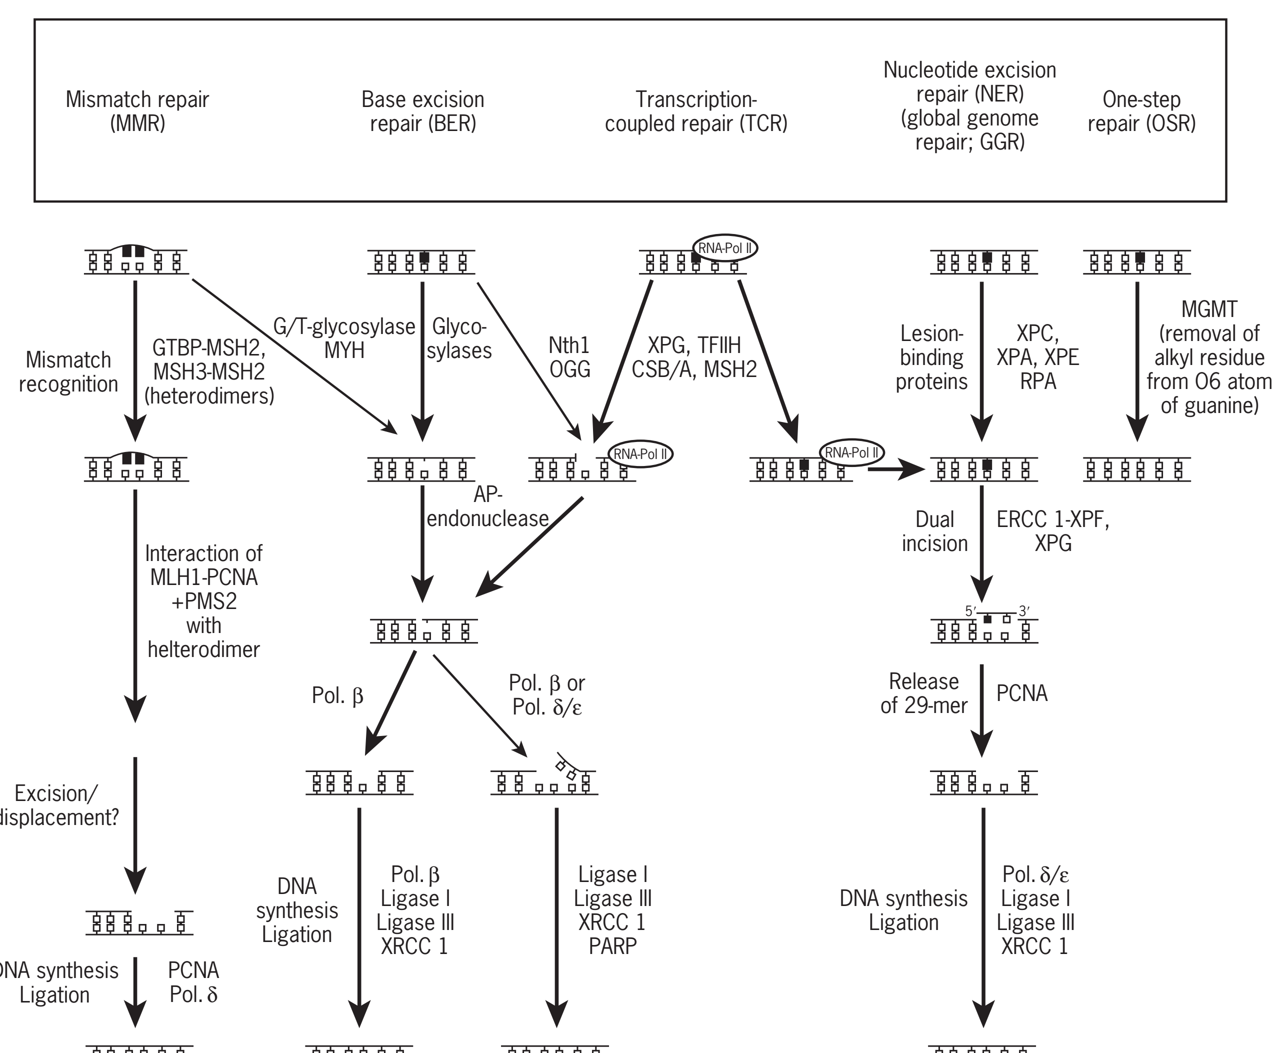

Figure 2 DNA repair pathways in mammalian cells.

broad spectrum of structurally diverse, mostly 'bulky' DNA lesions, NER is a highly versatile pathway involving the concerted action of about 30 different proteins. The human excision nuclease (comprising six repair factors) removes a 24–32 nucleotides long oligomer from the damaged DNA strand after incision on either side of the lesion, followed by DNA repair synthesis (by DNA polymerases δ and ε) using the intact strand as a template, and closing of the gap by ligation. Compared with BER, there appears to be much less redundancy in the NER pathway. So-called 'global' or 'overall' NER (GGR) operates on genomic DNA independent of gene transcription; certain NER proteins may also participate in genetic recombination (as probably required in the repair of DNA interstrand cross-links). Depending on DNA sequence context and chromatin structure, extensive positional heterogeneity regarding the efficiency of NER within defined genes has been found by analyses at very high or even single-nucleotide resolution.

A discrete pathway, transcription-coupled repair (TCR), is responsible for the rapid removal of DNA lesions that block transcription by RNA polymerase. TCR has been found to operate much faster than GGR, usually, but not in all cases, with a bias in favour of the transcribed strand (Le Page *et al*., 2000).

In BER, the removal of a single modified base from one DNA strand is performed by DNA glycosylases via hydrolytic cleavage of the *N*-glycosylic bond. Some of these glycosylases exhibit pronounced lesion specificity, others recognize multiple, structurally different damaged bases and certain glycosylases display considerable promiscuity in terms of the range of reactions that they catalyse. The apurinic/apyrimidinic (AP) site left behind after cleavage of the *N*-glycosylic bond is hydrolysed 5′ by an AP endonuclease, and the 5′-deoxyribose phosphate is excised by a phosphodiesterase. The resulting single-nucleotide gap is then filled by polymerase β and ligated. Alternatives to this common BER pathway include the excision of a short oligonucleotide patch containing the AP site and filling of the gap by polymerase δ or ε. Base alterations caused by a large variety of agents and processes (e.g. spontaneous deamination, ionizing radiation, ROS, alkylating agents, DNA replication errors) are processed by BER. A common feature of the DNA lesions recognized by BER glycosylases is that they do not significantly distort the DNA helix.

Sensitive analytical methodology has been developed for detecting DNA damage and for determining DNA repair kinetics in human cells (Pfeifer, 1996). Notably, these techniques include (1) the radiolabelling and subsequent radiochromatographic analysis of DNA adducts as a function of time after their formation (^{32}P-postlabelling) and (2) immunoanalytical methods, i.e. the application of poly- or monoclonal antibodies to quantify distinct DNA lesions in DNA isolates from cell or tissue samples, in individual cells and in individual genes.

DNA Repair and Cancer Therapy

Cancer Therapy Resistance

Most present-day anticancer drugs and ionizing radiation interact with target cell DNA and exert their cytotoxic effects preferentially in replicating cells. In addition to the primary DNA lesions, secondary DNA alterations induced in the course of repair processes also contribute to the cytotoxic effects of DNA-reactive agents. In principle, DNA repair (except for MMR; see below) synergizes with other protective mechanisms used by cancer cells to outwit cytotoxic therapy (Chaney and Sancar, 1996). Cancer cells which efficiently carry out a mode of repair specifically required to counteract a particular anticancer agent may thus survive, and actually be selected for, in the course of therapy.

Cancer therapy resistance is multifactorial and based on the exceptional ability of malignant cells to adapt to altered microenvironmental conditions, including their exposure to cytotoxic agents. That DNA repair ranks high among the defence mechanisms of cancer cells becomes particularly impressive under laboratory conditions, when only in repair-defective target cells, and not in their repair-proficient counterparts, a given DNA-damaging drug is able to trigger apoptosis or other forms of cell death.

Notably, resistance of cancer cells to the widely used chloroethylnitrosoureas (e.g. *N*,*N*′-bis(2-chloroethyl)-*N*-nitrosourea (BCNU)) has proven to be positively correlated with their MGMT activity (more precisely, the size of the cellular MGMT pool and the rate of MGMT biosynthesis). In the formation of cytotoxic interstrand cross-links in target cell DNA, chloroethylnitrosoureas initially alkylate the O^6 atom of guanine. The resulting O^6-alkylguanine is a substrate of one-step repair by MGMT. Cellular MGMT levels have been found to be highly variable in different types of human tumours.

A notable exception to the rule that DNA repair enhances therapy resistance is MMR, the primary function of which is to correct mismatches generated by nucleotide misinsertion during semiconservative DNA replication or the bypassing of DNA lesions by low-fidelity DNA polymerases (see earlier). Moreover, MMR is involved in the initiation of p53-mediated and -independent apoptosis in response to excessive DNA damage.

In general, therefore, cells defective in MMR are hypermutable, their genome becomes destabilized and the probability of mutations in genes critically associated with carcinogenesis is enhanced. MMR-defective cancer cells, however, such as *p53* mutants, exhibit increased resistance to various anticancer drugs, i.e. these cells tolerate even high loads of DNA damage caused by alkylating agents such as temozolomide and procarbazine, or by cisplatin. This complicates the therapeutic situation, because MMR-deficient tumour cells will be at a selective advantage relative to MMR-proficient normal cells of the host. In the

case of germ-line defects of MMR genes, as exemplified by HNPCC, patients would be at higher risk of developing secondary cancers owing to the hypermutability of their cells.

Similar observations are made in an animal model of toxicity and carcinogenesis induced by a DNA methylating agent: while mice with an inactivating germ-line mutation of the *MGMT* gene ($MGMT^{-/-}$) are hypersensitive toward the lethal cytotoxicity of the agent, their sensitivity reverts to the wild-type ($MGMT^{+/+}$) level when the *MGMT* 'knockout' is combined with the inactivation of the MMR gene *MLH1*. At the same time, the highly elevated cancer susceptibility of $MGMT^{-/-}$ mice remains unchanged in the $MGMT^{-/-}MLH1^{-/-}$ 'double knockout' animals (Kawate *et al.*, 1998).

Individualized Cellular DNA Repair Profiles

As pointed out above, diverse genetic alterations and changes in signal transduction pathways and metabolism accumulate in the course of carcinogenesis and cancer progression. In principle, therefore, and if properly diagnosed, distinct molecular traits of malignant cells, including defects in specific modes of DNA repair, may be exploited to achieve more selective targeting by anticancer drugs.

Different DNA-reactive anticancer agents produce, or may be designed to produce, structurally distinct DNA lesions. These, in turn, require processing by different modes of DNA repair to protect cells from cytotoxic damage. Pretherapeutic determination of the DNA repair profiles of individual cancers (complemented by appropriate controls of the patient's normal cells) may thus permit us to specify the repair characteristics of the target cells as a basis for choosing the most effective drug or drug combination. Criteria to be used for the choice of drug would be (1) that the repair pathway responsible for processing the major cytotoxic DNA lesion produced by the drug shows the greatest possible differential between the cancer cells (low or missing activity) and critical normal cells (regular activity), and (2) that the chemical nature of the major cytotoxic DNA lesion is such that there is the least possible redundancy between different pathways for its repair. Novel or structurally modified drugs that meet the latter criterion better than existing agents may still need to be designed based on molecular recognition and mechanics in human DNA repair.

Cellular DNA repair profiling of individual cancers may be performed in two ways.

1. Via DNA damage dosimetry in primary cancer cells (leukaemic cells; tumour cells microdissected from surgical/biopsy specimens) as a function of time after exposure to model drugs *in vitro*, i.e. by direct measurement of the kinetics of repair of a panel of specific DNA lesions selected for being processed by distinct DNA repair pathways (Buschfort *et al.*, 1997). As an example, **Figure 3** shows the repair kinetics of a model DNA alkylation product (O^6-alkylguanine), as determined in normal and leukaemic lymphocytes isolated from three patients with chronic lymphatic leukaemia (CLL) by monoclonal antibody-based immunoanalysis of individual CLL cells.
2. By 'gene expression profiling' using gene chip (cDNA arrays) and differential display technology for comprehensive analysis of the RNA transcripts of a representative panel of human DNA repair genes, including repair-associated 'checkpoint,' cell cycle and apoptosis regulatory genes. This approach differs from the direct measurement of repair rates in the DNA of individual cells mainly in that repair gene expression is analysed at the level of RNA transcripts (not yet, unfortunately, at the level of functional repair proteins). Hence the gene expression data obtained do not readily translate into repair rates for specific DNA lesions. Moreover, the analyses require large numbers of cells and can therefore only provide overall averages for potentially heterogeneous cell populations. Nevertheless, this

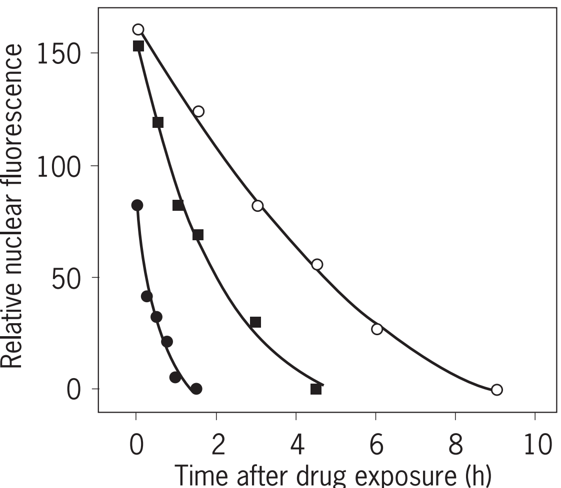

Figure 3 Pretherapeutic cellular DNA repair profiling in human chronic lymphatic leukaemia (CLL): repair kinetics of a model cytotoxic DNA alkylation product (O^6-alkylguanine; O^6-AG) in the nuclear DNA of primary CLL lymphocytes determined by monoclonal antibody-based immunocytological analysis. [O^6-AG]-specific nuclear immunofluorescence quantified via digital imaging of electronically intensified fluorescence signals (data points, mean values for 100 individual cells). Standard input of O^6-AG into DNA generated by pulse exposure of cells to *N*-ethyl-*N*-nitrosourea *in vitro*. Open circles, CLL that subsequently proved to be sensitive to clinical treatment with alkylating drugs (slow repair of O^6-AG in DNA); filled squares, CLL with intermediate drug sensitivity; filled circles, CLL clinically resistant to alkylating drugs (very fast repair). (From Buschfort *et al.*, unpublished work.)

technology permits the simultaneous, semiquantitative evaluation of the expression levels of multiple genes and may thus complement the direct analysis of DNA repair kinetics in a powerful way.

Cotherapeutic Inhibition of Drug-specific DNA Repair Mechanisms

An important objective is the development of specific inhibitors for distinct modes of DNA repair, to be used as 'cotherapeutic drugs' accompanying individualized cancer therapy (see the previous section). The application of repair inhibitors would appear particularly advantageous when the DNA repair pathway to be temporarily inactivated represents the 'backup' pathway for a primary pathway, or vice versa, that is defective or down-regulated in the tumour cells, contrary to normal host cells requiring protection.

The potential toxicity of repair inhibitors would necessitate careful evaluation regarding undesired side effects before they could be clinically applied. The only selective inhibitor of a distinct mode of DNA repair thus far available, and introduced to clinical testing, is the MGMT inhibitor O^6-benzylguanine. However, current advances in the use of high-throughput methodology for drug discovery should facilitate the search for further inhibitors specifically interfering with other DNA repair pathways.

Selective Protection of Haematopoietic Cells from DNA Damage-mediated Cytotoxicity Through Transgenic Enhancement of Repair

As an alternative to the above strategies attempting circumvention or temporary inhibition of DNA repair, it is also possible to exploit enhanced cellular DNA repair capacity to achieve more efficacious cancer therapy. Instead of focusing on the cancer cells, however, such an approach must be directed towards the protection of those normal cells that are of critical importance for the survival of the host.

Owing to their high drug sensitivity, the haematopoietic cells of the bone marrow constitute a major, if not the main, limiting factor in cancer chemotherapy. Normal bone marrow cells express the *MGMT* gene at an exceedingly low level, i.e. these cells are almost defenceless when exposed to drugs that exert their cytotoxic effect via the formation of O^6-alkylguanine in DNA (e.g. the chloroethylnitrosoureas). With the use of viral vectors, however, the *MGMT* gene can be transduced and expressed in haematopoietic progenitor cells *ex vivo* prior to their re-transfer into the host. When a mutant *MGMT* gene insensitive to the inhibitory effect of O^6-benzylguanine is applied, the transduced cells will remain protected against the cytotoxic action of chloroethylnitrosoureas even in the presence of the MGMT inhibitor which, at the same time, will sensitize cancer cells expressing the *MGMT* gene to these drugs (Reese *et al*., 1996).

THE MAMMALIAN CELL CYCLE

Basic Regulatory Mechanisms

Our understanding of the molecular mechanisms, pathways and molecules regulating cell proliferation has grown considerably in recent years and provides a new basis for rational approaches to cancer therapy. In this section we will give an introduction to the key regulatory processes involved in cell cycle control and show how this knowledge can be applied to the design of new therapeutic strategies.

Cell cycle progression in mammalian cells is controlled through fundamentally different regulatory pathways that are controlled either by the cell's microenvironment or by intrinsic checkpoints. Progression through G_1 across the restriction point (R-point; see **Figure 4**) is controlled by external signals which are transmitted, for example, by mitogens or through cell adhesion processes. Beyond this point, cell cycle progression is governed by a genetic programme that is largely independent of extracellular signals but subject to internally controlled checkpoints. These checkpoints ensure proper DNA replication, DNA integrity and mitotic cell division. A central role in cell cycle progression is exerted by the cyclin-dependent kinases (**Figure 4**) (Pavletich, 1999), which are composed of a regulatory cyclin subunit (e.g. cyclin A, B1, B2, D1, D2, D3 or E) and a catalytic kinase subunit (e.g. Cdk1/Cdc2, Cdk2, Cdk4 or Cdk6).

Cyclin-dependent Kinases

The activity of Cdk–cyclin complexes is controlled by multiple mechanisms, including Cdk phosphorylation, the regulation of cyclin mRNA expression and protein stability and the association of Cdk–cyclin complexes with specific protein inhibitors. These regulatory mechanisms are briefly reviewed below.

Regulation of Cyclins by Phosphorylation and Dephosphorylation

Two domains of the Cdk subunits are critical with respect to their regulation by phosphorylation. Whereas phosphorylation of Thr161 is required for kinase activity, the phosphorylation of Thr14 and Tyr15 is inhibitory. Thr161 is dephosphorylated during mitosis and becomes phosphorylated during the subsequent cell cycle by cyclin-activating kinase (CAK), composed of cyclin H and Cdk7. Thr14 and Tyr15 are phosphorylated by the dual-specificity kinase WEE1 and probably other kinases and are

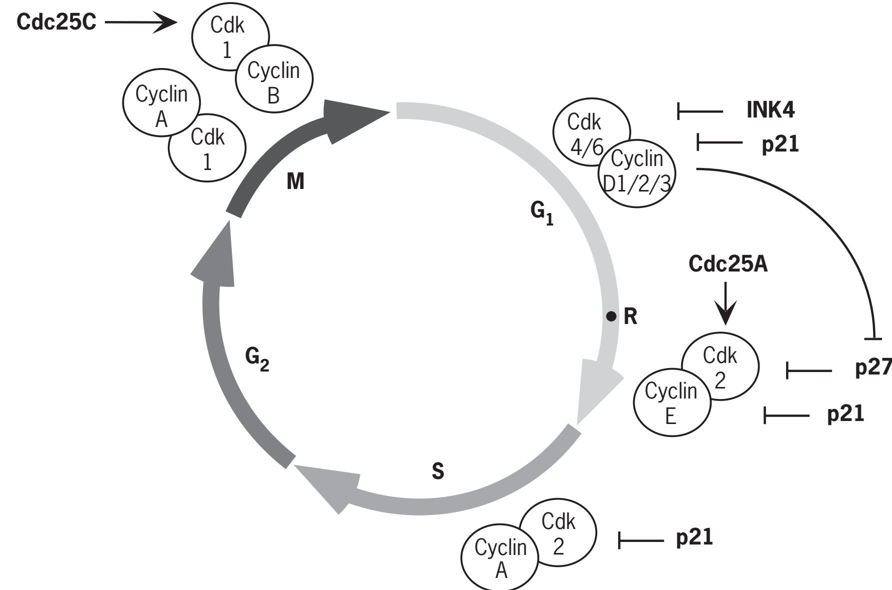

Figure 4 Phase-specific function of cyclin-dependent kinases (Cdk-cyclin complexes), their activating phosphatases (Cdc25A and C), and the Cdk inhibitors (INK4 family members, p21 and p27) during the mammalian cell cycle.

dephosphorylated by different Cdc25 phosphatases acting at different stages of the cell cycle (**Figure 4**).

Phase-specific Expression of Cyclins

Most of the regulatory Cdk subunits, the cyclins, are expressed in a phase-specific manner. Thus, the cyclin E gene is switched on in late G_1, the cyclin A gene at the G_1/S transition and the cyclin B genes in late S. In contrast, transcription of cyclin D genes fluctuates only marginally during a regular cell cycle (in contrast to mitogen-stimulated G_0 cells). Likewise, expression of most Cdk genes is not cell cycle regulated in normally cycling cells.

Phase-specific Proteolysis of Cyclins

The probably most important mechanism regulating the steady-state levels of cyclin A, B and E during the cell cycle is their periodic proteolysis. Following phase-specific ubiquitination by a complex and intricately regulated enzyme system, the modified proteins are degraded in the proteasome. The process is initiated by the attachment of ubiquitin to an ubiquitin-activating enzyme (E1) which is followed by its transfer to an ubiquitin-conjugating enzyme (E2). Subsequently, the ubiquitin moiety is transferred either directly or in conjunction with an ubiquitin ligase (E3) to the target protein. After linkage of additional ubiquitin molecules the polyubiquitinated protein is targeted for degradation. During the cell cycle, E3 complexes are instrumental with respect to the ubiquitination of cyclins and also other proteins (see below), and their subsequent degradation, thus allowing the transition from one phase to the next. One of the best studied examples in this context is the anaphase-promoting complex or cyclosome (APC/C). APC/C is an E3 complex that is responsible for the ubiquitination and subsequent degradation of cyclin B and anaphase inhibitors prior to completion of M phase, thereby controlling chromosome segregation and mitotic exit.

Cdk Inhibitors

Based on their structure, the Cdk inhibitors (CKIs) identified to date can be grouped into two different families: the INK4 family comprising $p15^{INK4b}$, $p16^{INK4a}$, $p18^{INK4c}$ and $p19^{INK4d}$, and the KIP/CIP family consisting of $p27^{KIP-1}$, $p57^{KIP-2}$ and $p21^{CIP-1}$. Of these, the INK4 proteins p15 and p16 and the KIP/CIP proteins p27 and p21 appear to play a major role in human oncogenesis owing to frequent mutations (INK4), deregulated expression (p27) or induction in response to chemo- or radiotherapy (p21). Whereas p21 is an inhibitor of multiple Cdks, the INK family members specifically inhibit cyclin D kinases, and the target of p27 is primarily Cdk2–cyclin E (**Figure 4**). p27 also associates with cyclin D kinases, but does not inhibit their enzymatic activity. Cyclin D complexes can thereby sequester and inactivate p27 (**Figure 4**), resulting in the upregulation of cyclin E kinase activity.

The CKIs are involved in different pathways controlling cell cycle progression, and are themselves regulated by different mechanisms. p21 plays an essential role in the cell's response to certain types of stress, such as DNA damage or metabolic perturbations, which induce a dramatic increase in *p21* gene transcription. This up-regulation of

the *p21* gene is brought about to a large extent by the tumour-suppressor and transcriptional activator p53, which is activated by DNA damage (discussed in detail below) and directly binds to cognate sites in the *p21* gene promoter. p27 levels, on the other hand, are up-regulated under unfavourable growth conditions, such as high cell density or lack of mitogens, to keep Cdk activity low in G_0 cells. However, as soon as cells progress though G_1, p27 is phosphorylated by Cdk2–cyclin E, which has been proposed to serve as a recognition signal for polyubiquitination and subsequent degradation by the proteasome. INK4 proteins seem to play a major role in cellular senescence where their expression is dramatically upregulated. In the case of p15, gene expression is blocked by the Myc oncoprotein, which appears to be an important step in Myc-induced immortalization.

Restriction Point Control

The G_1 Cdk–cyclin complexes regulate cell cycle progression across the R-point through phosphorylation of the retinoblastoma protein Rb and its kins p107 and p130 (Harbour and Dean, 2000). With respect to tumorigenesis, Rb seems to be the most relevant family member, since only Rb has been found to be mutated or deleted in human tumours and only the targeted disruption of the *Rb* gene predisposes mice to the development of tumours. In early–mid-G_1 the transcription factor E2F is found in complexes with Rb and chromatin remodelling factors, including histone deacetylase (HDAC) (**Figure 5**). These complexes actively repress transcription via E2F binding sites in the respective target genes. The phosphorylation of the E2F–Rb–HDAC complexes in mid-G_1 by cyclin D–Cdk4/6 disrupts the binding of Rb and HDAC. This permits the subsequent hyperphosphorylation of Rb by cyclin E–Cdk in late G_1 and disruption of the E2F–Rb complexes (**Figure 5**). This leads to the generation of transcriptionally active free E2F heterodimers, and consequently the induction of numerous E2F target genes.

The relevance of R-point control for tumorigenesis is emphasized by the fact that the Rb pathway is defective in basically all human tumours owing to direct genetic alterations or the indirect deregulation of its components as a consequence of mutations affecting other genes (asterisks in **Figure 5**). Genetic alterations directly affecting the Rb pathway include (1) loss or inactivation of Rb itself, (2) amplification or translocation-mediated deregulation of the cyclin D1 gene, (3) mutations of Cdk4 rendering it resistant to inhibition by INK4 proteins and (4) deletion or mutation of INK4 proteins, such as p15, p16 or p18. Most

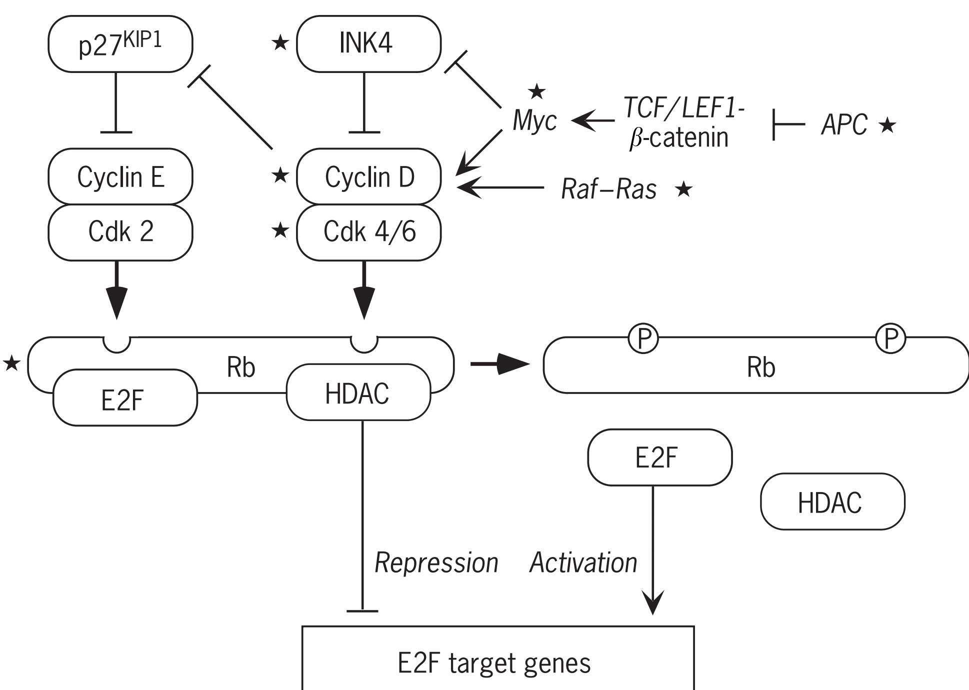

Figure 5 The Rb–E2F pathway and its regulation by cyclin-dependent kinases (cyclin D–Cdk4/6 and cyclin E–Cdk2) and their inhibitors (p27 and the INK4 family members p15, 16 and p18). The repressor function of the E2F–Rb complex is dependent on the association of Rb with a histone deacetylase (HDAC). The latter interaction is disrupted by cyclin D–Cdk4/6-mediated phosphorylation (P). This is followed by cyclin E–Cdk2-mediated phosphorylation of Rb, allowing the release of free, transcriptionally active E2F heterodimers. Also shown are other pathways (Myc and Ras–Raf) that are able to modulate the Rb–E2F pathway. APC: adenomatous polyposis coli tumour-suppressor protein. Asterisks denote frequent genetic alterations in human cancers.

human tumours show one of these genetic alterations. However, in those tumours that do not fall into this category, such as colon carcinoma, the Rb pathway is deregulated as a consequence of other genetic alterations. For example, the Myc oncoprotein (Eilers, 1999) can activate the cyclin D2 promoter through direct transcriptional activation, and can also repress the *p15* gene, and activated Ras and Raf can induce the cyclin D1 promoter via a MAP kinase pathway. Myc expression is frequently upregulated not only because of gene amplification or translocations, but also as a consequence of genetic alterations in other loci. In certain forms of colon carcinoma, for instance, the adenomatous polyposis coli tumour suppressor APC is lost and can therefore no longer constrain the transcriptional activator complex β-catenin–TCF/LEF-1, a potent inducer of the *myc* gene .

In view of its major role in human tumorigenesis, the Rb pathway and its regulators are obviously of major interest with respect to therapeutic intervention, as will be discussed in further detail below.

Checkpoint Control

DNA repair and cell cycle progression are linked via checkpoints that are activated in response to DNA damage and arrest the cell cycle in specific phases. Of particular importance in this context are the p53- and Cdc25A-governed checkpoints in G_1 (Mailand *et al*., 2000), the G_2 checkpoint controlled by Cdc25C and the mitotic APC/C-dependent checkpoint (**Figure 6**). Other checkpoints have been described, in particular in M phase (Muhua *et al*., 1998; Scolnick and Halazonetis, 2000), but their function and regulation are less well understood.

Linking DNA Damage and Checkpoint Control

Sites of damaged DNA are recognized by specific proteins that initiate the cell's response, such as DNA repair, cell cycle arrest or apoptosis (Rotman and Shiloh, 1999). Three protein kinases have been implicated in this step: the DNA-dependent protein kinase (DNA-PK), the ataxia telangiectasia mutated (ATM) kinase and the ATM-related (ATR) kinase. DNA-PK plays a critical role in mammalian DNA double-strand break repair and recombination events, such as immunoglobulin gene rearrangements. Its regulatory subunit Ku, a dimer of the Ku70 and Ku80 proteins, binds to DNA and recruits the catalytic subunit, DNA-PKcs. In cells lacking DNA-PK activity owing to a targeted genetic disruption, the p53-controlled G_1 checkpoint is intact, suggesting that the ATM and ATR (and perhaps other) kinases play a more important role in initiating checkpoint control in response to DNA damage. Subsequent to their activation, ATR and ATM phosphorylate the checkpoint kinase Chk1 and Chk2, respectively (**Figure 7**). The reason for the existence of two parallel pathways is not entirely clear, but may be related to a mediator function in response to different kinds of DNA damage. In the final step of the signalling cascade, Chk1

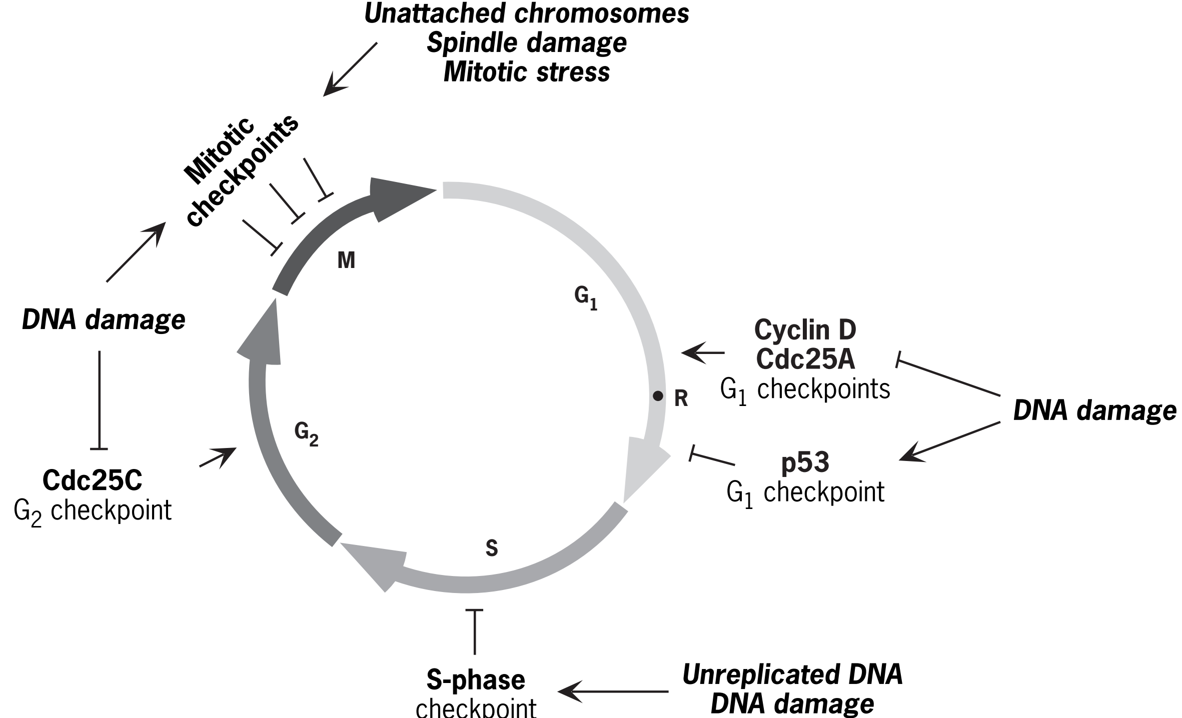

Figure 6 Checkpoints monitoring the integrity of the genome during cell cycle progression.

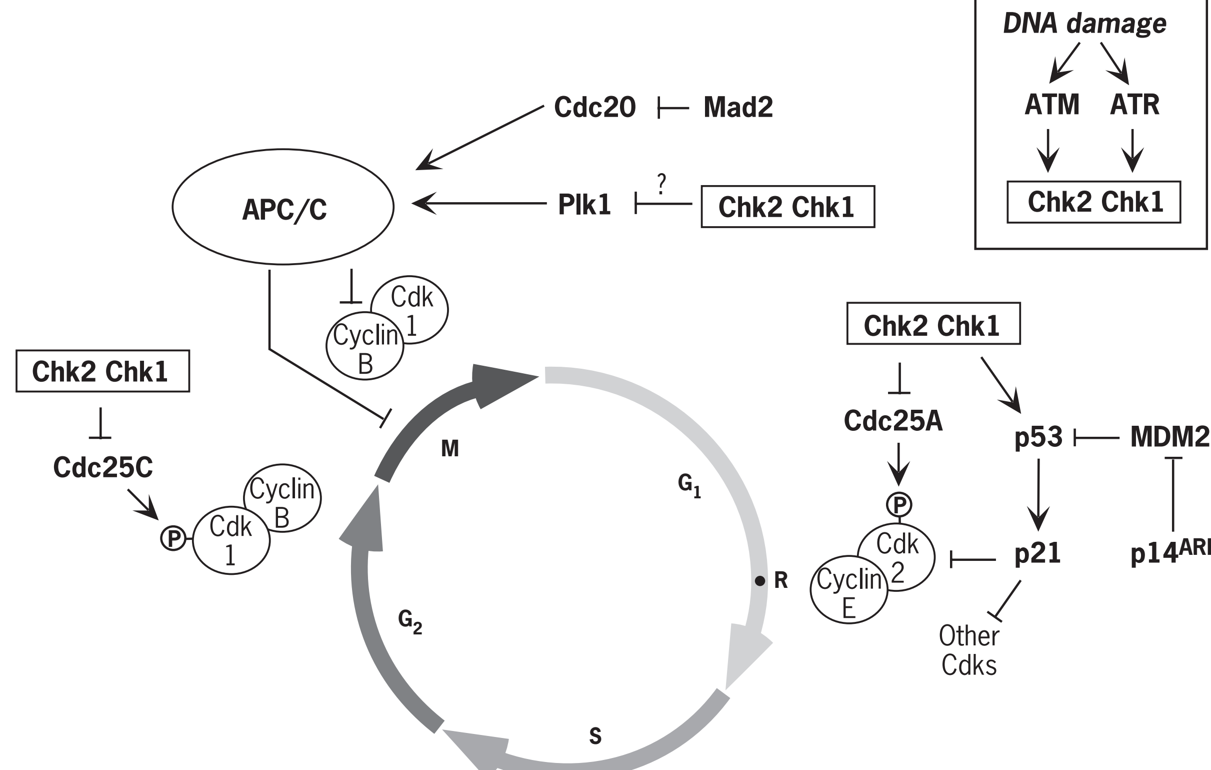

Figure 7 Regulation of the G_1 (p53 and Cdc25A), G_2 (Cdc25C) and spindle (APC/C) checkpoints in mammalian cells. APC/C: anaphase-promoting complex/cyclosome.

and Chk2 phosphorylate their target proteins, such as p53, Cdc25A, Cdc25C and other protein kinases (see below), resulting in the modulation of their activity (**Figure 7**).

p53-Dependent Checkpoint Control in G_1

A major role in checkpoint control in the G_1 phase of the cell cycle is exerted by the p53 tumour-suppressor pathway (**Figures 6** and **7**). In response to DNA damage, steady-state levels of p53 rise owing to its phosphorylation-mediated stabilization affected by the checkpoint kinases Chk1 and Chk2 and presumably others. The steady-state level of p53 is regulated by MDM2, an oncoprotein that associates with unphosphorylated p53 and targets it for ubiquitin-mediated degradation. MDM2 itself is targeted for proteolysis by the tumour suppressor $p14^{ARF}$ (or mouse $p19^{ARF}$). As a consequence of phosphorylation, p53 can therefore accumulate to high levels and activate the G_1 checkpoint via the transcriptional induction of the Cdk inhibitor p21. These observations indicate that p53 is regulated by a complex network of regulatory pathways that affect its function via different mechanisms.

p53 is not only capable of inducing a cell cycle arrest, but can also trigger apoptosis. The latter occurs, for example, in case of severe DNA damage, but is also induced by the untimely or deregulated expression of oncoproteins or cell cycle regulators, such as Myc and E2F1. Therefore, to suppress the proapoptotic potential of a deregulated Rb–E2F pathway, tumour cells acquire potent antiapoptotic mechanisms, among them the elimination of p53 function due to the loss of p53 itself or alteration of its regulators, such as MDM2 or $p14^{ARF}$. It should be noted, however, that Myc and E2F1 can induce apoptosis also via p53-independent pathways, so that other antiapoptotic mechanisms also play an essential role in suppressing their proapoptotic function. Nevertheless, the importance of deleting p53 function during tumour progression is clearly illustrated by the fact that the p53 pathway is defective in more than 50% of all human malignancies. This also emphasizes its relevance with respect to the development of new anticancer therapies.

Cdc25A-dependent Checkpoint Control in G_1

Another G_1 checkpoint activated in response to DNA damage is governed by Cdc25A, a protein phosphatase that is essential for the activation of cyclin E kinase activity prior to progression past the R point (**Figures 6** and **7**). Cdc25A itself is another target of the ATM–Chk2 and ATR–Chk1 pathways. The phosphorylation of Cdc25A leads to its ubiquitin-mediated proteolytic degradation with the consequence that Cdk2 is not dephosphorylated at Thr14 and Tyr15, which leaves the Cdk2–cyclin E complex in an inactive state (Mailand *et al*., 2000). In addition,

DNA damage can induce the proteolytic degradation of cyclin D (Agami and Bernards, 2000), thus preventing hyperphosphorylation of Rb. Each of these events is sufficient to arrest cell cycle progression at the R-point, so that DNA repair can occur prior to the onset of DNA replication. Since many anticancer drugs exert their function through DNA damage, this checkpoint may have a negative impact on their efficacy and therefore represent a potential target for the development of new drugs.

The G_2 Checkpoint

The same DNA damage-induced signalling pathway leading to Cdc25A phosphorylation in G_1 also mediates the phosphorylation of Cdc25C in G_2 (**Figures 6** and **7**). Cdc25C is instrumental in dephosphorylating and thereby activating Cdk1 (Cdc2) in a nuclear complex with cyclin B, a prerequisite for M-phase entry. The Chk1/Chk2-mediated phosphorylation of Cdc25C results in its association with a p53-induced specific isoform of the 14-3-3 protein and thus in its retention in the cytoplasm. This renders Cdc25C inactive, so that progression into mitosis is prevented until DNA repair is completed. By analogy with Cdc25-governed G_1 checkpoint, the G_2 checkpoint also seems to be a suitable target for therapeutic intervention with respect to improving the efficacy of DNA-damaging agents.

Mitotic Checkpoints

Multiple checkpoints operate during mitosis (**Figures 6** and **7**) to ensure that chromosomes segregate with maximum fidelity, to warrant genomic stability and to prevent premature cytokinesis. Mitotic checkpoints have been described to monitor prophase-to-metaphase, metaphase-to-anaphase and anaphase-to-telophase transitions. The checkpoint governing the prophase-to-metaphase transition is, for instance, activated by mitotic stress, such as drugs interfering with microtubule polymerization or function. Activation of this checkpoint is dependent on a gene termed *chfr*, which is frequently mutated in human cancer cells (Scolnick and Halazonetis, 2000). The checkpoint monitoring the anaphase-to-telophase transition is activated by misaligned spindles and delays cytokinesis. In yeast, this checkpoint requires a microtubule-associated protein that is a homologue of human EB1, a protein interacting with the adenomatous polyposis coli tumour-suppressor gene product (Muhua *et al*., 1998).

The best understood mitotic checkpoint operates at the metaphase-to-anaphase boundary, and is also referred to as the spindle assembly checkpoint (**Figure 7**). The target of this checkpoint is the E3 ubiquitin ligase APC/C. The checkpoint is activated early in mitosis unless all kinetochores are attached to microtubules of the mitotic spindle, or in response to microtubule-damaging agents such as taxol. Once activated, the checkpoint induces a signalling cascade involving several checkpoint kinases, eventually leading to the oligomerization of Mad2 at kinetochores. These Mad2 tetramers dissociate from kinetochores and inhibit APC/C activity through binding to its positive regulatory subunit cdc20. The inhibition of APC/C by Mad2 results in the accumulation of proteins whose destruction is required for sister chromatid separation (such as the human oncogene securin/PTTG), thus invoking an arrest in metaphase.

More recently it has been recognized that the checkpoint monitored by the APC/C is also activated in response to DNA damage (Smits *et al*., 2000). A major mediator in this process appears to be the Polo-like kinase Plk1 known as an activator of the APC/C. Plk1 itself is a substrate for the checkpoint kinases Chk1/2, and thus another downstream target of the pathways activating the p53 and Cdc25 checkpoints (**Figure 7**). Phosphorylation of Plk1 results in its inhibition as a consequence of DNA damage in G_2 or M phase, and consequently in a mitotic block due to low APC/C activity. These observations suggest that Plk1 is an important activator of DNA damage-mediated checkpoint control, and thus a potentially interesting therapeutic target.

Application to New Therapeutic Approaches

Cdk Inhibitors

As cancer is mainly a proliferative disease, the inhibition of specific proteins driving the cell cycle is an obvious strategy for the rational discovery of new anticancer drugs. In this context, it is of particular interest that the interference with coordinated cell cycle progression can result in apoptosis of tumour cells, which led to the definition of a new class of antitumour agents that function through a direct inhibition of proteins driving the cell cycle. One of the prototypes of this class of compounds is the synthetic flavone flavopiridol (Senderowicz, 1999). Flavopiridol is a general inhibitor of Cdks, induces cell cycle arrest and apoptosis and is not influenced by many of the genetic alterations conferring resistance on human tumour cells. Accordingly, flavopiridol has shown promising tumour responses in preclinical models and is currently undergoing clinical trials. Numerous other chemical Cdk inhibitors have recently been identified and are currently being evaluated for their antitumour properties (Sielecki *et al*., 2000). It should be noted, however, that these compounds may have other unknown activities that might add to their antitumour properties. Thus, the results obtained with flavopiridol cannot be exclusively attributed to the inhibition of Cdks. In this context, the induction of Bcl-2-independent mitochondrial depolarization is noteworthy, as it may infer a direct impact on mitochondria (Achenbach *et al*., 2000). Likewise, the flavopiridol-induced sensitization of tumour cells to taxol (Bible and Kaufmann, 1997) is tantalizing since it may suggest that flavopiridol interferes with a mitotic checkpoint.

Manipulation of Checkpoint Control

Other interesting targets for therapeutic intervention are the proteins governing checkpoint control, e.g. in response to DNA damage. As discussed above, checkpoint control can invoke a transient cell cycle block, but can also trigger apoptosis. Both types of checkpoints are relevant to tumour therapy. While the functionality of an apoptosis-inducing mechanism in response to drug- or radiation-induced cellular damage is desirable, checkpoint control leading to a mere cell cycle arrest is counterproductive for any therapy that relies on cell proliferation, such as radiation or conventional chemotherapy.

The p53 checkpoint is lost in many tumour cells, and thus the ability to undergo apoptosis in response to chemo- or radiotherapy. The restoration of this checkpoint could therefore sensitize many tumour cells to conventional therapies. Strategies along these lines involve the development of compounds that can reactivate mutant p53 or inhibit MDM2, or the use of gene therapeutic approaches for the reintroduction of functional *p53* genes (Nielsen and Maneval, 1998).

Other drug-based strategies aim at an inhibition of checkpoint control to improve the efficacy of existing therapies that rely on DNA damage, such as radiation or DNA-damaging chemotherapy, by means of minimizing the time available for DNA repair. Suitable targets in this context are the signalling pathways transmitting the damage signals to the checkpoint machinery. Prime candidates for the discovery of chemo- and radiosensitizing drugs are therefore proteins such as ATM, ATR, Chk1/2 and Plk1, which regulate checkpoints in G_1, G_2 and mitosis (see **Figure 7**). First results obtained with an inhibitor of checkpoint kinase Chk1, UCN-01 (Busby *et al*., 2000; Graves *et al*., 2000), suggest that this strategy may indeed be successful with p53-negative cells, although the consequences of eliminating checkpoint control in normal cells could remain a major problem with respect to therapy-induced side effects.

Perspective

These potential applications are just examples. Numerous other mechanisms controlling cell cycle progression have been discovered and approaches for therapeutic intervention are being developed, suggesting that targeting of the cell cycle has great potential for the development of new anticancer drugs. It can be anticipated that this new class of anticancer drugs will lead to important advances in clinical oncology.

INTRODUCTION TO GENE THERAPY

Historical Perspective

Gene therapy technology emerged naturally from the knowledge that DNA is the blueprint for the functional program of every cell, and of the recognition that specific alterations in DNA give rise to specific diseases. The common goal of all gene therapy strategies is to alter gene expression to treat, cure or prevent diseases resulting from inherited or acquired genetic damage. Successful gene therapy requires that the desired gene sequence be transferred to appropriate cells and expressed, and that expression be regulated. Genes destined for use in gene therapy are usually transferred via either viral vectors, which exploit the ability of viruses to adsorb to and infect eukaryotic cells, or nonviral vectors, which exploit the membrane properties of cells. Most gene therapy strategies currently in development target only somatic cells; once technical and ethical issues are resolved, however, the exploitation of germ-line gene therapy to prevent inherited genetic diseases has great potential.

In order to be considered successful, a gene therapy approach must accomplish three things. First, the gene must be delivered to the cell that will express it; second, it must be expressed; and third, expression must be regulated. For some applications, such as cancer, the expression may be transient. During early gene therapy clinical trials, many technological obstacles to meeting these three basic requirements became apparent, making vector design and gene expression studies critical to the further evolution of gene therapy. Phase I and II clinical trials are the appropriate venue in which to identify these limitations, and are generally designed to answer the following questions: Is the vector safe? What is the maximum tolerated dose? Did the gene transfer into the patient's cells? Is the gene expressed? Is there an indication of a therapeutic response? Additional research addressing optimization of all aspects of the clinical protocols is then required, so that therapeutic responses can be accurately analysed in further clinical trials.

Along with the technological obstacles, which confront the field of gene therapy, scientists and clinicians also face extensive regulations and public scrutiny. Some scientists have suggested that, in order to temper some of the distrust of gene manipulation technology, gene therapy might be presented as a more efficient method of administering conventional protein drug therapy (Wilson, 1999). Rather than manufacturing a therapeutic protein (such as insulin, erythropoietin, growth hormone or cytokines) at a pharmaceutical house, the machinery to produce the protein – the new gene – is introduced into the patient's cells and the protein is then manufactured by the cell type which normally produces it. The gene essentially becomes a pharmaceutical.

Early gene therapy research was aimed at inherited monogenic diseases – those caused by loss or alteration of one gene. Initial targets of gene therapy appeared to require a relatively simple strategy – insert and express a normal copy of the mutated or deleted gene and cure the disease. It has not proved so simple.

Testing of the first generation of viral vectors for gene transfer in 1990 unmasked several limitations. The transfer of genes was inefficient with the vectors available at the

time, expression was not stable for long periods, and the viral vectors were immunogenic. Improvements in vector design became a critical prerequisite to further developments in gene therapy, and the biopharmaceutical industry became involved in development and testing in the 1990s.

The first human gene therapy trials began in 1990. In these trials, cells to be altered were harvested from patients and the genetic material was manipulated *ex vivo*, or outside the patient. After insertion of the desired gene sequence into cultured cells, modified cells were transplanted back into patients. Early trials included gene therapy for an inherited form of immunodeficiency and treatment of children and adults with very high serum cholesterol levels.

Gene therapy rapidly evolved to the level of *in vivo* trials, in which the vector is administered directly to the patient. Early *in vivo* trials utilizing attenuated adenovirus to treat cystic fibrosis, and phase I and II clinical trials of gene therapy for ADA, Gaucher disease, haemophilia, Duchenne muscular dystrophy and sickle cell anaemia, have since produced promising results (Blaese *et al*., 1995; Crystal, 1995; Kiem *et al*., 1995; Miller and Vile, 1995).

Following pioneering studies with inherited monogenic disorders, gene therapy research expanded into acquired diseases with a genetic component, including infectious diseases such as AIDS, cardiovascular diseases and cancer.

In his Presidential Address at the Second Annual Meeting of the American Society of Gene Therapy, James M. Wilson identified four issues critical to the success of gene therapy (Wilson, 1999). First was an 'ongoing commitment to, and investment in, basic research relevant to somatic cell transplantation and gene transfer.' Second, Wilson discussed the 'role of clinical trials,' acknowledging that 'human data are absolutely critical in driving this field forward.' The third issue which Wilson presented to the gene therapy community was 'the value of our community and how we relate to one another as colleagues and competitors.' Wilson noted that true success would be measured by 'proof-of-concept in humans' and 'the commercial development of effective gene therapy products.' Reaching these goals will require cooperation from all involved in addressing ethical and regulatory issues. And, because the fourth critical issue was 'the development of gene therapy as a business,' Wilson stated that all participants have a responsibility to 'identify and address any potential barriers to commercial success.'

The rapid evolution of gene therapy from the laboratory bench to clinical trials has been possible thanks to major developments in the science of molecular genetics. Gene therapy as a topic in peer-reviewed journals climbed from less than 100 articles per year in 1989 to over 1200 in 1998. Rapid progress in the mapping of the human genome has allowed for the identification of the genetic component of many more diseases, broadening the pool of potential gene therapy targets.

Tools of Gene Therapy

In order to understand fully the rapidly expanding pool of new data, it is helpful to understand the basic tools of gene therapy, developed thanks to recent advances in the technology for isolation and characterization of genes and transfer into animals. This chapter will present only a general overview of these enabling technologies; the reader is directed to the section on The Molecular Basis of Cell and Tissue Organisation of *The Cancer Handbook* for more thorough coverage of molecular biology basics.

Basic Genetics – From Gene to Protein

Genes are the blueprints for the assembly of proteins from free amino acids. Each gene has a unique nucleotide sequence and occupies a specific region of a chromosome. A gene carries not only the unique nucleotide sequence which codes for the gene product, but also numerous regulatory sequences which can be turned on or off by other proteins in the cell, dictating whether a gene will be expressed.

Nearly every cell in an organism contains a complete set of inherited genetic material which defines its genotype; each cell will only express a subset of this suite of genes, however, depending primarily on each gene's promoter sequence. (See chapters on *Cell and Tissue Organisation*; *Regulation of the Cell Cycle*.) Gene expression depends on regulatory elements which act at the level of transcription (DNA to RNA) or of translation (RNA to protein). The resulting gene expression profile confers on a cell its phenotype.

Gene mutations, which alter the DNA sequence and therefore the genotype of all daughter cells, may cause a gene not to be expressed, to be expressed inappropriately, or to produce a nonfunctional protein. Mutations can occur in both alleles of a gene or in only one. Some gene products can be expressed normally if one undamaged copy remains, but others require two normal alleles. The loss of one allele is a heterozygous mutation; the loss of both is a homozygous mutation and results in total loss of gene function. In some cases a mutation in one allele is combined with loss of the other allele; for example, a point mutation in one allele of the tumour-suppressor gene *p53* is often combined with the loss of the p arm of the human chromosome 17. This is referred to as loss of heterozygosity (LOH), which can be detected by analysis of tumour cell DNA using methods discussed below. LOH in chromosome 17p, chromosome 10 or a number of other chromosomes in tumour cells often correlates with the level of malignancy to which a tumour has progressed. (See chapters on *Overview of Oncogenesis*; *Genomic Instability and DNA Repair*.)

The Tools

Manipulation of DNA

Gene therapy is entirely dependent on the technology which permits the isolation of DNA from a cell and

sequencing of nucleotides. In addition, a suite of enzymes, called restriction endonucleases, can cut DNA at specific nucleotide sequences, allowing for the isolation of entire genes or sections of genes. Fragments of DNA are separated according to size on a gel matrix, and specific known sequences can be visualized by 'probing' with labelled oligonucleotides. Other enzymes, called ligases, allow the joining together or ligation of previously unrelated pieces of DNA to form new gene sequences or DNA constructs, often with new promoter or regulatory sequences. A third class of enzymes, DNA polymerases, allows the synthesis of large amounts of new DNA in the laboratory.

One type of recombinant DNA construct useful in gene therapy is assembled by splicing a tissue-specific promoter sequence from one gene together with the protein-coding region of a second gene, resulting in a transgene which can be transferred into cells in tissue culture or into living organisms, and expressed, at the direction of the altered promoter sequence, in a different cell type. Some DNA constructs alter the structure, and therefore the function, of the final protein, and others insert an entirely new sequence in place of the original. (See chapters on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*; *Gene Knockouts in Cancer Research*.)

Gene Transfer

Gene sequences must be transferred into cells for expression to occur. This can be accomplished by several methods.

Transfection is the process of transferring new DNA into cells growing in culture. Cells take up the DNA and a small amount becomes incorporated and expressed. Transfected cells are then propagated to generate progeny which all contain the altered genotype and hopefully express the desired phenotype.

Viral vectors are DNA constructs built into a viral genome. Gene delivery via viral vectors exploits a virus's innate ability to bind receptors on and actively infect cells. The viral genome is altered in the laboratory to reduce expression of sequences required for replication, while maintaining the viral genes which are responsible for infection and expression. Desired eukaryotic gene sequences are inserted into the viral genome and then enter the cells as passengers within the viral nucleic acid. Viral vectors often contain powerful promoters to drive gene expression. Current progress in the development of viral vectors for cancer gene therapy will be discussed in this chapter.

Non-viral vectors, designed to deliver therapeutic genes without the need for intact virus, have shown promise in initial studies. Liposomes (lipids complexed with DNA), molecular conjugates (which attempt to target passenger DNA to a specific cell type using synthetic ligands coupled to DNA) and naked DNA have all been delivered to cells by mechanical means.

Animal Models in Gene Technology

Technology allowing alteration of the genetic make-up of entire organisms has been developed and the resulting animal models are useful in evaluating the biological function of new genes. Generation of transgenic animals (see chapter on *Transgenic Technology in the Study of Oncogenes and Tumour-Suppressor Genes*) involves injection of a transgene, or new DNA sequence, into fertilized mouse eggs which are subsequently placed in the oviducts of pseudo-pregnant mice. Progeny contain the transgene in every cell in the body, but expression is restricted by the specific promoter and regulatory sequences incorporated into the transgene. Using this technology, DNA of one species can be expressed in cells of another species. An example is the production of human growth hormone and insulin by transgenic laboratory animals.

Another useful animal model is the knockout mouse (see chapter on *Gene Knockouts in Cancer Research*), which provides a definitive method for establishing *in vivo* gene function. By deleting a specific gene sequence, the actual morphological or physiological outcome of the loss' of a specific gene can be evaluated; subsequent attempts to replace the missing gene product with a pharmaceutical or the missing gene via gene therapy can be evaluated for return of functional activity.

A more recent development is the knock-in mouse, a more technically sophisticated model in which a particular gene sequence is replaced with a modified functional gene or an entirely new gene sequence.

As is apparent from these advanced technologies, recombinant DNA technology, once a tool found only on the bench in a select few laboratories, has rapidly progressed through the laboratory animal and to the patient's bedside.

GENE THERAPY FOR CANCER

Introduction – Where Are We Now?

Suspicions that faulty gene expression might be the aetiological agent of cancer were voiced as early as 1914, when T. Boveri wrote (Boveri, 1929):

> *The unlimited tendency to rapid proliferation in malignant tumor cells [could result] from a permanent predominance of the chromosomes that promote division . . .. Another possibility [to explain cancer] is the presence of definite chromosomes which inhibit division . . .. Cells of tumors with unlimited growth would arise if those 'inhibiting chromosomes' were eliminated . . .. [Since] each kind of chromosome is represented twice in the normal cell, the depression of only one of these two might pass unnoticed . . ..*
>
> (T. Boveri, 1914; translation published in 1929)

As recently as 1966, many scientists still denounced the theory that neoplasms were the result of mutations in somatic cells. Ironically, Peyton Rous, who spoke out strongly against a role for mutations in tumorigenesis, discovered the tumour virus which eventually resulted in the universally accepted genetic paradigm that has driven cancer research in recent years (Bishop, 1991). It is now generally accepted that cancer is caused by multiple mutations in DNA, which take place sequentially and ultimately lead to transformation of a cell to the malignant phenotype. (See relevant chapters in section on the *Causation and Prevention of Cancer*.)

Early strategies for treating cancer focused on methods for surgical removal of neoplastic tissue, along with radiation therapy and chemotherapy to kill surviving tumour cells. The last two strategies exercise their effect on the tumour cell by damaging DNA; because the tumour cells are rapidly dividing, they are killed more rapidly than adjacent normal cells. More recently, immunotherapeutic strategies have been added to the arsenal and are often used in combination with radiation and chemotherapy to increase specificity or enhance the immune response. All of these treatment strategies involve significant systemic side effects to the patient, and also significant bystander damage to normal tissues. Although recent developments in all of these approaches have benefitted many patients, lack of specificity for the offending tumour cell and toxicity to the patient continue to limit their ability to cure cancer.

As the aetiology of cancer became more apparent, it became possible to consider attacking the disease at its root – the gene. Rather than destroying all cells in the process of synthesizing DNA, a particular gene might be isolated and replaced or repaired, leaving normal cells unaffected by treatment. Gene therapy, as was discussed in the previous section, offers the potential to overcome the lack of specificity inherent in most cancer therapies with an acceptable level of toxicity to the patient. Although gene therapy first arose as an approach to treating monogenic diseases, cancer therapy has become its number one application in recent years.

Modern tools and techniques of gene therapy are being applied to cancer via two distinctly different approaches. One approach involves augmentation of the more conventional approaches to cancer – immunotherapy and chemotherapy – and has been called 'gene therapeutics' (Roth and Cristiano, 1997). Strategies encompassed within this 'augmentative' approach attempt both to confer specificity and to reduce toxicity, and include transfer of cytokine genes to augment immunotherapy (see chapter on *Antibodies and Recombinant Cytokines*), drug sensitization with genes for prodrug delivery and transduction of drug resistance genes into bone-marrow stem cells as a means of protecting normal bone-marrow cells during high-dose chemotherapy (see chapter on *Drug Resistance and Reversal*). These strategies are discussed in detail in other chapters.

The second general approach to the gene therapy of cancer, which is the subject of this chapter, targets the underlying genetic lesion in the cancer cell – the aetiology of the disease – and has been called 'gene replacement' therapy (Roth and Cristiano, 1997). The gene families which have been implicated as the aetiological agents of the most common cancers include dominant oncogenes [mutant alleles of a class of normal genes called proto-oncogenes (Bishop, 1991)] and tumour-suppressor genes (Weinberg, 1991). Because strategies to replace functional copies of these genes target the underlying genetic lesion responsible for the disease, they have the ultimate potential both to treat and to prevent cancer.

Numerous proto-oncogenes and tumour-suppressor genes are expressed in normal cells, and their protein products are critical components of the cellular machinery which drives the normal processes of signal transduction (see chapter on *Signal Transduction Pathway Targeting*), DNA transcription, cell division, cell cycle arrest and programmed cell death (apoptosis). (See chapter on *Apoptosis*.) Alterations in these genes lead to disruption of normal processes, in effect altering the functional programme of the cell. In addition, most tumours develop subsequent alterations in expression of genes encoding the proteins that govern such processes as angiogenesis and cell locomotion, or invasion. In general, proto-oncogenes participate in signal transduction and transcription. Tumour-suppressor genes appear critical in governing proliferation by regulating transcription and cell cycle control. (See also relevant chapters in the section on *The Treatment of Human Cancer*.)

Only a single dominant oncogene allele need be mutated (by point mutation, amplification, translocation or rearrangement) to accomplish malignant transformation. Historically, it was believed that, because only one functional tumour-suppressor gene allele is normally required for adequate regulation of proliferation, malignant transformation by tumour-suppressor mutation required homozygous loss of function, with both copies of the gene either mutated, deleted or both (Harris, 1996). More recent studies, however, have provided evidence for haploid insufficiency (Tang *et al*., 1998). Tumour-suppressor genes can undergo homozygous loss of function by mutation and/or deletion, or, in some cases, one faulty allele is inherited in the germ line, and the second genetic alteration occurs as a somatic mutation at a later time.

The application of gene therapy to cancer is complicated by the fact that cancer is associated with multiple genetic lesions within each malignant cell. Some lesions contribute to the aetiology of the disease, while others occur due to the underlying genetic instability of transformed cells in general (see chapter on *Genomic Instability and DNA Repair*). In some cases, a genetic defect is inherited and lies undetected for years, until an additional mutation is acquired which confers the malignant phenotype.

Historically, many clinicians believed that gene replacement therapy for cancer was impractical because of the impossibility of correcting multiple genetic abnormalities in each cancer cell. Recent observations, however, suggest that correction of a single lesion – for example, elimination of expression of a dominant oncogene or insertion of a normal copy of a tumour-suppressor gene – may be sufficient to negate the malignant potential of a tumour cell. In addition, studies conducted by the author's colleagues (Mukhopadhyay *et al*., 1991; Fujiwara *et al*., 1993), using human cancer cells with multiple genetic abnormalities, have demonstrated that transduction with retroviral or adenoviral vectors expressing either wild-type p53 tumour-suppressor (wt-p53) or antisense K-*ras* (see chapter on Antisense and Ribozyme Therapy), resulted in inhibition of cancer cell growth. A common mechanism of cell death in these cells was apoptosis, or programmed cell death (Fujiwara *et al*., 1993), emphasizing the critical role of apoptosis in tumour cell demise and its regulation by tumour-suppressor genes. As demonstrated in clinical trials to date – mainly in patients with very advanced cancers previously proved to be refractory to conventional treatment – gene replacement and gene inactivation therapy can, indeed, induce tumour regression with acceptably low toxicity (Roth and Cristiano, 1997).

Inefficient viral transduction was once considered a potential limitation for the application of gene therapy to cancer, but it has become apparent from laboratory studies and early clinical trials that transduced cells and their products confer a 'bystander effect,' or growth inhibition effect, on neighbouring nontransduced tumour cells (Nishizaki *et al*., 1999).

An additional commonly asked question has been, why replace the faulty gene and not just the missing gene product? Attempts to restore p53 gene product function with small molecule pharmaceutical therapy have failed owing to complexities in the structure of the p53 protein (Harris, 1996); it is proving to be more practical to restore the function of defective genes in the cancer cell by gene transfer.

Tumour behaviour encompasses several functional realms, such as tumorigenesis, anchorage-independent growth and invasion and angiogenesis, (Bookstein *et al*., 1990; Takahashi *et al*., 1992), making it unlikely that all cells of a large tumour mass could be killed by current gene therapy strategies. Current approaches, though, are suitably designed to aid in control of locoregional recurrence of tumours and in systemic control of micrometastases.

Cell Biology and Biochemistry of Oncogenes and Tumour-suppressor Genes

Oncogenes, first identified as transforming sequences in retroviruses which were also present in normal cells (suggesting that they were 'appropriated' by the virus), are the mutated forms of normal genes called proto-oncogenes. The publication in 1987 of data demonstrating that many human tumours contained a point mutation in the proto-oncogene *RAS* led to increased suspicions that mutagenesis might play a role in the genesis of cancer (Barbacid, 1987). Other proto-oncogenes identified early included *myc* (mutated by translocation in Burkitt lymphoma and by amplification in carcinoma of the lung, breast and cervix), H-*RAS*, K-*RAS* and N-*RAS* (altered by point mutations in numerous carcinomas – small cell lung, colon, pancreas, thyroid, genitourinary tract – and in melanoma) and *SRC* (altered in colon carcinoma). By 1989, there were already more than 60 oncogenes described. Bishop (1991) defined proto-oncogenes as follows: 'if manipulation of any sort engenders a transforming allele (or "oncogene"), convention admits the normal counterpart to the ranks of proto-oncogenes.' Proto-oncogenes have now been identified as critical members of many signal transduction pathways, and several are prominent factors in gene transcription.

Tumour-suppressor genes are most easily studied when they are missing from the genome, a fact that placed severe limitations on the study of these critical genes until recently. Developments in molecular genetics have produced new technologies for gene manipulation, resulting in a rapidly expanding literature base on tumour-suppressor genes. Some of first tumour-suppressor genes described were *RB* (retinoblastoma), incriminated in retinoblastoma, osteosarcoma and carcinomas of breast, bladder and lung *p53*, associated with astrocytoma, carcinoma of breast, bladder and lung and osteosarcoma, *WT1*, associated with Wilms' tumour, and *DCC*, associated with colon carcinoma. *RB* and *p53* have since been identified as integral players in regulation of the cell cycle, signal transduction pathways, apoptosis and other normal cellular functions.

In normal cells, the protein products of proto-oncogenes and tumour-suppressor genes feed into several signal transduction pathways. The relevant protein products include polypeptide hormones and hormone receptors that act at the cell surface, along with proteins that convey signals across the membrane, through the cytoplasm and to the nucleus. These gene classes also encode several nuclear factors that control the mix of positive and negative signals from a complex transcription factor network governing gene expression. The initial step in these biochemical cascades is commonly an interaction between a growth factor and a growth factor receptor at the cell surface (see chapters on *Growth Factor Receptor Blockade*; *Signalling by Steroid Receptors*; *Signalling by Cytokines*). Activation of surface receptors results in the expression of enzymatic activity inside the cell, which acts like a switch to catalyse further chemical reactions. Eventually, barring any difficulties associated with nonfunctional genes or gene products, an appropriate signal is transmitted through the nuclear membrane, where

activation of DNA binding transcription factors alters the expression of genes and therefore the functional programme of the cell.

Regulation of the cell cycle (see chapter on *Regulation of the Cell Cycle*) is also critical to normal cellular function, and several pathways interact to provide numerous opportunities for regulation of cell growth, differentiation and proliferation – all critical parameters in the control of tumorigenesis. Normal cells of an adult remain in either G_0 or G_1 most of the time, maintained in that state by the proper balance of positive and negative signals from two intimately interwoven pathways, the RB pathway and the p53 pathway. Protein products of several proto-oncogenes and tumour-suppressor genes play critical roles in both of these pathways, and are often dysfunctional in tumour cells.

Briefly, the expression of a number of growth factors, oncogenes, cyclins and cyclin-dependent kinases (CDKs) all drive the cell cycle towards proliferation. Expression of tumour-suppressor genes and inhibitors of CDKs induce arrest of the cell cycle when appropriate. The Rb G_1 arrest pathway is initiated by the protein p16, the product of the *p16INK4* gene, and culminates in the arrest of cells in G_1 by inhibiting phosphorylation of the product of the retinoblastoma gene, *RB*. Phosphorylation of the Rb protein is catalysed by cyclin-dependent kinase 4 (CDK4) in association with cyclin D1 which releases the transcription factor E2F; therefore, inhibitors of CDK4 can inhibit phosphorylation of Rb preventing progression through the cell cycle.

The other G_1 arrest pathway, often designated the p53 pathway, is tightly interwoven with the Rb pathway and is regulated at the protein level by several other tumour suppressors and oncogenes. The protein product of the tumour-suppressor gene *p19ARF*, which is encoded by the same gene locus as *p16INK4a*, but is read in a different reading frame (Kamijo *et al*., 1997), inhibits the protein Mdm2 (product of the proto-oncogene *MDM2*) which is a regulator of p53 at the protein level. Deletion of *p19ARF* results in increased levels of Mdm2 and inactivation of p53, allowing progression through the cell cycle at an inappropriate time. Proto-oncogenes, such as *MYC* and *RAS*, inhibit Mdm2 by inducing expression of *p19ARF*. Mutations in *MYC* and *RAS* result in oncogene expression, loss of inhibition of Mdm2 and, again, dysregulation of the cell cycle through p53. Several informative reviews on this unique locus, now designated *INK4A/ARF*, and its associated pathways are listed in the Further Reading section at the end of this chapter.

In summary, control of proliferation in mammalian cells is essentially a function of these two pathways, with the Rb protein regulating maintenance and release from the G_1 phase and the p53 protein effecting growth arrest and/or apoptosis in response to cellular stress and DNA damage. Both of these tumour-suppressor genes and many of the proto-oncogenes involved in these pathways are commonly altered in a variety of cancers.

Tumour-suppressor Gene Replacement

Rationale

The most common mutation seen in cancer is in the tumour-suppressor gene *p53* (also known as *TP53*), and the inactivation of this gene appears to contribute to tumorigenesis; it follows, then, that replacement of a copy of a 'wild-type' (wt; nonmutated) gene might be sufficient to restore normal growth and proliferation pathways. The *p53* gene product (p53) is a phosphoprotein consisting of 393 amino acids and capable of complexing with viral proteins, which can inactivate the p53. The p53 protein seems to be multifunctional – it contains major domains that transactivate other genes, can bind other proteins, can bind sequence-specific DNA and can form oligomers with other p53 proteins. Abnormalities in any of these critical functions have the potential to eliminate or severely reduce the tumour-suppressor function of the p53 gene product.

Because tumour-suppressor genes normally regulate gene transcription and cell proliferation, gene replacement therapy might potentially have its effect through induction of apoptosis, by induction of tumour dormancy or by prevention of transformation of premalignant cells to the malignant phenotype. p53 is also a regulatory element for the progression of a cell from G_1 to G_2 in the cell cycle. Normally, when DNA is damaged p53 will cause arrest at G_1 until the DNA is repaired or will trigger apoptosis.

Loss of cell cycle regulatory function or DNA repair capabilities, or untimely expression of molecules normally held in check by the p53 protein, may make the cell more susceptible to transformation events. Therefore, replacement of p53 function has the potential to suppress other genes which drive the cell toward uncontrolled cell growth and the potential to activate genes that will suppress pre-existing signals for uncontrolled cell growth and progression to the transformed phenotype.

Preclinical Studies

Preclinical studies, both *in vitro* and *in vivo*, have demonstrated that the restoration of p53 function can result in the induction of apoptosis in cancer cells. Laboratory studies have demonstrated suppression of tumour growth in an orthotopic human lung cancer model, when retroviral p53 expression vector was administered (Fujiwara *et al*., 1994a). Functional *p53* gene expression, restored via a retroviral p53 expression vector, has been shown to suppress the growth of some human lung cancer cell lines, but not others (Cai, *et al*., 1993). Cells transduced with the *p53* gene were also shown to reduce the growth rate of nontransduced cells in human lung cancer, indicating the existence of a bystander effect. Recent evidence suggests that the bystander effect may be mediated by the antiangiogenic effects of wild-type p53 and by release of proapoptotic factors such as Fas ligand and Fas (Owen-Schaub *et al*., 1995; Bouvet *et al*., 1998). (See also

chapters on *Extracellular Matrix*; *Invasion and Metastasis*; *Angiogenesis*.)

An adenovirus vector, developed to deliver the wild-type human *p53* gene to tumour cells, was found to be capable of inducing apoptosis in cancer cells with altered non-functional p53, but did not appreciably affect proliferation of normal cells (Wang *et al*., 1995). In addition, the same vector inhibited tumour growth in a mouse model of human orthotopic lung cancer (Georges *et al*., 1993). Products of other tumour-suppressor genes, including *RB* and *p16*, have also been found to suppress tumour growth in animal models (Jin *et al*., 1995; Xu *et al*., 1996).

Clinical Application

Taken together, data from preclinical studies led to the approval by the Recombinant DNA Advisory Committee of the National Institutes of Health (NIH) and the US Food and Drug Administration (FDA) of the rationale for the first clinical protocol involving injection of recombinant retrovirus expressing the wild-type (normal) *p53* gene. This protocol aimed to replace a defective *p53* gene with a retroviral vector expressing normal *p53* (Roth, 1996a,b) in patients with unresectable lung cancer, which had proved resistant to other interventions. Of nine patients enrolled in this protocol, eight had received radiation, five chemotherapy and five surgical resection of the primary lung tumour (three) or of a brain metastasis (two). All eight patients who completed the protocol showed some evidence of gene transfer. Three of seven evaluable patients showed evidence of tumour regression in treated lesions, while other untreated lesions progressed. In these seven evaluable patients, no toxic effects were observed which were directly attributable to the vectors, although there were complications related to the procedure used to administer the vectors.

Based on results of studies in animal models demonstrating tumour regression following intratumoural injection of an adenovirus vector containing p53 complementary DNA, a phase I clinical trial was initiated with 28 non-small cell lung cancer patients whose cancers had progressed with conventional treatments (Swisher *et al*., 1999). Polymerase chain reaction (PCR) analysis demonstrated the presence of vector DNA in 80% of the evaluable patients, indicating successful gene transfer; vector-specific p53 mRNA, an indicator of gene expression, was detected in 46% of patients. Apoptosis of tumour cells was demonstrated in all but one of the group of patients expressing the gene and vector-related toxicity was minimal, despite up to six repeated injections per patient. Two of the 25 evaluable patients (8%) exhibited partial responses, 16 patients (64%) exhibited disease stabilization ranging from 2 to 14 months, and the remaining seven patients (28%) exhibited disease progression. The results of this study demonstrated efficient gene transfer and expression, low toxicity and an indication of antitumour activity. Similar studies have been carried out by Clayman and colleagues with patients with recurrent head and neck squamous cell carcinomas, with similar findings (Clayman *et al*., 1998).

Oncogene Suppression

Rationale and Preclinical Studies

The *RAS* family of oncogenes, which includes H-*RAS*, N-*RAS* and K-*RAS*, each encodes an oncoprotein localized on the inner plasma membrane. These proteins have guanosine triphosphatase (GTPase) activity and play a role in signal transduction. Point mutations in the *RAS* genes alter the protein product p21, interrupting the many signal transduction cascades in which p21 plays a role. Gene therapy strategies aimed at correcting the defect at *RAS* involve antisense technology, in which the therapeutic gene introduced into the cell has a DNA sequence complementary to the RNA sequence of the oncogene. When the antisense sequences bind to the sense sequences, the production of mutant RAS protein is inhibited. As reviewed (Roth and Cristiano, 1997), the growth rate of human lung cancer cells *in vitro* and in animal models has been reduced by transduction with either an antisense K-*RAS* DNA plasmid or a retroviral construct. Using a similar strategy, transduction of murine lung cancer cells with an antisense cyclin D1 gene construct reduced proliferation of tumour cells.

Another approach to oncogene suppression is the transfer of a gene that is known to block a particular activated oncogene (reviewed by Swisher and Roth, 1999). An example of this approach is the HER-2/*neu* oncogene that encodes an epidermal growth factor (EGF)-related tyrosine kinase. Overexpression of HER-2/*neu* has been observed in many cancers and correlates with poor prognosis. Her-2/*neu*-mediated malignant transformation has been inhibited by the gene product of an adenovirus construct, E1A (Zhang *et al*., 1995).

Critical Areas for Future Research

Identification of Synergies Between Gene-based Agents and Other Cancer Therapies

An exciting area for future research is the evaluation of combination therapeutic strategies. The molecular mechanisms responsible for tumour cell death after chemotherapy and radiation therapy (see chapter on *Molecular Mechanisms of Radiotherapy*), may involve p53-induced apoptosis. Tumours with altered or deleted p53 are often resistant to chemotherapy- or radiation-induced apoptosis. *p53* delivered by adenoviral vectors has demonstrated enhanced apoptosis in both *in vitro* and *in vivo* studies (Nguyen *et al*., 1996; Spitz *et al*., 1996).

Additional preclinical studies have demonstrated a synergistic relationship between p53 replacement therapy and DNA-damaging chemotherapeutic agents such as cisplatin and etoposide. In addition, studies have suggested that gene therapy may increase sensitivity to radiation. One study of human p53-deficient lung tumours growing as subcutaneous tumours in laboratory mice demonstrated that cisplatin was unable to cause tumour regression or apoptosis when delivered alone; however, when delivered with or following administration of an adenoviral p53 vector, tumours regressed and apoptosis was observed. p53, together with DNA-damaging agents such as cisplatin (Platinol) and ionizing radiation, might cause the induction of apoptosis when neither is capable of doing so alone. Fujiwara *et al*. (1994b) enhanced the sensitivity of p53-deficient cancer cell lines to CDDP by replacing the wt-*p53* gene. Other researchers (Son and Huang, 1994) have shown that the treatment of CDDP-resistant tumour cell lines with CDDP increases their sensitivity to transduction by DNA-carrying liposome vectors. In another approach, Chen *et al*. (1995) demonstrated improved tumour killing by combining interleukin expression with transduction via an HSV-TK vector. Based on the positive results in these and other studies, it follows that conventional therapy combined with gene therapy will indeed lead to enhanced therapeutic effects.

Vector Design

The technology for the manipulation of DNA and the generation of new DNA constructs is well developed. The major technological limitation facing gene therapy is the vector, which carries the desired DNA sequences to the cells in which they are to be expressed. The efficiency of gene transfer, induction of gene expression, regulation of gene expression and safety of the vector (including toxicity and immunogenicity) all must be optimized to optimize potential therapeutic benefits to the patient.

Viral Vectors

Most of the vectors currently in use in clinical trials are based on viruses and take advantage of the virus's unique ability to target, adhere to and infect cells. The challenge of viral vector development is to remove the disease-causing portion of the virus's own genome while retaining infectivity, and also include the desired gene sequence that will, when expressed, lead to therapeutic benefits for the patient.

The most commonly used viral vectors in gene therapy are retroviral, adenoviral and herpes vectors. Retroviruses are single-stranded RNA viruses that integrate into the host genome, providing potential for stable expression over time. Adenoviral and herpes vectors are DNA viruses and are maintained episomally – separate from the host's chromosomes. They may be passed on to progeny through several cell divisions, but are eventually lost; consequently, continued gene expression requires subsequent doses of virus. In spite of this limitation, herpes and adenoviral vectors are able to infect a higher percentage of cells, and so have become popular tools for gene therapy. In fact, unstable expression is not necessarily a disadvantage in cancer patients, because prolonged expression is not required or even necessarily desirable after destruction of the tumour cells. Unlike retroviruses, which infect only dividing cells, adenoviral vectors have the advantage of infecting both dividing and nondividing cells. They are also easily manipulated *in vitro*; therefore, large-scale production is feasible. Because of the antigenicity of adenoviruses, it remains to be discovered how many repeat treatments a patient will be able to receive without adverse effects. Numerous studies are under way to determine the best course to take in combating the limitations of adenoviral vector transfer.

Herpes vectors have generated interest because of their ability to establish latent infections in the brain. They have been studied for gene delivery to neurons and have potential application in brain cancer. Other viruses, including vaccinia viruses, poxviruses and baculoviruses, are also under investigation for potential gene therapy applications.

As of 1997, most approved clinical protocols for gene therapy involved retroviral vectors. Because retroviral vectors tend to integrate more efficiently into replicating cells, these have been the most useful for stable integration of desired DNA sequences into tumour cells. Retroviruses, however, can transfer only small pieces of DNA and large-scale production of vector is difficult, making the treatment of large tumours unlikely. Adenoviral vectors, on the other hand, are readily produced in large batches, but have several potential toxicity and immunogenicity issues limiting their widespread use.

Nonviral Vectors and Naked DNA

Other gene delivery strategies under investigation were reviewed by Roth and Cristiano (1997) and include naked DNA, proteins, lipids and combinations formed into synthetic particles. Liposomes, which consist of lipids complexed with DNA, are relatively simple to prepare, but the system lacks the ability to target to specific cell types. Molecular conjugates, on the other hand, result in highly specific and efficient gene delivery *in vitro*, but the duration of gene expression is very short. This approach, however, provides the groundwork for the generation of 'synthetic viruses,' capable of efficient gene delivery without the inherent risks and complications of intact viruses. Injection of 'naked DNA' into tissues offers by far the simplest delivery system, but this approach suffers from limitations such as lack of targeting, inability to reach a large number of cells and, in some cases, the need for surgical access to tissue.

Vector Targeting and Specificity

Enhancement of specificity of gene expression is being addressed through investigation of vector targeting,

tissue-specific promoters, route of delivery and modulation of immune receptors. The following is a brief summary of some current approaches; a more complete review can be found in Roth and Cristiano (1997).

Some viral vectors have a certain degree of built in specificity because of tropism for particular tissues. Adenoviruses, for example, normally infect lung epithelium and are also efficient at transducing lung epithelium. Herpes simplex virus efficiently infects neuronal cells. Although retroviruses exhibit no tissue tropism, the genes delivered are integrated and expressed only in dividing cells, making them especially suited to cancer gene therapy. Studies have shown that complexing viral vectors to a specific ligand for a cell surface receptor can enhance targeting to a specific cell type expressing that receptor. This approach provides potential to have developed targeted retroviral vectors and also the possibility of altering adenoviral-binding properties to limit or expand tissue tropism. Several ligands have been conjugated to nonviral vectors to increase targeting of these genes. Folate has been used to target ovarian carcinoma cells, which overexpress folate receptor, and asialoorosomucoid has been studied for its specificity for liver parenchyma. Additional experiments have demonstrated that overexpression of EGF receptors by some tumour cells has lead to specific uptake of EGF–DNA complexes. One obstacle to this approach has been DNA degradation when the receptor–ligand–DNA complex is internalized by receptor mediated endocytosis.

Another approach to enhancing specificity is the inclusion of tissue- or cell-specific promoters in the therapeutic gene construct. For example, the cytomegalovirus (CMV) promoter, the strongest promoter yet identified, is active primarily in rapidly dividing cells. A number of other specificity-enhancing sequences, including the carcinoembryonic antigen (CEA) promoter, and the regulatory sequence for a portion of the tyrosinase gene encoding the surfactant A protein, are under investigation. A truly novel approach to targeted gene therapy is the use of specific immune receptors on tumour-infiltrating lymphocytes to carry the therapeutic gene to the tumour. Single-chain antibodies to a renal cell carcinoma antigen have already been demonstrated to be capable of targeting tumours and lysing tumour cells. Unfortunately, the likelihood of identifying a universal cancer promoter sequence for use in gene therapy is slim, owing to the heterogeneity of tissues affected by cancer.

Integration, Expression and Regulation of Expression

In addition to reaching a target cell efficiently, a vector must be able to deliver the gene for successful integration into the cell nucleus and the gene must be expressed long enough to do its job, but not so strongly as to cause toxicity. As discussed previously, some viral vectors such as retroviruses and some adeno-associated viruses integrate into the host genome, resulting in long-term expression, which may also contribute to vector-associated toxicity. Short-term expression may be sufficient for most cancer therapy applications, so those genes which are episomally expressed provide excellent potential. Nonviral vectors, however, may provide the best potential of all.

Owing to the use of particularly strong promoters, such as CMV, it is also important to be able to regulate the promoter. Several inducible promoter sequences, including one which will increase gene expression after exposure to radiation, are under investigation. In addition, the incorporation of sequences from ‘temperature-sensitive’ viral mutants is being examined as a method to regulate viral gene expression.

Vector Immunogenicity and Toxicity

It is theoretically possible that there may be long-term vector-generated side effects associated with cancer gene therapy. No major side effects of retroviral delivery have been observed during clinical trials, but adenoviral vectors have two potential difficulties associated with their use. Systemic or local immune responses may develop owing to the need for repeated doses. Many toxic effects are expected to be overcome by improved vector targeting, elimination of some endogenous viral genes and the use of immunomodulators to ablate the immune response to vector preparations.

SUMMARY AND CONCLUSIONS

By June 1996, 13 clinical protocols using viral vectors to replace defective tumour-suppressor genes or inactivate oncogenes were in place. Of the 78 patients entered in those trials, 26 reports were evaluable in June 1996 and six had reported tumour regression. In spite of limitations to the gene therapeutic approach to cancer at this time, the current delivery strategies have been shown to have application in clinical situations and several facts stand out from the results of studies to date (Roth and Cristiano, 1997).

First, viral gene transfer has been demonstrated to be more efficient in cancer cells than was originally predicted from studies of gene transfer into normal tissues. Second, viral vectors appear to spread readily through a tumour mass and mediate cell death through apoptosis. A third and very critical fact – critical because of the low efficiency of transduction attainable with even the most potent vectors – transduced cells have proved to be capable of mediating bystander killing of nontransduced cells. Finally, earlier concerns about the potential applicability of gene therapy to cancer have been unfounded; in spite of multiple genetic alterations in tumour cells, correction of a single genetic lesion has yielded significant tumour regressions. As has

been observed in leukaemia, patients can undergo lengthy remissions in spite of the continued presence of malignant cells. It follows, then, that even partial irradication of a tumour would be clinically beneficial.

For the specialist and nonspecialist alike, and for the general public, several factors should be considered while attempting to evaluate the rapidly expanding collection of data in the scientific literature and in the public sector. Gene therapy is in its infancy. Strategies and new technologies which will revolutionize the field may be months or years from discovery, or they may be awaiting statistical analysis or in the hands of a reviewer as this sentence is being written or read. Maintenance of the current climate of cooperation between scientists and clinicians from multiple specialties and from all relevant communities – academic, healthcare and pharmaceutical industry – is necessary to continue the trend of taking these developments rapidly from the molecular biology laboratory bench to the patient's bedside.

In addition, public opinion of gene therapy technology will be shaped by the layman's perception of responsibility shown by those active in the field. As was suggested by James Wilson in his Presidential Address to the American Society of Gene Therapy (Wilson, 1999), much of the fear of gene therapy might be resolved by a widespread understanding that it is the machinery for the natural manufacture of a necessary protein that is being replaced in these strategies.

Current limitations of gene therapy, including efficiency of gene transfer and expression, along with control of potential side effects from the use of viral vectors, will be best battled if researchers and clinicians conform to strict guidelines for reporting complete data from clinical trials. Details on study design, patient population, prior treatment, vector design, gene expression and toxic side effects, as well as on therapeutic benefits observed, should be available to all researchers and clinicians involved in the development of gene therapy strategies. It is through the cooperation of scientists and clinicians in all fields that cancer will be controlled and eventually cured through the use of gene transfer technology.

ACKNOWLEDGEMENTS

This work was funded by grants from the National Cancer Institute and the National Institutes of Health (P01 CA78778-01A1) (J.A.R.), by a grant for a Specialized Program of Research Excellence (SPORE) in Lung Cancer (P50-CA70907), by gifts to the Division of Surgery and Anesthesiology from Tenneco and Exxon for the Core Laboratory Facility, by the UT M. D. Anderson Cancer Center Support Core Grant (CA16672) and by a sponsored research agreement with Introgen Therapeutics, Inc.

- Genetic Prodrug Activation Therapy (GPAT)
- Discussion

GENERAL INTRODUCTION

Few areas of research have raised as much interest and introspection, not to mention false optimism, as gene therapy. Indeed, few subjects can have produced quite so many philosophical editorials. The possibility of using DNA as a therapeutic tool first became theoretically feasible with the isolation and cloning of the genes responsible for inherited monogenetic disorders such as cystic fibrosis, Lesch–Nyhan syndrome and adenosine deaminase (ADA) deficiency associated with severe combined immune deficiency (SCID). These disorders could theoretically be cured by the introduction and expression of a normal functional copy of the faulty gene in the appropriate tissue, although the practical requirements for such gene therapy are formidable. After the gene has been isolated, its regulatory sequences must also be identified to ensure that expression of the transgene occurs in the appropriate tissue and at the appropriate time. Second, practical ways have to be found of delivering the gene to the requisite organ and, finally, once expression is achieved, it must continue indefinitely, to obviate the requirement for multiple and repeated treatments. Perhaps not surprisingly, initial clinical trials of gene therapy in cystic fibrosis and ADA-deficient SCID have met with very limited success.

At a superficial level, cancer is an even less attractive candidate for gene therapy than either cystic fibrosis or ADA-deficient SCID: the progression from normal tissue to invasive malignancy may involve up to six or more separate genetic events, all of which, in theory, would have to be corrected to reverse the malignant phenotype. Similarly, it would also be necessary to restore normal gene function to 100% of the cells within a tumour population, which is impractical with current vector technology.

However, novel gene therapy strategies for cancer have evolved that do not rely on gene complementation, and which thus circumvent some, but by no means all, of the difficulties listed above. One such strategy is genetic prodrug activation therapy.

GENETIC PRODRUG ACTIVATION THERAPY (GPAT)

GPAT, which is represented schematically in **Figure 1**, has two fundamental steps. The first is the delivery to tumour cells, usually via a recombinant virus, of the gene encoding a nonhuman enzyme. The enzyme has been selected for its ability to convert a nontoxic prodrug into a cytotoxic species, which will then kill the cell in which it has been formed. The production of active drug by the tumour cells themselves should allow the generation of higher drug concentrations within the tumour microenvironment than could be achieved by systemic administration alone, and thus lead to a higher therapeutic index.

The concept of GPAT arose from studies in antibody-directed enzyme–prodrug therapy (ADEPT) where the enzyme itself (rather than its gene) was delivered to tumour cells by means of an antibody directed against a tumour-specific antigen. The advantages of GPAT over ADEPT include the fact that the enzyme is generated within the tumour cell itself, rather than being present in the interstitium, thus generating higher concentrations of the active species inside the cell and allowing ready access to any cofactors that may be required for enzyme activity. Also, the inherent immunogenicity of antibody–enzyme conjugates may preclude multiple administrations.

The second important feature of GPAT is the so-called bystander effect. This describes the ability of active species generated in one cell to kill neighbouring, non-transduced cells, thereby eliminating the need to transduce every tumour cell, which is clearly impractical with current vector technology.

The ideal enzyme would consist of a single polypeptide species of reasonably low molecular mass and independent of post-translational modifications. Fundamentally, the catalytic activity or substrate specificity must be distinct from any human enzyme and so those in use are derived predominantly from bacteria and viruses. The desirable parameters of potential enzyme–prodrug combinations are a high differential toxicity of the active species relative to

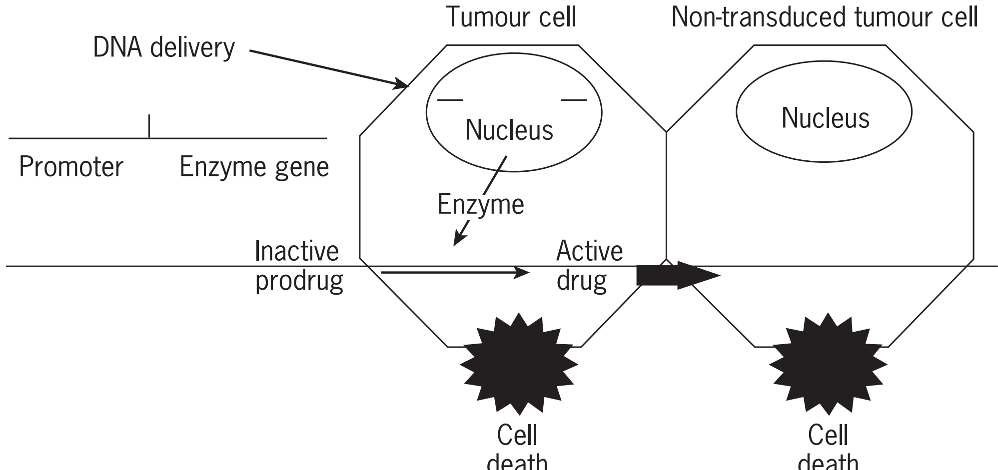

Figure 1 Genetic prodrug activation therapy.

the prodrug and a low K_M and a high K_{cat}, which will maximize production of the active species at any given concentration of prodrug and enzyme. The physicochemical properties of the prodrug and its cytotoxic species, such as lipophilicity, will influence tissue distribution, cellular uptake and bystander killing. The half-life of the activated cytotoxic agent will also affect its distribution and efficacy: a longer half-life should allow a more homogeneous distribution within a tumour, but this may be offset by a greater potential to diffuse into the vascular compartment, increasing the systemic concentration of the cytotoxic agent.

Many different potential enzyme–prodrug combinations have been described, but the general principles can be illustrated by consideration of the following systems.

Thymidine Kinase–Ganciclovir

In 1986, Moolten described the successful *in vitro* and *in vivo* sensitization of murine tumour cells to the anti-herpes drug ganciclovir (GCV), via expression of the herpes simplex virus 1 (HSV) thymidine kinase (*tk*) gene (Moolten, 1986). The HSV, but not mammalian, tk enzyme is capable of phosphorylating various nucleoside analogues, including ganciclovir and its relative acyclovir. Treatment of HSV tk-positive cells with ganciclovir leads to the formation of ganciclovir triphosphate (**Figure 2**), a potent antimetabolite that interrupts DNA synthesis by erroneous incorporation as a false nucleotide. Thus, in Moolten's original work, there was inhibition of growth of tk-positive cells following 3 days of incubation with GCV at concentrations of 10^{-7} mol/L, whereas tk-negative cells were not inhibited until concentrations of GCV reached 10^{-4} mol/L.

Since the original description of the effectiveness of HSV tk/GCV, there have been many reports of its use in the treatment, both *in vitro* and *in vivo*, of multiple tumour types, including breast, glioma, pancreatic, mesothelioma and colon, with the *tk* gene delivered by retrovirus, adenovirus, naked DNA and liposomes.

Figure 2 The activation of ganciclovir by herpes simplex virus thymidine kinase.

It was noticed in the original description of the effect of HSV tk–GCV combination that the mixing of tk-positive and tk-negative cells at high density in a ratio of 1:9

resulted in almost complete eradication of the tk-negative cells upon treatment with GCV at a concentration of 4×10^{-6} mol/L. In contrast, when the cells were plated at the same ratio at low density, there was almost complete survival of the tk-negative cells, implying that direct cell to cell contact between the enzyme expressing and non-expressing cells was capable of transferring sensitivity to GCV between cells, a process initially described as 'metabolic cooperation' (Moolten, 1986). It was subsequently shown in subcutaneous adenocarcinoma and fibrosarcoma models in mice that only 10% tk-positive cells were required for marked growth inhibition and that the normal tissue adjoining and overlying the tumours was unaffected by administration of GCV (Culver *et al*., 1992). In the same study, the delivery of HSV *tk* gene via injection of retroviral producer cells into experimental rat glioma produced complete regression in 11/14 animals on exposure to GCV. It has also been noted that a bystander effect can exist within the peritoneal cavity. Injecting tk-positive and negative sarcoma cells at a ratio of 1:9 into the peritoneum of mice resulted in significant extension of survival following treatment with GCV compared with those mice that received 100% tk-negative cells alone. If the ratio was 50:50, some of the mice survived long term (>70 days) (Freeman *et al*., 1993). Interestingly, Freeman *et al*. also noted that it was possible to prolong the survival of pre-existing tk-negative intraperitoneal tumours by injecting tk-positive tumour cells and GCV, without any attempt at gene transfer. However, other groups have shown that injecting tk-positive 3T3 fibroblasts into experimental gliomas in rats does not produce any bystander effect.

Samejima's group confirmed that cell–cell contact, or at least close proximity, was required for bystander killing in rodent fibroblasts expressing tk and that the process could be inhibited by coadministration of forskolin, the activator of adenylate cyclase. They also demonstrated that there was evidence of apoptosis in the cells killed by the bystander effect and suggested that phagocytosis by nonenzyme-expressing cells of apoptotic bodies released from dying cells could explain the mechanism of the bystander effect (Samejima and Merulo, 1995). However, it has become evident from more recent work that gap junctional activity is of fundamental importance to the bystander effect in the HSV tk–GCV enzyme–prodrug combination. It was demonstrated that the bystander effect seen in some tumour cell lines, such as SKHep J hepatocellular carcinoma cells (Elshami *et al*., 1996), which have little gap junctional activity, increased dramatically when transfected with connexin 43 or connexin 32, which are major gap junctional proteins. This finding could explain why nontransduced normal tissue immediately adjacent to tumours with little gap junctional connection with those tumour cells, was not affected by administration of GCV, whereas the tumour cells were rapidly eliminated.

There appears to be an additional mechanism which can give rise to a bystander effect *in vivo*. In a model of pulmonary metastases of the murine melanoma B16 line, it was noticed that the antitumour effect of HSV tk–GCV was markedly greater in immunocompetent mice than in immunodeficient animals. This effect was not due to the immunogenicity of tk itself and subsequent rechallenge of GCV-treated mice showed that some protection against wildtype tumour had been generated in the immunocompetent mice. This implies that the death of tumour cells following exposure to GCV results in the establishment of a systemic tumour-specific immunity (Vile *et al*., 1994). These findings were confirmed in murine colorectal carcinoma and rat hepatoma models and have also been shown for the cytosine deaminase–5-fluorocytosine enzyme–prodrug combination (see below). Vile *et al*. have suggested further that the protective immunity seen in the B16 Murine melanoma model is due to a T_{h1}-type response (Vile *et al*., 1997), that the induction of heat-shock protein 70 expression is a requirement for this immunity and that immunity is established after necrotic but not apoptotic cell death (Melcher *et al*., 1998).

More recently, it has been suggested that there is an opposite, 'good samaritan,' effect whereby the tk-positive cells are protected from the effects of the toxic metabolites of GCV via gap junctional activity, thereby allowing a more prolonged production of those toxic metabolites. The presumed mechanism is that the gap junctions allow rapid passage of the activated GCV away from the tk-positive cell, thereby sparing that cell (Wygoda *et al*., 1997).

Despite there being at least 20 clinical trials of HSV tk–GCV approved by the beginning of 1997, only a very small number have been published (Izquierdo *et al*., 1996; Ram *et al*., 1997; Sterman *et al*., 1998). In the first (Izquierdo *et al*., 1996), producer cells releasing tk-encoding retroviruses were implanted stereotactically into recurrent primary brain tumours in five patients, who then received 14 days of intravenous GCV at a dose of $5\,\mathrm{mg\,kg^{-1}}$ twice daily. One tumour in one patient showed a partial response, with progressive disease in all other injected tumours. The second trial protocol was very similar (Ram *et al*., 1997), with retroviral producer cells releasing tk-encoding virions injected into 19 tumours in 15 patients with recurrent primary and metastatic intracerebral tumours. Two tumours were resected 7 days after producer cell injection and *in situ* hybridization revealed only very small clusters of tk-positive cells. Accordingly, in the remaining patients who were treated with GCV twice daily for 14 days, there was a complete response in only two nodules (both in the same patient), a partial response in three nodules with no response in the remainder and no responses in any uninjected lesion. All the nodules that responded were under 2 mL in volume prior to treatment. On a more positive note, there were no severe adverse events. A similar, but larger scale multicentre trial has been published more recently (Shand *et al*., 1999). Forty-eight patients with

recurrent glioblastoma multiforme (GBM) were again injected with producer cells releasing tk-encoding retroviruses following resection of the recurrent tumour. GCV administration followed 14 days later at a dose of $5\,mg\,kg^{-1}$ intravenously twice daily for another 14 days. Fourteen of 48 patients had demonstrable vector DNA in peripheral blood (as assessed by polymerase chain reaction), thought to be secondary to transduction of lymphocytes within the resected tumour bed, which then migrated into the peripheral circulation. Disappointingly, the median survival for the patients was only 8.6 months, which is no better than would be expected in a population of patients who had surgical resection of recurrent GBM without any other treatment. Ten patients had tk-positive residual tumours present at post mortem examination, indicating that, whilst there had been tumour cell transduction, subsequent GCV treatment had failed to kill them, either because GCV penetrated poorly into the CNS or because the cells were not in the correct phase of the cell cycle at the time of treatment (see later).

In the first trial reported of this enzyme–prodrug combination in non-CNS tumours, an adenovirus encoding HSV tk was administered at doses of between 1×10^9 and 1×10^{12} plaque-forming units into the pleural cavity of 20 patients with pleural mesothelioma, followed by 14 days of GCV again at a dose of $5\,mg\,kg^{-1}$ twice daily (Sterman *et al*., 1998). Although no formal attempts were made to establish whether there were any clinical responses, there was evidence of gene transfer in 11 of 20 patients in a dose-related manner, again with minimal toxicity.

There has now been a reported phase I trial in recurrent localized prostate cancer (Herman *et al*., 1999) in which an adenovirus encoding HSV tk was injected directly into the prostate of 18 men at doses of between 1×10^8 and 1×10^{11} infectious units. After 24 h, 14 days of intravenous GCV (dose as in previous trials) was commenced. Three patients had an objective response (fall in serum prostate-specific antigen of at least 50%), the longest lasting 12 months.

There were only two severe adverse reactions, both at the highest dose level. One was thrombocytopenia, which resolved after 5 days, and the other was hepatotoxicity, with transient elevation of bilirubin, transaminases and alkaline phosphatase. There has also been a report of severe hepatotoxicity in a rat colorectal carcinoma model following portal vein delivery of adenoviruses encoding the *tk* gene and GCV administration. This implies that activated GCV may be toxic to noncycling hepatocytes, as this toxicity was not seen in rats that received the adenoviral tk without GCV or in those rats that received a control adenovirus expressing β-galactosidase, followed by GCV (van der Eb *et al*., 1998). Another potential safety concern was highlighted recently in a syngeneic rat glioma model (Dewey *et al*., 1999). Following adenovirally-delivered HSV tk and treatment with GCV, the brains of long-term (>3 months) surviving rats demonstrated extensive inflammation, with microglial and T lymphocyte infiltration, and also widespread demyelination. There was also evidence of persistent tk expression 3 months after a single injection of 2×10^7 infectious units of the adenovirus, implying both that the duration of transgene expression after adenoviral delivery may be much longer *in vivo* than previously imagined and also that the administration of GCV in clinical trials of tk–GCV should, perhaps, continue for much longer than the 14 days that most trials currently utilize.

Following reports of incomplete eradication of tumours following *tk* gene transfer due partially to poor gene transfer and poor GCV penetration, and given the probable benefits of immune system involvement in bystander killing *in vivo*, there have been recent attempts to increase the potency of the HSV tk–GCV system by combining it with immunotherapy. There are reports that IL-2, IL-4 and IL-7 can combine successfully with tk–GCV to increase the elimination of colorectal metastases, gliomas and non-small cell lung cancer models, respectively. The significance of these results is that prodrug-mediated killing of one tumour nodule may allow the elimination of distant nodules that do not express the prodrug-converting enzyme. There have also been reports of combined cytosine deaminase–5-fluorocytosine and HSV *tk*–GCV gene therapy being more effective than either alone in eliminating murine mammary adenocarcinoma tumours.

Others have attempted to improve the efficacy of tk–GCV by utilizing the thymidine kinase gene of other herpes virus species (Loubiere *et al*., 1999). There is some evidence that equine herpes virus tk mediates more rapid phosphorylation of GCV than that of HSV. Similarly, the thymidine kinase and phosphotransferase homologues of human herpesvirus-8 are both capable of phosphorylating GCV and may have potential for use in GPAT (Cannon *et al*., 1999). Other enhancements include the use of alternative prodrugs such as famciclovir and penciclovir that can also be activated by HSV tk, but which are orally active. This would facilitate a much longer duration of treatment than is currently possible with intravenous GCV, which would permit more cells to enter S phase and thereby become sensitive to the effects of the activated prodrug.

Cytosine Deaminase–5-Fluorocytosine

The second most commonly employed enzyme–prodrug combination utilizes the cytosine deaminase (*cd*) gene, which can be isolated from fungi and bacteria, and deaminates the antifungal drug 5-fluorocytosine (5-FC) into 5-fluorouracil (**Figure 3**), the main chemotherapy drug used in the treatment of gastrointestinal malignancies for 30 years.

5-FU itself is converted into 5-fluorouridine 5′-triphosphate and 5-fluoro-2′-deoxyuridine 5′-monophosphate, which function as potent inhibitors of both DNA and RNA synthesis via inhibition of thymidylate synthase and

$$\text{5-Fluorocytosine} + H_2O \xrightarrow{\text{Cytosine deaminase}} \text{5-Fluorouracil} + NH_3$$

Figure 3 The conversion of 5-fluorocytosine into 5-fluorouracil by the action of cytosine deaminase.

erroneous incorporation as false bases. That there is some inhibition of RNA synthesis as well as DNA synthesis should also produce some toxicity to quiescent cells, although the toxicity of 5-FU still depends critically upon the length of S phase. Initial reports in transfected or retrovirally transduced murine fibroblast lines demonstrated effective killing of cd-positive cells on exposure to 5-FC at a concentration of 5–10 $\mu g\,mL^{-1}$, whilst the parental cd-negative cells were unaffected by concentrations in excess of 100 $\mu g\,mL^{-1}$. However, in cell mixing experiments, there appeared to be selective killing of the cd-positive cells, with sparing of the cd-negative cells, implying no bystander effect (Mullen *et al*., 1992). A group that had independently cloned the *cd* gene from *Escherichia coli* confirmed the sensitization of cd-positive WiDR human colorectal carcinoma cells to 5-FC via its conversion to 5-FU (Huber *et al*., 1993), but showed that there was marked bystander killing *in vitro* when 33% of cells were cd positive and that this effect did not rely upon cell–cell contact. Also, there was a significant reduction in growth rates of mixed cd-positive and -negative subcutaneous WiDR xenografts in nude mice on treatment with 5-FC. It was possible to demonstrate this effect with only 2% cd-positive cells, implying a very powerful bystander effect *in vivo* with this enzyme–prodrug combination (Huber *et al*., 1994).

The same study also demonstrated that it was possible to generate a concentration of 5-FU of $>400\,\mu mol\,L^{-1}$ within cd-positive tumours following systemic 5-FC administration. There is no apparent explanation for the discrepant results between the two groups in terms of bystander activity, although other groups have subsequently recorded bystander activity for cd–5-FC. Equally, it has also been reported that *cd* gene delivery to normal liver can generate sufficient 5-FU to cause the regression of adjacent cd-negative colorectal metastases, without significant toxicity to those hepatocytes (Topf *et al*., 1998), which implies both a powerful bystander effect and lack of toxicity of 5-FU to noncycling cells.

An attempt was made to compare the efficacy of tk–GCV and cd–5-FC in WiDR cells and it was demonstrated that, on exposure to GCV, there was no reduction in size of subcutaneous xenografts that contained 10% tk-positive cells, yet there was a marked antitumour effect in cd-positive tumours on exposure to 5-FC with only 4% of cells enzyme positive (Trinh *et al*., 1995). However, the poor bystander effect for the tk tumours can be explained by the electron microscope finding that WiDR tumours do not express gap junctions.

Although the protocols of several clinical trials of cd–5-FC have been approved, only one trial has actually been completed (Pandha *et al*., 1999), in which plasmid DNA encoding cd under the control of the c-*erb*B-2 proximal promoter was injected directly into cutaneous metastases of 12 women with recurrent breast cancer positive for c-*erb*B-2. Overexpression of c-*erb*B-2 is seen in approximately 20% of breast carcinomas and is associated with poor prognosis. There was evidence of cd expression in 11 of 12 tumour nodules injected and transgene expression was limited to c-*erb*B-2 positive cells, indicating that transcriptional targeting using this promoter is feasible in human patients. Only eight of the 12 patients received 5-FC (200 $mg\,kg^{-1}$ per day as a 48-h infusion) and there was evidence of some local tumour response in two of these eight patients. There were also two minor responses in patients who received the *cd* gene but no 5-FC, which may reflect an immune response to the injected plasmid DNA.

As with HSV tk–GCV, there are now reports of combining cd–5-FC with immunotherapy. One recent report demonstrated that adenoviral GM-CSF and adenoviral *cd* gene transfer to melanomas in mice resulted in greater growth inhibition than with either cd or GM-CSF alone and that the combination also resulted in greater protective immunity to rechallenge with parental cells (Cao *et al*., 1998). The majority of published data on cd–5-FC has come from use of the *E. coli cd* gene. However, the cytosine deaminase of *Saccharomyces cerevisiae* is capable of deaminating 5-FC at least eight times faster than the *E. coli* enzyme and has a K_M 44-fold lower, suggesting that it would produce 5-FU much more efficiently than the bacterial enzyme (Hamstra *et al*., 1999).

Nitroreductase–CB1954

The active species of both tk–GCV and cd–5-FC are antimetabolites, which means that they will be predominantly toxic to cells that are replicating their DNA. Even within a rapidly growing tumour nodule, the proportion of cells that will be actively dividing may be as low as 6% (Tubiana and Malaise, 1976). The large proportion of cells resting in G_0 has been proposed to be a major factor underlying resistance to GCV. In one study, tumours outgrew 30 days of continuous GCV treatment, but remained sensitive on retreatment, indicating that cells can remain in G_0 for long periods and that acquired resistance to the prodrug was not the cause of the original regrowth (Golumbek *et al*., 1992). This potential shortcoming and the realization that enzyme-catalysed activation of alkylating agents from nontoxic prodrugs could provide some advantages over antimetabolites have prompted the search for alternative enzyme–prodrug combinations, one of the

most promising of which involves the prodrug 5-(aziridin-1-yl)-2,4-dinitrobenzamide (CB1954). CB1954 is a weak monofunctional alkylating agent which originally provoked interest in the 1960s following the discovery that Walker rat carcinosarcoma cells were extremely sensitive to CB1954-mediated killing (Cobb *et al*., 1969). The origin of the Walker cell sensitivity was later found to lie in the expression of DT diaphorase, a FAD-containing dehydrogenase that employs either NADH or NADPH as a cofactor, and which catalyses the bioreduction of CB1954 to its 4-hydroxylamino derivative, which is then converted by thioesters such as acetyl coenzyme A into a powerful bifunctional alkylating agent (Knox *et al*., 1988). The activated cytotoxic species is not phase specific and can kill noncycling cells (Bridgewater *et al*., 1995). Human DT diaphorase performs this reduction much less efficiently than the rat enzyme, which may explain the lack of efficacy of CB1954 in human subjects in an unpublished pilot clinical trial in the early 1970s. Recent studies have indicated that the molecular basis of the difference between the ability of human and rat DT diaphorase to reduce CB1954 may lie at residue 104, tyrosine in the rat enzyme and glycine in the human. Cells with the capacity to bioreduce CB1954 have been demonstrated to be 10^5 times more sensitive on a dose basis than those which do not (Roberts *et al*., 1986). An *E. coli* nitroreductase (NTR) was identified that is capable of reducing CB1954 and was shown to be a monomeric FMN-containing flavoprotein with a molecular mass of 24 kDa that also employed either NADH or NADPH as a cofactor. By comparison of amino acid sequences, it was also shown that NTR has homology to the 'classical nitroreductase' of *Salmonella typhimurium* and a nitroreductase in *Enterobacter cloacae*. It was further demonstrated that NTR reduced CB1954 up to 60 times more rapidly than rat DT diaphorase (Knox *et al*., 1992), although both the 4-hydroxylamino and the less toxic 2-hydroxylamino derivatives are generated in equal proportions (**Figure 4**).

NTR was selected for use in conjunction with CB1954, initially for antibody-directed enzyme–prodrug therapy, and subsequently for GPAT once the gene encoding NTR, *nfnB*, was identified and cloned from the B strain of *E. coli*.

Figure 4 The bioactivation of CB1954 by *E. coli* nitroreductase.

Studies by several groups have confirmed the prediction that mammalian cells expressing NTR would be sensitized to CB1954 and have demonstrated the existence of a bystander effect with this system (Bridgewater *et al*., 1995), although other studies have reported little or no bystander effect (Clark *et al*., 1997). Initial *in vivo* work was limited to two studies in transgenic mice. In one, NTR was expressed selectively in secretory epithelial cells of the mammary gland from an ovine β-lactoglobin promoter (Clark *et al*., 1997) and treatment with CB1954 resulted in ablation of the mammary epithelial tissue, with sparing of the adjacent myoepithelial cells, which were NTR negative, implying no bystander effect. However, in the other study (Drabek *et al*., 1997), in which NTR was expressed in T cells under the control of elements from the human *CD2* locus, CB1954 administration resulted in severe reduction in total cell numbers within the thymus with evidence of extensive apoptosis. There was also extensive cell reduction within the spleen, which contained a large number of non-T cells, implying a degree of bystander killing *in vivo*. This study also demonstrated that high doses of CB1954 (50 mg kg^{-1} day^{-1} for 5 days) were also very toxic to Balb C and C3H/He mice and there have been some attempts to discover less toxic alternative prodrugs that can also be activated by NTR.

Recently, the first demonstration of the efficacy of NTR/CB1954 in murine tumour models was published (McNeish *et al*., 1998), in which bearing NTR-expressing subcutaneous and intraperitoneal tumour cells were cured following exposure to two bolus doses of CB1954. The same study also indicated that a cisplatin-resistant ovarian tumour cell line remains as susceptible to the NTR-dependent cytotoxicity of CB1954 as parental cells, which has importance in any potential clinical application of NTR–CB1954, especially in the treatment of ovarian cancer.

As with tk–GCV and cd–5-FC, there is evidence that CB1954-mediated killing of NTR-positive tumours *in vivo* leads to the establishment of antitumour immunity. Again, this effect is not dependent upon the immunogenicity of the enzyme and is cell-type specific. There is, however, convincing evidence that NTR-positive cells killed following exposure to CB1954 undergo an apoptotic rather than necrotic death (Cui *et al*., 1999), implying that the previous observation with tk–GCV that necrotic rather than apoptotic death is required for the development of antitumour immunity following prodrug delivery may not be a universal phenomenon.

Data on the delivery of the *NTR* gene to murine tumour models using recombinant viruses are limited. However, one as yet unpublished study demonstrates that the delivery of a recombinant adenovirus encoding the *NTR* gene to nude mice bearing intraperitoneal SUIT2 pancreatic tumour cells followed by two doses of CB1954 leads to a significant increase in animal survival (Weedon *et al*., 2000). Interestingly, this study shows that delivery of the adenovirus itself into the peritoneal cavity of nude mice without prodrug administration leads to a small, but significant, increase in animal survival. A similar result was noted when recombinant adenoviruses were administered into the pleural cavity of nude mice in a model of malignant mesothelioma (Lan *et al*., 1997). However, these findings were not confirmed in models utilizing SCID mice, implying that natural killer (NK) cells, present in nude but not SCID mice, may be responsible for the observed antitumour effect of recombinant adenoviruses alone.

Others

There are many other potential enzyme–prodrug systems, some of which evolved from ADEPT strategies. Some of the more promising ones are listed in **Table 1**.

The human thymidine phosphorylase–5′-deoxy-5-fluorouridine, VZV thymidine kinase–araM and *E. coli* purine nucleoside phosphorylase–9-(β-D-2-deoxyerythropentofuranosyl)-6-methylpurine combinations will all generate toxic antimetabolite agents which are likely to meet with the same potential hurdles as tk–GCV and cd–5-FC. However, the other combinations all generate novel active species that are toxic to both cycling and noncycling cells and merit further discussion.

One possible advantage that the carboxypeptidase G2 (CPG2)-mediated activation of 4-[(2-chloroethyl)(2-mesyloxyethyl)amino] benzoylglutamic acid (CMDA) has over other combinations is that the active species produced by CPG2 requires no further modification by cellular enzymes, which contrasts with 5-FU and both activated CB1954 and GCV: if the enzymes required for further drug modification become deficient in tumour cells, this could lead to resistance to the activated drug. Like activated CB1954, the active species of CMDA is an alkylating agent, toxic to noncycling cells and less likely to induce resistance. One potential disadvantage of CPG2 is that the enzyme in its natural configuration is secreted and removal of the signal peptide to is required to prevent this. There is *in vitro* evidence that expression of this altered CPG2 is capable of sensitizing a range of ovarian and colorectal carcinoma cells to CMDA and that a modest bystander effect exists (Marais *et al*., 1996).

Cytochrome P450 isoenzyme 4B1 (CYP4B1) was first identified as an activator of the mould toxin 4-ipomeanol following a mysterious cattle pulmonary illness. It has also been shown to activate 2-aminoanthracene, although the precise nature of both active species is unknown. However, glioma cells stably expressing the rabbit isoform of the enzyme are sensitized both *in vitro* and *in vivo* to both prodrugs, with evidence of single-strand DNA breaks and an adequate bystander effect (Rainov *et al*., 1998).

Another cytochrome P450 enzyme, the human isoenzyme 1A2 (CYP1A2), is capable of activating the analgesic drug acetaminophen (paracetamol), which is used world-wide as an analgesic drug, but can be hepatotoxic when taken in overdose. There are several pathways

Table 1 Other potential enzyme–prodrug combinations for use in GPAT

E. coli purine nucleoside phosphorylase	9-(β-D-2-Deoxy erythropentofuranosyl) -6-methylpurine	6-Methylpurine	Sorscher *et al*. (1994); Hughes *et al*. (1995)
Carboxypeptidase G2	4-[2-Chloroethyl)(2-mesyloxyethyl)amino] benzoylglutamic acid (CMDA)	4-[2-Chloroethyl)(2-mesyloxyethyl) amino]benzoic acid	Marais *et al*. (1996)
Rabbit cytochrome	2-Aminoanthracene	Unknown	Rainov *et al*. (1998)
P450 isoenzyme 4B1	4-Ipomeanol	Unknown	
Human cytochrome P450 isoenzyme 1A2	Acetaminophen (paracetamol)	*N*-Acetyl benzoquinonimine (NABQI)	Thatcher *et al*. (1999)
Human carboxylesterase	7-Ethyl-10-[4-(1-piperidino)-1-piperidino] carbonyloxy camptothecin (CPT-11; irinotecan)	7-Ethyl-10-hydroxy camptothecin (SN38)	Kojima *et al*. (1998)
Linamarase	2-Hydroxyisobutyronitrile-β-D-glucopyranoside (linamarin)	Cyanide	Cortés *et al*. (1998)

of acetaminophen elimination, one of which involves CYP1A2, which oxidizes the drug into the toxic metabolite *N*-acetylbenzoquinonimine (NABQI). Normally, NABQI is detoxified by direct conjugation with reduced glutathione, but in overdose, however, the glutathione conjugation pathway is saturated, leading to excess NABQI and direct hepatic toxicity. An early report indicates that the expression of CYP1A2 in Chinese hamster V79 cells dramatically increases their sensitivity to acetaminophen-mediated toxicity (Thatcher *et al*., 1999). There is evidence of bystander killing of non-CYP1A2-expressing V79 cells at low concentrations of acetaminophen when mixed with only 5% of CYP1A2-positive cells. This effect is not cell-type specific, with evidence of killing of human ovarian carcinoma SKOV3 and colon carcinoma HCT116 cells when mixed with CYP1A2-expressing V79 cells.

The chemotherapeutic drug irinotecan, also known as CPT-11 {7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyloxycamptothecin}, is active against lung, cervical, ovarian and colorectal carcinomas. As with 5-FU, it should strictly be classified as a prodrug as its piperidino side chain is cleaved by the enzyme carboxylesterase (CE) to reveal the active species, SN-38 (7-ethyl-10-hydroxy-camptothecin). Uniquely amongst the other active species mentioned above, SN-38 functions as an inhibitor of mammalian DNA topoisomerase I, an enzyme whose functions include releasing the torsional stress of supercoiled DNA. However, SN-38 is insoluble and is therefore impractical as a chemotherapeutic agent in its own right. Administration of irinotecan is frequently associated with severe, but unpredictable, toxicity, especially diarrhoea. This may be due to a genetically determined person-to-person variability in the expression of the activating CE enzyme resulting in highly variable levels of SN-38 production. Expression of high levels of CE by tumour cells would permit much lower doses of irinotecan to be administered, with resultant reduction in toxicity. It has been shown that adenoviral delivery of the human *CE* gene to A549 lung carcinoma cells increases both SN-38 production and sensitivity to irinotecan, and can produce growth delay in subcutaneous A549 xenografts in nude mice (Kojima *et al*., 1998).

The enzyme–prodrug combination linamarase and 2-hydroxyisobutyronitrile-β-D-glucopyranoside (linamarin) is of interest because the enzyme derives not from a virus or fungus, but from the cassava plant, *Manihot esculenta* Crantz. Linamarase is a β-glucosidase that hydrolyses linamarin into glucose and acetone cyanohydrin. The latter is unstable at pH >6 and spontaneously degrades into acetone and hydrogen cyanide. The hydrolysis of linamarin does not take place in normal mammalian tissue and the prodrug is excreted unchanged in the urine. Expression of linamarase in range of human and rodent cells has been shown to increase both their sensitivity to linamarin and the production of cyanide.

The cyanide ion (CN^-) is freely diffusible and HCN is a gas, which would suggest that any bystander effect of this system would not rely upon gap junctional activity or

cell–cell contact. There is *in vitro* evidence that a 50 : 50 mixture of linamarase-expressing and nonexpressing murine ψCRIP cells is completely eradicated on exposure to concentrations of linamarin that are nontoxic to the parental cells (Cortés *et al*., 1998).

Given the toxicity of cyanide and the diffusible nature of the active species, there would be considerable concern that the use of this enzyme–prodrug combination *in vivo* would be associated with extensive toxicity. In a rat glioma model, direct infusion of linamarin into the brains of rats bearing linamarase-positive tumours resulted in complete tumour eradication with no discernible toxicity to the animals. However, there was no attempt to deliver the linamarin systematically, as there is evidence that bacteria present in normal gut flora of both rodents and humans contain β-glucosidases that are capable of releasing cyanide from linamarin. This problem would have to be overcome safely if this enzyme–prodrug combination were ever to reach clinical trials.

DISCUSSION

Genetic prodrug activation therapy has great potential as a gene therapy strategy for the treatment of malignant disease. The two most studied combinations (herpes simplex virus thymidine kinase–ganciclovir and cytosine deaminase–fluorocytosine) have produced much promising *in vitro* and preliminary animal data. However, early clinical trials have been disappointing, with low rates of gene transfer and few objective clinical responses. These disappointments, in addition to the theoretical shortcomings of antimetabolites as active species, have driven the investigation into alternative enzyme–prodrug combinations. However, none of the novel combinations has yet been subjected to the reality of a clinical trial, where trial shortcomings may also be exposed.

In a defence of gene therapy, early clinical trials of any new treatment involve patients with recurrent and metastatic disease that is, by definition, refractory to current conventional therapy. It is, therefore, little surprise that there have been few clinical responses in published trials. However, the degree of prior expectation has ensured that these results are heralded as a wholesale failure of gene therapy. Gene therapy, especially as a treatment for malignant disease, is a technique in its infancy (a excuse that has been used for over a decade, but surely cannot be valid indefinitely) and it is very unlikely that any one gene therapy strategy will ever produce dramatic cures for all types of malignant disease. Much more likely, combined gene therapy strategies will be used in conjunction with existing modalities in the treatment of residual postsurgical disease. To this end, there is ongoing research using enzyme–prodrug therapy as a radiosensitizer (Szary *et al*., 1997) and even double enzyme–prodrug therapy (tk–GCV and cd–5-FC) with the genes delivered by a selectively replicating adenovirus and used in conjunction with radiotherapy (Freytag *et al*., 1998).

One of the other persistent criticisms of gene therapy, as highlighted by the Varmus report, has been the poor design of clinical trials, which has reduced the amount of useful information that can be gleaned from any negative results. Therefore, future trials of gene therapy must be sophisticated in design with clear and distinct scientific endpoints if the potential of this existing technology is to realized.

Stem Cell Transplantation

Arnon Nagler
Chaim Sheba Medical Center, Tel Hashomer, Israel

CONTENTS

- Introduction
- Autologous Stem Cell Transplantation (ASCT)
- Allogeneic SCT
- Indications for Allogeneic SCT
- Chronic GVHD
- Unrelated SCT
- Cord Blood Transplantation
- Haploidentical SCT
- Adoptive Immunotherapy and Donor Lymphocyte Infusion
- Cytokine-mediated Immunotherapy
- Low-intensity and Nonmyeloablative SCT
- SCT for Autoimmune Diseases

INTRODUCTION

Stem cell transplantation (SCT) is recognized as a conventional, occasionally even front-line, mode of therapy for an increasing number of haematological malignancies including leukaemias and lymphomas and certain solid tumours, not curable by other therapeutic modalities (Slavin and Nagler, 1991). In addition, allogeneic SCT is the treatment of choice for (1) clinical syndromes associated with the life-threatening deficiency of marrow stem cells (e.g. severe aplastic anaemia) or stem cell products (e.g. T lymphocytes in severe combined immunodeficiency, osteoclasts in osteopetrosis, granulocytes in Kostmann's syndrome) and (2) certain genetic disorders leading to production of abnormal marrow products (e.g. β-thalassaemia major) or enzyme-deficiency disorders (e.g. metachromatic leukodystrophy, Gaucher's disease) (Slavin and Nagler, 1991). The history of SCT started in the late 1950s when attempts to treat human patients with total body irradiation or chemotherapy and marrow infusion were reported (Thomas *et al*., 1957). Mathe *et al*. achieved the first persistent allogeneic marrow graft in a patient with leukaemia (Mathe *et al*., 1965). In 1977, Thomas *et al*. reported 100 patients with advanced acute leukaemia who were transplanted from a human leucocyte antigen (HLA) – matched siblings, eight of them still alive and well (Thomas *et al*., 1977). In the past few years, major progress has been made in several aspects of SCT including alternative sources of haematopoietic stem cells (PBSC) and cord blood-derived stem cells (Gluckman *et al*., 1997; Schmitz *et al*., 1998), unrelated and mismatched family related including haploidentical PBSC transplantation (Aversa *et al*., 1998; Hansen *et al*., 1998), donor lymphocyte infusion (DLI) and adoptive immunotherapy and cytokines mediated immunotherapy for prevention and treatment of relapse post-BMT (Slavin *et al*., 1996; Nagler *et al*., 1997). Finally, transplantation using less toxic preparative regimens to induce mixed chimaerism (Slavin *et al*., 1998) makes transplants today applicable both to elderly and to heavily treated high-risk patients traditionally considered ineligible for allogeneic transplants using conventional preparative regimens. In addition, these types of modern transplants make possible an application to other disease categories including autoimmune diseases (Van Bekkum, 1998).

AUTOLOGOUS STEM CELL TRANSPLANTATION (ASCT)

In the last decade, autologous stem cell transplantation has increasingly become the alternative treatment modality for patients with haematological malignancies such as leukaemias and lymphomas, as well as with solid tumours (Varadi and Nagler, 1994) (**Table 1**). This therapy involves the use of high-dosage or dose-intensive chemoradiotherapy in conjunction with autologous marrow or peripheral stem cell rescue. According to the International Bone Marrow Transplantation Registry, the number of autologous transplantations is increasing at a higher rate than that of allogeneic transplantations. For treatment of leukaemias, autologous transplantation has several advantages

Table 1 Indications for autologous stem cell transplantation (ASCT)

Disease	Comment
Acute myeloid leukaemia	Best results from SCT performed as consolidation therapy during first complete remission, or with stored marrow during first relapse
Acute lymphoid leukaemia	High relapse rate; early detection of relapse important
Chronic myeloid leukaemia	Best results obtained after induction of Philadelphia chromosome negativity in marrow or stem cells
Non-Hodgkin lymphoma	Consider early ASCT in patients with high-risk lymphomas
Hodgkin disease	ASCT best performed during second relapse; consider early SCT for patients with high-risk disease
Multiple myeloma	Substantial responses also in older patients and those with responsive but recurrent disorder
Breast cancer	Greatest benefit in patients with lymph node involvement responsive to standard chemotherapy

over allogeneic transplantation, as follows: SCT is available for more patients, since it can be used for patients who do not have HLA identical donors and for adults up to age 60 years who achieve initial remission and are in good clinical condition. Intensive immunosuppression is not required for ASCT and therefore transplant-related toxicity and mortality are significantly lower. The preparative regimen provides the maximum dose-intensive therapy with the goal of eradicating the malignancy. Patients receiving ASCT can tolerate more intensive conditioning regimens, since there is no graft versus host reaction. In addition, the patient's immune reconstitution is much faster and therefore there is a decreased risk of infectious complications such as cytomegalovirus. There are also theoretical disadvantages for ASCT: the graft versus leukaemia effect observed with allogeneic transplantation is lacking. There is an additional concern of malignant cell contamination of the harvested autologous bone marrow and peripheral blood stem cells (Brenner, 1995).

Regarding the pre-ASCT conditioning regiments, there appear to be no significant differences between the various conditioning regimens for ASCT in terms of disease-free survival and cure rates, and it is likely that the current chemoradiotherapeutic conditioning regimens are at the limit of multiorgan toxicity. Overall, the relationship between the dosage of chemoradiotherapy and tumoricidal effect is logarithmic, and substantial dosage increments would be needed for total eradication of malignancy (Varadi and Nagler, 1994). Recombinant haematopoietic growth factors and autologous peripheral stem cell reduced substantially the morbidity and mortality associated with chemoradiotherapy and autologous transplantation, (Gianni *et al*., 1989). However, alternative approaches such as cell-mediated and cytokine-mediated immunotherapy will be used to control residual clonogenic tumour cells that have escaped the conditioning procedures.

ALLOGENEIC SCT

Bone marrow has been the major source of haematopoeitic stem cells (HSCs) used for allogeneic transplantation until it was discovered that growth factors were able to mobilize HSC into the peripheral blood (Gianni *et al*., 1989). The optimum number of nucleated cells needed for long-term engraftment is estimated at 2×10^8 kg^{-1}. The identifications of markers of progenitor stem cells such as the CD34 antigen has allowed the development of methods for the isolation and purification of immature progenitors. The critical number of transplanted T cells for induction of acute graft versus host disease (GVHD) is within the range 1×10^5–1×10^6 kg^{-1}. In order to prevent GVHD, several methods of T cell depletion have been used, including negative selection with monoclonal antibodies, positive selection of CD34+ cells with immunomagnetic beads or biotin–avidin columns (Aversa *et al*., 1998; Slavin and Nagler, 1991). This manipulation gives an enrichment of CD34+ cells with a 2–3 logarithmic T cell depletion. These methods of T cell depletion are mostly used in family HLA mismatched or in unrelated transplantation. It has been shown that T cell depletion increases the risk of rejection and leukaemic relapse. This complication can be overcome by increasing the dose of conditioning and the number of cells infused (Aversa *et al*., 1998). Other protocols investigate selective T cell depletion or addition of donor peripheral blood lymphocytes after transplant (Nagler *et al*., 1997). The incidence of chronic GVHD seems to be higher following allogeneic G-CSF mobilized PBSCT (Schmitz *et al*., 1998).

INDICATIONS FOR ALLOGENEIC SCT

Indications for allogeneic SCT include malignant and nonmalignant disorders. Most of the allogeneic SCT (about 80%) are performed for haematological malignancies which include in decreasing order: chronic myeloid leukaemia (CML) mainly in chronic phase but also in more advanced disease, acute myeloid leukaemia (AML) (two-thirds are performed in first complete remission and about third in more advanced disease), acute lymphatic leukaemia (ALL) (about half are performed in first complete remission and the other half in more advanced

disease), myelodysplastic syndrome (MDS) and recently also in chronic lymphatic leukaemia (CLL) in increasing numbers. In other haematological malignancies such as non-Hodgkin lymphoma (NHL), multiple myeloma (MM) and Hodgkin lymphoma (HD) autologous SCT is the first choice. However, in patients who either failed autoSCT or suffer from primary refractory or resistant disease, alloSCT is an legitimate alternative. About 10% of the alloSCT are performed in these disease categories. AlloSCT in solid tumours including renal cancer, breast cancer, ovarian cancer, melanoma, central nervous system malignancies, neuroblastoma, etc., have been reported, but they should be performed only in the context of experimental clinical protocols.

As for nonmalignant disorders, severe aplastic anaemia and Fanconi anaemia are the leading indication for alloSCT, followed by haemoglobinopathies (mainly thalassaemia major), inborn errors and immunodeficiency syndromes. About 10% of the alloSCT are performed in nonmalignant disorders. Recently, several alloSCT have been performed in autoimmune diseases.

Chronic Myeloid Leukaemia (CML)

Patients with CML under the age of 60 years may be treated by allogeneic SCT from sibling donors on a routine basis. The transplant should ideally be performed in chronic phase within 1 year from diagnosis, but patients in advanced phases may also be offered transplants on an individual basis. The timing of transplant for patients with compatible donors who achieve a major or complete cytogenetic response to interferon-α remains uncertain. The number of transplants using unrelated donors is increasing. The effect that the recent compound ST1571 will have on the algorithm of transplantation in CML has yet to be seen.

Acute Myeloid Leukaemia

Patients with AML in first remission may be treated by allogeneic SCT on an individual basis or within the context of a clinical study. Patients who fail to achieve complete remission after two courses of induction chemotherapy may be treated by allogeneic SCT with an HLA-identical sibling. Patients with AML in early relapse or in second or later remission may also be treated by allogeneic SCT. Patients in established relapse are not generally recommended for allogeneic transplant. Transplants involving unrelated donors for AML in remission should proceed largely in the context of a clinical research protocol.

Acute Lymphoblastic Leukaemia (ALL)

Selected patients with ALL, especially those with poor prognostic features (e.g. adults, patients of any age with Philadelphia chromosome-positive ALL), are currently considered for treatment by allogeneic SCT in first remission if they have a sibling donor. The same stipulations apply to a patient with standard-risk ALL treated with chemotherapy only in first remission who relapses and is then restored to second remission with further chemotherapy. As with AML, ALL patients who fail to achieve complete remission after two courses of induction chemotherapy may be treated by allogeneic SCT with an HLA-identical sibling or, if time permits, by allografting from a matched unrelated donor.

Mylelodysplastic Syndromes (MDS)

Allogeneic SCT is considered the treatment of choice for patients with MDS or secondary AML (sAML) offering a good chance of long-term disease-free survival if the transplant is performed in an early stage of the disease (i.e. refractory anaemia or refractory anaemia with excess of blasts) or if the patient is transplanted in complete remission after chemotherapy. The transplant is limited to patients aged less than 55 years with an HLA-identical sibling. Allogeneic SCT may also be considered for patients aged less than 45 years who have a fully matched unrelated donor.

Chronic Lymphocytic Leukaemia (CLL)

Selected patients under the age of 55 years with HLA-identical sibling donors may be treated by allogeneic transplantaion in the context of a clinical research protocol. Such patients will usually be adults with poor prognostic features at diagnosis who have responded to conventional therapy pretransplant.

Multiple Myeloma (MM)

Allogeneic SCT in MM is preferably carried out in patients up to the age of 55 years who have responded to first-line treatment, or before second-line treatment if the patient has not responded to first-line treatment. Allogeneic transplantation with sibling donors may also be considered for selected patients who are nonresponsive or who have already received several lines of treatment. Transplant with unrelated donors should only be considered in the context of a clinical research protocol.

Malignant Lymphoma (NHL and HD)

Allogeneic SCT for lymphoblastic lymphoma might be considered for young adults in first remission. AlloSCT may be considered for patients with NHL or HD with an HLA-identical sibling donor who relapse postautografting or patients with primary refractory or resistant relapse in the setting of an experimental protocol.

Nonmalignant Disorders

Severe Aplastic Anaemia (SAA)

Allogeneic SCT from an HLA-identical sibling is the treatment of choice for patients with acquired SAA under the age of 45 years. The conditioning regimen should probably not include irradiation because of the high risk of secondary tumours. In older patients, or in the absence of a matched sibling, an initial course of immunosuppressive treatment is recommended. Unrelated donor transplants are still associated with significant morbidity and mortality and should be undertaken within clinical research protocols.

Immunodeficiency Syndromes, Inborn Errors and Haemoglobinopathies

For severe immunodeficiency syndromes such as severe combined immunodeficiency (SCID), allogeneic SCT from a matched donor or a haploidentical SCT from a parent is recommended. For all severe homozygous thalassaemias and also for sickle cell disease, allogeneic SCT from an HLA-identical sibling is the only chance of cure.

CHRONIC GVHD

Chronic GVHD (cGVHD) is a major complication occurring in 25–45% of patients 100 days after allogeneic SCT (Sullivan *et al*., 1981). It resembles connective tissue–autoimmune like immunological disorder characterized by cutaneous and mucosal manifestations (Sullivan *et al*., 1981). The hallmark of the disease is lichenoid or sclerodermoid lesions of the skin (Sullivan *et al*., 1981).

Autoreactive T cells specific for the common determinant of MHC class II molecules and production of unusual patterns of cytokines including IL-4 are most probably involved (de Gast *et al*., 1987). However, the precise mechanism still has to be elucidated, and a broad array of effector cells and cytokines are believed to participate. Current treatment options for cGVHD are limited and consist of immunosuppressive agents including methylprednisolone, cyclosporin and azathioprine, thalidomide and total lymph node irradiation, with a limited success rate (Neudorf *et al*., 1984). Halofuginone, an inhibitor of collagen type $\alpha 1$ (I) synthesis and gene expression is a new potential therapy for cGVHD (Nagler and Pines, 1999). Halofuginone is a plant alkaloid known to inhibit specifically collagen $\alpha 1$ (I) gene expression and collagen synthesis (Nagler and Pines, 1999). We have previously demonstrated in two murine models of cGVHD, (1) B10.D2 $\rightarrow$ Balbc and (2) tight skin (TSK) mice, that halofuginone abrogated in a dose-dependent manner the increase in collagen $\alpha 1$ (I) gene expression and the increase in skin collagen and prevented thickening of the dermis and loss of subdermal fat, all of which are characteristics of cGVHD (Levi-Schaffer *et al*., 1996; Halevy *et al*., 1996). Recently, we treated a cGVHD patient by topical application of halofuginone. Halofuginone-containing ointment was applied daily on the left side of the neck and shoulder of the cGVHD patient. Collagen $\alpha 1$ (I) gene expression and collagen content in skin biopsy specimens were evaluated by *in situ* hybridization and sirius red staining, respectively. After 3 and 6 months, a marked reduction in skin collagen synthesis was observed, accompanied with increased neck rotation on the treated side. After cessation of treatment, the sclerosis, skin tightness and collagen $\alpha 1$ (I) gene expression returned to the baseline level. No adverse effects were observed, and no plasma levels of halofuginone could be detected. Halofuginone may thus provide a promising novel and safe therapy for cGVHD patients (Nagler and Pines, 1999).

UNRELATED SCT

Only 30–40% of the patients in the Western hemisphere who are in need of SCT have an HLA-identical sibling who can serve as an allogeneic marrow donor (Beatty *et al*., 1988). Patients who do not have a compatible donor must make do with a donor who is a partially matched sibling, a family member, or unrelated (Kernan *et al*., 1993). The major obstacles for successful allogeneic BMT are GVHD and graft rejection (Slavin and Nagler, 1991). These complications were found to be directly correlated with the degree of HLA disparity between the patient and the stem cell donor (Anasetti *et al*., 1989). Furthermore, in order to increase the success of SCT across a major HLA barrier, the intensity of conditioning must be increased to achieve maximum immunosuppression and a large number of cells must be administered (Aversa *et al*., 1998). This superintensive conditioning is liable to result in higher transplant-related morbidity and mortality. Until recently, donor selection was based mainly on identity of serologically defined HLA class I and class II antigens. At present, molecular analysis of HLA class II alleles has also become mandatory for unrelated donor selection (Petersdorf *et al*., 1991). HLA A–B and DR antigens are the three loci considered to be crucial for donor selection. However, recent publications and circumstantial evidence indicate the possible importance of additional HLA loci, particularly HLA-C of class I, which have so far not been included in the criteria for selecting unrelated bone marrow donors (Nagler *et al*., 1996). We recently analysed the impact of molecular HLA-C disparity on postallogeneic unrelated SCT outcome and complication and were able to demonstrate that the GVHD and graft rejection were significantly higher and the actuarial survival and disease-free survival significantly lower in molecular HLA-C mismatched than matched patients (Nagler *et al*., 1996). We conclude, therefore, that a mismatch in locus C may be

detrimental to SCT outcome and should therefore be included as a risk factor in routine pre-SCT HLA phenotyping.

CORD BLOOD TRANSPLANTATION

Cord blood (CB) is an alternative source of haematopoietic progenitors of allogeneic transplantation of patients lacking an HLA-matched marrow donor (Varadi *et al*., 1995). The demonstration of the presence of HSC in CB suggested the use of these cells for transplantation and the first successful CB transplantation (CBT) was performed by Gluckman *et al*. and reported in 1989 (Gluckman *et al*., 1989). Since then more than 2000 patients all over the world have received related or unrelated CB transplants for a variety of haematological and genetic diseases (Gluckman *et al*., 1997; Rubinstein *et al*., 1998). Most CB recipients have been children with an average weight of up to 44 kg. The progression-free survival rates reported thus far are comparable to results achieved following allogeneic bone transplantation, with a suggestion that CB may produce less GVHD (Rocha *et al*., 2000).

The benefits of using umbilical cord blood cells for transplantation are immediate availability of cells, absence of donor risks and low risk of transmitting infectious diseases (Varadi *et al*., 1995). Other potential advantages of CBT include the ability to increase markedly the number of allografts available, and thus the number of patients who could be transplanted, given the availability and ease of collecting CB from placental veins prior to disposal of the placenta compared with collecting bone marrow from an unrelated living donor. This new source of haematopoietic progenitors will allow the transplant community to target collection of CB from normal pregnancies in minority populations to treat the high incidence of genetic diseases. Additionally, the efficiency of gene transfer into CB progenitors appears to be higher than that reported into marrow or peripheral blood progenitors cells (PBPCs) (Zhov *et al*., 1994). Banks of cryopreserved and HLA typed CB have now been established worldwide (Rubinstein *et al*., 1995). The most important advantage of CBT is less GVHD, which is the main obstacle for successful allogeneic SCT (Rocha *et al*., 2000). Rocha *et al*. (2000) studied 113 HLA identical sibling umbilical CB transplants reported to the International Bone Marrow Registry and Eurocord Cord Blood Transplant Group between 1990 and 1997, and compared them with 2052 HLA identical sibling bone marrow transplants performed during the same time period. Children ($\leq$15 years old) were included in the study. Multivariate analysis demonstrated lower risks of grade II–IV acute GVHD ($p = 0.001$) and chronic GVHD ($p = 0.02$) in umbilical CBT recipients. Since acute GVHD results from activation, clonal expansion and proliferation of donor-derived T lymphocytes that recognize alloantigen presented by either host or donor antigen-presenting cells, the lower GVHD risk after CBT transplantation might be due to impairment of these functions in CB cells. It has been shown that CB lymphoid cells are naive, immature and have different cytokine requirements than bone marrow cells. Data from *in vitro* and *in vivo* studies demonstrated that umbilical cord blood lymphocytes (1) are either functionally or phenotypically naive compared with adult blood lymphocytes, (2) have a unique cytokine profile (producing fewer cytokines and expressing mRNA transcripts for interferon-γ, IL-4 and IL-10, but very little IL-2), (3) have a fully constituted polyclonal T cell repertoire, (4) could be protected from apoptosis due to low levels of CD95 and (5) have functions that are inducible through *in vitro* or *in vivo* activation. Consequently, early NK and T cell cytotoxicity is impaired, but secondary activation can occur. All these immunological properties might result in a reduced capacity of transplanted CB T cells to induce GVHD (Rocha *et al*., 2000).

The main disadvantage of CBT is delayed neutrophil and platelet recovery (Gluckman *et al*., 1997; Rubinstein *et al*., 1998; Rocha *et al*., 2000). Expansion of CB progenitors *ex vivo* prior to infusion could potentially ameliorate the slower haematopoietic recovery by generating a higher number of haematopoietic progenitors. One way to obtain *ex vivo* expanded CB derived haematopoietic progenitor cells is by using copper chelators (Peled *et al*., 1999). We have previously demonstrated that metallic ions, including copper, have a regulatory role in proliferation and differentiation of HPC. Depletion of copper by polyamine chelators such as tetraethylenepentamine (TEPA) transiently blocks differentiation, thus allowing increased and prolonged cytokine supported expansion of HPC with minimal cell differentiation. In a recent study, CD34+ cell-enriched populations derived from human CB were cultured in Flt-3, TPO, SCF and IL-6. TEPA-containing cultures produced clonogenic and CD34+ cells continuously for at least 11 weeks (**Table 2**). During this period, total cells increased by up to 1×10^6-fold and CFU and CD34+ cells by up to 1×10^4-fold each. A significant subset of the population remained

Table 2 *Ex vivo* expansion of CB-derived HPC

Weeks	+TEPA			−TEPA		
	CFU[a]	CD34(%)	CD34[b]	CFU[a]	CD34%	CD34[b]
4	352	7.6	60	288	3.9	29
5	ND	7.2	179	ND	3.2	72
7	7936	6.0	422	947	2.0	43
10	11264	6.0	7620	0	<0.5	<5
11	ND	5.0	5000	0	<0.5	<5

Cultures initiated with 1×10^4 CB-derived CD34+ cells mL^{-1} were supplemented with SCF, Flt-3, TPO and IL-6 (50 mg mL^{-1} each) with or without TEPA (15 μM).
[a] $\times 10^3$.
[b] Total CD34 cells $\times 10^4$.

morphologically undifferentiated. Removal of the chelator resulted in cell differentiation. In the absence of TEPA, clonogenic and CD34+ cells expanded for 4–8 weeks; thereafter, their numbers declined rapidly as they differentiated. These results demonstrate that reducing copper availability delays differentiation and maintains self-renewal of a subset of CB-derived HPC and thereby promotes their long-term expansion. These effects are transient and reversible, indicating that chelator-treated cells maintain the potential for normal development. This method could be utilized for *ex vivo* manipulation of pluripotent stem cells and committed progenitor cells for clinical applications. A prephase I clinical trial using TEPA for *ex vivo* expansion of CB-HPC for transplantation is under way (Peled *et al*., 1999).

HAPLOIDENTICAL SCT

The application of SCT for the treatment of patients with haematological malignancies and other diseases is hampered by the lack of availability of suitable major histocompatibility complex (MHC)-matched donors (Beatty *et al*., 1988; Anasetti *et al*., 1989; Petersdorf *et al*., 1991; Kernan *et al*., 1993; Nagler *et al*., 1996; Aversa *et al*., 1998). Less than 30% of patients who might benefit from SCT have HLA-identical siblings, and only 3–5% have a relative with only a single HLA locus mismatch. The recent establishment of large registries of HLA typed individuals has led to a substantial increase in transplants from unrelated donors (Hansen *et al*., 1998). Although 40–50% of Caucasian patients in the USA are successful in locating an HLA-A, B DR matched, unrelated donor, other ethnic groups have a much lower probability of finding donors owing to marked polymorphism; in general, many patients fail to find an appropriate (related or unrelated) donor. By contrast, nearly all patients have an HLA-haploidentical relative (parent, child, sibling) who could serve as a donor.

During the 1980s, transplantation of bone marrow from family donors who were not fully histocompatible with the recipients was unsuccessful because of graft failure and severe GVHD, at times affecting as many as 90% of recipients. Thorough depletion of T cells from the donor's bone marrow succeeded in preventing GVHD in children with severe combined immunodeficiency disease, but the results of this procedure were disappointing in patients with leukaemia, because the benefit of preventing GVHD was offset by graft failure.

Recently, the Reisner group has demonstrated that a megadose of T cell-depleted bone marrow can overcome MHC barriers in sublethally irradiated mice (Bachar-Lustin *et al*., 1995). They suggested that this facilitating activity is mediated by cells within the CD34+ population, endowed with potent veto activity (Gur *et al*., 1999). Applying this concept to patients Aversa *et al*. were able to achieve high rate of engraftment in recipients of T cell-depleted mismatched transplants who were also given high numbers of haematopoietic stem cells from bone marrow and peripheral blood (Aversa *et al*., 1998). Subsequently the same group transplanted 43 patients with high-risk acute leukaemia with PBSC following CD34 positive selection with no GVHD prophylaxis (Aversa *et al*., 1998). In all the patients, full donor type engraftment was achieved. In none of the patients who could be evaluated did acute or chronic GVHD develop. Regimen-related toxicity was minimal. Transplantation-related mortality was 40%. After a median follow-up of 18 months (range 8–30 months), 12 of the 43 patients were alive and free of disease.

Similarly, Henslee-Downey *et al*. reported 88% engraftment at 32 days, 16% grade II–IV acute GVHD and 8% severe cGVHD in 72 patients transplanted from partially mismatched related donors using the T10 B9 monoclonal antibody for T cell depletion (Henslee-Downey *et al*., 1997). Recently, additional novel approaches for haploidentical transplants were developed. Guinan *et al*. transplanted 12 patients from mismatched donors following induction of alloantigen specific anergy using the CTLA-4 immunoglobulin an agent that inhibits B7:C28-mediated co-stimulation (Guinan *et al*., 1999). Sykes *et al*. performed HLA mismatched transplants by induction of mixed lymphohaematopoietic chimaerism and tolerance (Sykes *et al*., 1999).

ADOPTIVE IMMUNOTHERAPY AND DONOR LYMPHOCYTE INFUSION

Allogeneic SCT is the most effective modality to date to eradicate haematological malignancies in patients at high risk of relapse or resistant to conventional doses of chemo-radiotherapy. High-dose, myeloablative chemo-radiotherapy may also be supported by autologous SCT; however, the rate of anticipated relapse is much higher owing to the lack of graft versus leukaemia (GVL) effects mediated by alloreactive donor-derived T cells (Horowitz *et al*., 1990). A number of approaches including SCT are available to improve antitumour effects. However, these approaches have already been proven to be hazardous since recipients of fully matched marrow allografts, not perfectly matched allografts or matched unrelated allografts, may develop GVHD, shown to be consistently lethal. Allogeneic cell-mediated immunotherapy (alloCT) by donor lymphocyte infusion (DLI) in graded increments of donor-derived peripheral blood lymphocytes is much safer and allows control of GVHD and induction of the GVL effect (Naparstek *et al*., 1995; Slavin *et al*., 1996). Furthermore, we have recently documented that host-type tumour cells resistant to DLI may still respond to unstimulated or *in vitro* activated lymphocytes supported *in vivo* by a short

course of well-tolerated doses of IL-2 (Slavin *et al*., 1996). Our data suggest that alloCT, especially when antileukaemia effector cells are activated by IL-2, may develop into a very effective modality for both treatment and prevention of relapse in patients with resistant disease (Slavin *et al*., 1996) or at high risk of relapse (Slavin *et al.*, 1996). The marked therapeutic benefits of alloCT induced by DLI always carry the risk of GVHD, with an incidence and severity that are unpredictable (Kolb *et al*., 1995; Slavin *et al*., 1996). New approaches to limit the lifespan of donor-derived T cells in the case of uncontrolled GVHD are currently under development. The most promising modality for controlling GVHD, and its incidence after discontinuation of anti-GVHD prophylaxis, is the use of donor T cells transduced with the herpes simplex virus thymidine kinase gene (Bonini *et al*., 1997). Genetically modified T cells of donor origin still retain their GVL capacity. Hence, in the event of uncontrolled GVHD, these antitumour effector cells can be successfully eliminated by administration of conventional doses of ganciclovir (Bonini *et al*., 1997).

Recently there have been some preliminary data that may support the existence of a graft versus tumour (GVT) effect similar to the GVL effect. We have documented possible antitumour responses in six breast cancer patients with documented metastatic breast cancer relapsing following autologous SCT transplantation and 13 patients with advanced malignant lymphoma treated with DLI obtained from an HLA matched sibling. Donor lymphocytes were activated with IL-2 *in vitro* and *in vivo*. One of the patients treated with no evidence of disease at the time of alloCT is still event and disease free over 5 years past therapy (Or *et al*., 1998a,b). Similarly, recently, Porter *et al*. described 18 patients with diverse malignant disorders including Hodgkin disease (HD), melanoma, renal cell carcinoma and non-Hodgkin lymphoma (NHL) who received DLI for relapsing disease postautologous SCT (Porter *et al*., 1999). Four patients developed acute GVHD. Three of the four patients with acute GVHD responded, one with durable complete remission (Porter *et al*., 1999).

CYTOKINE-MEDIATED IMMUNOTHERAPY

Although both HD and NHL are responsive to conventional doses of chemotherapy, in a substantial proportion of the patients, particularly with NHL, relapse cannot be avoided. Patients with primary resistant disease or with relapse following front-line remission induction protocols due to residual tumour cells acquiring resistance to subsequent doses of chemotherapy are unlikely to be cured unless they respond to high, myeloablative doses of chemoradiotherapy supported by autologous SCT (Varadi and Nagler, 1994). However, the relapse rate following autologous SCT (autoSCT) using maximum tolerated doses of chemoradiotherapy is still very high owing to minimum residual disease (MRD) which cannot be eliminated with any of the available modalities (Varadi and Nagler, 1994). A variety of recombinant cytokines may potentially be used to prevent or treat relapse following autoSCT. Some of these cytokines may cause direct antitumour effects, while others may facilitate immunological recognition or activate antitumour effector mechanisms following autoSCT. Immune suppression, including depressed absolute number of CD4+ T cells, decreased T cell response to mitogens, antigens or allogeneic stimulation and profound impairment of IL-2 production, has been observed for up to 1 year following autoSCT, hence it seems important to restore the immunocompetence of the recipient that may be impaired by high-dose chemotherapy required to reduce the tumour load.

In view of the above and in order to reduce relapse rates following autoSCT by induction of lymphokine mediated antitumour effects, we conducted a phase IIb clinical trial on 56 malignant lymphoma (ML) patients with MRD post-autoSCT utilizing a combination of IL-2 and IFN-α subcutaneously (s.c.) in an outpatient setting, and compared the results with 61 matched historical controls (Nagler *et al*., 1997).

The overall survival of ML patients who received immunotherapy was significantly higher than that of ML patients who did not. Survival at 48 months was 90% for the immunotherapy patients and 46% for the historical controls ($p < 0.01$). Similarly, the overall survival was significantly higher for the HD and NHL patients who received immunotherapy when compared with the historical controls. The survival rates at 48 months were 100 and 80% versus 57 and 42%, respectively ($p < 0.02$).

The overall disease-free survival (DFS) of ML patients who received immunotherapy was significantly higher than that of comparable ML patients in the historical control group who did not receive immunotherapy. The actuarial DFS at 48 months was 70 and 48%, respectively ($p < 0.01$). Similarly, the actuarial DFS was significantly higher for the NHL and HD patients after immunotherapy than for the historical controls. The actuarial DFS for NHL patients receiving immunotherapy at 48 months was 64 and 41% for patients who did not receive immunotherapy ($p < 0.01$). The actuarial DFS for patients with HD receiving immunotherapy at 48 months was 88 and 60% for patients who did not receive immunotherapy ($p < 0.042$).

The relapse rate was significantly lower for ML patients who received immunotherapy than for a similar cohort of patients belonging to the historical controls. Of the 56 patients who received immunotherapy, 11 (20%) relapsed (eight NHL and three HD patients), whereas of the 61 patients who did not receive immunotherapy 29 (46%) relapsed (21 NHL and eight HD patients) ($p < 0.01$).

We subsequently wanted to see whether modification of the immunotherapy schedule by reducing rIL-2 to 1 week

($3–6 \times 10^6$ IU/m^2 day^{-1}), followed by combined rIL-2 6×10^6 IU/m^2/day interferon-α 3×10^6 IU/day for 1 month and extending interferon-α to 6 months (3×10^6 IU day^{-1} $\times$ 3 per week) would improve efficacy and/or tolerability. Thirty-eight ML patients were enrolled in the (plus IL-2 followed by IFN-α maintenance immunotherapy) protocol. The results were similar to those obtained with the original protocol (Slavin and Nagler, 1998). We are currently conducting a multicentre prospective randomized trial, investigating our newest rIL-2/interferon-α combination for intermediate-and high-grade lymphoma and HD in an attempt to confirm the benefit of cytokine mediated immunotherapy in the setting of minimal residual disease.

LOW-INTENSITY AND NONMYELOABLATIVE SCT

Considering the role of alloreactive donor lymphocytes in mediating GVL and GVT effects, including in patients who are resistant to conventional anticancer modalities, we have introduced the concept of using the bone marrow transplantation procedure as a platform for induction of host versus graft transplantation tolerance rather than as a means of eradicating all tumour cells. Safe and stable transplantation tolerance can best be accomplished by induction of mixed chimaerism, which can be achieved using nonmyeloablative conditioning. Once host versus graft tolerance allows consistent and durable engraftment of donor immunohaematopoietic cells, donor lymphocytes can be added if needed for induction of GVL and GVT effects to displace residual malignant or genetically abnormal host cells. Patient age in the first cohort that entered our protocol ranged between 1 and 64 years (median, 38 years) (Slavin *et al.*, 1998). Conditioning included immunosuppressive treatment with six daily infusions of fludarabine (Fludara, Schering), 30 mg m^{-2} (days -10 to -5), oral busulfan, 4 mg kg^{-1} day^{-1} for two consecutive days (days -6 to -5), and anti-T lymphocyte globulin (ATG), 10 mg kg^{-1} day^{-1} for four consecutive days (days -4 to -1). Organ toxicity was minimal (Slavin *et al.*, 1998). The protocol was much better tolerated in comparison with the anticipated side effects following a standard myeloablative regimen. No cases of grade 3 or 4 toxicity (World Health Organisation criteria) were observed, and grade 2 mucositis was documented in only a few cases. In one-third of the patients, ANC did not decrease below 0.1×10^9 L^{-1}; some patients never experienced an ANC lower than 0.5×10^9 L^{-1}, and in some the platelet counts did not decrease below 20×10^9 L^{-1}, thus requiring no platelet support at all.

Engraftment was documented in all patients by increasing blood counts and using either amelogenin polymerase chain reaction (PCR) for detection of residual male cells in a recipient of female cells or using VNTR-PCR in sex-matched donor recipient pairs. Severe GVHD (grade 3 or 4) was the single major complication diagnosed and was the only cause of mortality in 13% of the patients, most of whom developed the first signs of disease while off cyclosporin A (CSA). The incidence of relapse was not higher than anticipated following conventional alloSCT. Minimal residual disease was consistently reversed by discontinuation of CSA or using DLI as soon as patients were off CSA. A response was observed in approximately half of the patients who experienced relapse with no GVHD (Slavin *et al.*, 1998). Overall this protocol was given to 70 patients with haematological malignancies (CML ($n = 19$), AML ($n = 17$), ALL ($n = 10$), NHL ($n = 15$), MDS and second leukaemia ($n = 6$), HD ($n = 2$) and MM ($n = 1$)), 16 patients with Matched Unrelated (MUD) and nine patients receiving an allograft following failure of autoBMT. Patients age ranged between 18 and 52 years (median, 34 years). They received fully matched ($n = 66$) or single locus mismatched ($n = 4$) stem cells on day 0. The preliminary results were holding. The protocol was very well tolerated by patients of all age groups. Day 100 mortality was 4%, 0% in patients with nonmalignant diseases and 7% in patients with malignancy. Fast and durable engraftment was observed in all patients with a matched sibling. Persistent evidence of disease or recurrent disease in mixed chimaeras was treated by discontinuation of CSA or by graded increments of DLI with 10 of 15 patients responding. After 3 years, with an observation period of 3–39 months (median, 24 months) the actuarial probability of survival was 68% and disease-free survival was 48%. Corresponding numbers for MUD at 12 months were 75%, and for recipients of second BMT at 18 months 48%, respectively. However, GVHD remains the single major problem (Slavin *et al.*, 1998).

Anderson's group performed a pilot trial of purine analogue-containing nonmyeloablative therapy for 25 patients with AML or MDS considered ineligible for myeloablative therapy and allogeneic transplantation because of either age or medical conditions (Giralt *et al.*, 1997). They used the Flag-ida (fludarabine + idarubicine + Ara-c) or the 2CDA + Ara-c protocol. Twenty patients had neutrophil recovery a median of 11 days after transplant (range 9–21 days), and 17 achieved platelet transfusion independence a median of 15 days after transplant (range 8–78 days). One patient died from infectious complications secondary to graft failure. The 1-year survival for all patients was 23%; disease-free survival was 15% (Giralt *et al.*, 1997). McSweeney *et al.* reported a preparative regimen consisted of TBI 200 cGy as a single fraction, followed by post-transplant immunosuppression with CSA from day -1 to $+35$ and mycophenolate mofetil (MMF) (McSweeney *et al.*, 1998). Eight patients with haematological malignancies (CLL, 2; AML-CR, 3; myeloma, 2; RAEB, 1) were treated. Myelosuppression was minimal, with only one patient developing neutrophil counts of $< 0.5 \times 10^9$ L^{-1}. Some degree of donor T cell engraftment was observed in all

patients: 15–100% donor by day 28 and 5–100% donor by day 56 (McSweeney *et al.*, 1998). Induction of mixed chimaerism by the nonmyeloablative approach with combination of less cytotoxic regimens, intense immunosuppression and high number of HSC is particularly attractive for nonmalignant diseases such as genetic diseases (Slavin *et al.*, 1998) or autoimmune diseases.

SCT FOR AUTOIMMUNE DISEASES

Autoimmune diseases result from self-reactive T-lymphocytes and autoantibodies, produced most likely in cooperation with T cell-dependent B cells. Until recently, nonspecific suppression of self-reactive lymphocytes or the inflammatory process mediated by the ongoing anti-self-reactivity represented the main goal of therapy, but in most cases neither cure nor remission could be obtained (Van Bekkum, 1998). Prior data for experimental animals and humans indicated that high-dose chemotherapy, especially myeloablative chemoradiotherapy supported by autologous SCT (Karussis *et al.*, 1992) and allogeneic SCT, can result in effective control of autoimmune diseases (Van Bekkum *et al.*, 1989). Fassas *et al.* (1997) performed autoSCT in patients with multiple sclerosis (MS) in a progressive phase. The patients were conditioned with the BEAM regimen and ATG. Improvement in the neurological scale was observed in 35% of the patients. One patient died of invasive aspergillosis (Fassas *et al.*, 1997). SCT may help overcome lack of response to self-antigens since the conditioning prior to the transplantation procedure normally involves myeloablative treatment that results in elimination of host-type immunohaematopoietic cells, T cells included, followed by stem cell rescue which results in regeneration of new T cells tolerant to self-antigens. Hence, if the autograft is T cell depleted, newly regenerating T cells are likely to become tolerant to self antigens since self-reactive T cells, certainly high-affinity self-reactive T cells, are likely to undergo apoptosis *in status nascendi* in the thymus. Similarly, following the use of T cell-depleted stem cell allograft, which can also be used for rescue of the myeloablated recipient, it seems very reasonable that both anti-self and anti-host reactivity will be abolished by the aforementioned procedure. The technical possibility of performing alloSCT and inducing a state of mixed chimaerism and tolerance with very low toxicity by using nonmyeloablative conditioning is thus very attractive for autoimmune diseases.

- The Future
- Conclusion

INTRODUCTION

Surgery is still the only potentially curative treatment that can be offered for many cancers, in particular gastrointestinal malignancies. This is despite extensive research into alternative treatments, including immunotherapy and gene therapy, at a high pecuniary cost.

Probably the greatest advance that has been made in surgery over the last decade has been the development of minimal access technology, which has led to a new philosophy in surgery: that of minimizing trauma to the patient. This has been made possible due the advances that have been made in fibre optics and computer-enhanced imaging. This has, therefore, given rise to many developments in all fields of surgery including the introduction of endoscopic surgery and image-guided surgery such as stereotactic and radioimmunoguided surgery.

PRINCIPLES OF SURGICAL ONCOLOGY

Surgery has evolved from the previous dogma of radical resection of the primary tumour and surrounding structures as surgeons appreciate the systemic nature of cancer and develop strategies that minimize locoregional recurrence. This is illustrated by the replacement of Halstead's radical mastectomy in the management of breast cancer with a more conservative approach: the use of wide local excision or segmentectomy coupled with radiotherapy or the use of the ABBI system (see the section Stereotactic Breast Surgery) in the management of suitable breast tumours. However, it is important that this more conservative approach must not compromise the oncological success of the surgery.

Although the exact management of different malignancies will vary, there are some basic principles that must be followed during surgical resection. An in-depth knowledge of the anatomy with special regard to the lymph node drainage and the vasculature remains paramount.

Curative or Palliative Therapy

The treatment of solid tumours can be considered to be either potentially curative or palliative and, therefore, the type of surgical therapy used will depend on both the patient and tumour's characteristics.

If the patient's health is such that major surgery is likely to be detrimental, then a more conservative or palliative approach is warranted. Likewise, if the primary cancer is unresectable and/or metastases are present, curative treatment will usually be unsuccessful and palliative therapy should be instigated. Palliation may include surgery, for example, the bypassing of an obstructing, inoperable tumour for symptomatic relief. Medical management such as pain control is discussed in more detail elsewhere in this book.

The mainstay of curative treatment of most solid tumours is surgical resection of the primary growth. Exceptions include radiotherapy or topical 5-fluorouracil in the management of suitable squamous cell carcinomas of the skin or radical radiotherapy for prostate cancer. Surgical therapies are now part of a multidisciplinary

approach to cancer management and can be used in combination with preoperative (neoadjuvant) or postoperative (adjuvant) radiotherapy or chemotherapy.

Clinical Staging

In producing the treatment plan for the patient, it is important to stage the tumour clinically. This allows the identification of those patients with (1) metastatic disease for whom extensive surgery will be unnecessary and (2) tumours that require neoadjuvant therapy, e.g. patients with locally advanced rectal carcinoma benefit from preoperative radiochemotherapy. Knowledge of the common sites to which a particular tumour metastasizes will aid in deciding on the appropriate investigations to be ordered. For example, radioisotope bone scanning is used in screening for metastases in prostate cancer and liver imaging is used for gastrointestinal tumours.

The different methods used for staging are summarized in **Table 1**. Symptoms elicited from the patient's history such as weight loss or bone pain are suggestive of metastatic disease. Clinical examination may reveal hepatomegally compatible with liver metastases or can be used to assess the primary tumour itself, such as assessing the fixity of a rectal cancer during a rectal examination.

Radiological investigations commonly used include ultrasonography, computer tomography, magnetic resonance imaging and less commonly positron emission tomography (PET), all of which can be used for imaging the primary tumour to assess local disease as well as the liver and other organs in the search for metastases. Other radiological techniques include radioisotope scanning, which can be used for staging patients with prostate, breast or thyroid cancer.

Ultrasonography probes have been modified for use intraluminally such as the use of transrectal ultrasound in the local staging of rectal tumours and for staging and to aid in the histological diagnosis of prostate cancer. Fibreoptic endoscopes have also been adapted to incorporate an ultrasound probe and have been used to increase the accuracy of staging of oesophageal, gastric and pancreaticobiliary tumours.

The use of virtual colonoscopy, which can accurately detect lesions as small as 1 cm in size, may with further development assessment become a part of the radiologists' regular armament. Further developments include the use of magnetic resonance (MR) endoscopy in which the coil is incorporated into the tip of the fibre-optic scope.

More invasive techniques are now being developed with the increasing use of staging laparoscopy and thoracoscopy in the management of a variety of tumours. These advances will be discussed in more detail later in the chapter. Although now rare with the recent development of imaging techniques, patients occasionally require a laparotomy, especially if the diagnosis is in doubt.

Table 1 Methods for clinical staging

Method	
Clinical	
History, e.g. cachexia, bone pain	
Clinical examination	
Radiological	For the assessment of the primary tumour and metastatic disease, e.g. liver secondaries from gastrointestinal malignancies
Ultrasonography	
Computed tomography	
Magnetic resonance imaging	
PET scanner	
Radioisotope scan	E.g. for bone metastases from breast, prostate, kidney, thyroid and bladder cancers
Endoscopy	
Endoscopic ultrasound	
Surgical	
Staging laparoscopy/thoracoscopy	
Laparoscopic ultrasonography	
Sentinel lymph node mapping	
Laparotomy	

Operative Principles

Prevention of locoregional recurrence remains the goal in surgical oncology. The surgeon should resect all of the malignant tissue from the primary organ and any other structure involved locally, together with the lymphatics, vascular structures and tissue through which the tumour is likely to spread. For example, in colonic surgery, the vessels should be ligated at their origin, allowing removal of the mesentery, which also contains the draining lymph nodes.

During surgery the tumour should be handled as little as possible to avoid tumour spillage. This problem may account for the reports of early port-site recurrences following minimal access surgery for malignancy during the infancy of advanced laparoscopic surgery (see the section Disadvantages of Laparoscopic Surgery). It is also imperative that the tumour is excised with adequate margins to reduce the risks of local recurrence. It has been shown, for example, that wedge resection of non-small cell carcinoma of the lung results in high recurrence rates compared with lobectomy. Problems arise particularly in oesophageal surgery where the tumour infiltrates submucosally, so making it difficult to identify whether the margins are microscopically clear at the time of the operation. Other strategies such as early ligation of vessels in colonic surgery to prevent tumour dissemination during surgical mobilisation have not been proved to be beneficial.

Although removal of the draining lymphatics remains an important principle in oncological surgery, there has recently been a change in practice. For some cancer operations, lymphadenectomy may be associated with a

high degree of morbidity, such as surgery for malignant melanoma and breast carcinoma. This has led to the development of sentinel lymph node mapping, which identifies those patients who do not require more extensive surgery (see the section Sentinel Lymph Node Mapping).

Summary

Although total excision of the primary tumour in continuation with its lymphatics and locally involved tissue remains the aim in oncological surgery, curative resection may not be possible in some situations. Debulking surgery together with radiotherapy or chemotherapy may achieve some degree of control of the disease and may prolong survival, but it is important to remember that the aim of surgery is also to improve the quality of life.

LAPAROSCOPY

Staging of Malignancy

In 1911, Bernheim reported the use of organoscopy in a patient with pancreatic cancer to 'reveal general metastases or a secondary nodule in the liver, thus rendering further procedures unnecessary' (Bernheim, 1911). Staging laparoscopy is used, therefore, for patients with a known diagnosis of cancer to ascertain the tumour's suitability for resection and so help in the surgical management of these patients.

Although ultrasound scanning, computed tomography (CT) and magnetic resonance imaging (MRI) can detect liver metastases with a sensitivity and specificity of 75–85%, these imaging modalities are poor at detecting subcapsular liver deposits and peritoneal disease.

Staging laparoscopy has gained increasing favour more recently in the management of cancers where the majority of patients present with advanced disease that is not curable, such as gastro-oesophageal, pancreatic and biliary malignancies. It not only allows direct visualization of the intrabdominal organs, but also enables the surgeon to perform biopsies of unsuspected lesions and cytological examination of peritoneal lavage samples. This process allowed the detection of occult metastases in over 30% of patients with pancreatic cancer in a recent study (Jimenez *et al.*, 2000).

The accuracy of staging has been further enhanced by the use of both endoscopic and laparoscopic ultrasound (**Figure 1**). Both have been shown to increase the accuracy of staging of upper gastrointestinal malignancies especially in the management of pancreatico-biliary cancers where laparoscopic and endoscopic ultrasound can detect nodal disease and early invasion of the portal vein and thereby identify patients with unresectable disease (van Dijkum *et al.*, 1999). Further developments include the use of endoscopic magnetic resonance imaging, which has the coil situated in the tip of the endoscope, and this is currently undergoing evaluation in the authors' institution.

Laparoscopic pelvic lymph node dissection is also used in the staging of prostate adenocarcinoma. It is used for patients at high risk of nodal metastases, who would otherwise be suitable for potentially curative treatment such as radical radiotherapy or radical prostatectomy. At-risk patients have been defined as those with a prostate-specific antigen level $>20\ \mathrm{ng\,mL^{-1}}$, a Gleason score of ≥ 7 and stage T2b–T3a disease (Stone *et al.*, 1997).

Laparoscopic Surgery

Laparoscopic and laparoscopic-assisted surgery are both well described now for most abdominal and pelvic malignancies, including gastro-oesophageal, pancreatic, gynaecological and urological cancers, with laparoscopic colorectal cancer surgery being the most commonly performed oncological procedure.

For laparoscopic surgery to be an accepted method of the surgical management of cancers, a number of parameters must be considered, as must be when any new treatment is used. It must be as safe as or safer than conventional surgery as assessed by operative morbidity and mortality, and offer benefits in terms of length of hospital stay, postoperative pain and cost. Also, sound oncological principles must not be compromised.

Oncological Principles and Laparoscopic Surgery

Parameters that have been used to assess the adequacy of oncological procedures include number of lymph nodes harvested and adequacy of resection margins.

With regard to colorectal cancer, it was first shown on cadavers that an adequate lymphadenectomy could be performed laparoscopically. Since then, comparative studies have shown no differences in the number of lymph nodes harvested by open or laparoscopic techniques.

The length of specimen retrieved and proximal and distal margins have also been studied. These parameters are comparable between laparoscopic and open colectomy. In rectal cancer surgery, the radial margin is most important in predicting local recurrence. In a series of 12 patients undergoing laparoscopic abdomino-perineal resection, our unit showed that there was not a significant difference in the radial margins when compared with a similar number of patients undergoing conventional surgery (Monson *et al.*, 1992).

Advantages of Laparoscopic Surgery

Laparoscopic colorectal surgery has been shown, when compared with open surgery, to result in a more rapid return of gastrointestinal function, less postoperative pain, a reduction in length of stay and an earlier return to normal activities. This is probably related to reduced

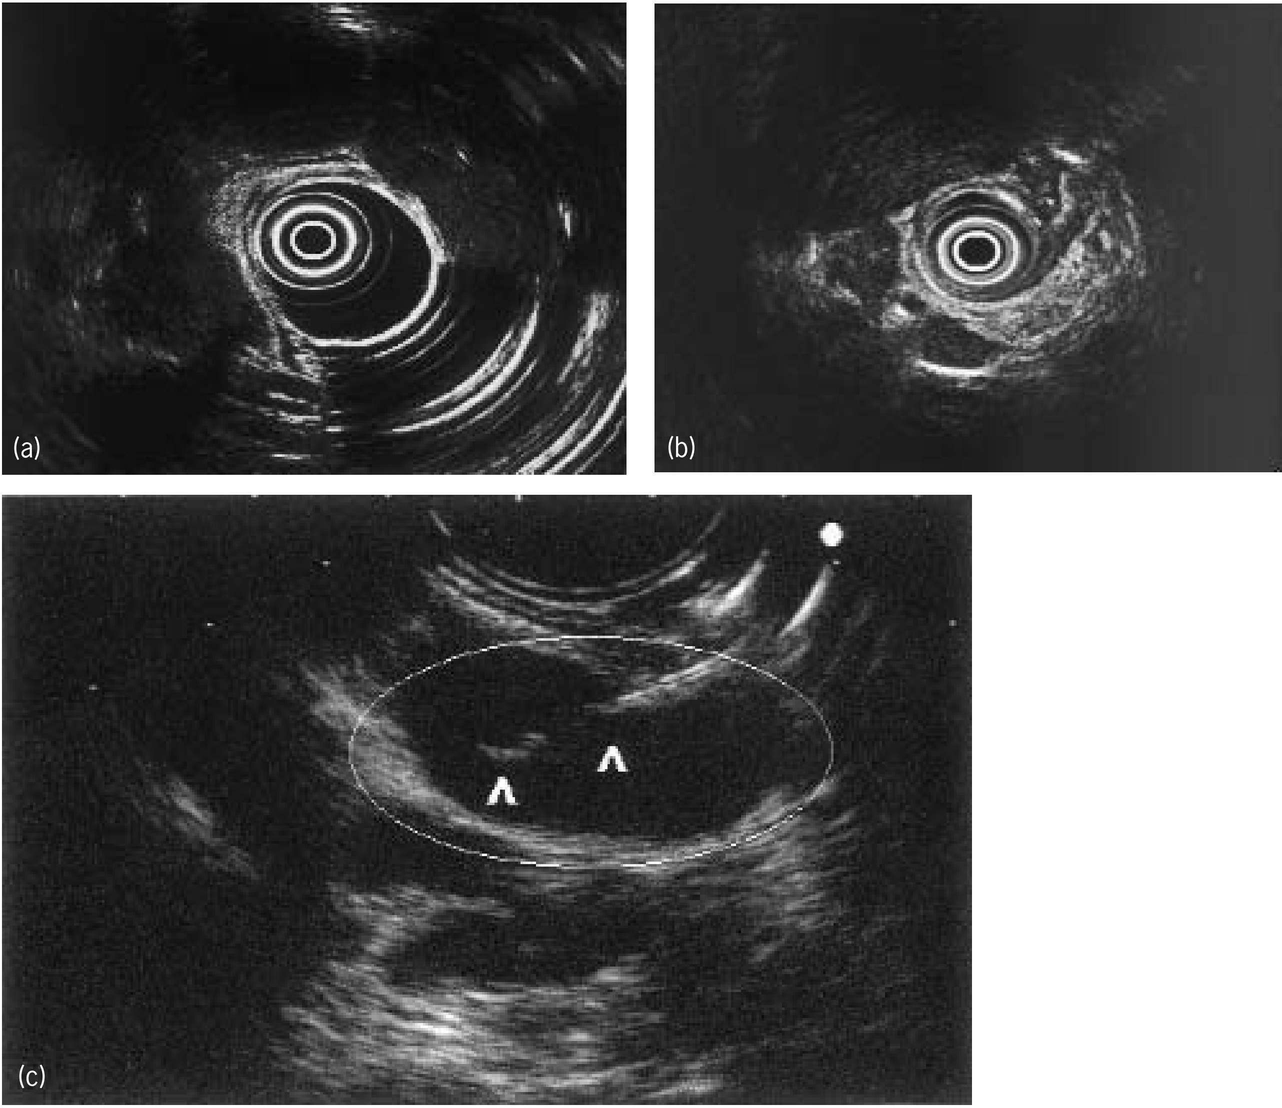

Figure 1 (a) Endoscopic ultrasound showing a carcinoma of the head of pancreas with sonographical pathological perihepatic lymph nodes (b) (courtesy of Mr David Bowrey, Cardiff, UK). (c) Endoscopic ultrasound image showing a transgastric ultrasound-guided fine needle aspiration (arrows) of a 2 × 1 cm coeliac axis lymph node (outlined).

access-related trauma, as seen by a reduced cytokine response following laparoscopic colorectal resection (Schwenk *et al*., 2000).

Although the actual cost of the laparoscopic procedure is higher than open surgery, there may be more long-term cost savings with regard to shorter convalescence and earlier return to work.

Disadvantages of Laparoscopic Surgery

Laparoscopy lacks the manual dexterity afforded by open surgery, which may give rise to some theoretical problems. It has been reported that synchronous tumours have gone unrecognized during laparoscopic surgery and there are other reports of healthy bowel having been resected under the belief it contained small tumours while the diseased bowel was left *in situ*. Poor tactile feedback may also make it more difficult to identify important structures such as the ureter during sigmoid colon mobilization.

One of the major controversies since the introduction of laparoscopic surgery in the treatment of cancer has been the phenomenon of port-site metastases (Wexner and Cohen, 1995). Port-site recurrences have been reported in a number of different cancers such as colorectal, gall-bladder, gynaecological, pancreatic, lung and urological malignancies. In colorectal surgery the incidence varies between 2 and 23% and these metastases appear to develop not only in patients with advanced disease, but also following surgery for early lesions such as Dukes A colorectal carcinoma.

There may be a number of reasons for this occurrence. First, it may be due to surgical inexperience during the initial development of laparoscopic surgery, resulting in the inappropriate handling of the tumour, resulting in cancer dissemination. It has been shown that the instruments can become contaminated with tumour cells. Extraction of the specimen through small trocar sites may also cause exfoliation of cells into the wound. The evidence that surgical skill plays an important role is twofold. First, a recent study showed that following laparoscopic splenectomy in an animal tumour model, the incidence of port-site recurrences decreased with increasing experience (Lee *et al*., 1998). Second, early results from ongoing randomized controlled studies have shown a much lower incidence.

Other causes may be technical problems associated with laparoscopic surgery. These include aerosolization of viable tumour cells by the pneumoperitoneum and the 'chimney effect,' which involves the drawing up of cells to the port sites by microscopic leakages around the laparoscopic instruments.

The pneumoperitoneum itself may play a role. A number of animal studies have shown that a carbon dioxide pneumoperitoneum causes an enhancement in tumour growth and peritoneal dissemination compared with air or gasless laparoscopy (Bouvy *et al*., 1998) and work from the author's unit has shown increased tumour cell invasiveness following exposure to an *in vitro* CO_2 pneumoperitoneum.

Only the results from ongoing prospective randomized, controlled trials will address both the short- and long-term outcomes following endoscopic surgery for malignancy. At present laparoscopic oncological surgery should be reserved for patients entered into trials or for those patients requiring palliative surgery.

Hand-assist Laparoscopic Surgery

As already mentioned, one of the drawbacks of laparoscopic surgery is the lack of tactile feedback afforded by open surgery and poor depth perception with two-dimensional display. In addition, advanced laparoscopic procedures have not been adopted owing to technical difficulties and to limitations of the instrumentation. To overcome these problems, hand-assist laparoscopic surgery (HALS) has been developed.

With this procedure, the surgeon inserts a hand into the peritoneal cavity to aid in the laparoscopic dissection while the pneumoperitoneum is maintained. This approach utilizes, from the start of surgery, an incision that would be necessary for the retrieval of the specimen later during the operation (**Figure 2; see colour plate section**).

The Handport System (Smith and Nephew, MA, USA) consists of base retractor, a bracelet and a sleeve. The bracelet is attached to the surgeon's wrist, which is usually the nondominant hand, before the sleeve is placed over the forearm and fastened to the bracelet. An incision equivalent in centimetres to the surgeon's glove size is made in the abdominal wall and the inner ring of the base retractor, is inserted into the abdominal cavity after the creation of the pneumoperitoneum. This is secured against the abdominal wall by inflating the base retractor, producing a seal that will maintain the pneumoperitoneum after the hand is introduced into the abdomen and the sleeve attached to the outer ring of the retractor.

A review of the use of HALS has been published recently (Litwin *et al*., 2000). Included in the review were a number of cases of colonic cancer requiring right hemicolectomy, sigmoid colectomy and in one case transverse colectomy. HALS compares favourably in terms of length of operation, postoperative pain and length of hospital stay with previously published data on comparable conventional laparoscopic procedures. Problems encountered with HALS include leakage of the pneumoperitoneum around the Handport device, hand fatigue, which may be due to poor placement leading to bad ergonomics, and slipping of the base retractor in obese patients as the abdominal wall may be too thick for the device.

Colorectal disease lends itself well to this procedure as it is a complex procedure, difficult to perform purely laparoscopically and it also requires an incision to remove the specimen. Other procedures that have utilized this technique include splenectomy, gastric surgery, adrenalectomy and cryoablation of liver metastases.

HALS, therefore, may help surgeons in advanced laparoscopic procedures by offering tactile feedback, safe hand retraction and the ability to use blunt dissection.

Endoscopic Surgery

Until recently, radical surgery had been the method of choice in the treatment of cancers. Now there is an increasing move to less radical surgery in the treatment of early cancers as seen in breast surgical oncology. Local resection requires accurate staging of the primary tumour prior to surgery, with, for example, endoanal ultrasound in the management of rectal cancer, as there is a increased propensity of lymph node metastases with more advanced cancers. Local resection would not be appropriate if there was a high risk of lymph node metastases.

Transanal Endoscopic Microsurgery

Transanal endoscopic microsurgery (TEM) was first described by Buess in 1985 in the resection of rectal tumours and enables the surgeon to resect tumours and suture inside the rectal cavity up to 20 cm from the anal margin (Buess *et al*., 1985). It requires the use of a 40-mm diameter rectoscope, videoscopy and gas insufflation to produce an operating space in the rectum (**Figure 3; see**

colour plate section). The rectoscope also has access for the surgeon to use up to four surgical instruments. Full thickness resections are possible, but can only be performed in the extraperitoneal part of the rectum (**Figure 4; see colour plate section**).

TEM has an obvious role in the surgical management of benign rectal adenomas, but it is now known that its use results in similar local recurrence rates and 5-year survival figures compared with anterior resection in the management of low-risk early (T1) rectal cancers. However there is unlikely to be a role for TEM in the curative treatment of high-risk T1 lesions (i.e. those with early lymphatic invasion) and T2 lesions, both of which are associated with an increased risk of lymph node disease.

Endoscopic Resection of Upper Gastrointestinal Malignancies

Although the majority of patients in the Western world presenting with gastric cancer have advanced disease, a small number are diagnosed with early gastric cancer (EGC). Endoscopic resection of EGC is now well described, especially by Japanese surgeons where the proportion of patients with EGC is much higher.

It has been suggested that tumours suitable for endoscopic resection are those cancers that are confined to the mucosa and that measure no more than 1cm in size (Tis or T1 tumours), as tumours of this size have a low incidence of lymph node disease (Nakamura *et al*., 1999). Results of endoscopic resection compare favourably from an oncological perspective with those for radical gastrectomy when used in these selected patients.

COLONIC STENTING

Stents have for a long time been used in the palliation of dysphagia in patients with oesophageal cancer, using celestin tubes and more recently expandable metal stents. The use of these metallic stents in colonic surgery has recently increased, particularly in the management of malignant large bowel obstruction.

Classically, patients were treated with a three-stage procedure: formation of a defunctioning loop colostomy to relieve the obstruction, then excision of the tumour and anastomosis and finally reversal of the loop colostomy. This method was used as full colonic preparation is not possible and anastomosing unprepared colon greatly increases the risk of a leak. Alternatives to this are to resect the tumour with the formation of an end colostomy (as in a Hartman's procedure) or to resect the diseased bowel, perform on-table colonic lavage and primary anastomosis (one-stage procedure). However, following the former over 60% of patients do not have their colostomy reversed and the latter is not suitable for high-risk cases, as are many of these patients. Mortality rates following emergency surgery for malignant large bowel obstruction can be as high as 20%.

Expandable metal stents such as the Enteral Wallstent™ (Microvasive Endoscopy, Boston Scientific, Boston, MA, USA) are sufficiently strong and yet flexible to conform to the curvature of the large bowel. The stents are positioned under fluoroscopic control alone or in combination with endoscopy. A guidewire is passed through the stricture and the position is checked radiologically using water-soluble contrast. The two ends of the stricture are marked with radio-opaque skin markers for accurate placement of the stent. Dilatation of the stricture may be performed prior to inserting the stent, but this is rarely necessary. An alternative to dilatation is laser ablation of the tumour to widen the lumen.

The stent is used for palliation if the patient is not curable, but is also a treatment option in the management of acute malignant large bowel obstruction. This will therefore relieve the obstruction allowing the patient to be rehydrated and fed, the bowel to be prepared, colonoscopic examination for synchronous tumours and full oncological staging prior to surgery. This therefore permits the surgeon to perform a one-stage procedure. Although the procedure can be performed in an outpatient setting and stents are successfully placed in 95% of cases, there are as yet no data to support the benefit of stenting in this situation (Lo, 1999).

This procedure, however, does have a number of adverse consequences with a morbidity and mortality rate of 18% and 2% respectively. Documented complications include stent migration, bowel perforation, bleeding and pain that may be abdominal or rectal in origin.

Therefore, metallic stenting can provide quick symptomatic relief in the management of malignant large bowel obstruction prior to surgery and also in the palliative setting, although the associated morbidity needs to be recognized.

THORACIC SURGERY

Thoracoscopy

Jacobaeus first described thoracoscopy in 1910 when he used a cystoscope to examine the thoracic cavity to help in the diagnosis and treatment of tuberculosis (Jacobaeus, 1910). Advances in technology have allowed surgeons to revisit this procedure and develop video-assisted thoracoscopic surgery (VATS).

Diagnostic Thoracoscopy

The most generally accepted use of thoracoscopy in oncology is as an aid to diagnosis, allowing the surgeon to visualize and biopsy pleural, mediastinal and parenchymal lesions.

A randomized, controlled study by Santambrogio showed that VATS excision of solitary pulmonary nodule for diagnostic purposes resulted in less postoperative pain and a shorter hospital stay when compared with conventional surgery (Santambrogio *et al*., 1995a). However, it is not suitable for excising lesions larger than 3 cm in size as these have a high risk of being malignant. The same group also recently described how thoracoscopic ultrasound might aid the identification of deep, invisible pulmonary lesions to help biopsy a suspect lesion (Santambrogio *et al*., 1995b).

Staging Thoracoscopy

Mediastinoscopy is the gold standard for staging lung cancer, but it does have its limitations. For example, access to the subcarinal and subaortic window lymph nodes is poor. VATS, however, offers good visualization of both of these regions from the right and left side, respectively.

As with laparoscopy, VATS also allows the inspection of the pleural surfaces for detection of metastatic disease and to help in the management of suspected mesothelioma.

Thoracoscopic Resection for Malignancy

Thoracoscopic wedge resection and lobectomy for non-small cell lung cancer (NSCLC) have both been described. However, wedge resection for NSCLC gives inferior results in the management of early (T1) tumours in terms of both local recurrence rates and 5-year survival and should be reserved for patients not suitable for more radical surgery. Also, although some studies report advantages of thoracoscopic lobectomy for cancer in terms of reduced postoperative pain and hospital stay compared with thoracotomy, this is not borne out by the only randomized control trial that has been published comparing VATS and muscle-sparing thoracotomy (Kirby *et al*., 1995). As a consequence, open lobectomy should remain the treatment of choice in the management of malignancy outside of clinical trials.

SENTINEL LYMPH NODE MAPPING

Over the last two decades, breast surgery has also seen a move to less radical surgery with the use of wide local excision or quadrantectomy plus radiotherapy compared with the previous widespread use of radical mastectomy as advocated by Halstead.

The recent advance that has been seen in the surgical treatment of breast cancer is in the management of the axillary lymph nodes. The standard treatment for patients with invasive carcinoma is complete or level three axillary dissection, or lymph node sampling followed by radiotherapy to the axilla if histology confirms lymph node involvement. Both of these management strategies are associated with complications, e.g. pain, numbness, limited arm movement, upper limb lymphoedema, brachial plexus neuropathy and radiotherapy-induced osteonecrosis. Therefore, nearly all patients underwent some form of axillary dissection for both staging and therapy, and as a consequence were at risk of developing these complications. This led to the development of sentinel lymph node (SLN) mapping (**Figure 5; see colour plate section**), which has the potential to eliminate axillary dissection for the enlarging cohort of breast cancer patients who are node-negative and so avoid the possibility of the previously discussed complications.

The principle of SLN mapping is that it seeks to identify the first draining lymph node from the primary tumour. Using a radioisotope, patent blue dye or both methods, surgeons can successfully localize SLNs in more than 90% of cases. Generally it has been found that using a combination of radioisotope and blue dye is superior to using either technique alone. After identification of the SLN, the node is examined for evidence of metastatic disease by frozen section, imprint cytology, histology or immunohistochemistry. SLN mapping reliably predicts axillary node status in 98% of all patients and 95% of those who are node-positive (Cox *et al*., 1998).

SLN mapping has also found a role in the management of cutaneous malignant melanoma. Until the emergence of SLN-guided surgery, clinically node-negative patients with poor prognosis melanoma, i.e. melanoma thicker than 1.5 mm, underwent elective lymph node dissection (ELND). However there are no data that show any survival benefit over a selective policy, probably because a large proportion of these patients will have node-negative disease. This, together with the high morbidity of lymphadenectomy with seroma formation, wound breakdown and lymphoedema, means that ELND as routine practice has gone out of favour.

SLN mapping for malignant melanoma is performed, as in breast cancer, using blue dye, radioisotope or both. The marker is injected intradermally around the primary tumour or scar, and this method identifies the sentinel node in more than 90% of cases as seen with breast cancer (Schachter *et al*., 2000).

Therefore, SLN mapping can help identify those patients with microscopic lymph node metastases who may benefit from a block dissection, while sparing those with true node-negative disease an unnecessary major operation. It may also allow better staging of the disease to aid in the planning of adjuvant therapy. SLN could also benefit patients with truncal melanoma. These patients are likely to have multiple draining nodal basins and it has been shown that multiple diseased basins correlate with a poorer prognosis.

However, the use of SLN mapping in the management of breast cancer and malignant melanoma has still to be shown to be better than conventional therapy in terms of long-term outcome. Randomized clinical studies are to start shortly in breast surgery.

IMAGE-GUIDED SURGERY

Stereotactic Breast Surgery

Open surgical biopsies are commonly performed for non-palpable, mammographic abnormalities, but about 70% of these lesions will be found to be benign. These lesions are difficult to manage with regard to localization, amount of tissue to be excised and cosmesis.

Although fine needle aspiration cytology (FNAC) has a role in the management of breast lesions, accuracy is both operator and cytologist dependent. It is also difficult to diagnose carcinoma *in situ* with FNAC. Core biopsies may provide enough tissue sample for histological diagnosis, but it is not always sufficient for biochemical assessment of receptor status.

Other instruments have been developed to excise a greater amount of tissue, allowing a more accurate diagnosis to be made. These include the Mammotome and the Advanced Breast Biopsy Instrumentation (ABBI) system. The mammotome is used for percutaneous breast biopsy and is guided by either stereotaxis or ultrasound. It consists of a hollow outer sleeve through which a vacuum is applied, drawing the breast tissue into the probe prior to the advancement of a rotator cutter producing a larger specimen than conventional techniques.

The ABBI system is used under stereotactic guidance. Different-sized cannulas allow lesions up to 20 mm in diameter to be excised through a small skin incision. The lesion is initially centred using a compression paddle and two stereotactic views are taken. The three-dimensional position of the lesion is calculated from these views and the coordinates are programmed into the computer system. Under local anaesthetic the lesion is localized with a 14-gauge needle coaxial to the cannula and the position is again checked prior to the insertion of a steel wire. After a skin incision long enough to accommodate the cannula has been made, it is advanced into the breast while the blade is rotated. When the blade is approximately 15 mm beyond the radiological abnormality, the cannula is advanced and the blade retracted. The specimen is excised using cautery and withdrawn in the cannula. Radiographs are taken of the breast and specimen to ensure adequate excision.

Initial experience with the ABBI system shows that the advantages that it has over open biopsy includes improved cosmesis as it excises a smaller amount of tissue to produce an accurate diagnosis (Damascelli *et al.*, 1998). It is also less expensive than surgery as it can be performed in the radiology department on an outpatient basis. However, it does take over 1 h to perform this technique and the digital images used are not as good as conventional mammography.

Stereotactic Neurosurgery

Until recently, neurosurgeons used free-hand techniques based on the hand–eye coordination of the surgeon and information derived from a neurological examination and radiographs. Consequently, lesions were often difficult to localize despite the use of generous exposures.

Advances in both computer and radiological imaging technology have allowed the development of stereotactic surgery. The introduction of CT and, later, MRI allowed the surgeon to visualize the tumour and plan the operation in more detail and, with the development of interactive image-guided neurosurgical techniques, surgical access and the amount of tissue damage can be minimized as the lesion can be accurately located during surgery.

Stereotactic neurosurgery requires a head holder for fixing the skull rigidly, a mechanism for directing the instrument to the target, a stereotactic data acquisition unit and surgical instruments which can be directed to the lesion through a frame. Initially anatomical atlases were used for 'imaging' to direct the surgeon, but stereotactic surgery is now performed with the aid of three-dimensional real-time images derived from CT or MR scanning.

Neuronavigation systems have now been developed. These are intraoperative position sensing systems that display in real time the location of the surgical tool on preoperative images (**Figure 6; see colour plate section**). The first system, described in 1987 by Watanabe, consisted of a six-joint articulated positioning arm, an image scanner and a 16-bit microcomputer which tracked the position of the joints of the operating arm. Others have since been developed, including the Neuro-Sat and the Milano Arm.

The first US Food and Drug Administration (FDA)-approved system was the ISG Viewing Wand (ISG Technologies, Canada), the use of which has been well described for both primary and metastatic brain tumours and nononcological procedures. This equipment has in the main replaced stereotactic surgery by removing the need for a cumbersome frame and intraoperative scanning. The use of the Viewing Wand resulted in a shorter operating time and length of hospital stay, reduced the exposure required, aided localization of vital structures in anatomy distorted by the pathology and, as an accuracy of 1–2 mm can be achieved using this system, minimised trauma to normal tissue (Sandeman *et al.*, 1994). An obvious disadvantage of the Viewing Wand is the size and weight of the articulated arm. To overcome this problem, armless devices have now been developed which use sonic, electromagnetic or infrared motion analysis systems to track the instrument.

Radioimmunoguided Surgery

Despite patients undergoing what is perceived to be a 'curative' operation for cancer, many still go on to develop locoregional recurrence and metastatic disease. This is due to the presence of occult disease not detected at surgery or by standard diagnostic and staging techniques.

The Radioimmunoguided Surgery System (RIGS) has been developed to increase the detection and excision of cancer. It is used intraoperatively to detect microscopic disease and to assess the extent of the malignant process. The system uses a radioiodine-labelled antitumour-associated glycoprotein monoclonal antibody. Both overt and occult disease are identified at surgery by a gamma-detecting probe that identifies the antibody in the tissue.

Its use has been most widely reported in the staging and treatment of colorectal cancer but it has also been used in pancreatic cancer. In one series, 25% of patients had their surgical management altered by the RIGS system and 27% of patients with incurable disease were identified solely by RIGS. More recently, it has been demonstrated that it may help improve the outcome of patients undergoing surgery for recurrent colorectal cancer by identifying all residual disease (Martinez *et al*., 1997).

Interventional Magnetic Resonance (IMR) and Surgery

The development of dynamic real-time MRI has led to new possibilities in image-guided surgery. It combines the soft-tissue imaging capabilities of MR with real-time or dynamic imaging. The scanner at the author's institution is a Signa 0.5-T Spio IMR (**Figure 7a**), which is an open configuration system allowing the surgeon access to patients. In order to operate in the IMR unit, magnetic safe instruments, which the scanner also has the ability to track, have had to be developed.

Although the use of intraoperative MRI is in its infancy, its use in a number of different procedures has been reported. IMR has been used in the localization and biopsy of breast lesions, but there are still a number of problems that need to be overcome, including needle artefact, tissue shift during the procedure and fast equalization of contrast enhancement. We have performed a number of different procedures in the IMR including the excision of benign breast lumps (**Figure 7; see colour plate section**), colectomies and laparoscopic procedures such as cholecystectomy.

IMR-guided biopsies, craniotomies and microsurgical tumour resections have been performed by neurosurgeons. The accurate and immediate information that is provided by intraoperative MR imaging allows definitive localization and targeting of the lesion while monitoring the anatomical changes that occur during surgery.

The advantages that may be gained with IMR include visualization of structures deep to the two-dimensional image during endoscopic surgery and clarification of the surgical anatomy and may aid in defining the excision margins required for complete resection of cancers. This is particularly pertinent in neurosurgery, where tissue damage needs to be kept to a minimum.

Interstitial Thermotherapy (ITT)

Approximately 50% of patients with colorectal cancer develop metastatic disease including liver secondaries. Only a minority of patients are suitable for liver resection surgery, which would offer the best outcome. Thermal ablation techniques have been described under ultrasound, CT or conventional MR guidance, but these methods are limited by lack of real-time imaging and difficulties in the interpretation of grey-scale changes during thermal ablation.

The IMR overcomes these limitations with the use of a real-time colourization thermal monitoring system that detects changes in tissue temperature and hence can show the site and size of the evolving thermal lesions (**Figure 8; see colour plate section**). The liver tumours are punctured after the administration of intravenous Mangafodipir trisodium using dynamic MRI, usually under local anaesthetic. The tumour is then treated using a water-cooled interstitial fibre and Nd:YAG laser source while the treatment is monitored with real-time colour sequencing. Although complete tumour ablation may be achieved after only one procedure, repeated thermotherapy can be performed (de Jode *et al*., 1999). IMR has also been used with interstitial thermotherapy in the treatment of other cancers such as head and neck tumours, where clinical symptoms such as swallowing difficulties and nerve compression were improved, and in the management of pelvic soft tissue tumour recurrences.

Therefore, ITT may be used to treat metastatic disease and can obtain good local tumour control.

THE FUTURE

As further developments are made in computer hardware and software, there is likely to be more integration of imaging into surgical practice in the planning phase, to practice the operation and also during the procedure. The Virtual Human Project is a major initiative in medical education and research. It aims to make available both sectional and digitally reconstructed images of the human body – the virtual human. This project will build up a library of tomographic three-dimensional images that may be used in the future for simulation and the operation itself.

Robotic technology in the form of master–slave manipulators is already being used in the operating theatre, particularly in the field of minimal access surgery. Robotic camera assistants, such as EndoAssist™ and the Automated Endoscopic System for Optimal Positioning (AESOP) robot, have been used in a number of procedures such as laparoscopic adrenalectomy. The robot can be controlled with a foot pedal, via a voice-controlled interface, as with the AESOP, or by tracking the head movement of the surgeon. These robots have been shown to

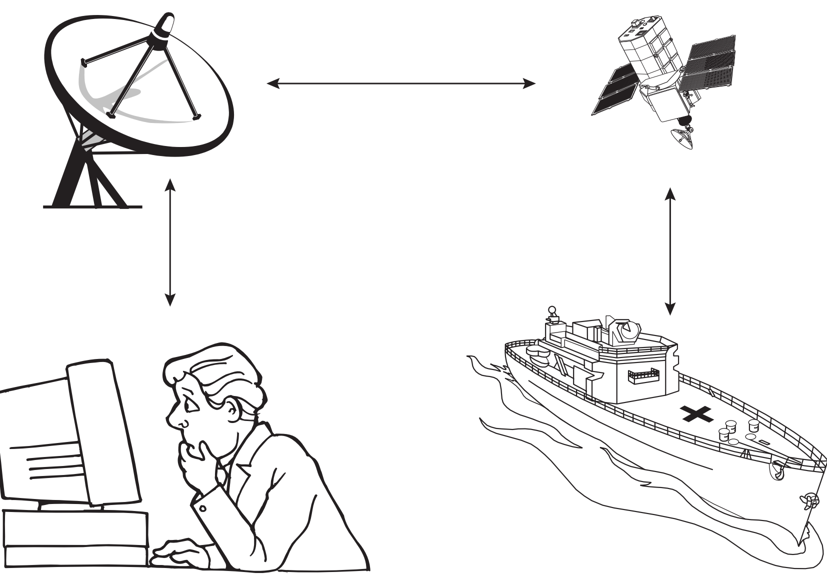

Figure 10 With the aid of surgical robotics, it can easily be envisaged that in the near future surgeons will be able to perform operations at a site remote from the patient.

be superior to the human assistant. The robot reduces the number of camera corrections that are made and the frequency of lens cleaning, both of which can disrupt the surgeon's performance. These tools may aid surgeons as endoscopic surgery for malignancy becomes more popular.

The Da Vinci^{TM} System (Intuitive Surgical, USA) is a computer-enhanced, minimal access surgical system that uses advanced electronics, mechanics and three-dimensional visualization to improve surgical techniques. It has been designed to make minimal access surgery more precise and easier to perform, which may lead to more complex procedures, that at present are not technically possible, being performed endoscopically.

This surgical system consists of two parts: the surgeon's viewing and control console, and the surgical arm unit. This latter unit controls detachable instruments, which access the operative site through 1-cm skin incisions, and these instruments have been designed with 6° of movement to enhance the dexterity of the surgeon's hand and wrist movements (**Figure 9; see colour plate section**).

The surgeon performs the operation from the console, which displays a high-resolution three-dimensional image of the surgical field. The surgeon holds an instrument below the monitor and the surgeon's exact hand movements are simultaneously transferred from the console to precise movements of the instruments at the operative site.

Over 250 operations have been performed with the Da Vinci system, including coronary bypass and mitral valve replacement. Nissen's fundoplication and benign colorectal procedures such as rectopexy have been performed in the author's unit. Although new, this technology may help the conversion of more complex open surgery into minimal access procedures including in the field of surgical oncology.

The development of these robots may eventually lead to remote surgery or telerobotics, enabling surgeons to operate on patients miles away from the medical centre (**Figure 10**).

CONCLUSION

Recent advances in oncological surgery have been in the development of techniques which result in the reduction of access related trauma. This is due to the advances that have been made in optics and computer-enhanced imaging, resulting in the production of images the quality of which aids the surgeon in the preparation and execution of a procedure. However, it is important that any new technique is fully assessed as to its oncological safety before it is offered as routine practice.

INTRODUCTION

In order to improve the quality of care for cancer patients and to prevent, treat and potentially cure this group of devastating diseases, new therapies must continually be developed. Each year, the Cancer Therapeutic Evaluation Program (CTEP) at the National Cancer Institute (NCI) screens over 20 000 potential new anticancer agents using tumour cell assays. The pharmaceutical industry screens at least as many potential agents, if not more. The most promising agents are then further evaluated in animal studies. Only about 30 new agents are taken to human clinical trials per year. In the United States there are over 60 cancer centres encompassing 1700 institutions with over 8000 clinical investigators. The majority of these centres participate in one or more of 10 government-funded cooperative clinical trials groups (**Table 1**). These groups are consortia of academic institutions and clinical practitioners that take a lead role in defining the value of proposed new therapies for cancer. Together, over 20 000 cancer patients are treated on clinical trials per year using these government-supported mechanisms. The pharmaceutical industry, in cooperation with these groups or institutions, frequently funds additional studies to evaluate new drugs. Despite these efforts, only 3% of all patients with cancer are treated on clinical trials. In many cases, this occurs because of limitations imposed by patients' diseases or performance status. However, additional efforts are needed to enroll patients on clinical research studies to accelerate the pace of cancer treatment improvement. Clinical trials, which are expensive and time consuming, require careful planning and execution in order to answer clinically relevant

questions regarding the safety, feasibility and efficacy of new agents or combinations. This chapter provides an overview of the purpose, design, and implementation of phase I, II and III clinical trials and addresses some legal and ethical issues involved in human research.

The Food and Drug Administration (FDA) is a division of the Department of Health and Human Services. Its purpose is to ensure the safety and efficacy of new drugs before they are marketed in the United States. It takes, on average, 8.5 years for a drug to go from the laboratory through animal testing to the completion of clinical trials before it is approved. Prior to entering human clinical trials, a pharmaceutical or institutional application for an Investigational New Drug (INDA) must be submitted to the FDA's Center for Drug Evaluation and Research (CDER). Based on the studies carried out in animal models, the IND application may be approved, and only then can the drug be tested in human subjects.

PHASE I TRIALS

This is the first time a drug will be administered to humans. The goal of a phase I clinical trial is to determine the maximum tolerated dose (MTD) of a new drug or treatment regimen, and to make recommendations regarding the dose and schedule to be used in future studies. In addition, the route of drug administration (oral, intravenous, subcutaneous or intramuscular injection) and information regarding the clinical pharmacology of these new agents are determined. Pharmacokinetics, or the relationship between time and plasma concentration, encompasses absorption, distribution, metabolism and excretion of the drug. These studies are designed to learn about how the patient affects the drug. Pharmacodynamic studies determine how the drug affects the patient by examining the relationship of the plasma concentration and drug effect. Expected and unexpected toxicities are recorded. Phase I trials are neither powered nor designed to determine the efficacy of a drug (although patients are routinely evaluated for clinical response). As such, there is no need to utilize homogeneous populations of patients with regard to disease site or extent of prior treatment. Indeed, individuals who enroll in phase I studies are usually heavily pretreated patients who have failed conventional therapies for their underlying disease or for whom no standard therapy exists. For obvious safety reasons, patients with abnormal end-organ function or poor overall performance status are usually excluded.

In phase I studies, conservative safe starting doses and rules for dose escalation are preset. It has been traditionally assumed that the higher the dose, the more efficacious is the drug, and that the probability of toxicity increases with increasing dose. This presumption has been accurate for conventional cytotoxic agents, but may prove overly simplistic in the evaluation of biological agents that manipulate the host response or perturb cell signalling mechanisms. Animal studies most often utilize rats and mice, but frequently must include larger mammals and subhuman primates, particularly if relevant targets are present in these species. Historically, a safe starting dose has been one-tenth the murine equivalent LD 10 (0.1 MELD 10), expressed in milligrams per square metre of body surface area. The LD 10 is the dose at which 10% of study mice die when that dose is administered. If there is discordance between the mouse and rat data, then beagle dogs are often used as the animal model, given the similarities between human and canine biliary systems. In this case, one-third of the toxic dose low (TDL) in dogs is used as the starting dose. Dose limiting toxicities (DLTs) are clearly defined prior to initiating the study. Toxicities are traditionally graded on a scale of 1–4 using the NCI common toxicity criteria guidelines (National Cancer Institute–Cancer Chemotherapy Evaluation Program, 1999). Provided that no dose-limiting toxicity is encountered in the first cohort, the dose in the second cohort of patients is escalated. Using the modified Fibonacci dose escalation scheme, the second cohort receives a 67% increase of the first dose, the third cohort would receive a 50% increase over the dose given to the second group and the fourth cohort 40% of the dose given to the third group. Subsequent cohorts receive 33% dose increments until a maximum tolerated dose is determined (Collins *et al*., 1986). Usually, 2–3 patients per cohort are used (Simon *et al*., 1997). Typically, three patients are treated initially at each dose level. If none of the patients experiences a dose-limiting toxicity, then the dose is escalated to the next higher level for three additional patients. If one of the three patients experiences a DLT, three additional patients are accrued at the same dose. If two or more of the six total patients in a given dose level experience a DLT, then the MTD has been exceeded and additional patients are treated at the next lower dose level, to confirm that this dose is safe for future studies.

This approach allows a more aggressive initial dose escalation for presumably nontherapeutic doses of the agent. The Fibonacci dose escalation scheme has some disadvantages, such as requiring a relatively large number of patients, and frequently takes many months to complete, as the decision to go to the next level is based on first-cycle toxicities. As the majority of clinical responses occur in patients who receive 80–120% of the recommended phase II dose (Von Hoff *et al*., 1991), there are increasing ethical concerns about treating an excessive number of patients at doses which are retrospectively determined to be subtherapeutic. As a result, there have been a number of attempts to increase the starting dose in a safe manner, and to utilize quicker, yet safe, dose escalation schemes. Two novel approaches include escalation with overdose control (EWOC) (Babb *et al*., 1998) or a modified continual reassessment method (MCRM) (Goodman *et al*., 1995). Under EWOC, dose levels are selected so that the

probability that the dose exceeds the MTD is less than a specified value. The most likely curve describing the probability of a DLT versus dose, based on the experience in the previous patients is computed. This method is statistically designed to converge towards the MTD from doses below the MTD, and controls the probability that any given patient will receive an overdose. Similarly, the MCRM continually modifies the predicted function describing the dose toxicity curve based on the toxicity experienced by all of the patients entered onto the trial. Both of these methods decrease the number of patients required for each dose level, thereby decreasing the number of patients treated at subtherapeutic levels. However, patients still must be observed for defined intervals of time (typically 3–6 weeks) in order to escalate safely to the next highest dose level. The other disadvantage to these accelerated methods of dose escalation is that it limits opportunities to observe interpatient variability in pharmacokinetics and toxicity that might otherwise be seen. As endpoints other than toxicity become more important in identifying working doses for future studies (i.e. measured target effects), assigning fewer patients to each dose level may be detrimental to using potentially unvalidated measures of biological responses to define future working doses. Conceivably, this drawback might be overcome by modifying the designs of phase II studies.

In summary, phase I clinical trials are dose-finding studies to identify toxicity, the MTD and to determine the appropriate dose for further study. Relatively few patients with a variety of primary tumours are enrolled. Historically, only 4–6% of patients enrolled in phase I trials have clinically significant documented tumour responses, but virtually all drugs that are approved exhibit at least some anti-tumour activity in phase I trials. Approximately 70% of the drugs tested in a phase I clinical trial go on to further testing in phase II studies.

PHASE II TRIALS

Once a maximum tolerated dose has been determined in phase I studies, a recommended dose for further study in phase II trials is established. This is usually the dose level below which 33% of patients treated experienced dose-limiting toxicity. The purpose of a phase II trial is to determine the efficacy of the new agent (or combination) in a relatively homogeneous patient population. These trials are designed to eliminate those agents with insufficient activity before embarking on larger, more expensive phase III studies. Patients on phase II trials typically have the same primary tumour, similar prior treatment histories, or may be previously untreated. Typically, if the response rate in a phase II study is less than 20%, then the agent is unlikely to have any significant clinical benefit. If no clinical responses are observed in the first 14 patients treated in a phase II trial, there is less than a 5% likelihood that the employed agent(s) will exhibit a 20% response rate, and the trial can be terminated. However, the number of patients treated in a phase II study is typically greater than the number in any given phase I trial. Additional information regarding toxicity, clinical pharmacology and feasibility is also gleaned in phase II trials.

The endpoint of the phase II study is most often the clinical response rate, although this does not always translate into clinical benefit or increased survival. Therefore, clinical response parameters need to be defined. By convention, a complete response is defined as the disappearance of all clinical evidence of a tumour for a minimum of 4 weeks. A partial response (PR) is usually defined as a 50% or greater decrease in the sum of the products of two perpendicular diameters of all measured lesions for a minimum of 4 weeks, without simultaneous increase in size of any lesion or the appearance of any new lesions. Progression of disease (PD) is defined as an unequivocal increase of at least 25% in the size of any measurable lesion. Stable disease is defined as less than a partial response without evidence of progression, lasting a minimum of 8 weeks. Newer criteria for measuring response has recently been put forth by the NCI (Therasse *et al*., 2000). The RECIST criteria for disease evaluation utilize the sum of the longest diameters of up to 10 identified target lesions. By these criteria, a complete response is defined as the disappearance of all target lesions, a partial response is at least a 30% decrease in the sum of the longest diameter of target lesions and progression is defined as at least a 20% increase in the sum of the longest diameter of the target lesions. Stable disease is defined as neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD. For biological agents that target host response or perturb tumour cell signalling mechanisms, response rate may not be a reasonable study endpoint, and time to disease progression or quantifiable improvement in quality of life may be utilized instead.

There are two types of phase II trial designs: single-stage and two-stage. Single-stage trials employ a fixed sample size (Gehan, 1961). The null hypothesis (that is, that the drug is inactive) is rejected if there is a predetermined number of responders. This may vary according to the indication. For example, the proportion of responders that would justify continued development might be as low as 10% for drug-resistant malignancies such as pancreatic cancer, but might be much higher for low-grade lymphoma, where many drugs have significant antitumour activity as single agents. Potentially active drugs typically go on to phase III study. If the threshold number of responders is not achieved, the drug is deemed inactive and further development for that indication is terminated. In two-stage designs, on the other hand, a given number of patients are enrolled in the first stage of the study. If there is less than a predetermined number of responders, the trial is terminated. If there are more responders, then additional patients are enrolled. By

employing an early stopping rule, the trial is terminated if fewer than expected responses are noted, deeming the agent ineffective. This minimizes the number of patients treated with an agent not likely to provide benefit. Most phase II trials are single-arm studies. Both phase I and II studies are subject to serious selection bias, secondary to investigator bias, and random variation bias, given the small number of patients enrolled.

Randomized phase II trials are frequently employed when several experimental agents are available for testing in a given study population. Patients who meet specific inclusion and exclusion criteria can be randomized to receive one treatment or another. These trials are not designed to be comparative, but may help in selecting the most promising agents or schedule for further study.

In summary, while phase II studies further evaluate safety and toxicity, they are designed to determine efficacy of the drug against a given tumour type. Given the strict patient criteria regarding performance status, extent of prior therapy and anticipated life expectancy, these studies can suffer from selection bias. Frequently, promising phase II results do not hold up in larger generalized populations. Only about one-third of the drugs tested in phase II studies are promising enough to be selected for phase III evaluation.

PHASE III TRIALS

After successfully completing the second stage of trial testing, a drug or combination is deemed safe and reasonably active for a particular disease in a group of highly selected individuals. At this point the drug enters phase III testing. These much larger studies directly compare the agent with a known control, usually the standard treatment for that particular group of patients, in order to determine the relative merits of treatment. Once patients meet eligibility criteria, they are randomized to receive one of the study's treatment regimens. Phase III endpoints are usually response, overall survival or progression-free survival (the time from randomization to death or progression). These trials employ large numbers of patients, and are most often conducted at multiple institutions that include community-based practices. Eligibility criteria are also less restricted, to ensure that the results of the study can be generalized to an unselected population. These trials must be statistically powered to assure that a sufficient number of events are observed in a reasonable length of time.

There are two types of phase III trials: equivalency and factorial. Equivalency trials are designed to demonstrate that the new treatment has efficacy equal to, but not necessarily superior to, that of the standard treatment arm, but may be less toxic. Factorial designs answer two or more questions. In a 2×2 factorial design, patients are randomized to receive treatment A or B. Once randomized, patients undergo a second randomization for another variable, for example differing length of treatment or an additional agent C. There are therefore four treatment arms: patients receiving A only, those receiving B only, those receiving both A and C and those receiving B and C. Randomization decreases chance and bias (unconscious and conscious) and balances predictive factors (known and unknown). Ethical aspects regarding the process of randomization have been discussed at length. It is considered an ethical process in the setting of 'equipoise,' that is, a state of genuine uncertainty on the treating physician's part or that of the medical community regarding the relative merits of different therapies (Fried, 1974).

Statistical Considerations for Phase III Trials

The sample size for any given phase III trial is predetermined and formulated to ensure that adequate numbers of events will occur in a timely fashion, and that differences between the arms can be determined. Sample size is chosen based on four factors: probability of type I error, probability of type II error, power and variability. Type I error (α) is the probability of rejecting the null hypothesis when, in fact, the null hypothesis is true, that is, a false-positive result. A false-negative result or the probability of accepting the null hypothesis, when in fact the null hypothesis is false, is the type II error (β). Power ($1-\beta$) is an estimate of the smallest difference, or treatment effect, that the investigators wish to detect. For a fixed sample size, as the difference between the two treatment arms is increased, the power to detect it also increases. Power increases with increasing sample size. Lastly, variance describes the variability of the outcome measure across the patients in the study group. Greater variability among patients requires larger sample sizes in order to achieve a given power. Studies typically are designed with an α error of 5% and an 80–90% power to detect differences.

Analysis of Phase III Trials

The intention-to-treat principle states that once randomized, all patients are evaluated as members of that group, whether or not the intended therapy was completed. This limits biasing the reported results by excluding patients who withdrew from the study or deviated from the treatment plan for any reason, as those patients might have experienced greater toxicity. If such patients are excluded from the analysis, conclusions drawn are suspect.

Analysing the data prior to final accrual and completion of the trial is called an interim analysis. This has ethical and statistical value in that interim analyses may prevent investigators from further treating additional patients in the event that one arm is clearly more superior or significantly more toxic than the other. It would be unethical to continue treating patients on the inferior arm or withholding more

Table 2 Comparison of phase I, II and III trials

Phase	Purpose	No. of patients	Type of patients	Study design
I	Dose finding	20–30	All tumour types Usually pretreated	Dose escalation
II	Efficacy	30–60	One tumour type Usually no prior therapy	One or two stage
III	Compare with standard	Hundreds	One tumour type Identical cohorts	Randomized Frequently multicentre

effective treatment from the general population. However, as more interim analyses are performed throughout a given trial, the statistical likelihood of detecting a difference between the arms increases spuriously (i.e. increasing the type I error). This can be misleading, and frequently accrual to a randomized trial falls off prematurely owing to physician bias, once the results of an interim analysis have been made available. Therefore, data monitoring committees, independent of the investigators participating in the trial, have been established to perform such analyses.

Phase I, II and III trials are compared in **Table 2**.

META-ANALYSIS

Despite large sample sizes, randomized trials are not always powered to detect small differences that when applied to the general population might have a significant health benefit. Meta-analysis is a reasonable way to draw conclusions about treatments by combining the results of many small, well-designed randomized trials. Basically, all data from randomized trials are pooled and analysed. This includes all relevant randomized trials, both published and unpublished, to eliminate the hazards of publication bias. Most published studies report positive findings while those studies with negative results appear in less widely read journals or are not published at all. Some additional drawbacks to meta-analyses is that these studies are retrospective and not all the information about each trial is readily available. The treatment regimens and patient populations studied have to be similar enough to make conclusions from these studies clinically meaningful.

THE PROTOCOL DOCUMENT

The clinical protocol is a written document that outlines the plan of the study and encompasses a variety of details (**Table 3**). It includes background information which validates the purpose of the trial and defines the study endpoints. The population to be studied is identified through specific inclusion and exclusion eligibility criteria. Patient registration and randomized procedures as well as plans for data collection and data analysis are determined. Drug supplier, starting doses, dose escalations and modifications are predetermined. The biostatistical section of the protocol is perhaps the most essential, as the number of patients needed to support or refute the hypothesis is calculated. The appropriate statistical methods to be used to evaluate the data are defined. Finally, an approved consent form for patient participation is included in the protocol document.

Table 3 Contents of a clinical protocol document

1.0	Introduction
2.0	Objectives
3.0	Selection of patients
4.0	Registration procedures to be used
5.0	Study plan
6.0	Measurement of effect
7.0	Study parameters
8.0	Drug information and procurement
9.0	Statistical considerations
10.0	Adverse event reporting
11.0	Pathology review
12.0	Records to be kept
13.0	Patient informed consent
14.0	References
15.0	Appendix

INFORMED CONSENT

The term 'informed consent' is often felt to refer to the written document that patients sign, agreeing to participate in a clinical trial. However, studies have shown that despite reading such a document which clearly outlines the treatment plan, risks and potential benefits and toxicities that a patient may experience, almost half of patients cannot reiterate this type of pertinent information that the term 'informed consent' implies (Olver *et al.*, 1995). True informed consent has three elements: disclosure, comprehension and voluntary consent. Disclosure of information to patients regarding the nature of their disease, and the proposed treatment plan (with its side effects, risks and potential benefits) as well as alternatives to participating in such a study is carried out by treating physicians through an open discussion. Clinical researchers must ensure that the patient has demonstrated an understanding of this information. The agreement to participate in the study is

entirely voluntary, and patients need to know their rights to withdraw from a study at any time, without undesirable consequences. There are guidelines for writing an informed consent document in the institutional review board guidebook available through the Office of Human Research Protections. The consent form should include the purpose of the study, the treatment procedures and schedule, potential risk and benefits of participating in the study as well as alternatives to treatment. In addition, a consent form should include a person to contact in the event that the participant has any additional questions or concerns regarding the study.

INSTITUTIONAL REVIEW BOARDS

Each institution that conducts clinical research has an institutional review board (IRB). The purpose of the institutional review board is to protect human subjects involved in research. The IRB is made up of a diverse group of individuals, each with an area of expertise. IRB members include medical, administrative, and legal professionals as well as clergy, ethicists, patient advocates and other community members. By law, the board must have at least five members, include both genders and include one member not affiliated with that particular institution. The responsibilities of an IRB include reviewing and approving every clinical research protocol involving human subjects conducted at that institution, to ensure that medically important questions are being asked in a scientifically and ethically sound manner, and to protect the rights and welfare of patients participating in that clinical research. In addition to reviewing the clinical protocol, the IRB reviews the informed consent document to ensure that it is written in a clear and understandable way, and contains all of the necessary components. In addition, protocols are periodically reviewed on a regular basis to include adverse events, and amendments to the protocol.

Once a new drug has been evaluated in all three phases of clinical study, the drug sponsor can choose to submit a New Drug Application. The Oncologic Drugs Advisory Committee (ODAC), composed of research scientists and medical professionals, provides advice to the Food and Drug Administration (FDA) regarding all of the available evidence for safety, effectiveness and appropriate uses of the new agent. Usually this committee must approve the application before the FDA recommends the drug for marketing.

GEMCITABINE IN PANCREATIC CANCER

To illustrate the process of evaluating new drugs in clinical trials, the development of several agents will be reviewed. An example of a conventional cytotoxic antimetabolite, gemcitabine, has undergone phase I through phase III testing. Gemcitabine is a novel nucleotide deoxycytidine analogue with similarities to cytarabine. Intracellular gemcitabine is activated to gemcitabine monophosphate and then to the diphosphate and triphosphate forms. The mechanism of gemcitabine activity is inhibition of DNA synthesis through chain termination and substrate depletion. When gemcitabine is incorporated into DNA, only one deoxynucleotide can be inserted before the DNA polymerase fails to complete further elongation. The depletion of the DNA substrate is achieved by inhibition of the enzyme ribonucleotide reductase by gemcitabine diphosphate.

In preclinical studies, gemcitabine has a broad activity for solid organ tumours including colon, breast, lung and pancreatic tumour cell lines. The drug has undergone numerous phase I studies on several different dosing schedules. When administered daily $\times 5$, gemcitabine caused a high incidence of non-haematological toxicities with a maximum tolerated dose of only 10 mg/m^2. No antitumour responses were noted (O'Rourke *et al*., 1994). When given twice weekly as a 30-min infusion, myelosuppression was the dose-limiting toxicity. MTDs, depending upon duration of infusion, were 65 and 150 mg/m^2 (Popllin *et al*., 1992). Gemcitabine was then administered weekly for 3 weeks by a 24-h continuous infusion with an MTD of 180 mg/m^2. In this setting, neutropenia and lethargy were dose-limiting toxicities (Anderson *et al*., 1996). When given over 30 min every other week, a much higher MTD of 4560 mg/m^2 was identified. The most commonly used weekly regimen, administered 3 weeks on with 1 week of rest, has had the most favourable toxicity profile to date. Further evaluation of the weekly schedule was therefore proposed for phase II study in various solid organ malignancies including lung cancer, ovarian cancer, breast cancer and pancreatic cancer. A phase I/II study was carried out in pancreatic cancer with a starting dose of gemcitabine of 800 mg/m^2 and then in the absence of dose-limiting toxicity, doses were escalated to 1000, 1250 and 1500 mg/m^2. Of the 44 patients entered into this study that were evaluable for response, five had evidence of objective response with a median duration of 13 months. The median survival was 5.6 months with 23% alive at 1 year. Most interestingly, performance status either stabilized or improved in all of the responding patients and documented analgesic requirements were decreased in three of the five responders (Casper *et al*., 1994). A larger phase II trial was carried out in Europe with a regimen similar to that used in the US study for locally advanced or metastatic disease. Of the 32 evaluable patients, two (6.3%) achieved a partial response and six (18.8%) had stable disease. Median survival was 6.3 months and again a similar experience in symptomatic relief, improvement in performance status and decreased analgesic consumption was noted. Neither of these trials had included formal quality of life assessments, however. Therefore, two subsequent

studies – a randomized phase III trial in previously untreated and a phase II trial in 5-fluorouracil (5-FU)-refractory patients – were undertaken (Rothenberg *et al.*, 1996; Burris *et al.*, 1997). The phase III randomized trial compared gemcitabine versus 5-FU in previously untreated patients with locally advanced or metastatic pancreatic carcinoma. A total of 126 patients were assigned to receive either 5-FU 600 mg/m^2 over 30 min weekly or gemcitabine 1000 mg/m^2 for 7 weeks followed by 1 week rest then weekly $\times 3$ every 4 weeks. The primary endpoint of this study was a clinical benefit response as demonstrated by decreased pain intensity, decreased analgesic intake or improvement of Karnofsky performance status. A clinical benefit response was reported in 23.8% of the gemcitabine-treated patients and only 4.8% of the 5-FU recipients ($p = 0.0022$). The median duration of clinical benefit was 18 weeks with gemcitabine and 13 weeks with 5-FU. Tumour responses were dismal in both groups at 5.4% and 0%, respectively. Although the median survival of 5.7 months in the gemcitabine versus 4.41 months in the 5-FU arm were not considerably different, the clinical benefits of receiving gemcitabine were confirmed.

The phase II study that assessed clinical benefit response of gemcitabine enrolled only patients with pancreatic carcinoma who had progressed on 5-FU-based therapy. Similarly, the endpoints in this trial were palliative. Sixty-three patients received gemcitabine using the same regimen as employed in the phase III study with dose escalation up to 1250 mg/m^2 if no grade 2 toxicity had been observed. A clinical benefit response was achieved in 27% of the patients with a median time to response of 3 weeks and a duration of response of 14 weeks. There was no association between clinical benefit and survival. Although the improvement in overall survival is modest, symptom palliation appears to be markedly improved with the use of gemcitabine. This drug received FDA approval and is now considered the standard of care for metastatic pancreatic cancer. The development of gemcitabine illustrates the need to evaluate multiple dosing schedules in a variety of cancers to identify a useful drug and indication, and that objective response rates may not always be the best indicator of clinical benefit. However, the modest efficacy of gemcitabine in pancreatic cancer indicates the urgent need to develop new agents and therapeutic strategies.

THE STORY OF HERCEPTIN AND RITUXAN

As we begin to understand cancer on a molecular level, new therapeutic targets are discovered. Two novel antitumour agents that have undergone extensive clinical trial testing in all three phases will be reviewed. Herceptin (trastuzumab) and Rituxan (rituximab) are monoclonal antibodies that have been rationally designed to target different cellular membrane proteins. Her2/*neu* is a cellular receptor that is frequently overexpressed on the surface of malignant cells, particularly breast cancer. It belongs to a family of receptor tyrosine kinases that play a critical role in the control of cell cycle progression. As such, it is a very attractive target for new agents. In the mid-1980s, monoclonal antibodies were developed against this receptor. A recombinant humanized version of the anti-Her2/*neu* monoclonal antibody, which binds to the extracellular domain of this receptor, entered clinical trials. Three phase I trials were undertaken in patients with tumours that overexpressed Her2/*neu* to evaluate the safety and pharmacokinetics of trastuzumab as a single agent and in combination with cisplatin. The drug was found to be well tolerated when given on a weekly schedule with doses ranging from 10 to 500 mg.

Pharmacokinetic studies revealed an increased serum half-life of trastuzumab with increasing dose. No pharmacokinetic interactions were noted when this new agent was administered with cisplatin. Trastuzumab was further evaluated in two phase II clinical trials to determine its anticancer activity in patients with refractory metastatic breast cancer when given as a single agent as well as with cisplatin. Based on pharmacokinetic parameters, a loading dose was used to achieve therapeutic levels rapidly with continued weekly administration. Objective tumour responses were the efficacy endpoints of these trials. In one study objective responses were seen in five of 43 patients (11.6%) to include one CR and four PRs (Baselga *et al.*, 1996). In the other phase II trial, a 24% partial response rate was demonstrated in 37 evaluable patients (Pegram *et al.*, 1998). After demonstrating efficacy in this group of previously treated refractory patients, this novel agent went on to phase III study in combination with chemotherapy for patients with metastatic breast cancer whose tumours overexpressed Her2/*neu*. In one phase I trial, patients who had not received prior anthracycline therapy were randomized to receive adriamycin and cyclophosphamide alone versus adriamycin, cyclophosphamide and trastuzumab. Those patients who had previously received prior anthracycline therapy were randomized to paclitaxel alone versus paclitaxel plus trastuzumab. Primary endpoints in this trial included time to disease progression with secondary endpoints being response rate, response duration, time to treatment failure and 1-year overall survival. This international trial enrolled 469 patients at 150 clinical sites in 14 countries. The overall response rate of chemotherapy alone was 36.2%. When given with trastuzumab, the response rate increased to 62%. In both drug regimens, the addition of trastuzumab significantly increased the response rate and decreased the time to tumour progression. A significant increase in cardiac toxicity was seen in the adriamycin arm, which illustrates the need for vigilant monitoring as these targeted therapies may not only demonstrate new side effects, but may potentiate known toxicities. As a result, this agent has now

received FDA approval for use in women with metastatic breast cancer as a single agent and in combination with paclitaxel.

Rituximab is another novel chimaeric monoclonal antibody which targets CD20. CD20 is a 35 000-Da phosphoprotein that is found on B lymphocytes including B cell lymphomas. By binding to the CD20 antigen, the monoclonal antibody activates complement, induces antibody-dependent cellular cytotoxicity, inhibits proliferation and directly induces apoptosis. Rituximab was the first monoclonal antibody approved for cancer treatment and perhaps illustrates the minimum amount of time a drug can take from early development to FDA approval. Rituximab entered phase I clinical trials in 1993 in a single intravenous dose trial. Initial doses started at $10\,mg/m^2$ and were escalated to $500\,mg/m^2$ with no significant dose-limiting toxicities noted (Maloney *et al*., 1994). B cell depletion lasting 1–2 months was observed at doses as low as $50–100\,mg/m^2$. A second phase I trial with multiple dosing was undertaken. Rituximab was given weekly $\times4$ at doses ranging from 125 to $375\,mg/m^2$. Tumour responses were observed at all dose levels. Again, no dose-limiting toxicities were noted, illustrating the 'new paradigm' of noncytotoxic drug development. Given the lack of cumulative toxicity, the upper dose level of $375\,mg/m^2$ was chosen for phase II study. In a multicentre clinical phase II trial, 37 patients with relapsed low-grade or follicular non-Hodgkin lymphoma were treated. Seventeen of the 34 evaluable patients demonstrated a partial or complete response for an overall response rate of 50%. Time to tumour progression for these responding patients was approximately 1 year. In a pivotal phase II study conducted at 31 centres, 166 patients with relapsed indolent lymphoma were treated with four weekly doses of rituximab, $375\,mg/m^2$ (McLaughlin *et al*., 1998). The response rate of 48% was comparable to that seen with single-agent cytotoxic chemotherapy. This led to the approval of rituximab in this setting, and illustrates that drug approval need not require a phase III study if it is clearly effective. Commonly observed toxicities in the phase I and phase II trials included fever, chills, pruritus, fatigue and transient hypotension. The more serious toxicities of bronchospasm and significant hypotension were seen in patients with greater tumour burden and it has been postulated that complement mediated rapid tumour lysis may have occurred. As such, it was recommended that infusions of rituximab start at $50\,mg\,h^{-1}$ with premedication with a slow increase in the rate in the absence of symptoms. Most patients can be treated subsequently with minimal side effects.

Rituximab has been studied extensively combined with CHOP-based chemotherapy. In 40 patients with low-grade/follicular non-Hodgkin lymphoma, CHOP was administered at standard doses every 3 weeks for six cycles along with six infusions of rituximab at the recommended phase II dose. Two doses of the antibody were given at the beginning and the end of therapy and single doses before the third and fifth cycles. Thirty-eight patients were treated with an overall response rate of 100% (58% complete response, 42% partial response) with a median duration of response of 39.1 + months. This phase II study (Czuczman *et al*., 1999) demonstrated that rituximab could be safely combined with CHOP and produced a high response rate with a prolonged time to disease progression. Interim results of a large randomized trial evaluating CHOP versus CHOP plus rituximab in elderly patients with diffuse large cell lymphoma were recently presented in preliminary form at the American Society of Hematology Meeting, 2000. The addition of rituximab to CHOP increased the CR (76% versus 60%, $p = 0.004$) and also significantly improved event-free and overall survival (69% versus 49% and 83% versus 68%, respectively) (Coiffer *et al*., 2000). Rituxan has been approved by the FDA for relapsed or refractory CD20 (+) low-grade or follicular non-Hodgkin lymphoma. A phase III trial of front-line CHOP versus CHOP plus rituximab in older patients with high-risk non-Hodgkin lymphoma is currently ongoing through the Eastern Cooperative Oncology Group.

The process of taking a new therapeutic anticancer agent from the laboratory to widespread use is long and arduous. The pitfalls encountered in clinical trial design, implementation and interpretation are numerous. As we enter an era of molecularly targeted new agents, measurement of biological effects will become increasingly vital. Carefully planned and executed clinical and laboratory correlative studies are of paramount importance in advancing the treatment and prevention of malignant disease.
