Dedication

To

Francis N. Marzulli, Torkil Menne, and Ian White for their dedication to expanding dermatotoxicology's scientific and public health horizons.

Contents

Preface xv
Editors xvii
Contributors xix

Chapter 1 Pharmacogenetics and Dermatology 1
Ernest Lee and Howard I. Maibach

Chapter 2 Ethnic Differences in Skin Properties: Objective Data 5
Sarika Saggar, Naissan O. Wesley, Natalie M. Moulton-Levy, and Howard I. Maibach

Chapter 3 Occlusion and Barrier Function 31
Hongbo Zhai and Howard I. Maibach

Chapter 4 Anatomical Factors Affecting Barrier Function 39
Nancy A. Monteiro-Riviere

Chapter 5 Percutaneous Penetration Enhancers: Overview 51
Haw-Yueh Thong, Hongbo Zhai, and Howard I. Maibach

Chapter 6 Percutaneous Absorption of Complex Chemical Mixtures 63
Jim E. Riviere

Chapter 7 Percutaneous Absorption: Short-Term Exposure, Lag Time, Multiple Exposures, Model Variations, and Absorption from Clothing 71
Ronald C. Wester and Howard I. Maibach

Chapter 8 Percutaneous Absorption: 7 Roles of Lipids 81
Philip W. Wertz

Chapter 9 Chemical Partitioning into Powdered Human Stratum Corneum: A Useful *In Vitro* Model for Studying Interactions of Chemicals and Human Skin 87
Xiaoying Hui, Ronald C. Wester, Hongbo Zhai, Anne K. Cashmore, Sherry Barbadillo, and Howard I. Maibach

Chapter 10 Sensitive Skin 95
Harald Löffler, Caroline Weimer, Isaak Effendy, and Howard I. Maibach

Chapter 11 Transdermal Drug Delivery System: An Overview 101
Cheryl Y. Levin and Howard I. Maibach

Chapter 12 Iontophoresis: From Historical Perspective to Its Place in Modern Medicine 107
Angela N. Anigbogu and Howard I. Maibach

Chapter 13 Irritant Dermatitis: Clinical Heterogeneity and Contributing Factors 125
Sara Weltfriend and Howard I. Maibach

Chapter 14 Systemic Contact Dermatitis 139
Niels K. Veien, Torkil Menné, and Howard I. Maibach

Chapter 15 Allergic Contact Dermatitis 155
Francis N. Marzulli and Howard I. Maibach

Chapter 16 Mechanisms in Irritant and Allergic Contact Dermatitis 159
Iris S. Ale and Howard I. Maibach

Chapter 17 Occupational Allergic Contact Dermatitis: Rational Work-Up 169
Iris S. Ale and Howard I. Maibach

Chapter 18 Systemic Toxicity 175
Philip Hewitt and Howard I. Maibach

Chapter 19 Concepts in Molecular Dermatotoxicology 189
Hans F. Merk, Jens M. Baron, Ruth Heise, Ellen Fritsche, Peter Schroeder, Josef Abel, and Jean Krutmann

Chapter 20 Molecular Basis of Allergic Contact Dermatitis 201
Jean-Pierre Lepoittevin and Valérie Berl

Chapter 21 Photoirritation (Phototoxicity, Phototoxic Dermatitis) 209
Natalie M. Moulton-Levy and Howard I. Maibach

Chapter 22 Permeability of Skin to Metal Compounds, with Focus on Nickel and Copper 215
Jurij J. Hostýnek

Chapter 23 Chemically Induced Scleroderma 227
Glenn G. Russo

Chapter 24 Chemical Agents That Cause Depigmentation 235
Sahar Sohrabian and Howard I. Maibach

Chapter 25 Carcinogenesis: Current Trends in Skin Cancer Research 241
Karen J. Auborn

Chapter 26 Retinoids and Mechanisms of Their Toxicity 245
William J. Cunningham

Chapter 27 Mechanisms in Cutaneous Drug Hypersensitivity Reactions 259
Margarida Gonçalo and Derk P. Bruynzeel

Chapter 28 Drug-Induced Ocular Phototoxicity 269
Joan E. Roberts

Chapter 29 Water: Is It an Irritant? 279
Tsen-Fang Tsai

Chapter 30 Sodium Lauryl Sulfate 283
Cheol Heon Lee and Howard I. Maibach

Chapter 31 Factors Influencing Applied Amounts of Topical Preparations 295
Tanzima Islam, Nikolay V. Matveev, and Howard I. Maibach

Chapter 32 Barrier Creams 299
Hongbo Zhai and Howard I. Maibach

Chapter 33 OECD Guidelines for Testing of Chemicals 303
Klaus-Peter Wilhelm and Howard I. Maibach

Chapter 34 Methods for *In Vitro* Percutaneous Absorption 307
Robert L. Bronaugh

Chapter 35 Percutaneous Absorption of Hazardous Substances from Soil and Water 311
Ronald C. Wester and Howard I. Maibach

Chapter 36 Pesticide Percutaneous Absorption and Decontamination 317
Danny Zaghi, Ronald C. Wester, and Howard I. Maibach

Chapter 37 Tape Stripping Method versus Stratum Corneum 327
Myeong Jun Choi, Hongbo Zhai, Jong-Heon Kim, and Howard I. Maibach

Chapter 38 Parameters Influencing Stratum Corneum Removal by Tape Stripping 339
Harald Löffler, Caroline Weimer, Frank Dreher, and Howard I. Maibach

Chapter 39 Quantification of Stratum Corneum Removed by Tape Stripping 343
Frank Dreher

Chapter 40 Isolated Perfused Porcine Skin Flap 347
Jim E. Riviere

Chapter 41 Physiologically Based Pharmacokinetic Modeling 359
James N. McDougal

Chapter 42 Methods for *In Vitro* Skin Metabolism Studies 373
Robert L. Bronaugh

Chapter 43 Predictive Toxicology Methods for Transdermal Delivery Systems 377
Anne Chester, Wei-Qi Lin, Mary Prevo, Michel Cormier, and James Matriano

Chapter 44 Animal, Human, and *In Vitro* Test Methods for Predicting Skin Irritation 383
Cheryl Y. Levin and Howard I. Maibach

Chapter 45 Kawai Method for Testing Irritation 391
Keiichi Kawai

Chapter 46 Analysis of Structural Change in Intercellular Lipids of Human Stratum Corneum Induced by Surfactants: Electron Paramagnetic Resonance (EPR) Study 401
Yoshiaki Kawasaki, Jun-ichi Mizushima, and Howard I. Maibach

Chapter 47 Water and Saline Compresses in Treatment of Irritant Contact Dermatitis: Literature Review 415
Cheryl Y. Levin and Howard I. Maibach

Chapter 48 Reaction of Skin Blood Vessels to Successive Insults on Normal and Irritated Human Skin 417
Ethel Tur and Howard I. Maibach

Chapter 49 Specificity of Retinoid-Induced Irritation and Its Role in Clinical Efficacy 423
Jennifer L. MacGregor and Howard I. Maibach

Chapter 50 Topical Corticosteroids in the Treatment of Irritant Dermatitis: Do They Work? 431
Cheryl Y. Levin and Howard I. Maibach

Chapter 51 Tests for Sensitive Skin 437
Alessandra Pelosi, Enzo Berardesca, and Howard I. Maibach

Chapter 52 Test Methods for Allergic Contact Dermatitis in Animals 443
Georg Klecak

Chapter 53 Test Methods for Allergic Contact Dermatitis in Humans 463
Francis N. Marzulli and Howard I. Maibach

Chapter 54 Allergic Contact Dermatitis: Elicitation Thresholds of Potent Allergens in Humans 469
E. Jerschow, Jurij J. Hostýnek, and Howard I. Maibach

Chapter 55 Allergic Contact Dermatitis to Topical Anesthetics: A Cross-Sensitization Phenomenon 481
Christopher J. Dannaker, Erik Austin, and Howard I. Maibach

Chapter 56 Contact Urticaria and Anaphylaxis to Chlorhexidine: Overview 485
C. Heinemann, R. Sinaiko, and Howard I. Maibach

Chapter 57 Immunoadjuvants in Prospective Testing for Contact Allergens 497
Henry C. Maguire, Jr.

Chapter 58 Local Lymph Node Assay 505

Ian Kimber, Rebecca J. Dearman, Catherine J. Betts, David A. Basketter, Cindy A. Ryan, and G. Frank Gerberick

Chapter 59 Iontophoresis in Humans: Regional Variations in Skin Barrier Function and Cutaneous Irritation 517

Jagdish Singh, Babu Medi, Burt Sage, and Howard I. Maibach

Chapter 60 Contact Urticaria and Contact Urticaria Syndrome (Immediate Contact Reactions) 525

Smita Amin, Arto Lahti, and Howard I. Maibach

Chapter 61 *In Vitro* Approaches to Assessment of Skin Irritation and Phototoxicity of Topically Applied Materials 537

David A. Basketter and Penny A. Jones

Chapter 62 Photoirritation (Phototoxicity) Testing in Humans 547

Francis N. Marzulli and Howard I. Maibach

Chapter 63 Measuring and Quantifying Ultraviolet Radiation Exposures 551

David H. Sliney

Chapter 64 Determination of Subclinical Changes of Barrier Function 561

Véranne Charbonnier, Marc Paye, and Howard I. Maibach

Chapter 65 Assessing Validity of Alternative Methods for Toxicity Testing: Role and Activities of ECVAM 569

Thomas Hartung and Valérie Zuang

Chapter 66 Animal Models of Contact Urticaria 577

Antti I. Lauerma and Howard I. Maibach

Chapter 67 Diagnostic Tests in Dermatology: Patch and Photopatch Testing and Contact Urticaria 581

Smita Amin, Antti I. Lauerma, and Howard I. Maibach

Chapter 68 Cosmetic Reactions 587

Bobeck S. Modjtahedi, Jorge R. Toro, Patricia Engasser, and Howard I. Maibach

Chapter 69 Decreasing Allergic Contact Dermatitis Frequency through Dermatotoxicologic- and Epidemiologic-Based Intervention? 613

Naissan O. Wesley and Howard I. Maibach

Chapter 70 Cutaneous Corticosteroid-Induced Glaucoma 617

Nara Branco, Bruno C. Branco, Joseph Mallon, and Howard I. Maibach

Chapter 71 Evaluating Efficacy of Barrier Creams: *In Vitro* and *In Vivo* Models 621

Hongbo Zhai and Howard I. Maibach

Chapter 72 Light-Induced Dermal Toxicity: Effects on Cellular and Molecular Levels 629
Andrija Kornhauser, Wayne G. Wamer, and Lark A. Lambert

Chapter 73 Failure of Standard Test Batteries for Detection of Genotoxic Activity of Some Chemicals Used in Dermatological and Cosmetic Products 659
Giovanni Brambilla and Antonietta Martelli

Chapter 74 Exogenous Ochronosis: Update 669
Cheryl Y. Levin and Howard I. Maibach

Chapter 75 Diagnostic Patch Test: Science and Art 673
Iris S. Ale and Howard I. Maibach

Chapter 76 Irritant and Allergic Contact Dermatitis Treatment 689
Hongbo Zhai, Angela N. Anigbogu, and Howard I. Maibach

Chapter 77 Factors Affecting Children's Susceptibility to Chemicals 697
Anna Makri, Michelle G. Goveia, and Rebecca Parkin

Chapter 78 Utilization of Irritation Data in Local Lymph Node Assay 707
Peter Ulrich and Hans-Werner Vohr

Chapter 79 Air Bag Injuries 713
Monica Corazza, Maria Rosaria Zampino, and Annarosa Virgili

Chapter 80 Cigarette Smoking and Skin 721
Yung-Hian Leow

Chapter 81 Chemical Analysis of Tattoo Pigments Cleaved by Laser Light 725
Rudolf Vasold, Natascha Naarmann, Heidi Ulrich, Daniela Fischer, Burkhard König, Michael Landthaler, and Wolfgang Bäumler

Chapter 82 Dermatotoxicology of Specialized Epithelia: Adapting Cutaneous Test Methods to Assess Topical Effects on Vulva 733
Miranda A. Farage and Howard I. Maibach

Chapter 83 Anti-Irritants: Myth or Reality? Overview 743
Christina Ford and Howard I. Maibach

Chapter 84 Evaluating Mechanical and Chemical Irritation Using the Behind-the-Knee Test: Review 749
Miranda A. Farage

Chapter 85 Need for More Sensitive Tools as We Reach Limits of Our Ability to Detect Differences in Skin Effects from Mild Products 759
Miranda A. Farage

Chapter 86 Drug Patch Testing in Systemic Cutaneous Drug Allergy 765
Annick Barbaud

Chapter 87 Hormesis and Dermatology 773
Haw-Yueh Thong and Howard I. Maibach

Chapter 88 Diagnosis of Drug Hypersensitivity *In Vitro* 781
Hans F. Merk and D. Hoeller Obrigkeit

Chapter 89 Immunologic Patterns in Allergic and Irritant Contact Dermatitis: Similarities 787
Emi Dika, Nara Branco, and Howard I. Maibach

Chapter 90 Water Decontamination of Chemical Skin and Eye Splashes: Critical Review 795
Alan H. Hall and Howard I. Maibach

Chapter 91 Chemical Substances and Contact Allergy: 244 Substances Ranked According to Allergenic Potency 807
Eva Schlede, W. Aberer, T. Fuchs, I. Gerner, H. Lessmann, T. Maurer, R. Rossbacher, G. Stropp, E. Wagner, and D. Kayser

Chapter 92 Use of Modified Forearm Controlled Application Test to Evaluate Skin Irritation of Lotion Formulations 839
Miranda A. Farage

Chapter 93 Hair in Toxicology 851
Ken-ichiro O'goshi

Chapter 94 Popliteal Lymph Node Assay 865
Guillaume Ravel and Jacques Descotes

Chapter 95 Pigmentation Changes Resulting from Arsenic Exposure 873
Nikolay V. Matveev and Molly L. Kile

Chapter 96 Textiles and Human Skin, Microclimate, Cutaneous Reactions: Overview 881
Wen Zhong, Malcolm M.Q. Xing, Ning Pan, and Howard I. Maibach

Chapter 97 *In Vivo* Human Transfer of Topical Bioactive Drugs among Individuals: Estradiol 891
Ronald C. Wester, Xiaoying Hui, and Howard I. Maibach

Chapter 98 Is There Evidence That Geraniol Causes Allergic Contact Dermatitis? 897
Jurij J. Hostýnek and Howard I. Maibach

Chapter 99 Operational Definition of a Causative Contact Allergen—Study with Six Fragrance Allergens 911
Jurij J. Hostýnek and Howard I. Maibach

Chapter 100 Sodium Lauryl Sulfate-Induced Irritation in Human Faces: Regional- and Age-Related Differences.....919
Slaheddine Marrakchi and Howard I. Maibach

Chapter 101 Classification of Irritant Contact Dermatitis.....923
Ai-Lean Chew and Howard I. Maibach

Chapter 102 *In Vitro* Skin Irritation Testing on SkinEthic™-Reconstituted Human Epidermis: Reproducibility for Fifty Chemicals Tested with Two Protocols.....927
Carine Tornier, Martin Rosdy, and Howard I. Maibach

Chapter 103 Identifying Source of Textile-Dye Allergic Contact Dermatitis: Guidelines.....945
Kathryn L. Hatch, Herbert Motschi, and Howard I. Maibach

Chapter 104 Functional Map and Age-Related Differences in Human Faces: Nonimmunologic Contact Urticaria Induced by Hexyl Nicotinate.....951
Slaheddine Marrakchi and Howard I. Maibach

Chapter 105 Is Contact Allergy Lifelong in Humans? An Overview of Patch-Test Follow-Ups.....955
Ernest Lee and Howard I. Maibach

Chapter 106 Irritants in Combination with Synergistic or Additive Effect on Skin Response: Overview of Tandem Irritation Studies.....959
Francisca Kartono and Howard I. Maibach

Chapter 107 Allergic Contact Dermatitis from Iodine Preparations: A Conundrum?.....967
Simon K. Lee, Hongbo Zhai, and Howard I. Maibach

Chapter 108 Human Skin Buffering Capacity: Overview.....971
Jacquelyn Levin and Howard I. Maibach

Appendix.....981

Index.....985

Preface

Dermatotoxicology—First edition, published in 1977, covered much of the embryonic field in 567 pages.

The seventh edition (2007)—consisting of 108 chapters—summarizes much of the current field, defining what was largely an intuitive science to today's often refined metrics and mechanisms.

Most chapters from previous editions have been revised. New chapters reflect the expanding science. Major areas include pharmacogenetics, racial differences, percutaneous penetration enhancers, sensitive skin, mechanisms of allergic contact dermatitis (ACD) and irritant contact dermatitis (ICD), occupational ACD, mechanisms in cutaneous drug hypersensitivity reactions, OECD guidelines, stratum corneum quantification, Kawai method for testing irritation, tests for sensitive skin, ACD threshold doses, ECVAM, corticosteroid-induced glaucoma, genotoxic activity, exogenous ochronosis, air bag injuries, cigarette and skin, chemical analysis of tattoo, anti-irritant, medical device regulation, diagnosis of drug hypersensitivity, water decontamination, hair in toxicology, textiles and human skin, *in vivo* human transfer of topical bioactive drug, fragrance allergens, ten genotypes of ICD, reconstituted human epidermis, functional map, and skin buffering.

Society (government, the media, the public, and the law) has become increasingly aware of the skin as an important route of systemic exposure to chemicals—adding impetus to the field of dermatotoxicology.

Unfortunately, in spite of the seventh edition's mass, much science was left out—so that editions one through six remain not relics—but sources of relevant information.

Our special thanks go to Patricia Roberson for the meticulous management of this complex volume. We welcome your critiques and suggestions for the eighth edition.

Hongbo Zhai
Klaus-Peter Wilhelm
Howard I. Maibach

Editors

Hongbo Zhai, M.D., is a senior research fellow at the Department of Dermatology in the University of California at San Francisco. He has over two decades of experience in the prevention of contact dermatitis and the development of skin disease-related products. He has contributed to the development of innovative skin-related products in collaboration with many global pharmaceutical and cosmetic companies. He has published more than 100 scientific articles in his research areas. Dr. Zhai is also the 2003 winner of the international "Niels Hjorth Prize."

Klaus-Peter Wilhelm, M.D., is extraordinary professor of dermatology at the University of Lübeck, Germany, and president and medical director of proDERM Institute for Applied Dermatological Research Schenefeld/Hamburg, Germany. He is secretary of the International Society for Bioengineering and the Skin, and a member of several scientific associations and societies. He has published over 100 manuscripts and reviews and coauthored three books in the bioengineering of the skin series. Dr. Wilhelm received an M.D. degree from the Medical University of Lübeck, Germany.

Howard I. Maibach, M.D., is professor of dermatology in the School of Medicine at the University of California, San Francisco. He has several decades of research experience in skin diseases and the development of skin-related products. He has published more than 2000 papers and over 80 textbooks. He is a consultant to government agencies, universities, and industry.

1.1 INTRODUCTION

Pharmacogenetics is the study of genetically determined variations in response to drugs in humans or in laboratory organisms.[1] For the clinician, this concept is relevant when asking why a drug is efficacious for one segment of the population, ineffective for another, and fatal or toxic to a third.[2] The spectrum of effectiveness depends on issues such as compliance, drug availability, proper dosing, and pharmacogenetics.

Considering the role of pharmacogenetics in dermatology, its influence is more commonplace than is probably realized. For example, we see its role even in a small degree in one of the most common reasons for an office visit to a dermatologist: acne. Numerous acne drugs exist, but efficacy rates are variable. The reasons for this are incompletely known: this disease tends to be multifactorial and it is difficult to isolate the purely genetic component.

Pharmacogenetics not only has a role in the efficacy of a drug in the population but also when considering the use of two drugs for a single disease entity. For chronic idiopathic urticaria, both loratadine and cetirizine are considered first-line therapy. Although some may benefit equally from both drugs, one drug or the other may be better for certain individuals due to differing genetic profiles.[3]

Another important area of pharmacogenetics is the concept of drug–drug interactions. This issue has gained increasing notoriety with the well-documented adverse cardiac effects of the antihistamines astemizole and terfenadine. In fact, many commonly used dermatologic drugs, can cause QT prolongation and *torsades de pointes*,[4] include antibiotics such as flouroquinolones, macrolides, and the imidazole antifungal agents. Roos and Merk have summarized important drug interactions in dermatology.[5]

The patients at greatest risk of adverse drug interactions (ADI) were stated by Andersen and Feingold as the following: those with impaired hepatic and renal function, the elderly, those with AIDS (acquired immunodeficiency syndrome), those who are acutely ill, those using prescriptions from several physicians, and those suffering from polypharmacy.[6]

What follows next are the classes of commonly encountered medications used in dermatology where pharmacogenetics plays an important role in its efficacy and safety.

1.2 AZATHIOPRINE

Advances have been made in understanding pharmacogenetics in the use of azathioprine in dermatology.[7] Eleven percent of the population has low thiopurine methyltransferase (TPMT) activity and is vulnerable to myelosuppression with azathioprine treatment.[8] Furthermore, one in 300 individuals has undetectable TPMT activity, and is susceptible to rapid-onset, prolonged, life-threatening pancytopenia if treated with conventional doses of azathioprine.[9] For over 40 years, azathioprine has been extensively used as an immunosuppressant. Most frequently it is used for the immunobullous disorders but occasionally for atopic dermatitis[10] also as a corticosteroid-sparing adjunctive therapy.[11] Much of the drug's pharmacokinetic and phamacodynamic characteristics are incompletely characterized despite widespread clinical experience. Most are aware of inactivation of 6-mercaptopurine (6-MP), the major azathioprine metabolite, by xanthine oxidase and the potential interaction with allopurinol, a xanthine oxidase inhibitor. However, fewer note the other routes of 6-MP metabolism and their relevance to toxicity and therapeutic response to azathioprine: namely TPMT and hypoxanthine-guanine phosphoribosyl transferase, which

Modified by permission of Edizioni Minerva Medica from *Giornale Italiano di Dermatologia e Venereologia*, 136(4), 249–252, 2001.

produce several active toxic thiopurine metabolites including 6-thioguanine nucleotides (6-TGN).

Objective evidence to support azathioprine efficacy is largely uncontrolled in nature: a search revealed two large, randomized, controlled studies that have attempted to evaluate efficacy in atopic dermatitis,[12,13] one for chronic actinic dermatitis,[14] one for bullous pemphigoid[15] and none for pemphigus vulgaris. The data on atopic dermatitis did support a role for azathioprine in the treatment of otherwise treatment-resistant disease. Of note is the study by Meggitt et al.,[12] who performed their study with dosing based on TPMT activity: patients with normal TPMT activity received 2.5 mg/kg/day of azathioprine whereas those with decreased TPMT activity received 1 mg/kg/day. There was a similar response to therapy in both groups of patients receiving azathioprine and no myelotoxicity was reported in the five azathioprine recipients with heterozygous TMPT activity. In the trial for chronic actinic dermatitis, marked improvement in the clinical status of actively treated patients led to early termination of the trial and the conclusion that oral azathioprine therapy is an effective and usually well-tolerated treatment in chronic actinic dermatitis. There was no consideration of differing enzyme levels between patients in this trial.

The data in the bullous pemphigoid trial did not support the dogma of a corticosteroid-sparing effect with azathioprine in bullous pemphigoid, but failure to consider the impact of interpatient variability on azathioprine metabolism and the adoption of a fixed-dosage regimen led to underdosage of some patients.[16] There is a need for adequately powered, prospective studies to determine efficacy and safety of azathioprine in pemphigoid and pemphigus. This should include measurement of the patient's TPMT activity and the regular monitoring of 6-TGN levels to confirm compliance and detect underdosage and toxicity. Enzyme levels need to be determined before dosing to avoid underdosing or toxicity, as well as monitoring adherence.

1.3 DAPSONE AND CYCLOSPORINE

Singer et al. review the interactions of cytochrome P-450 3A with dermatologic therapies.[17] Dapsone is one mainstay of dermatology whose metabolism is by the P450 3A class of hepatic microsomal enzymes. This drug has many uses, but in dermatology, it is used mostly in Hansen's disease (leprosy) and dermatitis herpetiformis. When concurrently used with rifampin, a P4503A inducer, it may result in as much as a 7–10-fold decline in dapsone levels. Dosage adjustments may be required in the treatment of such diseases as *Pneumocystis carinii* pneumonia, but not during concurrent rifampin therapy for leprosy because dapsone concentrations are still higher than the minimum inhibitory concentration.[18] Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency may have profound hemolysis during sulfone, dapsone, or sulfapyridine therapy, and those at risk of having the deficiency (blacks, Asians, and those of Mediterranean descent) should have a G6PD level ordered before starting therapy.[19]

Cyclosporin A is also a substrate for P450 3A. Therefore any drug that inhibits or induces this enzyme system can affect drug levels. Inducers P450 3A include the anticonvulsants carbamazepine, phenobarbital, phenytoin, the antituberculous agents rifampin and isoniazid, and drugs such as clotrimazole, griseofulvin, phenylbutazone, and dexamethasone.[20] Confirmed inhibitors include ketoconazole,[21] diltiazem, verapamil, progestrone, and the erythromycins.[22]

1.4 ANTIHISTAMINES

An important drug class with adverse interactions is the antihistamines, though these interactions are more significant from a historical perspective as terfenadine and astemizole have now largely been withdrawn from the market for pretreatment of chronic urticaria. Like loratadine, terfendaine and astemizole are metabolized by the major human liver enzyme, CYP3A4. Any drug that induces or inhibits this enzyme can affect drug levels. When these aforementioned medications were still on the market, the concurrent administration of terfenadine or astemizole with erythromycin, itraconazole, or ketoconazole had the potential to cause life-threatening ventricular arrhythmias such as *torsade de pointes*.[23] Cimetidine also has the potential to interact with the various drugs that use the P-450 metabolic pathway. By inhibiting this pathway, it can cause increased and potentially dangerous levels of warfarin, imiprimine, phenytoin, and theophylline.[24,25]

1.5 ANTIFUNGALS

Bickers summarized the potential interactions of antifungals with other classes of drugs.[26] Itraconazole is used for many molds such as *Aspergillus*, yeasts, and dermatophytes. Essentially, as a P450 3A3/4 inhibitor, any drug that uses this metabolic pathway is affected. Along with fluconazole and ketoconazole, it can increase levels of astemizole, cisapride, cyclosporin, dapsone, erythromycin, tacrolimus, and terfenadine.

Amphotericin B binds sterols in the fungal membrane. It is produced by *Streptomyces nodosus* as an amphoteric polyene macrolide. Its most common adverse effect is nephrotoxicity from an increased excretion of potassium leading to hypokalemia and renal tubular acidosis.[27] Because of this potential, this drug can further exacerbate hypokalemia caused by corticosteroids and digitalis glycosides.[28] Amphotericin B may also act synergistically with flucytosine by augmenting fungal membrane penetration.[29] The newer oral antifungal agent terbinafine has important drug interactions with caffeine, cimetidine, cyclosporine, nortriptyline, rifampin, theophylline, and warfarin.[30]

1.6 ANTIBIOTICS

Some macrolides and fluoroquinolones inhibit hepatic enzymes. P450 enzymes are inactivated by erythromycin[31] and can cause high levels of benzodiazepines, warfarin, cyclosporin A, and

theophylline on coadministration. Clarithromycin has fewer interactions and azithromycin does not seem to cause adverse drug interactions with the above.[32] With fluoroquinolones, important drug interactions include antacids, iron, sucralfate, cimetidine, caffeine, cyclosporine, hydantoins, anticoagulants, and theophylline.[33] For example, seizures and other important interactions have been reported with theophylline.[34] However, each drug within this class has its own safety profile. While enoxacin and ciprofloxacin inhibit some hepatic cytochrome P-450s, ofloxacin has little or no effect on theophylline clearance.[35]

Of the tetracyclines, P-450 enzymes metabolize only doxycycline.[36] Therefore, enzyme inhibitors or inducers will affect it. Tetracyclines may cause digitalis toxicity by interacting with digoxin possibly through effect on the bowel flora.[37] Coadministration of minocycline and amitriptyline may accelerate cutaneous pigmentation.[38]

Potential ADIs with antibiotics and oral contraceptives are of great relevance in dermatologic practice. The enterohepatic circulation of contraceptive steroids can be interfered with by antibiotic effects on bacterial flora in the bowel, and lower serum levels of the contraceptives can result. Some have suggested increasing the estrogen component of the pill to 50 μg or adding other forms of birth control for the duration of antibiotic therapy.[39] However in practice, the failure of oral contraceptives with oral antibiotics is low.[40] In fact, a recent review of the literature suggests that there is little convincing evidence to show a systematic interaction between antibiotics and oral contraceptives other than rifampin.[41]

1.7 CONCLUSION

Pharmacogenetics is and will continue to be an important concept in clinical medicine. Its importance in dermatology is reflected in the increasing number of articles being written on this subject. We refer to reviews by Lowitt and Shear[42] or Ameen et al.[43] for further reading. In addition, websites exist that summarize important P450 drug interactions.[44] We provide a detailed evidence-based description of this literature—in a manner that permits the health care provider the tools to understand what is and is not known. Dermatology, with its numerous drug therapies, will certainly intertwine with pharmacogenetics as it researches and develops its pharmacologic arsenal.

2.1 INTRODUCTION

Ethnic differences in skin properties may explain disparities seen in dermatologic disorders and provide insight into appropriate differences in the management of these disorders. However, ethnic differences in skin have been minimally investigated by objective methods and the data are often contradictory. The current experimental human model for skin is largely based upon physical and biochemical properties known about Caucasian skin. Thus, anatomical or physiological properties in skin of different races that may alter a disease process or treatment of that disease are not being accounted for.

Early studies show similarities in black and white skin. For example, Thomson[77] and Freeman et al.[27] conclude that the stratum corneum (SC) is of equal thickness in blacks and whites. However, in 1974, Weigand et al.[85] demonstrated a difference in black and white skin with regard to a variable other than color. They demonstrated that the SC of black skin contains more cell layers and black skin requires more cellophane tape strips to remove the SC than white skin. Greater variability in the number of tape strips used within the black subject pool was also found, compared with the white subject pool, but this variability was not correlated with degree of skin pigmentation. The mechanisms behind greater intercellular adhesion among black individuals may involve lipids,[10] because the lipid content of the SC ranges from 8.5 to 18.4%, with higher values in blacks.[61] Since SC thickness is believed to be equal,[87] the data reflected greater intercellular adhesion among the black individuals.[85] Recently developed quantitative techniques for determining SC mass are yet to be utilized for this purpose.[24]

While Weigand et al.[85] objectively demonstrated a different physical property in black and white skin, some other studies demonstrating differences used more subjective methods. For example, erythema has been used as a measure of demonstrating skin irritation.[6,46,85] Since erythema is difficult

Adapted from NO Wesley and HI Maibach, Racial (ethnic) differences in skin properties: the objective path, *American Journal of Clinical Dermatology*, 4(12), 843–860, 2003. With permission.

to assess in a person with dark skin, such subjective methods are not sufficient in evaluating ethnic disparities. Thus, to accurately report ethnic differences in skin properties, objective methods should be utilized. Objective measurements that have been studied are transepidermal water loss (TEWL), water content (WC) (via conductance, capacitance, resistance, and impedance), corneocyte variability, blood vessel reactivity, elastic recovery/extensibility, pH gradient, lipid content, surface microflora, electron microscopy and immunoelectron microscopy of mast cell granules, confocal microscopy of epidermal innervation, microtopography, sebaceous function, vellus hair follicle distribution, morphology and distribution of melanosomes, and resistance to photodamage.

Given the increasing ethnic diversity in the United States, it is essential to clarify relationships among race, color, ethnicity, and disease process. Even though these objective methods have been used to compare skin of different races, the data that exist remain minimal. Additionally, the data are often confusing and difficult to interpret. We explore and attempt to clarify the objective data available in differentiating skin properties of different races. Objective definitions of skin color are yet to be established. We introduce certain objective differences that have been established to date. We searched MEDLINE®, MD Consult, Science Citations Index, the Melvyl Catalogue in the CDL-Hosted Database of University of California, San Francisco, California, Yahoo, Google, standard dermatology textbooks, and University of California, San Francisco, California surge building library files from 1967 to August 2006. Keywords in searches included words pertaining to race (i.e., race, ethnicity, black, African, white, Caucasian, Asian, Hispanic) and dermatology (i.e., skin, skin physiology, skin function). The references of each study were then reviewed for other studies that examined ethnic differences with objective methods. Studies pertaining to ethnic differences in hair were excluded to keep the review focused on skin function/physiology. Words used to describe race/ethnicity of study individuals are the same as those used by the authors in the respective texts.

2.2 TRANSEPIDERMAL WATER LOSS

One role of the skin is to maintain an effective barrier against loss of body fluids and absorption of externally applied substances.[54] The total amount of water vapor passing the skin can be divided into water vapor passing the SC by passive diffusion and water vapor loss as a result of sweating.[66] Baseline water diffusion (imperceptible or unnoticed perspiration) amounts to 2.25 $\mu L/m^2$/sec and is distinct and separate from sweat gland secretion.[41] Originally, the term TEWL was used to indicate the amount of water vapor passing through the SC by passive diffusion.[66] Current literature, however, refers to TEWL as the total amount of water vapor loss through the skin and appendages, under nonsweating conditions.[66] Therefore, note that TEWL is a true reflection of SC barrier function only when there is no sweat gland activity. In addition to characterizing the water barrier function of skin, measurement of TEWL has been utilized widely in studies to perform predictive irritancy tests and to evaluate the efficacy of therapeutic treatments on diseased skin.[23] To date, TEWL is the most studied objective measure in defining differences between the skin of different ethnicities.

Wilson et al.[87] demonstrated higher *in vitro* TEWL values in black compared with white skin. Water evaporation measured from skin taken from 10 African-American and 12 Caucasian cadavers matched for age and gender was then converted into TEWL using an equation. In addition to finding differences in black and white skin physiology, the investigators also found that the TEWL of both races increased with skin temperature. These results were explained on the basis of a prior *in vivo* study from 1941 showing that blacks had a lower skin and rectal temperature during exercise.[65] Thus, in maintaining equal temperatures between black and white skin, they concluded that it would be expected that black skin would have a greater rise in temperature to achieve the same endpoint temperature and therefore a higher TEWL.[87] Although comparisons between *in vitro* and *in vivo* studies are frequently made in medicine, note that the *in vitro* study may not have accounted for some physiological functions, such as sweating. Also, accounting for physiologic temperature differences by race in skin may be difficult in an *in vitro* study. Since TEWL depends on passive water vapor loss, and based on laws of physics regarding passive diffusion, the rate of water vapor diffusion across the SC is theoretically directly related to the ambient relative humidity and temperature,[5] then, it is reasonable to assume that the increased TEWL in black skin is associated with an increase in temperature if, in fact, a difference in black and white skin temperature does exist.

A subsequent *in vivo* study by Berardesca and Maibach[7] supported the findings of the *in vitro* study. The investigators determined the difference in irritation between young black and white skin. They applied 0.5 and 2.0% sodium lauryl sulfate (SLS), a water-soluble irritant (surfactant), to untreated, preoccluded, and predelipidized skin and quantified the resulting level of irritation using WC, TEWL, and laser Doppler velocimetry (LDV) of the SC. No statistical difference was found in irritation between the two groups based on WC and LDV, however, a statistical difference in the TEWL results of 0.5% SLS applied to the preoccluded skin was found. In that test, blacks had 2.7 times higher TEWL levels than whites ($p < 0.04$), suggesting that blacks in the preoccluded state are more susceptible to irritation than whites. This theory opposes the traditional clinical view, based on observing erythema,[6] that blacks are less reactive to irritants than whites.

Berardesca and Maibach[8] used the same model to compare differences in irritation between Hispanic and white skin. Although there were no significant differences in TEWL, WC, or LDV between the groups at baseline, the data showed higher values of TEWL for Hispanics compared with whites after SLS-induced irritation. However, these values were not statistically significant. The investigators noted that the reaction of Hispanic skin to SLS resembles that of black skin when irritated with the same substance.[7] Since skin

pigmentation varies greatly within the Hispanic and black communities, the degree of skin pigmentation, according to Fitzpatrick's model,[25] could represent an important variable.

However, in a later study, Berardesca et al.[12] found no significant difference *in vivo* in TEWL between race or anatomic site for baseline observation. The investigators examined 15 blacks, 12 whites, and 12 Hispanics to account for degree of skin pigmentation, matched for age and gender, and measured TEWL, WC (via skin conductance), skin thickness, and biomechanical properties, such as skin extensibility, at two sites, the dorsal and volar forearm. Skin sites that vary in sun exposure were used to highlight the protective effects of melanin from ultraviolet (UV)-induced damage. Ethnic differences in skin conductance (blacks $>$ whites) and skin elasticity were found and are discussed in Sections 2.3 and 2.6. However, even though the investigators expected a higher TEWL in blacks, based on previous studies[7,87] and based on a higher WC (skin conductance) in blacks found in their current study, no significant difference in TEWL was found between races or anatomic sites. They accounted for the higher WC in black skin with no ethnic differences in TEWL on the basis that black skin might have increased intercellular cohesion[85] and increased lipid content[61] keeping the water in.

In contrast, Kompaore et al.[39] found significantly higher TEWL values in blacks and Asians compared with whites. After the application of methyl nicotinate (a vasodilator), the investigators evaluated TEWL and lag time to vasodilatation by LDV, before and after removal of the SC by tape stripping. The participants were seven black men, eight white subjects (six male and two female), and six Asian men all living in France, aged 23–32 years, without skin disease. Before tape stripping, TEWL was 1.3 times greater in blacks and Asians compared with whites ($p < 0.01$); no difference was found between blacks and Asians. After 8 and 12 tape strips, TEWL values were highest in Asians overall (Asians 1.7 times greater than whites) ($p < 0.05$). The investigators concluded that, similar to previous studies,[7,87] skin permeability measured by TEWL was higher in blacks than in Caucasians. However, they also concluded that Asian skin had the highest permeability among the groups studied. Although the methods of this study were impressive and well documented, this finding has not yet been duplicated.

Sugino et al.[70] (abstract only) also included Asians in their study but found that baseline TEWL was, in decreasing order, blacks $>$ Caucasians $>$ Hispanics $>$ Asians. Aramaki et al.[3] compared TEWL, SC hydration, sebum secretion, laser Doppler flowmetry, content of melanin, and erythema on forearm at baseline and after SLS-induced irritation in 22 Japanese women (mean age 25.84 years) and 22 German women (mean age 26.94 years). There were no significant differences in TEWL between Japanese and German women before or after SLS stress. Another study (unpublished data) referenced in a review article[88] about Asian skin, compared TEWL in Asians and Caucasians and also found no statistically significant differences at baseline or after tape stripping; however, no vasoactive substance was applied.

In an attempt to compare degree of skin pigmentation as opposed to race, Reed et al.[59] compared 7 subjects with skin types V and VI (4 African Americans, 2 Filipinos, and 1 Hispanic) to 14 subjects with skin types II and III (6 Asians and 8 Caucasians). The investigators used TEWL to assess the ability of the SC to withstand or recover from insults to the epidermal permeability barrier (i.e., tape stripping). Subjects with skin type V/VI required more tape strippings (66.7 ± 6.9) compared to skin type II/III (29.6 ± 2.4) to achieve the same TEWL, i.e., skin type V/VI had increased barrier strength (integrity). These findings correlate with those of Weigand et al.[85] that black skin has more cell layers and increased intercellular adhesion. Furthermore, it was also found that water barrier function (measured by TEWL) in skin type V/VI recovered more quickly. This study demonstrated differences in SC barrier function as measured by TEWL between different skin types possibly independent of race. Since the sample size with skin types V and VI was small, further studies with larger sample sizes should be conducted to support these findings.

Warrier et al.[83] recognized the discrepancies in data comparing skin of blacks and whites. Thus, in an attempt to clarify the data, the investigators studied TEWL, electrical capacitance, skin pH, elasticity, dryness/scaling, and skin microflora in 30 black and 30 white women, aged 18–45 years. In contrast to all previous studies which found an increase in TEWL in blacks compared with whites,[7,39,87] Warrier et al.[83] found TEWL to be significantly lower on the cheeks (20% less) and legs (17% less) in blacks compared with whites ($p < 0.05$). TEWL was also lower on the forearms in blacks, but this was not statistically significant. Prior studies examined the forearm, inner thigh, and back. Does the anatomic site act as a confounding variable in obtaining TEWL values? In a study on Caucasian subjects, TEWL values of the posterior auricular and forehead SC were higher than SC of the arm, forearm, or the abdomen.[67] Thus, perhaps there are also differences in TEWL when comparing the sites examined (cheeks and lower legs) by Warrier et al.[83] to those of prior studies (forearm, inner thigh, and back).[7,8,12,39,87] Although this study used a larger sample size, the discrepancy in data warrants further studies with large sample sizes and comparisons of various anatomic sites.

Berardesca et al.[11] examined differences in TEWL as well as pH in 10 Caucasian (skin types I and II) and 8 black African-American (skin type VI) women at baseline and after tape strippings. TEWL increased for both races with each tape stripping. Interestingly, even though black women had a higher TEWL at baseline and after each tape stripping compared with Caucasian women, the differences were only statistically significant (1.2 times greater) after three ($p < 0.05$) and six ($p < 0.03$) tape strips. Similar to the study by Reed et al.,[59] it was also found that recovery of water barrier function, as measured by TEWL 48 h after stripping, was greater in blacks as compared with Caucasians, but the difference was not statistically significant.

Tagami[74] provided additional information on Asian skin by comparing TEWL between 120 Japanese and 322 French

women, aged 20–70 years. The skin type of the French women was not specified. His research team measured TEWL on cheeks and midflexor surface of forearms of all subjects, under the same environmental conditions. Although, TEWL was lower in Japanese women, the data were not statistically significant. These findings further supported those of Aramaki et al.[3]

Hicks et al.[33] grouped patients on the basis of skin color (Fitzpatrick skin type), as in Reed et al.,[59] in studying the difference between susceptibility of black and white skin to irritant contact dermatitis (ICD). The 14 participants were grouped as 8 whites (skin types II/III) and 6 blacks (skin types V/VI), between the ages of 18 and 40 years. The skin on the volar forearm was exposed to 4 and 1% SLS and evaluated by reflectance confocal microscopy, TEWL, laser Doppler velocimetry, and routine histology at 6, 24, and 48 h after initial application. Changes in TEWL and SC thickness after exposure to 4% SLS at 48 h were negatively correlated in both groups. White participants showed a trend toward greater mean increases in TEWL after SLS exposure than black participants, supporting the possibility that the barrier function in black skin is more durable than white skin, but the differences were not statistically significant. Overall, results from all methods of evaluation suggested reduced susceptibility of black skin to ICD. However, while there was no significant difference between SC thickness of control sites in both groups (consistent with Weigand et al.), the SC thickness was significantly less in blacks as compared to whites after exposure to 4% SLS at 48 h ($p < 0.05$). This pattern of SC thinning seems to contradict the findings of reduced susceptibility of black skin to ICD. A larger sample size may be necessary to clarify this discrepancy and achieve a statistically significant trend in TEWL changes.

In another evaluation of differences between African American and white skin, Grimes et al.[29] did not find significant differences in TEWL *in vivo*. The subjects consisted of 18 African American and 19 white adults between the ages of 35 and 65, with a subset of 8 (3 black, 5 white) participating in chemical challenge of 5% SLS. Methods of evaluation included clinical evaluation and instrumental measurements of sebum level, pH, moisture content, and TEWL. Although there were differences in visual assessment of photoaging and hyperpigmentation, the baseline instrumental findings from all methods indicated no significant differences between African American and white skin. Within 6 h of irritation, there was a significant change in TEWL in white participants; however, after 24 h, TEWL in both groups was similar. Owing to the small sample size of the chemical challenge subset, statistical analysis on these data was not performed. The overall findings of this study support the postulation that, objectively, there is little difference between African American and white skin. However, again based on small sample size, it is difficult to make definitive conclusions based on the data.

Pershing et al.[53] found a significant difference in TEWL between Caucasians and Asians with topical application of capsaicinoids. The study measured TEWL, skin surface temperature, and erythema after application of various capsaicinoid analogs at various concentrations on volar forearms of six Caucasians and six Asians, aged 19–63 years. The results were baseline adjusted, control site-corrected over time for each parameter to normalize data for inherent differences among skin sites. Increasing concentrations of total capsaicinoid were not associated with a proportional change in TEWL in either Caucasians or Asians. However, a capsaicinoid concentration of 16 mg/mL produced statistically less TEWL in Asians than Caucasians ($p < 0.05$); specifically, there was an increase of the mean TEWL in Caucasians but a decrease in Asians. The investigators concluded that changes in TEWL between Caucasians and Asians with capsaicinoids, but not irritants (such as SLS in Aramaki et al.[18]), may reflect the effect of vehicle composition (isopropyl alcohol for capsaicin versus water for irritants) or other physiologic skin functions (such as cutaneous blood flow) in determining TEWL.

Astner et al.[4] evaluated ethnic variability in skin response to a household irritant (Ivory dishwashing liquid) by applying the irritant to the anterior forearms of 15 Caucasian subjects and 15 African-American subjects. The investigators observed significantly higher mean values for TEWL in Caucasians compared to African Americans ($p \leq 0.005$) like Warrier et al. had found previously. The 30 participants were patch tested to graded concentrations of Ivory soap and evaluated with clinical scoring, reflectance confocal microscopy, TEWL, and fluorescence excitation spectroscopy. There was a positive, dose-dependent correlation between TEWL values and irritant concentration in all groups. However, not only was the mean TEWL higher in Caucasians, but the relative increment of increase in response to the graded irritant concentrations were also higher in Caucasians when compared to African Americans ($p \leq 0.005$). The researchers suggested the lower values of TEWL in African Americans in this study may reflect the greater intercellular cohesiveness in African-American skin (Weigand et al.[84]).

While the data regarding TEWL (summarized in Table 2.1) are conflicting, the overall evidence, except for the 1991 study by Berardesca et al.,[12] and later, the studies by Hicks et al.[33] and Grimes et al.,[29] supports some difference between black and Caucasian skin. Most studies using the forearm, back, and inner thigh[7,11,39,59,70,87] showed a greater TEWL in blacks compared with whites; however, the only study that used a larger sample size, by Warrier et al.,[83] found TEWL to be less in blacks than whites when measured on the cheeks and legs. In addition, like Warrier et al., a smaller study by Astner et al.,[4] found the mean TEWL on forearms of whites to be greater than those on blacks after irritant stress. Perhaps, the anatomic site examined causes discrepancies in TEWL values. Also, TEWL measurements with regard to Asian skin may be deemed inconclusive as baseline measurements have found Asian skin to have TEWL values that are equal to black skin and greater than Caucasian skin,[39] less than all other ethnic groups,[70] and no different than other ethnic groups.[3,74,88] Additionally, Pershing et al.[53] found an increase in TEWL of Caucasians but a decrease in TEWL of

TABLE 2.1
Transepidermal Water Loss (TEWL)[a]

Study	Technique	Subjects	Site	Results
Wilson et al.[87]	*In vitro*	Blacks 10 (mean age 38.6 y) Caucasians 12 (mean age 41.1 y)	Inner thigh	• TEWL blacks 1.1× > Caucasians (mean corrected log TEWL 2.79 and 2.61 μg/cm²/h, respectively) ($p < 0.01$ for both values)
Berardesca et al.[7]	*In vivo*—topical application of SLS (irritant)	Black men 10 (age 29.9 ± 7.2 y) White men 9 (age 30.6 ± 8.8 y)	Back	• No significant difference in TEWL between blacks and whites at baseline **After SLS stress** • TEWL blacks (untreated, preoccluded, and predelipidized) > whites but only statistically significant (2.7× greater) for 0.5% SLS applied in the preoccluded area ($p < 0.04$)
Berardesca et al.[8]	*In vivo*—topical application of SLS (irritant)	Hispanic men 7 (age 27.8 ± 4.5 y) White men 9 (age 30.6 ± 8.8 y)	Upper back	• No significant differences in TEWL between Hispanics and whites at baseline **After SLS stress** • TEWL Hispanics (untreated, preoccluded, and predelipidized) > whites, but not statistically significant
Berardesca et al.[12]	*In vivo*	Blacks 15 (mean age 46.7 ± 2.4 y) Whites 12 (mean age 49.8 ± 2 y) Hispanics 12 (mean age 48.8 ± 2 y)	Volar and dorsal forearm	• No significant difference in TEWL between site or ethnicity at baseline
Kompaore et al.[39]	*In vivo*—topical application of MN-vasodilator	Blacks 7 Caucasians 8 Asians 6 (age 23–32 y, all)	Volar forearm	**MN given before tape stripping** • TEWL blacks and Asians 1.3× > Caucasians ($p < 0.01$); no difference between blacks and Asians **After 8 and 12 tape strips** • TEWL Asians > blacks > Caucasians ($p < 0.05$) (Asians 1.7× greater than Caucasians)
Sugino et al.[70]	*In vivo*	Blacks, Caucasians, Hispanics, Asians (no. of subjects, ages not specified)	Not documented	• Baseline TEWL blacks > Caucasians ≥ Hispanics ≥ Asians
Reed et al.[59]	*In vivo*	Skin type V/VI: African American 4 Filipino 2 Hispanic 1 Skin type II/III: Asian 6 Caucasian 8 (age 22–38 y, all)	Volar forearm	• Skin type V/VI required more tape strippings (66.7 ± 6.9) compared to skin type II/III (29.6 ± 2.4) to achieve the same TEWL, i.e., skin type V/VI had increased water barrier strength (integrity) • Barrier function in skin type V/VI recovered more quickly
Warrier et al.[83]	*In vivo*	Black women 30 White women 30 (age 18–45 y, all)	Left and right medial cheeks, midvolar forearms, lateral midlower legs	• TEWL blacks < whites on cheeks (20% less) and legs (17% less) at baseline ($p < 0.05$); also lower on forearm but not statistically significant
Berardesca et al.[11]	*In vivo*	Black women 8 Caucasian women 10 (mean age 42.3 ± 5 y, both)	Midvolar forearm	**After tape stripping** • TEWL blacks 1.2× > Caucasians after 3 ($p < 0.05$) six tape strips ($p < 0.03$)
Aramaki et al.[3]	*In vivo*—topical application of SLS (irritant)	Japanese women 22 (mean age 25.84) German women 22 (mean age 26.94)	Forearm	• No significant difference at baseline or after SLS stress
Tagami[74]	*In vivo*	Japanese women 120 French women 322 (age 20–70 y, all)	Cheeks and midflexor forearm	• TEWL Japanese < whites but not statistically significant

TABLE 2.1 (continued)
Transepidermal Water Loss (TEWL)[a]

Study	Technique	Subjects	Site	Results
Hicks et al.[33]	*In vivo*—topical application of 1 and 4% SLS (irritant)	White: Skin Type II 6 Skin Type III 2 Black: Skin Type V 5 Skin Type VI 1 (age 18–40 y, all)	Volar forearm	• TEWL whites > blacks but not statistically significant
Grimes et al.[29]	*In vivo*—topical application of 5% SLS (irritant)	African American 18 White 19 (age 35–65 y, women, all) SLS stress: African American 3 White 5	Inner forearm	• Baseline: No significant difference • After SLS stress: Immediate increase in TEWL of white subjects, but increase no longer evident after 24 h and found to be similar to African Americans (not statistically significant)
Pershing et al.[53]	*In vivo*—topical application of capsaicinoid analogs	Caucasians: Male 3 Female 3 Asians: Male 3 Female 3 (age 19–63 y, all)	Volar forearm	• Increasing concentrations of total capsaicinoid not associated with proportional change in TEWL, in all subjects. • Capsaicinoid concentration of 16 mg/mL produced ↑ mean TEWL in Caucasians, ↓ mean TEWL in Asians ($p < 0.05$)
Astner et al.[4]	*In vivo*—topical application of Ivory soap (irritant)	Caucasians 15 (Skin type II/III) African Americans 15 (Skin type V/VI) (age 18–49 y, all)	Anterior forearm	• Positive dose-dependent correlation between TEWL and irritant concentration: Mean TEWL Caucasians > African Americans ($p \leq 0.005$) • Relative increment of increase in TEWL after irritant: Caucasians > African Americans ($p \leq 0.005$)

Note: MN = methyl nicotinate; SLS = sodium lauryl sulfate; y = years.

[a] All of the evidence supports TEWL blacks > whites, except for Berardesca et al.,[12] Hicks et al.,[33] and Grimes et al.[29] who all found no significant difference; and Warrier et al.[83] and Astner et al.[4] who found blacks < whites. TEWL measurements of Asian skin are inconclusive as they have been found to be equal to black skin and greater than Caucasian skin (Kompaore et al.[39]), equal to Caucasian skin (Aramaki et al.[3] and Tagami[74]), and less than all other ethnic groups (Sugino et al.[70]). Pershing et al.[53] found an increase in TEWL of Caucasians but a decrease in TEWL of Asians in response to high concentrations of topical capsaicinoids.

Asians in response to high potency capsaicinoids, the results of which are difficult to categorize.

If water barrier function truly depends on degree of pigmentation, this has implications as to whether the SC gains or loses barrier integrity in cases of acquired hyper- or hypopigmentation. Further, differences in barrier integrity/function, as measured by TEWL, also has implications in the ability of people with different skin types and colors to withstand and recover from environmental insults as well as the ability to absorb topical therapeutic agents. Furthermore, TEWL may vary under different pathologic and physiologic conditions. Thus, the health and physiologic state of the subjects should be noted in future studies.

2.3 WATER CONTENT

WC or hydration of the skin can be measured by several methods including skin capacitance, conductance, impedance, and resistance. The use of capacitance to measure WC is based on the high dielectric constant of water compared with other substances.[22] Conductance is also based on the changes in the electrical properties of the SC when the skin is hydrated.[79] Dry SC is a medium of weak electrical conduction, while hydrated SC is more sensitive to the electrical field.[22] Resistance is the reciprocal of conductance. In general, skin capacitance and conductance show similar behavior with regards to measuring WC of the skin, while resistance and impedance are opposite. Possible sources of error or variation in measurement include sweat production, filling of the sweat gland ducts, the number of hair follicles, the electrolyte content of the SC, and artifacts from applied topical agents.[79]

In 1962, Johnson and Corah[34] found that blacks had higher levels of skin resistance at baseline than whites ($p < 0.01$) at two different laboratories in St. Louis, Missouri and San Diego, California. The St. Louis study examined 174 children

(22 black boys, 32 black girls, 65 white boys and 55 white girls), aged 83–92 months, while the San Diego study examined 42 subjects (16 black men, 5 black women, 16 white men, and 5 white women), mean age 23 years. While the investigators in this study did not correlate their measurements of skin resistance to WC in the skin, knowing the relationship of skin resistance to WC, we can deduce that a higher resistance in blacks may be correlated with a lower WC.

In addition to comparing TEWL, Berardesca and Maibach also compared WC by capacitance before and after topical administration of SLS in blacks and whites, and in another study, in Hispanics and whites.[7,8] There were no significant differences in WC between blacks and whites at baseline or after SLS stress.[7] In comparing Hispanics and whites, there was an increase in WC in Hispanics at baseline, but the difference was not significant; however, after SLS application, they found a significant increase in WC in Hispanics compared with whites when a negative visual score (i.e., no erythema) was given for irritation ($p < 0.01$).[8] In reviewing the data, however, we found that although the mean values for WC in Hispanics were greater than in whites, the standard deviations were also large. When an irritant reaction was visually detectable, the WC was proportionally increased in both races, eradicating a difference between them.

Berardesca et al.[12] examined WC by conductance on the volar and dorsal forearm of 15 blacks, 12 whites, and 12 Hispanics in addition to examining TEWL, skin thickness, and extensibility. Within each race studied, significant differences existed in WC between the volar and dorsal forearms (Table 2.2). Whites and Hispanics demonstrated decreased WC on the dorsal aspect of each arm compared with the volar side (22% less and 11% less, respectively), whereas blacks demonstrated a 13% decrease in WC on the volar aspect compared with the dorsal side. The differences, however, were statistically more relevant for white skin ($p < 0.001$) and less for blacks ($p < 0.02$) and Hispanics ($p < 0.05$). In comparing the races with each other, blacks and Hispanics had increased WC compared with whites on the dorsal forearm. On the volar forearm, however, Hispanics demonstrated greater WC than blacks and whites. Their findings do not correlate with those of the prior studies; however, this study measured WC at baseline using conductance, whereas the prior studies measured WC at baseline using resistance,[34] and at baseline and after SLS stress using capacitance.[7,8] The variability in WC observed between site and race are difficult to interpret. The investigators noted, however, that the white subjects had an increased amount of hair on the forearms compared with the other two groups, possibly accounting for some differences in the results.

Sugino et al.[70] measured WC with an impedance meter in blacks, whites, Hispanics, and Asians. They found that WC was highest in Asians compared with Caucasians, blacks, and Hispanics. The exact values and study size were not documented. The investigators correlated high WC with high ceramide and low TEWL values also measured in their study.

Warrier et al.[83] examined WC by capacitance at baseline in 30 black and 30 white women, aged 18–45 years. Black women had a significantly higher WC on the cheeks ($p < 0.05$), but there were no significant differences at baseline between blacks and whites on the forearms and the legs. They proposed that the difference found on the cheeks might be related to evidence of more elaborate superficial vasculature and more apocrine and mixed eccrine–apocrine glands in facial skin of blacks,[48] as well as on differences in melanin content, the packaging of melanocytes, and their ability to prevent epidermal photodamage.[26,35,49]

Manuskiatti et al.[45] studied seven black and five white women (mean age 25.8 ± 4.2 years) and five black women and five white women (mean age 64.7 ± 3.8 years) and measured WC (by capacitance) as well as desquamation index, as a measure of skin scaling, on the preauricle, posterior neck, dorsal upper arm, dorsal forearm, volar forearm, lower back, abdomen, thigh, and lower leg. The results of desquamation index are discussed in Section 2.4. They found no ethnic differences in WC, but did find significant differences between the younger and older women (younger had higher WC than older women).

Sivamani et al.[68] compared differences in friction coefficient, impedance, and amplitude/mean calculation of friction coefficient curves between Caucasian, African-American, Hispanic, and Asian subjects. Participants included 22 Caucasians, 14 African-Americans, 14 Hispanics, and 9 Asian volunteers aged 18–60 years. In addition to measuring baseline differences, the researchers assessed differences in response to polyvinylidene chloride occlusion, topical petrolatum, and topical glycerin applied to the volar forearm, based on gender, age, and ethnicity. Baseline measurements showed no significant differences in impedance between age, gender, or ethnicity. Notably, although there were no significant differences between right and left forearms, significant baseline variation was found between the distal and proximal volar forearms; the proximal forearms showed lower impedance than the distal forearms ($p < 0.001$). As impedance is a measure of WC, we can infer baseline differences in WC among anatomic sites from this study. Additionally, all interventions produced decreases in impedance from baseline (degree of decrease varied by intervention), but no significant differences between age, gender, or ethnicity. The authors concluded that there is little variation in volar forearm skin across gender, age, and ethnicity, providing an adequate site for testing of skin and cosmetic products.

Grimes et al.[29] measured baseline moisture content on the inner forearms of 18 African American and 19 white women, aged 35–65 years, based on capacitance. The study found no significant variation in baseline moisture content between African-American and white subject inner forearms.

The WC results of each study are summarized in Table 2.2. While Johnson and Corah[34] did not correlate resistance to WC in their study, it can be implied from their data that ethnic variance was found in WC. However, the SLS-induced irritation studies by Berardesca and Maibach[7,8] revealed no significant differences in WC between the races at baseline or after SLS stress, except for a questionable difference (high standard deviations) of Hispanics having greater WC than whites after SLS stress. Since it is believed that artifacts from

Johnson and Corah[34]	*In vivo*—resistance	**St. Louis study**: Black boys 22; black girls 32 White boys 65, white girls 55 (age 83–92 months, all) **San Diego study**: Black men 16, black women 5 White men 16, white women 5 (mean age 23 y, all)	First and third fingers of right hand	• Skin resistance: Blacks > whites at baseline ($p < 0.01$), i.e., blacks have lower water content
Berardesca et al.[7]	*In vivo*—topical application of SLS (irritant)—capacitance	Black men 10 (age 29.9 ± 7.2 y) White men 9 (age 30.6 ± 8.8 y)	Back	• No significant differences between blacks and whites at baseline or after SLS stress
Berardesca et al.[8]	*In vivo*— topical application of SLS (irritant)—capacitance	Hispanic men 7 (age 27.8 ± 4.5 y) White men 9 (age 30.6 ± 8.8 y)	Upper back	• No significant differences between Hispanics and whites at baseline **After SLS stress** • Hispanics > whites when negative visual score was given for irritation ($p < 0.01$) (large standard deviations)
Berardesca et al.[12]	*In vivo*—conductance	Blacks 15 (mean age 46.7 ± 2.4 y) Whites 12 (mean age 49.8 ± 2 y) Hispanics 12 (mean age 48.8 ± 2 y)	Volar and dorsal forearm	• Blacks (13% less) volar < dorsal forearm ($p < 0.02$) • Whites (22% less) dorsal < volar forearm ($p < 0.001$) • Hispanics (11% less) dorsal < volar forearm ($p < 0.05$) • Blacks and Hispanics > whites on dorsal forearm at baseline • Hispanics > blacks and whites on volar forearm at baseline
Sugino et al.[70]	*In vivo*—impedance	Blacks, Caucasians, Hispanics, Asians (no. of subjects, ages not specified)	Not documented	• Asians > Caucasians, blacks, and Hispanics
Warrier et al.[83]	*In vivo*—capacitance	Black women 30 White women 30 (age 18–45 y, both)	Left and right medial cheeks, midvolar forearms, lateral midlower legs	• Blacks > whites on cheeks at baseline ($p < 0.05$) • No significant difference between two groups on forearms and legs
Manuskiatti et al.[45]	*In vivo*—capacitance	Black women 7 White women 5 (mean age 25.8 ± 4.2 y, both) Black women 5 White women 5 (mean age 64.7 ± 3.8 y, both)	Preauricle, postneck, dorsal upper arm, dorsal forearm, volar forearm, lower back, abdomen, thigh, lower leg	• No significant differences between blacks and whites at baseline
Sivamani et al.[68]	*In vivo*—impedance, topical application of petrolatum and glycerin	White 22 African American 14 Hispanic 14 Asian 9 (age 18–60 y, all)	Volar forearm	• Baseline: No significant differences in electrical impedance between age, gender, or ethnicity; impedance of proximal < distal forearm ($p < 0.001$) • After topical interventions: All interventions produced decrease in impedance; degree of decrease varied by intervention. No significant differences between age, gender, or ethnicity
Grimes et al.[29]	*In vivo*—capacitance	African American 18 White 19 (age 35–65 y, women, all)	Inner forearm	• Baseline: African Americans < whites, but not statistically significant

Note: SLS = sodium lauryl sulfate; y = years.

[a] Ethnic differences in water content, as measured by resistance, capacitance, conductance, and impedance are inconclusive.

Source: Wesley, N.O. and Maibach, H.I., *Am. J. Clin. Dermatol.*, 4(12), 843–860, 2003. With permission.

topically applied substances may alter values measured by capacitance or conductance,[22] this may play a factor in some of the values obtained by the SLS-irritant induced study. Additionally, Manuskiatti et al.[45] found no difference in WC between blacks and whites, but did find differences based on age. Berardesca et al.[12] and Warrier et al.,[83] however, did demonstrate ethnic variability in WC but the values varied by anatomic site. Sugino et al.[70] also demonstrated ethnic variability with Asians having a higher WC than other ethnic groups based on impedance. In contrast, Sivamani et al.[68] recently reported no ethnic differences in WC, both baseline and after various topical interventions, based on impedance; they did find variation of WC between different anatomic sites and with specific interventions. Of note, impedance, as used in the latter two studies, is less widely used than capacitance and conductance has been shown to be more sensitive to environmental and technical factors that affect the SC,[22] this makes it difficult to compare the results presented by these latter two studies. In another recent study using capacitance, Grimes et al.[29] showed no significant variation in baseline moisture content between African-American and white subjects inner forearms, further supporting studies by Berardesca and Maibach[7,8] and Manuskiatti et al.[45]

These findings, by measuring skin capacitance, conductance, impedance, and resistance, are difficult to interpret in terms of SC WC because other physical factors, such as skin microrelief, sweat production, and the presence of hair on the measuring site, may modify the quality of skin electrode contact.[22] Thus, it seems there may be factors other than race in the determination of WC and no conclusions with regard to race and WC can be made at this time. Studies with more subjects and the use of more than one method of measuring WC for accuracy should be considered in the future. In addition, since variation has been shown by anatomic sites, care should be taken to use consistent anatomical sites when comparing measurements of WC.

2.4 CORNEOCYTE VARIABILITY

Corneocytes differ in shape from the keratinocytes that produce them. The disk-like shape of corneocytes allows them to present with a large surface area in the horizontal position.[67] In Caucasians, the surface area of corneocytes differs by body site[55,67] and age.[42,67] It has also been demonstrated in Caucasians that corneocyte surface area is an important factor in the permeability of the skin to water loss and to percutaneous absorption of topically applied substances.[67]

Corcuff et al.[17] compared corneocyte surface area and spontaneous desquamation (via corneocyte count) on the upper outer arm in black African Americans, white Americans of European origin, and Asian-Americans of Chinese extraction. There were 18–25 age-matched subjects per group who were free from dermatological disorders. No difference in corneocyte surface area was found between the groups. However, spontaneous desquamation (corneocyte count) was increased in blacks by a factor of 2.5 compared with white and Asian skin ($p < 0.001$). The investigators felt that their findings were not consistent with earlier studies that showed increased intercellular adhesion[84] or increased TEWL[7,87] in black skin. This enhanced desquamation may (partially) account for "ashing" frequently seen clinically in black people.

In contrast, Warrier et al.[83] conducted a study that included corneocyte desquamation and had different results. The investigators studied 30 black and 30 white subjects, matched for age, and found that the desquamation index was greater on the cheeks and forehead of white subjects compared with black subjects. No difference was found on the legs. The investigators attributed the lower corneocyte desquamation on the cheeks and foreheads of blacks compared with whites to possible differences in moisturizing properties of sebum. These findings did not correlate with dry skin frequently seen clinically in black people. Since it is believed that corneocyte surface area varies by anatomic site in Caucasians,[67] perhaps corneocyte desquamation also varies by site. Corcuff et al.[17] studied the upper outer arm, whereas Warrier et al.[83] examined the cheeks, forearms, and lower legs. More studies of corneocytes desquamation should be conducted on the anatomic areas where dry skin is more frequently experienced. Additionally, the climate of the area where the study is done should be considered as it may influence desquamation. Warrier et al.[83] conducted their study over a 6-week period in winter, from December through February in Cincinnati, Ohio when temperatures and relative humidity are low and frequency of dry skin (winter xerosis) is high. In contrast, the city and climate are not documented in the study by Corcuff et al.[17]

In addition to measuring WC, Manuskiatti et al.[45] also examined the desquamation index in seven black and five white women (mean age 25.8 $\pm$ 4.2 years) and five black women and five white women (mean age 64.7 $\pm$ 3.8 years) on the preauricle, posterior neck, dorsal upper arm, dorsal forearm, volar forearm, lower back, abdomen, thigh, and lower leg. There were no differences in desquamation index between blacks and whites at all areas measured, except at the preauricular area ($p = 0.02$). However, whether blacks or whites had a higher desquamation index at this area was not specified. The investigators discounted the difference found at the preauricular area and attributed the difference to the small sample size used. Like the results found for WC, they also found significant differences in desquamation index based on age (older individuals had higher desquamation index than younger individuals at the preauricle). Overall, they concluded that age and anatomic site but not race demonstrate a significant influence on skin roughness and scaliness.

Overall, Corcuff et al.,[17] Warrier et al.,[83] and Manuskiatti et al.[45] reveal statistically significant results, but the findings are contradictory and therefore inconclusive (Table 2.3). Corcuff et al.[17] demonstrate greater corneocyte desquamation in blacks compared with whites on the upper outer arm. In contrast, Warrier et al.[83] found a greater desquamation index on the cheeks and forehead of whites compared with blacks. Additionally, Manuskiatti et al.[45] found a difference on the preauricular area only out of the numerous areas examined,

TABLE 2.3
Corneocyte Variability[a]

Study	Subjects	Site	Results
Corcuff et al.[17]	Black (mean age 33.5 ± 7.5 y) Caucasian (mean age 31 ± 7 y) Asian (mean age 26.5 ± 7.5 y) (18–25 subjects per group)	Upper outer arm	• No difference in corneocyte surface area • Spontaneous desquamation (corneocyte count) blacks 2.5× > Caucasians and Asians ($p < 0.001$)
Warrier et al.[83]	Black women 30 White women 30 (age 18–45 y, both)	Left and right medial cheeks, midvolar forearms, lateral midlower legs	• Desquamation index Blacks < Whites on cheeks (18% less) and forearms (20% less) ($p < 0.05$); but no significant differences on the legs
Manuskiatti et al.[45]	Black women 7 White women 5 (mean age 25.8 ± 4.2 y, both) Black women 5 White women 5 (mean age 64.7 ± 3.8 y, both)	Preauricle, postneck, dorsal upper arm, dorsal forearm, volar forearm, lower back, abdomen, thigh, lower leg	• No difference in desquamation index between blacks and whites except at preauricular area ($p = 0.02$) (which ethnicity greater not specified)

Note: y = years.

[a] Ethnic differences in corneocyte desquamation are inconclusive. The most clinically provocative observation is that of Corcuff et al.[17]—a 2.5 times greater spontaneous desquamation rate in blacks compared to Caucasians and Asians.

Source: Wesley, N.O. and Maibach, H.I., *Am. J. Clin. Dermatol.*, 4(12), 843–860, 2003. With permission.

but whether blacks or whites have a higher desquamation index is not specified.

Does the site of measurement of corneocyte desquamation, the WC and TEWL at that site, and the climate of the area where the study was done act as confounding variables for these results? In light of what is now known about WC and TEWL, the issue of corneocyte desquamation should be re-visited as these may be contributing variables. Corneocyte desquamation may have clinical implications in issues regarding the diagnosis and treatment of xerosis frequently seen in African Americans.

2.5 BLOOD VESSEL REACTIVITY

Cutaneous blood flow has been examined on numerous occasions to assess skin physiology, irritation, evaluation of dermatologic pathology/treatments, effects/delivery of drugs, and wound healing among other areas of interest.[82] The visual assessment of cutaneous microcirculation has been measured for centuries by the degree of erythema or pallor/blanching (visual scoring). However, the introduction of objective techniques for the evaluation blood flow has shown that the human eye is rather unreliable. Two techniques utilized by the papers to be discussed are LDV and photoplethysmography (PPG).

LDV is a noninvasive method that continuously follows the flow of red blood cells. It is based on measurement of the Doppler frequency shift in monochromatic laser light backscattered from moving red blood cells. It detects the frequency-shifted signal and derives an output proportional to the number of erythrocytes multiplied by their velocity in the cutaneous microcirculation.[50,82] LDV has been applied to skin physiology; diagnostics (especially scleroderma, Raynaud disease, and patch test reactions); predictive testing of irritancy (topical drugs, cosmetics, detergents, cleansing agents, products used in industry); and effects of drugs (vasodilators, minoxidil, sunscreens and UV light, topical corticosteroids [blanching]).[82]

PPG can be defined as the continuous recording of the light intensity scattered from a given source by the tissues and collected by a suitable photodetector.[13] Specific to the skin, it allows the registration of pulsative changes in the dermal vasculature and is synchronized with heartbeat. Infrared light from a transducer is absorbed by hemoglobin, and the backscattered radiation is detected and recorded. The backscattered light depends on the amount of hemoglobin in the skin, and the result obtained will therefore reflect the cutaneous blood flow. PPG has been used for studies of skin physiology, dermatological disorders, as well as systemic diseases.[82]

Guy et al.[31] enrolled six black subjects aged 20–30 years, six white subjects aged 20–30 years, and six white subjects aged 63–80 years, with good general health, no recent skin disease, and taking no prescription medications, and studied their response to topically applied vasodilator methyl nicotinate. The substance was applied to the volar forearm and blood vessel reactivity was measured by LDV and PPG. There was no significant difference between the ethnic groups in time to peak response, area under the response–time curve, or time for response to decay to 75% of its maximum value. However, the PPG maximum response was 40% less in the young black group than in the young white group ($p < 0.05$). The authors made note of the fact that the sensitivities of the two methods of study (LDV and PPG) were not

equivalent. They concluded that, overall, the data suggested a similarity in response among races and ages. The investigators did not discuss the significance or implications of the lower maximum PPG seen in the black subjects.

Berardesca and Maibach[7] performed a study to determine the difference in irritation between young black and Caucasian skin. They applied 0.5 and 2.0% SLS to untreated, preoccluded, and predelipidized skin and then quantified the resulting level of irritation using LDV, TEWL and WC of the SC. There were no significant differences between black and white skin for LDV at baseline or after application of SLS. The authors did note, however, that in blacks, application of the 0.5% SLS to untreated skin revealed minimal changes in cutaneous blood flow (as measured by LDV) compared with baseline. They used this finding to explain the decreased irritant-induced perceptible erythema in blacks.[85] However, after reexamining the data, we might consider that there was about the same degree of minimal change from baseline to application of 0.5% SLS in untreated skin in the Caucasian group.

Berardesca and Maibach[8] used the same model to compare differences in irritation between Hispanic and Caucasian skin. Like the SLS-induced irritation study comparing blacks and white, the same study comparing Hispanics and whites revealed equivalent blood vessel responses between the two groups.

Berardesca and Maibach performed a subsequent study using LDV, but this time examined ethnic differences induced by corticosteroid application (a vasoconstrictive stimulus).[9] They examined six black and eight Caucasian men, matched for age, and measured cutaneous hyperemia using LDV, before and after the application of 0.05% clobetasol ointment to the forearm. The following parameters were analyzed: (i) the area under the curve response from the starting point of the hyperemic response until the return of blood flow to basal values; (ii) the magnitude of the maximum peak response; (iii) the slope of the rise from immediate postocclusion to peak reactive hyperemic flow; and (iv) the slope of the decay from peak reactive hyperemic flow to resting levels. After the vasoconstrictive stimulus was given, the black subjects showed a 40% decreased area under the curve response ($p < 0.04$), a 50% decreased peak response ($p < 0.01$), and a decreased decay slope after peak blood flow ($p < 0.04$) compared with the whites. Overall, their data were consistent with a decrease in blood vessel reactivity of blacks compared with whites.

Gean et al.[28] also found differences in blood vessel reactivity between different ethnic groups; however, their data conflict with the findings of Berardesca and Maibach.[9] Gean et al.[28] examined five black subjects (skin types V or VI), five Asian subjects (skin type IV), and five Caucasian subjects (skin type II), aged 20–35 years, with no history of skin disease, who were nonsmokers and were not taking prescription medications, and applied three different concentrations of methyl nicotinate to the upper third of the ventral forearm. Methyl nicotinate-induced vasodilation was assessed visually and by LDV. At three different dose levels, the following parameters were compared: (i) the diameter of the maximum visually perceptible erythematous area; (ii) the area under the erythematous diameter versus time curve; (iii) the maximum LDV response; and (iv) the area under the LDV response versus time curve. Since we are reviewing only the objective data, the first two parameters measuring erythema revealed no significant differences and will not be discussed. The investigators observed that the area under the curve for LDV response versus time was greater in blacks than Caucasians for all methyl nicotinate concentrations ($p < 0.05$). This contrasts with prior studies, which found either no difference[7,31] or a decrease[9] in the area under the curve response in blacks. Note, however, that in this study a vasodilator (methyl nicotinate) was given, whereas in the prior study by Berardesca and Maibach[9] a vasoconstrictor was given. They also found that the area under the curve response versus time was greater in Asians compared with Caucasians for higher dose levels of methyl nicotinate ($p < 0.05$).

Kompaore et al.[39] evaluated TEWL and lag time to vasodilatation by LDV, before and after removal of the SC by tape stripping in seven black men, eight Caucasian subjects (six male and two female), and six Asian men. After application of methyl nicotinate, but before tape stripping, there was no difference between the groups in basal perfusion flow (by LDV), but lag time before vasodilatation was greater in blacks and less in Asians compared with Caucasians ($p < 0.05$). After 8 and 12 tape strips, lag time before vasodilatation decreased in all three groups, but decreased significantly more in Asians compared with Caucasians and blacks ($p < 0.05$). The order of sensitivity to methyl nicotinate was Asian > Caucasian > black. After topical application of methyl nicotinate, TEWL measurements indicated that black and Asian skin was more permeable to water than Caucasian skin (see Table 2.1); however, LDV-recorded lag time to vasodilatation results revealed that Asian skin had a higher permeability to methyl nicotinate than Caucasian and black skin. This study confirmed the importance of the SC in barrier function, but could not explain the reason behind the ethnic differences in TEWL and lag time to vasodilatation.

Aramaki et al.[3] evaluated LDV at baseline and after SLS-induced irritation in 22 Japanese and 22 German women. There was no difference in LDV at baseline and after SLS-induced irritation. Few studies measuring LDV have examined persons of Asian descent. Although it is difficult to compare a study that used tape stripping[39] with one that used a vasoactive substance,[3] note that Aramaki et al.[3] had a larger sample size than Kompaore et al.[39] and found no baseline difference in LDV.

An investigation done by Hicks et al.[33] demonstrated no significant difference in blood vessel reactivity between black and white participants. SLS was applied to the volar forearm, and response was recorded using LDV. The results obtained are in conflict with several previous studies that have suggested differences between black and white skin.[9,28,31,39] However, the investigators expressed doubt in the validity of the LDV measurements due to technical difficulties in using the flowmeter while conducting the study.

TABLE 2.4
Blood Vessel Reactivity[a]

Study	Technique	Subjects	Site	Results
Guy et al.[31]	Topically administered MN (vasodilator); LDV and PPG	Blacks 6 (age 20–30 y) Whites 6 (age 20–30 y) Whites 6 (age 63–80 y)	Volar forearm	**MN given** • No significant difference in time to peak response, area under response–time curve, or time for response to decay to 75% of its max value • PPG max response young black (40% less) < young white ($p < 0.05$)
Berardesca et al.[7]	Topically administered SLS (irritant); LDV	Black men 10 (age 29.9 ± 7.2 y) White men 9 (age 30.6 ± 8.8 y)	Back	**SLS stress** • No significant difference between blacks and whites • Blood vessel reactivity minimal in blacks from baseline to application of 0.5% SLS on untreated skin
Berardesca et al.[8]	Topically administered SLS (irritant); LDV	Hispanic men 7 (age 27.8 ± 4.5 y) White men 9 (age 30.6 ± 8.8y)	Upper back	**SLS stress** • Similar LDV response in Hispanics and whites
Berardesca et al.[9]	Topically administered corticoid (vasoconstrictor); LDV	Black men 6 Caucasian men 8 (mean age 27 ± 3 y, both)	Forearm	**After vasoconstrictor given** • 40% decreased area under the curve response blacks compared with whites ($p < 0.04$) • 50% decreased peak response in blacks compared with whites ($p < 0.01$) Decreased decay slope after peak blood flow in blacks compared to Caucasians; in blacks, $y = 3.3672–0.0737\times$ before treatment compared to $y = 2.5347–0.0367\times$ after treatment ($p < 0.04$), i.e., less blood vessel reactivity in blacks
Gean et al.[28]	Topically administered MN (vasodilator); LDV	Blacks 5 Caucasians 5 Asians 5 (age 20–35 y, all)	Upper 1/3 volar forearm	**MN given** • Area under the curve for LDV response versus time blacks > Caucasians for all MN concentrations ($p < 0.05$) • Area under the curve for LDV response versus time Asians > Caucasians for higher dose levels of MN ($p < 0.05$)
Kompaore et al.[39]	Topically administered MN (vasodilator); LDV	Blacks 7 Caucasians 8 Asians 6 (age 23–32 y, all)	Volar forearm	**MN given** • Before tape stripping: no difference between the groups in basal perfusion flow, but lag time before vasodilatation was blacks > Caucasians > Asians ($p < 0.05$) • After 8 and 12 tape strips: lag time before vasodilatation decreased in all three groups, but significantly decreased in Asians > Caucasians > blacks ($p < 0.05$)
Aramaki et al.[3]	Topically administered SLS (irritant); LDV	Japanese women 22 (mean age 25.84 y) German women 22 (mean age 26.94 y)	Forearm	• No significant difference at baseline or after SLS stress

TABLE 2.4 (continued)
Blood Vessel Reactivity[a]

Study	Technique	Subjects	Site	Results
Hicks et al.[33]	Topically administered SLS (irritant); LDV	White 7 Black 6 (age 18–40 y, all)	Volar forearm	• SLS stress: no significant difference in LDV response between groups

Note: Corticoid = clobetasol propionate 0.05% ointment; LDV = laser Doppler velocimetry; MN = methyl nicotinate; PPG = photoplethysmography; SLS = sodium lauryl sulfate; y = years.

[a] Studies cannot be compared to each other because each uses different vasoactive substances. However, each study, except for Berardesca and Maibach[8] comparing Hispanics and whites, Aramaki et al.[3] comparing Japanese and German women, and Hicks et al.[33] comparing blacks and whites, reveals some degree of ethnic variation in blood vessel reactivity.

Source: Wesley, N.O. and Maibach, H.I., *Am. J. Clin. Dermatol*., 4(12), 843–860, 2003. With permission.

The results of the studies on blood vessel reactivity are summarized in Table 2.4. Since each study administered different vasoactive substances that may act on different receptors on blood vessels, they could not be objectively compared.[36] As was noted by Hicks et al.,[33] it has been previously reported that small changes in position of the measuring probe can produce significant changes in measurements and may result in decreased reliability of results. Additionally, measurements may differ according to anatomic sites.

2.6 ELASTIC RECOVERY/EXTENSIBILITY

In addition to examining TEWL and skin conductance, Berardesca et al.[12] also examined biomechanical properties, such as elastic recovery and skin extensibility, on the dorsal and volar forearm in 15 blacks, 12 whites, and 12 Hispanics. These biomechanical properties were determined by applying a specific torque parallel to the skin's surface and then measuring how stretchable the skin was (skin extensibility) and recording the time required for the skin to return to its original state after release of the torque (elastic recovery). For skin elastic recovery, they found no significant difference between the races on the dorsal forearm (blacks > whites, but not significant). However, elastic recovery was 26% less in blacks compared with whites on the volar forearm ($p < 0.001$). There was no significant difference in elastic recovery between whites and Hispanics. The authors explained the significantly decreased elastic recovery in blacks compared with whites on the volar forearm, with a higher recovery in blacks on the dorsal side (although not significant), on the basis of greater actinic damage on the dorsal side of whites, with melanin as a photoprotective factor in blacks.

For skin extensibility, within each race, Berardesca et al.[12] found significant differences between dorsal and volar forearms in Hispanics and whites (dorsal < volar) ($p < 0.0002$ and $p < 0.0001$, respectively), but extensibility was the same on both sides of the forearm in blacks. When comparing the races to each other, blacks had greater extensibility than whites on the dorsal forearm, but decreased extensibility than whites on the volar forearm ($p < 0.01$ for both). Skin elasticity overall is defined as elastic recovery divided by extensibility. When looking at this ratio the investigators found no significant differences between the races. They explained the variability in these biomechanical properties of skin based on the protective role of melanin from UV rays. They believed that blacks did not show differences in skin extensibility between the dorsal and volar forearm because they were more photoprotected. Furthermore, they believed that blacks had greater extensibility on the dorsal forearm compared with whites for the same reason. However, if blacks are presumed to also be more photoprotected on the volar forearm compared with whites, this reasoning does not explain why whites were found to have a greater extensibility than blacks on the volar side.

Warrier et al.[83] examined elastic recovery in 30 black and 30 white women but did not record skin extensibility. There was no significant difference between blacks and whites on the legs, but elastic recovery on the cheeks was 1.5 times greater in blacks than in whites ($p < 0.05$). These findings contradicted those of Berardesca et al.[12] who found a 26% decrease in elastic recovery on the volar forearm of blacks. Warrier et al.[83] explained their findings of higher elastic recovery on the cheeks of blacks based on the higher WC that they found on the same anatomic area, thus presumably resulting in a higher elastic deformation.

The data on skin biomechanics, specifically elastic recovery and extensibility, vary by anatomic site and by race. However, the conclusions drawn by Berardesca et al.[12] contradict those of Warrier et al.[83] The data not only vary by race and by site, but age may also be a contributing factor. In the study by Berardesca et al.,[12] the subjects were all within the same age range (mean age 46.7–49.8 years). However, even though Warrier et al.[83] had a larger number of study subjects, the age range was 18–45 years. Overall, the ethnic differences in skin biomechanics are inconclusive and warrant further study (see Table 2.5).

2.7 MICROTOPOGRAPHY

Skin microrelief reflects the three-dimensional organization of the deeper layers and functional status of the skin.[30] Research has been performed relating changes in skin

TABLE 2.5[a]

Study	Technique	Subjects	Site	Results
(a) Skin Elastic Recovery				
Berardesca et al.[12]	*In vivo*	Blacks 15 (mean age 46.7 ± 2.4 y) Whites 12 (mean age 49.8 ± 2 y) Hispanics 12 (mean age 48.8 ± 2 y)	Volar and dorsal forearm	• No significant difference between groups on dorsal forearm • Elastic recovery Blacks (26% less) < whites on volar forearm ($p < 0.001$)
Warrier et al.[83]	*In vivo*	Black women 30 White women 30 (age 18–45 y, both)	Left and right medial cheeks, midvolar forearms, lateral midlower legs	• No significant difference between groups on the legs • Elastic recovery Blacks 1.5× > whites on cheeks ($p < 0.05$)
(b) Skin Extensibility				
Berardesca et al.[2]	*In vivo*	Blacks 15 (mean age 46.7 ± 2.4 y) Whites 12 (mean age 49.8 ± 2 y) Hispanics 12 (mean age 48.8 ± 2 y)	Volar and dorsal forearm	• Significant dorsal < volar extensibility within whites and Hispanics ($p < 0.001$ and $p < 0.002$, respectively) • Black > white extensibility dorsal forearm ($p < 0.01$) • Black < white extensibility volar forearm ($p < 0.01$)
(c) Microtopography				
Guehenneux et al.[30]	*In vivo*—skin replicas and interferometry	Caucasian 356 Japanese 120 (age 20–80 y, women, all)	Volar forearm	• ↑ in the density of lines > 60 μm and ↓ in the density of lines < 60 μm in depth with increasing age in both; change in Caucasians > Japanese and at earlier age in Caucasians • Anisotropy: ↑ with age in Caucasians, no change in Japanese
Diridollou et al.[21]	*In vivo*—SkinChip	310 women (age 18–61 y, all; African American, Caucasian, Asian, Hispanic)	Dorsal and ventral forearms	• Roughness and anisotropy ↑ with age on both dorsal and ventral forearms in all groups; Caucasians > Hispanic and Asians and African Americans • Density of the line intersections: Caucasians and Hispanics < Asians and African Americans
(d) pH Gradient				
Berardesca et al.[11]		Black women 8 Caucasian women 10 (mean age 42.3 ± 5 y, both)	Midvolar forearm	• No significant difference in pH at baseline **After tape stripping** • pH significantly decreased in blacks after three tape strips, i.e., superficial SC layers • No differences between ethnicitiess after 9, 12, and 15 tape strips, i.e., deeper SC layers
Warrier et al.[83]		Black women 30 White women 30 (age 18–45 y, both)	Left and right medial cheeks, midvolar forearms, lateral midlower legs	• pH blacks (pH = 5.15) < whites (pH = 5.52) on cheeks at baseline ($p < 0.05$) • No significant difference in pH on the legs at baseline
Grimes et al.[29]		African American 18 White 19 (age 35–65 y, women, all)	Above left eyebrow	• Baseline: African Americans < whites, but not statistically significant

Study	Technique	Subjects	Site	Results
(h) Vellus Hair Follicles				
Mangelsdorf et al.[44]	*In vivo*—skin surface biopsies	Asian 10 African American 10 (age 25–50 y, males, all) (results compared to Caucasians studied in Otberg et al.[52])	Forehead, back, thorax, upper arm, forearm, thigh, calf	• Distribution of follicle density for different body sites same in all groups: highest on forehead, lowest on calf. • Follicle density on forehead: Caucasians > African Americans > Asians ($p < 0.01$); no significant differences on other sites. • Calf and thigh: Asians and African Americans – smaller values for volume ($p < 0.01$, both), potential penetration surface ($p < 0.01$, both), follicular orifice ($p < 0.01$ and $p < 0.05$, respectively), and hair shaft diameter ($p < 0.01$, both)

Note: EM = electron microscopy; PLS = parallel-linear striations; SC = stratum corneum; y = years.

[a] In summary, we are unable to draw conclusions regarding ethnic differences in skin biomechanics (skin elastic recovery and extensibility) due to insufficient and conflicting evidence. It is difficult to compare microtopography studies due to different techniques. However, studies demonstrate an increase in anisotropy with age in Caucasians. Three skin pH studies demonstrate pH of black less than white skin. However, Berardesca et al.[11] demonstrate this difference after superficial tape stripping of the volar forearm, but not at baseline; while Warrier et al.[83] demonstrate the difference at baseline on the cheeks but not on the legs; and the results from Grimes et al.[29] did not reach statistical significance. Ethnic differences in lipid content and sebaceous function are inconclusive. Ethnic differences in sebaceous function are inconclusive. Larger mast cell granules, increased PLS, and increased tryptase localized to PLS in black compared to white skin. Lastly, we are unable to draw conclusions regarding ethnic differences in vellus hair follicle distribution and morphology due to insufficient evidence.

microtopography to age and, more recently, relating changes to ethnic origin (see Table 2.5). Guehenneux et al.[30] (abstract only) studied changes in microrelief with age in 356 Caucasian and 120 Japanese women, aged 20–80 years, whose volar forearms were examined via skin replicas and analyzed by interferometry, simultaneously during winter in Paris and Sendai. Of the 12 "global parameters" and 13 "local parameters," the abstract reported the analysis of 3 local parameters: orientation of lines, depth of lines, and anisotropy index. Both Caucasian and Japanese women showed an increase in the density of lines measuring >60 μm in depth and a decrease in the density of lines measuring <60 μm with increasing age. However, this change was found to be more pronounced and occur at a younger age in Caucasian women. In addition, although no changes in orientation of lines with age were found in Japanese women, changes correlating with an increase in skin anisotropy with age were found in Caucasian women. Note that it is difficult to assess the reliability of comparing these results as the subjects were studied in two distinct geographical locations where environmental exposures may differ.

A study by Diridollou et al.[21] (abstract only) compared skin topography among 310 women, aged 18–61 years, including subjects of African American, Caucasian, Asian, and Hispanic descent; the ethnic distribution was not delineated in the abstract. Skin microrelief of the dorsal and ventral forearms was investigated according to age and ethnicity in terms of the density of line intersections in which a higher density of the intersection indicated smoother skin, and line orientation in which a smaller angle difference between the two main directions of the lines indicated higher anisotropy. The results were gathered using SkinChip, a device based on active capacitance imaging technology and image analysis software. On the ventral forearms, the data supported that the roughness and anisotropy of the skin increases with age in all four ethnic groups; the density of intersection decreased and angle between lines of different orientation became smaller. The same results were produced by the dorsal forearms, a sun-exposed site, but changes were significantly less pronounced for the African-American subjects, indicating a possible resistance to photoaging in this group. Overall, the density of the intersections was less for Caucasians and Hispanics than for Asians and African Americans. In addition, the anisotropy was higher for Caucasians than for Hispanics or Asians, and significantly higher than African Americans.

Diridollou et al.[21] concluded that roughness and anisotropy are more pronounced in Caucasian skin, than in Hispanic, Asian, and African-American skin. Guehenneux et al.[30] also found more pronounced changes of topography and higher anisotropy in Caucasian skin as compared to Asian skin, and at an earlier age. However, the results of both studies cannot be compared or integrated as they used different tools of investigation and different evaluation parameters.

2.8 pH GRADIENT

Ethnic differences in pH of the skin have also been explored. In addition to examining TEWL, Berardesca et al.[11] also examined differences in pH in 10 Caucasian (skin types I and II) and eight black African-American (skin type VI) women at baseline and after tape strippings. They found no significant differences between the two races in pH at baseline. After tape stripping, however, they found a significantly lower pH in blacks compared with whites after three tape strippings, but no significant differences after 9, 12, and 15 strippings. Thus, there was a lower pH in black skin compared with white skin in the superficial layers of the SC, but not in the deeper layers. The investigators stated that the data were difficult to explain. It was hypothesized that since the TEWL was also found to be increased after 3 and 6 tape strippings, the increased TEWL might allow for an increase in the hydrogen ion concentration in a normally hydrophobic SC. Of note, although the difference between the races in pH was not significant at deeper layers of the SC, the pH in both races did decrease with more tape strippings, but TEWL did not follow the same trend. Thus, an increase in TEWL does not fully explain the findings in pH.

Warrier et al.[83] also included pH in their study of 30 black and 30 white women; however, they only examined pH at baseline, not after tape stripping. There was a decreased pH on the cheeks of blacks compared with whites, pH = 5.15 versus pH = 5.52, respectively ($p < 0.05$). There was also a decreased pH in blacks on the legs, but the difference was not significant. The authors attributed the decreased pH in blacks to lactic acid and dicarboxylic amino acids in sweat secretions mixed with sebum, and evaporation of sweat causing acidity to increase[20] with the idea that there might be a higher number of sweat glands in blacks.[48]

Similar results were also produced in the study by Grimes et al.[29] The skin pH, measured above the left eyebrow in 18 African American and 19 white women, aged 35–65 years, was found to be lower in African Americans than whites, but the results did not reach statistical significance.

The skin pH has been found to be lower in blacks compared with whites in three different studies, but under different circumstances. Berardesca et al.[11] only demonstrate this difference in the superficial layers of the SC on the volar forearm, but not at baseline; while Warrier et al.[83] demonstrate the significant difference at baseline on the cheeks but not on the legs. Grimes et al. [29] demonstrated a difference on the forehead, but lacked statistical significance. Thus, it can be implied that may be some difference between whites and blacks in SC pH but the etiology of this finding and its confounders remain to be explored (see Table 2.5).

2.9 LIPID CONTENT

Skin lipids may play a role in modulating the relation between SC water content and TEWL, resulting in higher conductance values in blacks and Hispanics; greater intercellular cohesion with a normal TEWL could produce a higher WC.[10] Sugino et al.[70] correlated high WC values with high ceramide (lipid) levels and low TEWL. They studied WC (by impedance), TEWL, and ceramide levels in black, white, Hispanic, and Asian subjects. The number of subjects, age, and sample site were not documented in the published abstract. Ceramide levels were 50% lower in blacks compared with whites and Hispanics (total ceramides: 10.7 ± 4.7 μg/mg, 20.4 ± 8.1 μg/mg, 20.0 ± 4.3 μg/mg, respectively; $p < 0.05$). Though they noted that WC levels were highest in Asians, they did not document the ceramide levels of Asians (according to their hypothesis, Asians should have the highest ceramide levels). Thus, the correlation that was made between WC, TEWL, and ceramide levels was not fully exemplified.

The finding of low ceramide levels in blacks by Sugino et al.[70] is important, because several studies base their findings of increased WC in blacks[12,83] upon a 1959 study by Reinertson and Wheatley[61] which, in contrast to Sugino et al., showed higher total epidermis lipid and sterol content in blacks compared with whites. They took abdominal skin from four cadavers (one black man and three white men), and back and thigh skin from one black and one white man, all aged 49–68 years, and examined lipid and sterol content. Although they found that lipid and sterol levels were higher in blacks, they had a small sample size and compared skin from both deceased and living subjects at different anatomic sites.

Harding et al.[32] analyzed scalp SC lipid content in 41 UK, 31 Thai (dry season), and 31 Thai (humid season) subjects, aged 20–40 years, in an attempt to evaluate ethnic differences in dandruff. They observed that decreased levels of scalp SC free fatty acids, cholesterol, and ceramides were found in subjects with dandruff. However, the overall levels of scalp lipids were similar in the UK and Thai subjects.

Overall, it seems as though ethnic differences in skin lipid content are inconclusive because one study finds decreased lipids in blacks compared with whites,[70] another finds increased lipids in blacks,[61] and still another finds no difference between people from the UK and Thailand (see Table 2.5).[32]

2.10 SEBACEOUS FUNCTION

Sebum is a semisolid secreted onto the skin surface by glands attached to the hair follicle by a duct.[57] The functions of sebum include protection from friction, reduction of water loss, and protection from infection. Sebum levels have been confirmed to decline with age; however, there are few studies on the effect of race on baseline sebum secretion. Grimes et al.[29] used a sebumeter to measure sebum levels on the forehead as a component of baseline parameters in their study of 18 African-American and 19 white women, aged 35–65 years. The results showed lower levels of sebum on African-American skin than on white skin, but differences were not statistically significant.

A study by de Rigal et al.[19] (abstract only) investigated the skin sebaceous function of 387 women of African-American, Hispanic, Caucasian, or Chinese descents, aged 18–70 years. Measurements were performed using a sebumeter and sebutape on the forehead and cheeks to compare sebum excretion

rate and number of sebaceous glands according to ethnicity and age. The mean gland excretion was the same across ethnic groups. However, the number of sebaceous glands was lower in Chinese and Hispanic groups as compared to Caucasian and African American groups. In addition, the normal sebum decrease with age was different in each population; the decrease was linear in the Chinese group, but the other three groups exhibited a sudden decrease around age 50 years.

Aramaki et al.[3] assessed sebum secretion as a part of their study investigating skin reaction to SLS at concentrations of 0.25 and 0.5%. Before and after application of SLS to the forearms of each subject, sebum levels were determined by a sebumeter. The baseline sebum levels were lower in Japanese women than in white women. However, after application of SLS 0.25 and 0.5%, sebum levels were higher in the Japanese women ($p < 0.05$).

The latter two studies suggest that significant differences exist between sebum levels according to ethnicity. The de Rigal et al.[19] study found that although, the mean sebum excretion was the same across ethnic groups, the number of sebaceous glands and the normal sebum decrease with age varied between groups. This may indicate a difference in distribution of sebum independent of sebum levels among ethnic groups. Aramaki et al.[3] determined sebum levels to be lower in Japanese women as compared to white women at baseline, but Japanese women expressed an increase in sebum levels in response to irritant stress. This irritant response may represent a physiologic attempt to increase barrier defense. Further studies will be useful to elucidate whether differences in barrier defense between ethnic groups are based on varying baseline sebum levels or varying sebaceous response to physical stress (see Table 2.5).

2.11 MAST CELL GRANULES

Based on frequent clinical observations of pruritus and scratching in African Americans, Sueki et al.[69] evaluated differences in mast cells between black and white skin (see Table 2.5). They took 4-mm punch biopsies of normal buttock skin from four African-American males (mean age 29.2 $\pm$ 3.0 years) and four white males (mean age 29.4 $\pm$ 1.2 years) with no prior history of skin disease or atopy and processed the biopsies routinely for electron microscopy. Mast cells in black skin contained 1.5 times larger granules ($p < 0.0001$), 15% more parallel-linear striations (PLS) ($p < 0.05$) and 30% less curved lamellae ($p < 0.05$) compared with white skin. In addition, the investigators also examined the subgranular distribution of mast cell proteases, tryptase, and cathepsin G by immunoelectron microscopy. They found that tryptase immunoreactivity localized to PLS regions in black skin, compared with curved lamellae regions in white skin ($p < 0.0001$). In contrast, cathepsin G localized to electron-dense amorphous subregions in both black and white skin.

The investigators attributed the larger mast cell granules in black skin to possible increased fusion or division of the granules in blacks. However, they noted that the larger percentage of PLS and smaller percentage of curved lamellae in blacks was more difficult to explain. They hypothesized that it might be influenced by the mediator content, especially the amount of tryptase. From other studies suggesting the participation of mast cells in aberrant fibrosis in skin disorders such as keloid scars[18] and hypertrophic scars,[37] the investigators suggested the involvement of tryptase in these disorders. Keloid scarring is frequently observed in black individuals and blacks were found to have increased amounts of tryptase in this study compared with whites. Even though the study had a small sample size and only examined skin from one anatomic region, the researchers still found significant structural differences in mast cells between black and white skin. Further investigation of proinflammatory mediators should be done to corroborate these findings. This discovery should also prompt further electron microscopic evaluation of other cells involved in dermatologic disorders.

2.12 VELLUS HAIR FOLLICLES

As follicular morphology and distribution may affect penetration of topical medications and consequent treatment response, Mangelsdorf et al.[44] investigated vellus hair follicle size and distribution in Asians and African Americans as compared to whites. Skin surface biopsies were taken from seven body sites of 10 Asians and 10 African Americans, aged 25–50 years. The body sites were matched to locations described by Otberg et al. [52] in their study on Caucasians. In comparing the results of the three ethnic groups, the distribution of follicle density at different body sites was the same; the highest average density was on the forehead and the lowest on the calf for all groups. However, follicular density on the forehead was significantly lower in Asians and African Americans ($p < 0.001$). The Asians and African Americans also exhibited smaller values for volume ($p < 0.01$, both groups), potential pentration surface ($p < 0.01$, both groups), follicular orifice ($p < 0.01$ and $p < 0.05$, respectively), and hair shaft diameter ($p < 0.01$, both groups) on the thigh and calf regions. In addition, the follicular reservoir, as described by follicular volume, was generally higher in Caucasians. The authors concluded that the significant ethnic differences in follicle structure and pattern of distribution, especially in calf and forehead regions, emphasize the need for skin absorption experiments on different skin types to develop effective medications for prevention and treatment of skin disorders.

2.13 EPIDERMAL INNERVATION

While TEWL, WC, and blood vessel reactivity have been used as measures of irritancy, Reilly et al.[60] sought to explain ethnic differences in irritancy in terms of differences in skin innervation and nociceptor activity. They utilized confocal microscopy to examine epidermal innervation of the volar forearm pretreated with capsaicin in 20 European Caucasian, 8 Japanese-American, and 8 Chinese-American volunteers. However, no differences in innervation, including the biochemical properties of the nerve fibers, was found.

2.14 MELANOSOMES

Ethnic differences in number of melanocytes, number of melanosomes, and morphology of melanosomes has been of great interest in working toward the development of objective definitions of skin color (see Table 2.6). The biosynthesis of melanin, a cutaneous pigment, occurs in a melanosome, a metabolic unit within the melanocyte; melanosomes are then transported via melanocyte dendrites to adjacent keratinocytes.[75]

In 1969, Szabo et al.[17] examined five Caucasoids, six American Indians, three Mongoloids (from Japan and China), and seven Negroids to observe melanosome groupings using electron micrographs. The melanosomes in keratinocytes of Caucasoids and Mongoloids were found to be grouped together with a surrounding membrane. In contrast,

TABLE 2.6[a]

Study	Technique	Subjects	Site	Results
(a) Melanosomes				
Szabo et al.[71]	*In vivo*—EM	Caucasoid 5 American Indian 6 Mongoloid 3 Negroid 7 (age not reported)	Not reported	• Caucasoids and Mongoloids: grouped melanosomes • Negroids: longer and wider melanosomes, predominantly individually dispersed
Alaluf et al.[1]	*In vivo*—EM; alkali solubility of melanin	European 10 Chinese 8 Mexican 10 Indian 10 African 10	Dorsal forearm and volar upper arm	• Average melanosome size: dorsal forearm > volar upper arm, in all ethnic groups ($p < 0.001$); African > Indian > Mexican > Chinese > European • Melanosome size ~ total melanin content ($p < 0.0001$) • Light melanin fraction: African < (Mexican and Chinese) < Indian < European • Dark melanin fraction: African and Indian > (Mexican and Chinese) > European • Total amount of melanin: African and Indian > Mexican and Chinese and European ($p < 0.001$)
Thong et al.[78]	*In vivo*—EM	Chinese 15 (Skin type IV/V, age 10–73 y) Caucasian 3 (Skin type II, age 22–49 y) African American 3 (Skin type VI, age 18–52 y)	Volar forearm	• Proportion of individually distributed to clustered melanosomes: African Americans > Asians > Caucasians ($p < 0.05$) • Mean ± SD size of melanosomes distributed individually > clustered, in all ethnic groups. • Mean ± SD size of random melanosomes: African Americans > Asians > Caucasians ($p < 0.05$)
(b) Skin Surface Microflora				
Rebora et al.[58]		Black men 10 White men 10 (age 21–59 y, both)	Forearm	• *Candida albicans* blacks (150% greater) > whites ($p < 0.025$) • Aerobes blacks (650% greater) > whites ($p < 0.025$)
Warrier et al.[83]		Black women 30 White women 30 (age 18–45 y, both)	Left and right medial cheeks, midvolar forearms, lateral midlower legs	• Density of *Propionibacterium acnes* blacks > whites, but not statistically significant • No significant difference in aerobes

Note: EM = electron micrograph; SD = standard deviation; y = years.

[a] Darker skin has more individually dispersed melanosomes in comparison to lighter skin, and individually dispersed melanosomes tend to be larger in size than clustered melanosomes. Additionally, there is insufficient and conflicting evidence to draw conclusions regarding ethnic differences in skin microflora.

Source: Wesley, N.O. and Maibach, H.I., *Am. J. Clin. Dermatol.*, 4(12), 843–860, 2003. With permission.

the Negroid keratinocytes showed numerous melanosomes, longer and wider than in other racial groups, and mostly individually dispersed. Additionally, they observed an increase in melanosomes of keratinocytes of all races after irradiation, with grouping of melanosomes maintained in Caucasoids and Mongoloids. The authors concluded that individually dispersed melanosomes give a more uniform and dense color than the grouping found in fair skin.

In 1973, Konrad et al.[40] studied melanosome distribution patterns in hyperpigmented white skin alone and found that when comparing hyperpigmented lesions to control areas, there were no uniform differences in the distribution patterns of melanosomes. In addition, the degree of clinical hyperpigmentation was not associated with specific distribution patterns. However, they did note an important relationship between melanosome size and distribution: the percentage of melanosomes dispersed singly increased with increasing melanosome size. The authors also reported findings with experimental pigment donation showing that large melanosomes are taken up individually by keratinocytes and dispersed singly within their cytoplasm while small melanosomes are incorporated and maintained as aggregates. This data suggested melanosome size differences as the basis for skin color differences between black skin and white skin.

More recently, Thong et al.[78] quantified variation in melanosome size and distribution pattern in Asian, Caucasian, and African-American skin. The volar forearms of 15 Chinese (phototypes IV–V; aged 10–73 years), 3 Caucasians (phototype II; aged 22–49 years), and 3 African Americans (phototype VI, aged 18–52) were examined by electron microscopy of 4-mm punch biopsies. The proportions of individual and clustered melanosomes were compared for each ethnic group and showed statistically significant differences ($p < 0.05$). Melanosomes in Caucasian skin were distributed as 15.5% individual versus 84.5% clustered. Meanwhile, in African Americans, the melanosomes were distributed as 88.9% individual versus 11.1% clustered. The Asian melanosome distribution was intermediate between the latter two groups, as 62.6% individual versus 37.4% clustered. The investigators also determined the mean ± standard deviation (SD) size of melanosomes distributed individually to be larger in comparison to those distributed in clusters for each ethnic group. The mean ± SD of random melanosomes in each group differed as African-American skin showed significantly larger melanosome size than Caucasian skin, and Asian skin showed melanosome size as intermediate between the two other two groups. Thus, there was a trend of progressive increase in melanosome size when moving from Caucasian to African-American skin that corresponded with the progression from predominantly clustered to predominantly individual melanosome distribution. In addition, degradation patterns of melanosomes in the upper levels of epidermis varied by ethnic group. As keratinocytes became terminally differentiated and migrated to the SC, melanosomes were completely degraded and absent in the SC of light skin, while intact melanosomes could be seen in the SC of dark skin. Asian skin showed an intermediate pattern where few melanosomes remained in the corneocytes; interestingly, the remaining melanosomes were predominantly individual, indicating that clustered melanosomes may be degraded more efficiently during this process.

Alaluf et al.[1] examined the morphology, size, and melanin content of melanosomes on the volar upper arms and dorsal forearms of 10 European, 8 Chinese, 10 Mexican, 10 Indian, and 10 African subjects living in South Africa. Four-millimeter punch biopsies were analyzed based on electron micrographs of melanosomes and on alkali solubility of extracted melanin. The melanosome size of dorsal forearm (photoexposed) skin was observed as approximately 1.1 times larger than melanosome size of volar upper arm (photoprotected) skin ($p < 0.001$) when data were pooled from all ethnic groups; each ethnic group separately showed a similar trend, but lacked statistical significance. In addition, a progressive and statistically significant increase in average melanosome size was observed when moving from European (light) to African (dark) skin types. The melanosome size was directly correlated with total melanin content in the epidermis of all subjects ($p < 0.0001$). When comparing the epidermal melanin content among ethnic groups, the investigators found as downward trend in the amount of alkali soluble melanin (light-colored pheomelanin and DHICA-enriched eumelanin) in epidermis as the skin type became progressively darker; African skin contained the lowest amount ($p < 0.02$). Indian skin presented an exception to this trend with higher concentrations of light melanin fractions than both Mexican and Chinese skin ($p < 0.05$). However, both African and Indian skin showed about two times more of the alkali insoluble melanin (dark-colored DHI-enriched eumelanins) than the Mexican, Chinese, and European skin types ($p < 0.001$). Overall, the melanin composition showed a trend toward higher fractions of alkali-soluble melanins while moving from darker (African) skin to lighter (European) skin. In addition, African and Indian skin revealed the highest total amount of melanin ($p < 0.001$) and did not differ significantly from each other. There was no significant difference in total epidermal melanin between the remaining groups.

Despite the data showing differences in number and distribution of melanosomes, recent studies find no evidence of differences in numbers of melanocytes among ethnic groups.[75] For example, Alaluf et al.[2] found no significant difference in melanocyte number between African ($n = 10$), Indian ($n = 10$), Mexican ($n = 10$), or Chinese ($n = 8$) skin types using immunohistochemical methods. They did consistently find 60–80% more melanocytes in European ($n = 10$) skin than all other skin types ($p < 0.01$), but the authors felt a larger sample size would be necessary to confirm this observation. Tadokoro et al.[73] also found approximately equal densities of melanocytes in unirradiated skin of Asian, black, and white subjects ranging from 12.2 to 12.8 melanocytes per millimeter.

Thus, it is generally accepted that differences in skin color are supported more by differences in melanosome distribution, size, and content rather than melanocyte number. Szabo et al.[71] observed larger and more individually dispersed melanosomes in Negroid keratinocytes and

concluded that individually dispersed melanosomes may contribute to a more dense skin color. Konrad et al.[40] further noted that the number of singly dispersed melanosomes increased as melanosome size increased. Thong et al.[78] quantified the ethnic differences in melanosome size and distribution, finding a gradient in relative proportion of individual versus clustered melanosomes that corresponded with size of melanosomses. At one extreme, African-American skin showed larger melanosomes that were predominantly individually dispersed; and with Asian skin displaying intermediate results, Caucasian skin was at the other extreme, showing smaller melanosomes that were predominantly clustered. Alaluf et al.[1] also revealed a progressive increase in melanosome size as ethnic skin went from lighter to darker. Furthermore, dark skin contained more total melanin and a larger fraction of DHI-enriched (dark-colored) eumelanin than light skin.

2.15 SURFACE MICROFLORA

Ethnic differences in skin microflora have also been examined. Rebora and Guarrera[58] inoculated the forearm skin of 10 black men and 10 white men, aged 21–59 years, with *Candida albicans* and examined the severity of ensuing dermatitis as well as the population of *Candida* and other aerobes at the inoculum site. The severity of dermatitis was scored subjectively by observation of pustules. However, population of microflora was assessed objectively by colony counts after aerobic incubation at 95°F (35°C) for 2 days. Black skin harbored 150% more yeast after inoculation with *C. albicans* and 650% more aerobes both at baseline and after inoculation than white skin ($p < 0.025$).

In addition to investigating TEWL, capacitance, desquamation index, elastic recovery, and skin pH, Warrier et al.[83] also examined facial skin microflora in 30 black and 30 white women, aged 18–45 years. They found no significant differences in the density of aerobes (mostly *Staphylococcus* spp.) between blacks and whites. In contrast, although not statistically significant, there was a higher density of *Propionibacterium acnes* in blacks compared with whites. They felt that this might be due in part to a believed increase in sebum output in blacks.[38]

Both studies demonstrated increased skin microflora in blacks in that Rebora and Guarrera[58] found that blacks harbor significantly more *C. albicans* after inoculation, and Warrier et al.[83] found higher density of *P. acnes,* but the values were not statistically significant. However, Rebora and Guarrera[58] found blacks to have significantly higher levels of aerobes both at baseline and after inoculation with *C. albicans,* while Warrier et al.[83] found no significant ethnic differences in the density of aerobes. Since the minimal data that exist are conflicting, no conclusions regarding skin microflora can be made until investigators examine the issue further (see Table 2.6). Perhaps the age of subjects, anatomic site, and humidity of the geographic environment where the study was conducted cause variation in skin microflora and should be accounted for in the future studies.

2.16 ANTIMICROBIAL PROPERTIES

In 2001, Mackintosh[43] reviewed evidence discussing the role of melanization of skin in the innate immune defense system. He reported that a major function of melanocytes, melanosomes, and melanin in skin is to inhibit the proliferation of bacterial, fungal, and other parasitic infections in the dermis and epidermis. Numerous studies are cited showing evidence that melanocytes and melanosomes exhibit antimicrobial activity and are regulated by known mediators of inflammatory response. The review aims to support the hypothesis that immunity and melanization are genetically and functionally linked. The author notes that previous reports have implied a reduced susceptibility of dark-skinned individuals to skin disease. In addition, it is postulated that the evolution of black skin could represent high pressures from infection, especially in tropical regions. In five out of six recent investigations, people of African descent have been shown to be less susceptible than whites to scabies, fungal dermatophytosis, cutaneous *C. albicans* infections, and bacterial pyodermas. Additionally, although Rebora and Guarrera[58] demonstrated increased skin microflora in blacks, they found that the severity of dermatitis in black subjects was significantly less ($p < 0.01$) suggesting the possibility of increased barrier defense. This evidence may explain the existence of melanocytes and melanization among different parts of the body is independent of sun exposure, as in the genitalia, as well as the latitudinal gradient in skin melanization. The evolutionary data presented in this review article are compelling and indicate a necessity for controlled studies to clarify whether the number or melanocytes, size of melanosomes, or type of melanin can affect the antimicrobial properties of skin.

2.17 PHOTODAMAGE

Although there is evidence for objective differences in skin color, it remains unclear what role these differences in melanin and melanosomes play in dermatologic disorders. Section 2.16 of this chapter introduced the potential role of melanosomes in antimicrobial defense. The most extensively studied function of darker skin color, however, has been in resistance to photodamage from UV radiation. End effects of photodamage include skin cancer, which are well documented as affecting lighter skinned individuals more than those with darker skin.

In determining a relationship between melanosome groupings and sun exposure, studies have observed that dark-skinned whites, when exposed to sunlight, have nonaggregated melanosomes, in contrast to light-skin, unexposed whites who have aggregated melanosomes. Similarly, there are predominantly nonaggregated melanosomes in sunlight-exposed Asian skin, and primarily aggregated melanosomes in unexposed Asian skin.[62,75]

Alaluf et al.[1] noted an increase in melanosome size in photoexposed skin versus photoprotected skin in all ethnic groups; the melanosome size was directly correlated with epidermal melanin content, suggesting increased melanogenesis

in photoexposed areas. Van Nieuwpoort et al.[81] demonstrated that with increased melanogenesis, light skin melanosomes showed elongation and reduction in width with no significant change in surface area, while dark skin melanosomes enlarged in both length and width with an increase in volume. Based on these data, although all skin types show an increase in epidermal melanin with sun exposure, both distribution and morphology may influence unequal filtering between light and dark skin types.

In another study, Rijken et al. [63] investigated response to solar-simulating radiation (SSR) among white and black skin. Six healthy Dutch white subjects, with skin phototype I–III and mean age of 24.5 years, were exposed to 12,000–18,000 mJ/cm^2 of SSR. Six healthy West-African or Afro (South) American black subjects, skin phototype VI, and mean age of 25.3 years, were exposed to 18,000 mJ/cm^2 of SSR. Six other white subjects were also added to study the effects of erythema effective doses of SSR. Skin pigment, DNA photodamage, infiltrating neutrophils, photoaging-associated proteolytic enzymes, keratinocyte activation, and the source of interleukin 10 (IL-10) in skin biopsies taken before and after radiation. The significance of IL-10 lies in the fact that IL-10 producing cells may be involved in skin carcinogenesis. In each white volunteer, SSR caused DNA damage in epidermal and dermal cells, an influx of neutrophils, active proteoytic enzymes, and keratinocyte activation. Also, three white volunteers showed IL-10 producing neutrophils in the epidermis. In black-skinned individuals, aside from DNA damage in the suprabasal epidermis, there were no other changes found; basal keratinocytes and dermal cells were not damaged. The authors concluded that these results were best explained by difference in skin pigmentation and that melanin functions as a barrier to protect basal keratinocytes and the dermis from photodamage.

Other studies have suggested that filter properties of melanin alone do not provide sufficient protection against DNA damage in underlying cells. Tadokoro et al.[72] investigated the relationship between melanin and DNA damage after UV exposure in 37 subjects of 5 ethnic origins (black, white, Asian, others not specified), and Fitzpatrick phototypes I through VI. They found measurable damage to DNA in all groups, and DNA damage was maximal immediately after irradiation, gradually returning to baseline over time. The immediate DNA damage levels were higher in whites and Asians in comparison to blacks and Hispanics. In addition, the whites and Asians showed lower constitutive levels of melanin content. However, the kinetics of DNA damage differed among subjects. Upon monitoring the percentage of removal of damage toward baseline 7 days after UV exposure, no correlation was found between melanin content or ethnic group and the efficiency of DNA damage removal. There were variable rates of DNA repair within individual groups indicating that DNA repair rates were not associated with skin type. The authors noted that other properties of melanin, such as antioxidant properties and radical scavenging properties, may play roles in minimizing UV damage. Ethnic differences in expression of receptors involved in melanosome uptake and melanocyte-specific proteins, both before and after UV exposure, are also being investigated.

2.18 CONCLUSION

The U.S. census bureau estimates that the population is composed of 12.1% black or African American, 13.9% Hispanic, or Latino, and 11.9% other nonwhites.[80] It has been predicted that people with skin of color will constitute a majority of the United States and international populations in the twenty-first century.[56] These statistics highlight the importance of objective investigation of differences in structure and function of skin of different colors, relationships between race, color, ethnicity, and process and presentation of disease in these groups. It is imperative that we have a deeper understanding of these characteristics, as they play an important role in learning how to appropriately modify patient treatment. Differences do exist in structure and physiology of skin among different races, and may differentially affect disease. However, data on ethnic differences in skin, physiology, and function are few; the studies that do exist consist of typically small patient populations. Consequently, few definitive conclusions can be made. The FDA currently recommends inclusion of more ethnic groups in dermatologic trials, citing evidence that physiologic differences in skin structure between races can result in varying efficacies of dermatologic and topical treatments.[15]

There exists reasonable evidence (Table 2.7) to support that black skin has a higher TEWL, variable blood vessel reactivity, lower skin surface pH, larger mast cell granules, and larger melanosomes with more individual distribution when compared with white skin by means of objective measurements. Although some deductions have been made about Asian and Hispanic skin, the results are contradictory and further evaluation of Asian and Hispanic skin needs to be done. A review by Robinson[64] also supported the notion that the evidence comparing Asian and Caucasians is insufficient and less than compelling. Perhaps more specificity about the origin of their heritage should also be included since "Asian" and "Hispanic" encompass a broad spectrum of people. Ethnic differences in skin WC, corneocyte desquamation, skin elastic recovery/extensibility, microtopography, lipid content, sebaceous function, follicular morphology and distribution, and skin microflora, although statistically significant, are minimal and contradictory. Thus, no conclusions regarding these objective data can be made.

One issue that must be raised when interpreting these studies is the definition of race or ethnicity. Race seems to emcompass genetic variations based on natural selection, which include, but are not limited to pigmentation,[15] pigmentation appears to be based mainly on erythema, melanin, and the skin's response to physiologic insult. Anthropologists divide racial groups into Caucasoid (e.g., Europeans, Arabs, Indians), Mongoloid (e.g., Asians), Australoid (e.g., Australian

TABLE 2.7
Summary

Evidence Supports	Insufficient Evidence for	Inconclusive
• TEWL black > white skin • Variable ethnic blood vessel reactivity • pH black < white skin • Larger mast cell granules, increased PLS, and increased tryptase localized to PLS in black compared to white skin • Darker skin has more individually dispersed melanosomes; larger than clustered melanosomes	• Deductions regarding Asian and Hispanic skin Ethnic differences in:[a] • Skin elastic recovery/extensibility • Skin microflora • Epidermal innervation • Microtopography • Vellus hair follicle morphology/distribution	Ethnic differences in: • Water content • Corneocyte desquamation • Lipid content • Sebaceous function

Note: PLS = parallel-linear striations; TEWL = transepidermal water loss.

[a] Skin elastic recovery/extensibility, skin microflora, epidermal innervation, microtopography, and vellus hair follicle morphology/distribution were labeled as "insufficient evidence for" ethnic differences rather than "inconclusive" because only two studies or less examined these variables.

aborigines), Congoid or Negroid (e.g., most African tribes and descendants) and Capoid (e.g., the Kung San African tribe) with the idea that racial variations were selected to facilitate adaptations to a particular environment.[16,76] Some reject the relevence of any genetic basis for race, stating that 90–95% of genetic variation occurs within geographic populations rather than across racial groups.[15] Furthermore, the concept of race has been dismissed by some as being an artificial, nongenetically defined construct, lacking scientific basis, and a hindrance for research, diagnosis, and treatment of skin disease.[15,86]

Ethnicity, in contrast, is a more general term, encompassing biologic and cultural factors. Ethnicity has been defined as how one sees oneself and how one is seen by others as part of a group on the basis of presumed ancestry and sharing a common destiny, often with commonalities in skin color, religion, language, customs, ancestry, and occupation or region.[51] Thus, ethnicity not only encompasses a set of categories that overlaps with race but also depends on more subjective and cultural factors, while race seems to encompass genetic variations based on natural selection. With these obscure definitions based on both biology and the subjective manner in which one labels oneself, the basis of objective research on racial or ethnic differences is already somewhat subjective and therefore problematic. However, studies show that differences, whether based on genetic variations or on subjective labels, do exist. Perhaps future studies in dermatology should also address how one defines oneself as part of a particular race or ethnic group in addition to examining degree of skin pigmentation. This will help determine whether the differences are truly the result of genetic variations that were selected for by race or of biologic variations in melanin content that vary between and within each race. Further research in both genetics and dermatology are warranted to draw any final conclusions with regards to race/ethnicity as the etiology for differences in skin physiology.

References 35

3.1 INTRODUCTION

In general, occlusion may increase percutaneous absorption of applied compounds, but with exception (Bucks et al. 1988; Bucks et al. 1991; Bucks and Maibach 1999). It has been used in dermatology to increase topical corticosteroids efficacy (Scholtz 1961; Sulzberger and Witten 1961). However, it also obstructs normal ventilation of the skin surface; increases stratum corneum (SC) hydration, and hence may compromise skin barrier function (Agner and Serup 1993; Kligman 1996; Warner et al. 1999; Kligman 2000). Evaluation and investigation of the impact of occlusion on barrier function are important in skin physiology, pathology, pharmacology, and dermatology (Zhai and Maibach 2002). This updated chapter from Zhai and Maibach (2004) emphasizes the effects of occlusion on skin barrier function, particularly, as defined with objective skin bioengineering technology.

3.2 OCCLUSION AND ITS APPLICATION

With occlusion, the skin is covered directly or indirectly by impermeable films or substances such as diapers, tape, chambers, gloves, textiles, garments, wound dressings, transdermal devices, etc. (Kligman 1996). In addition, certain topical vehicles that contain fats or polymers oils (petrolatum, paraffin, etc.) may also generate occlusive effects (Berardesca and Maibach 1988).

Owing to its simplicity, occlusion is widely utilized to enhance the penetration of applied drugs in clinical practice. However, occlusion does not increase percutaneous absorption to all chemicals (Bucks et al. 1988; Bucks et al. 1991; Bucks and Maibach 1999). It may increase penetration of lipid-soluble, nonpolar molecules but has less effect on polar molecules: a trend of occlusion-induced absorption enhancement with increasing penetrant lipophilicity is apparent (Bucks et al. 1988; Treffel et al. 1992; Cross and Roberts 2000). In practice, increasing skin penetration rates of applied drug is far from simple. Skin barrier function can be ascribed to the macroscopic structure of the SC, consisting of alternating lipoidal and hydrophylic regions. For this reason, physico-chemical characteristics of the chemical, such as partition coefficient, structure, and molecular weight, play an important role in determining the facility of absorption (Wiechers 1989; Hostynek et al. 1996). Another factor to consider in drug percutaneous absorption is that the vehicle in which the drug is formulated acts on drug release from the formulation (Hotchkiss et al. 1992; Cross and Roberts 2000). Smith and Maibach (2005) provide an extensive overview of percutaneous penetration enhancers. In addition, the anatomical site may also influence the effects of occlusion on percutaneous absorption (Qiao et al. 1993).

In many industrial and food fields, protective gloves or clothing may protect the workers from hazardous materials or for hygiene. However, these protective measures may also produce negative events because of the nature of occlusion, which often causes SC hyperhydration and reduces the protective barrier properties of the skin (Graves et al. 1995). Many gloves do not resist the penetration of low molecular weight chemicals. As a result, those chemicals may enter the glove and become trapped on the skin under occlusion for many hours, possibly leading to irritation, and more seriously to dermatitis or eczematous changes (Van der Valk and Maibach 1989; Mathias 1990; Estlander et al. 1996; Chew and Maibach 2005).

Wound dressings have been employed to speed the healing processes in acute and chronic wounds. They keep

Modified from *Dermatotoxicology*, 6th Edition.

healing tissues moist and increase superficial wound epithelialization (Winter 1962; Winter and Scales 1963; Hinman and Maibach 1963; Alvarez et al. 1983; Eaglstein 1984; Berardesca and Maibach 1988). However, occlusive or semiocclusive dressings can increase microorganisms and hence induce wound infections (Aly et al. 1978; Rajka et al. 1981; Faergemann et al. 1983; Mertz and Eaglstein 1984; Berardesca and Maibach 1988). A significant increase in the density of *Staphylococcus aureus* and lipophilic diphtheroids were observed after 24 h occlusion in eczematous and psoriatic skin (Rajka et al. 1981).

Thus, the effects of occlusion on skin are complex and may produce profound changes that include altering epidermal lipids, DNA synthesis, epidermal turnover, pH, epidermal morphology, sweat glands, Langerhans cells stresses, etc (Faergemann et al. 1983; Berardesca and Maibach 1988; Bucks et al. 1991; Matsumura et al. 1995; Kligman 1996; Berardesca and Maibach 1996; Leow and Maibach 1997; Denda et al. 1998; Bucks and Maibach 1999; Warner et al. 1999; Kömüves et al. 1999; Fluhr et al. 1999; Kligman 2000).

3.3 SKIN BARRIER FUNCTION

Skin has numerous functions, one of which is to serve as a water permeability barrier to keep body fluids in and minimize dehydration. This function takes place largely in the SC or horny layer (Baker 1972). SC has been referred to as a brick and mortar structure. The bricks are protein-rich corneocytes separated by lipid-rich intercellular domains consisting of stacks of bilaminar membrane (Kligman 2000). Normally, the passage of water through the skin is closely controlled—allowing 0.5 cm^2/h to evaporate. When water content falls too low, water barrier function is impaired and the skin becomes more sensitive to repeated use of water, detergents, and other irritants. Barrier function may be disturbed by physical, chemical, pathological factors, and environmental changes (Denda et al. 1998).

Maintenance of the SC structural integrity is critical to barrier function. Increasing SC hydration can progressively reduce barrier efficiency (Bucks et al. 1991; Matsumura et al. 1995; Berardesca and Maibach 1996; Kligman 1996; Leow and Maibach 1997; Bucks et al. 1988; Haftek et al. 1998; Warner et al. 1999; Bucks and Maibach 1999; Fluhr et al. 1999; Tsai and Maibach 1999; Kligman 2000) and the changes of protein dynamics (Alonso et al. 2003). SC is extremely hygroscopic: it can pick up 500% of its dry weight in less than 1 h following immersing in water, swelling vertically to four to five times its original width (Kligman 2000).

3.4 EFFECTS OF OCCLUSION ON BARRIER FUNCTION

Healthy SC typically has a water content of 10–20% (Baker 1972). Occlusion can block diffusional water loss from skin surface, increasing SC hydration, thereby swelling the corneocytes, and promoting water uptake into intercellular lipid domains (Bucks et al. 1991; Bucks and Maibach 1999). Water content can be increased up to 50% with occlusion (Bucks et al. 1991; Bucks and Maibach 1999): even short-time (30 min) exposure can result in significantly increased SC hydration (Ryatt et al. 1988). With 24 h occlusion, the relative water content in SC can be increased significantly from 53% before occlusion to 59% (Faergemann et al. 1983). Occlusion of 24 h can induce morphological changes on the surface deepening skin furrows (Matsumura et al. 1995). Zhai et al. (2002) determined the level of skin hydration and skin permeability to nicotinates following occlusive patches and diapers at different exposure times. They found that permeation of nicotinates was increased for hydrated skin versus control even after only 10 min of patch exposure. No evidence of increased permeation rates with increased hyperhydration once a relatively low threshold of hyperhydration was achieved (e.g., which reached after a 10 min wet patch). Water under occlusion may disrupt barrier lipids and damage SC similar to surfactants (Warner et al. 1999). Kligman (1996) studied hydration dermatitis in man: 1 week of an impermeable plastic film did not injure skin; 2 weeks was moderately harmful to some but not all subjects; 3 weeks regularly induced dermatitis. Hydration dermatitis was independent of race, sex, and age. They examined the potential role of microorganisms in developing hydration dermatitis by using antibiotic solutions immediately following occlusion with plastic wrapping: microorganisms had no impact. In addition, hydrogels did not appreciably hydrate or macerate the surface by visual inspection when left in place for 1 week.

Some transdermal drug delivery systems (TDDS) may indeed provoke a dermatitis when applied twice weekly to the same site. These occlusive devices demonstrated marked cytotoxicity to Langerhans cells, melanocytes, and keratinocytes (Kligman 1996). However, Nieboer et al. (1987) evaluated the effects of occlusion with transdermal therapeutic systems (TTS) on Langerhans cell and skin irritation at different times ranging (6 h; 1, 2, 4, and 7 days). Irritation was judged on morphology, histopathologic, and immunofluorescence findings, and changes in the Langerhans cell systems. Occlusion provoked only slight or no skin irritation.

Bouwstra et al. (2003) recently reported that water only slightly changes the lipid transitions in the SC even at a hydration level of 300% wt/wt. No gradual increase in water level was observed in depth. At a very high hydration level (300% wt/wt), the corneocytes are strongly swollen except for the deepest cell layers adjacent to the viable epidermis. The corneocytes in these layers are not swollen. At 300% wt/wt hydration level, water domains are also present in intercellular regions. Between 17% wt/wt and 300% wt/wt, the cell thickness increases linearly with the hydration level suggesting that swelling of cells mainly occurs in the direction perpendicular to the skin surface. Fluhr et al. (1999) evaluated the barrier damage by prolonged occlusion on the forearm for 24–96 h and did not find significant changes in hydration and water-holding capacity. But transepidermal

water loss (TEWL) increased reaching a plateau on day two, concluding that occlusion induced barrier damage without skin dryness.

3.5 QUANTIFICATION WITH BIOENGINEERING TECHNIQUES

Recently, noninvasive bioengineering techniques have been utilized to better quantify skin barrier function. Modern noninvasive techniques can assess the mechanical and physiological properties of skin in health and disease. Their great value becomes apparent in providing accurate, reproducible, and objective measurements that can determine subtle differences before visual clinical signs. The unaided eye is not reliable for determining subclinical changes.

We briefly introduce some common useful noninvasive bioengineering techniques. Background, principles, extensive details, and validations of these techniques can be found in textbooks (Frosch and Kligman 1993; Elsner et al. 1994; Serup and Jemec 1995; Berardesca et al. 1995a,b; Wilhelm et al. 1997).

1. TEWL, as a marker of barrier function and structure changes, can be monitored by an evaporimeter (Tewameter) (Courage + Khazaka, Cologne, Germany, and Acaderm Inc., Menlo Park, California). It may also act as an indicator for the recovery of barrier function (Grubauer et al. 1989). Standard guidelines are utilized (Pinnagoda et al. 1990).
2. Cutaneous blood flux of test sites can be observed with a laser Doppler flowmeter (LDF) (Moor Instruments, Axminster, England) or laser Doppler velocimeter (LDV) (Acaderm Inc., Menlo Park, California). Methods and standard guidelines are described elsewhere (Bircher et al. 1994).
3. Skin color can be measured by a reflectance meter (such as a colorimeter) (Minolta, Osaka, Japan, and Acaderm Inc., Menlo Park, California), and the a* value (red–green axis) is considered a reliable quantification of erythema (Wilhelm et al. 1989; Wilhelm and Maibach 1989). Standard guidelines and measuring principle have been described in detail (Fullerton et al. 1996).
4. Capacitance as a parameter of SC hydration (or water content) can be determined with a capacitance meter (such as a Corneometer) (Courage + Khazaka, Cologne, Germany, and Acaderm Inc., Menlo Park, California). The measuring principle and methods are elsewhere (Triebskorn and Gloor 1993).

Brief quantification data of bioengineering measurements on occlusive skin conditions are summarized in Table 3.1.

TABLE 3.1
Brief Results of Bioengineering Measurements on Occlusive Skin Condition

Occlusive Manner and Time	Bioengineering Techniques	Results	References
Plastic film for 5 days	TEWL	TEWL increased from 0.56 mg/cm²/h (baseline) to 1.87 mg/cm²/h (occlusion) and showed essentially saturated after 2 days	Aly et al. (1978)
Plastic film for 1 h	TEWL and capacitance	Postocclusion TEWL was significantly greater than the normal sites	Orsmark et al. (1980)
Plastic film for 1, 3, and 8 days	TEWL and electromagnetic wave	Occlusion significantly increased TEWL and water content within 24 h	Faergemann et al. (1983)
Occlusion with polypropylene chamber or vehicles for 30 min; hexyl nicotinate (HN) as an indicator	LDV	The onset of action and time to peak were significantly shortened, and the peak height and area under curve (AUC) significantly increased under occlusion conditions	Ryatt et al. (1986)
Polypropylene chambers for 30 min; HN as an indicator	LDV	Occlusion significantly shortened both the time of onset of the LDV-detected response to HN and the time to peak response. In addition, the magnitude of the peak LDV response to HN and the AUC were significantly increased. Occlusion also significantly elevated the stratum corneum water content. There was a significant correlation between stratum corneum water content and area under the LDV response-time curve after 30 min occlusion	Ryatt et al. (1988)
Postapplication occlusion after short-term sodium lauryl sulphate (SLS) exposure for 5 consecutive days	TEWL	Occluded skin sites had a significant increase TEWL values (everyday and alternate-day schedule) when compared to unoccluded sites. Results indicated that postexposure occlusive treatment markedly enhanced irritant response	Van der Valk and Maibach (1989)
Chambers with 0.5% SLS, water, and empty chambers only for 3 h	TEWL	All values from SLS, water, and empty chambers were significantly increased as compared to normal skin	Pinnagoda et al. (1990)

(*continued*)

TABLE 3.1 (continued)
Brief Results of Bioengineering Measurements on Occlusive Skin Condition

Occlusive Manner and Time	Bioengineering Techniques	Results	References
Aluminum chambers and chambers with water, physiological saline, a paper disc or 0.002% of SLS for 24 h	Electrical impedance	Occlusion did not affect readings of electrical skin impedance taken 24 h or later after removal, but increased variance for readings taken 1 h after removal	Emtestam and Ollmar (1993)
Glove patch for 4 and 8 h, and empty dressing; HN as an indicator	LDV, TEWL, and skin surface roughness	Precorneal permeability, TEWL, compliance parameter were significantly increased after occlusion 4 and 8 h, and skin surface roughness was significantly reduced in terms of roughness parameters Ra and Rz by 4 and 8 h occlusion	Graves et al. (1995)
Plastic chambers with a series of sodium alkyl sulfates for 24 h	TEWL, capacitance, and a* values	All alkyl sulfates with the exception of sodium lauryl sulfate resulted in a temporary decrease of SC hydration 1 h after patch removal. At day 2, SC hydration levels of surfactant treated skin were not significantly different from controls. Thereafter, a second decrease in capacitance value was observed with lowest hydration at day 7	Wilhelm (1995)
Different occlusive and semipermeable dressings for 23 and 46 h on irritation and tape stripping skins	TEWL and capacitance	Occlusion did not significantly delay barrier repair	Welzel et al. (1995, 1996)
Short-term (6 h/day for 3 days) gloves on normal skin and gloves on SLS-compromised skin	TEWL, capacitance, and erythema index	Glove occlusion on normal skin for short-term exposure did not significantly change the water barrier function but caused a significantly negative effect on SLS-compromised skin for the same period	Ramsing and Agner (1996a)
Long-term (6 h/day for 14 days) gloves on normal skin and a cotton glove worn under the occlusive glove	TEWL, capacitance, and erythema index	This long-term using glove occlusion on normal skin caused a significant negative effect on skin barrier function, as measured by TEWL, which was prevented by the cotton glove	Ramsing and Agner (1996b)
Plastic chambers at 24, 48, 72, and 96 h	TEWL and capacitance	A significantly progressive increase under occlusion and reaching a plateau on day 2. Hydration and water-holding capacity did not show significant changes	Fluhr et al. (1999)
Occlusion with patches and diapers at different exposure times. Nicotinates as markers to evaluate skin permeability	Water evaporation rate (WER), skin blood flow volume (BFV), capacitance, and redness (a*)	Permeation of nicotinates was increased for hydrated skin versus control even after only 10 min of patch exposure. No evidence of increased permeation rates with increased hyperhydration once a relatively low threshold of hyperhydration was achieved (e.g., which reached after a 10 min wet patch)	Zhai et al. (2002)
Impermeable polyester film for 6 h	TEWL, impedance spectroscopy (IS) and attenuated-total-reflectance Fourier transform infrared (ATR-FTIR) spectroscopy	Occlusion of the skin either in the presence or absence of the cream caused TEWL to be increased when the treatment was terminated at 6 h. Uptake of ointment into the SC, on the other hand, inhibited the postapplication TEWL rate. In parallel, treatment with the ointment caused an increase in relatively low-frequency skin impedance, consistent with the entry of additional lipophilic constituents into the SC. The latter was confirmed by ATR-FTIR spectroscopic measurements	Curdy et al. (2004)

3.6 CONCLUSIONS

The effects of occlusion on skin barrier function have been defined with various techniques. Obviously, occlusion alone may damage skin barrier function. With application of chemicals/drugs under occlusion conditions, it can increase penetration of chemicals and antigens into the skin and therefore also increases dermatitis (Berardesca and Maibach 1988; Kligman 1996). Local reactions (i.e., irritation and sensitization) of TDDS, which are typically occlusive patches placed on the skin surface for 1–7 days to deliver the drugs into the systemic circulation have been widely reported (Boddé et al. 1989; Hogan and Maibach 1990, 1991; Patil et al. 1996; Murphy and Carmichael 2000). However, reactions can be minimized with immunosuppressive agents, antioxidants, local anesthetics, and other antiirritant technologies (Kydonieus and Wille 2000). Topical corticoids are another alternative but their role in the suppression of TDDS-induced dermatitis needs

better definition, especially for patients who require continued treatment with long-term application of such devices (Hogan and Maibach 1990). Advancements in design and construction of protective garments and wound dressings may reduce the level of skin hydration and dermatitis. Application of optimal hydrocolloid patches that absorb water in both liquid and vapor form can also decrease irritant reactions (Hurkmans et al. 1985; Fairbrother et al. 1992; Hollingsbee et al. 1995). A natural, pure, and nonwoven dressing has been made from calcium alginate fibers (Williams 1999). It can rapidly absorb and retain wound fluid to form an integral gellified structure, thereby maintaining an ideal moist wound-healing environment. It can also trap and immobilize pathogenic bacteria in the network of gellified fibers, stimulate macrophage activity and activate platelets, resulting in haemostasis and accelerated wound healing. Recent study indicated that with the silver-based wound dressing providing a more effective antimicrobial activity in a moist healing environment (Schaller et al. 2004).

Today, with the rapid development of the new technologies in the bioscience, we expect greater efficacy and optimal dressings or materials that can absorb excess water and reduce the unfavorable effects of occlusion.

4.1 INTRODUCTION

Dermatotoxicology is the branch of science dealing with the assessment of responses of the skin to specific toxicants. It is thought that the primary function of skin is a barrier between the well-regulated "milieu interieur" and the outside environment. This may give one the impression that the structure of skin is simple and solely focused on its barrier properties. Past research in percutaneous absorption and dermatotoxicology has reinforced this view. However, more recent research in percutaneous absorption and dermal toxicology now take into consideration the possibility that additional anatomical factors may also affect the barrier function of skin, thereby altering the rate of absorption. Many earlier model systems used to evaluate percutaneous absorption were primitive and not capable of modeling all of these factors. Therefore, it is the purpose of this chapter to illustrate to scientists working in this field the complexity of the integument and how anatomical structures within the skin contribute to and influence its barrier function.

4.2 GENERAL CHARACTERISTICS

Skin is a complex, integrated, dynamic organ that has many functions (Table 4.1), which go far beyond its role as a barrier to the environment. Although metabolism and drug biotransformation are important, the reader is directed to the chapters on this subject in the present text. Skin (derived from the Latin meaning *roof*) is the largest organ of the body and is anatomically divided into the epidermis, which is the outermost layer, and the underlying dermis (Figure 4.1). The epidermis consists of a stratified squamous keratinized epithelium derived from ectoderm in which 80% of the cells are keratinocytes. Other cell types such as the melanocytes (pigment formation), Langerhans cells (immunological function), and Merkel cells (sensory perception) represent the nonkeratinocytes. The epidermis undergoes an orderly pattern of proliferation, differentiation, and keratinization. However, these processes are not fully understood. In addition, the epidermis can become specialized to form skin appendages such as hair, sebaceous and sweat glands, feathers, horn, digital organs (hoof, claw, nail), and specialized glandular structures.

The human epidermis consists of four to five cell layers depending on the body site. The first layer, the stratum basale, is a single layer of cuboidal- to columnar-shaped cells that are attached laterally to adjacent cells by desmosomes and to the irregular basement membrane by hemidesmosomes. The basal cell population is heterogeneous in that there are two morphologically distinct types. The first can function as stem cells and has the ability to divide and produce new cells, whereas the second serves to anchor the epidermis to the basement membrane (Lavker and Sun, 1982, 1983). The second outer layer is the stratum spinosum or "prickle cell layer," which consists of several layers of irregular polyhedral cells. These cells are connected to the stratum basale cells below and to the adjacent spinosum cells by desmosomes. The most prominent feature in this layer is the tonofilaments. Along with desmosomes, tight junctions (zona occludens) may connect cells to one another. It is in the uppermost layers of the stratum spinosum, that membrane coating or lamellar granules first appear. The third layer is the stratum granulosum that consists of several layers of flattened cells lying parallel to the epidermal–dermal junction. Irregularly shaped,

nonmembrane bound electron dense keratohyalin granules are present and contain a structural protein known as profilaggrin, a precursor of filaggrin. It has been speculated that these granules are involved in keratinization and formation of the barrier function of the skin.

The lamellar or membrane-coating granules (Odland bodies, lamellated bodies) containing stacks of lamellar disks are found within the stratum granulosum and increase in number and size as they approach the surface. As epidermal differentiation progresses, the lipid is synthesized and packaged into lamellar granules. These granules fuse with the cell membrane to release their lipid contents by exocytosis into the intercellular space between the stratum granulosum and stratum corneum layers (Yardley and Summerly, 1981; Matolsty, 1976). The granules then undergo a biochemical and physical change to form the lipid sheets that constitute the permeability barrier. Extraction of lipids in skin has shown that the epidermal lipid composition dramatically changes as the keratinocytes differentiate. Lipid composition of the epidermis may consist of phospholipids, glucosylceramides, ceramides, cholesterol, free fatty acids, triacylglycerols, and sphingosine (Downing, 1992; Swartzendruber et al., 1989).

In exceptionally thick skin and hairless regions of the body, such as the plantar and palmar surfaces, a stratum lucidum layer is present. This is a thin, translucent, homogeneous line between the stratum granulosum and stratum

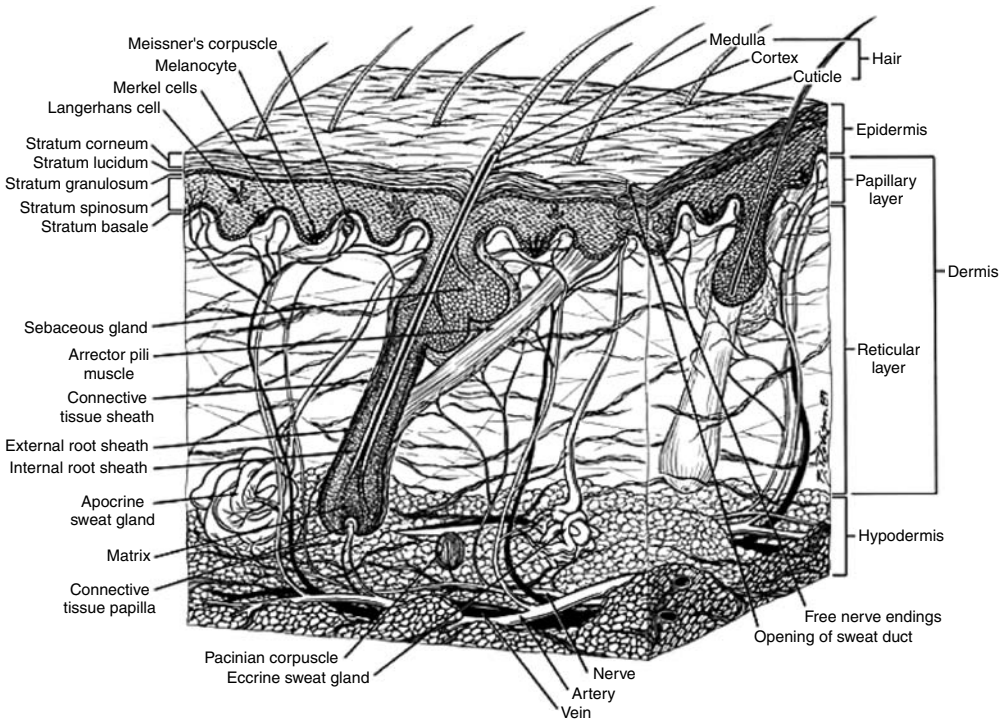

FIGURE 4.1 Schematic diagram illustrating the structure of mammalian skin (human and animal) from various regions of the body. (Reprinted from Monteiro-Riviere, N.A., in *Dermal and Ocular Toxicology: Fundamentals and Methods*, CRC Press, Boca Raton, FL, 1991. With permission.)

corneum, which consists of fully keratinized, closely compacted, dense cells that lack nuclei and cytoplasmic organelles. This translucent area contains a semifluid substance known as eleiden, which is similar to keratin but has a different staining pattern, as well as different protein-bound phospholipids (Leeson and Leeson, 1976). The outermost and final layer is the stratum corneum, which consists of several layers of completely keratinized dead cells, devoid of nuclei and cytoplasmic organelles that are constantly being shed. The most superficial layer of the stratum corneum is sometimes referred to as the stratum disjunctum. The thickness of the stratum corneum or number of cell layers varies depending on site and species (Monteiro-Riviere et al., 1990). It is this layer that provides an efficient barrier against transcutaneous water loss. Predominantly, it is the intercellular lipids, arranged into lamellar sheets that constitute the epidermal permeability barrier. Ruthenium tetroxide postfixation allows the visualization of these lipid lamellae at the ultrastructural layer (Swartzendruber, 1992). The number of lamellae may vary within the same tissue specimen. In some areas, it consists of a pattern of alternating electron-dense and electron-lucent bands that represent paired bilayers formed from fused lamellar granule disks as postulated by Landmann (Landmann, 1986; Swartzendruber et al., 1987, 1989; Madison et al., 1987).

It is widely acknowledged that the rate-limiting barrier to the absorption of most topically applied chemicals is the stratum corneum. Anatomical factors discussed such as the number of epidermal cell layers and the thickness of the stratum corneum may be parameters that modulate absorption. However, with knowledge that the pathway through the stratum corneum is via the intercellular lipids, the real resistance to absorption should relate to the length of this pathway. This has been clearly visualized using mercuric chloride staining in passive (Bodde et al., 1991) and iontophoretic (Monteiro-Riviere et al., 1994) drug delivery. Extraction of epidermal lipids using organic solvents reduces barrier function (Monteiro-Riviere et al., 2001; Hadgraft, 2001). The length is a function of the geometry of packing of the cells in the stratum corneum. The major route of a compound is via the intercellular bilipid channels, therefore, the absorption of a compound should be based on its diffusion path length (300–500 μm), not the actual thickness. Previous authors have described this spatial organization of vertical columns of interdigitating stratum corneum cells as resembling a tetrakaidecahedron. This 14-sided polygonal structure provides a minimum surface–volume ratio, which allows for space to be filled by packing without interstices (Menton, 1976a,b; Mackenzie, 1975). Therefore, the length is a function of the number of cell layers, overall thickness, the cell size, and the tortuosity of this pathway (Williams and Riviere, 1995).

As cells move outward from the basal layer, they undergo keratinization, which is the process by which epidermal cells differentiate. After the basal cells undergo mitosis, they migrate upward, increase in size, and produce large numbers of differentiation products (tonofilaments, keratohyalin granules, and lamellated bodies). Then the nuclei and organelles disintegrate, the filaments and keratohyalin arrange themselves into bundles, and the lamellated granules discharge their contents into the intercellular space coating the cells. The endpoint of this keratinization process is a nonviable, protein-rich terminally differentiated cell with a thicker plasmalemma, containing fibrous keratin and keratohyalin, surrounded by the extracellular lipid matrix. This forms the so-called "brick and mortar" arrangement, which is the morphological basis for the heterogeneous, two-compartment stratum corneum model (Elias, 1983).

The basement membrane is synthesized by the basal cells and separates the epithelium from the underlying connective tissue. This thin extracellular matrix is complex and consists of a highly organized structure of large macromolecules. By transmission electron microscopy, the cutaneous basement membrane is composed of four major components: (1) the cell membrane of the basal epithelial cell, (2) an electron lucent area beneath the plasma membrane called the lamina lucida, (3) an electron dense area beneath the lamina lucida called the lamina densa, and (4) the subbasal lamina containing anchoring fibrils, microfibril-like elements, and single-collagen fibers (Briggaman and Wheeler, 1975). In addition to this ultrastructural characterization, new epidermal–dermal junction biochemical components are constantly being identified and characterized. Representative examples of the most common ones include type IV collagen, laminin, entactin/nidogen, bullous pemphigoid antigen, heparan sulfate proteoglycan, fibronectin, GB3 (Nicein, BM-600, epiligrin), L3d (Type VII), 19-DEJ-1 (Uncein), epidermolysis bullosa acquisita, and the list is still growing. (Timpl et al., 1983; Woodley et al., 1984; Verrando et al., 1987; Fine et al., 1989; Rusenko et al., 1989; Briggaman, 1990). Many functions have been attributed to the basement membrane including a role in maintaining epidermal–dermal adhesion, and acting as a selective barrier between the epidermis and the dermis that restricts some molecules and permits the passage of others. In disease, they can also serve as a target for both immunologic and nonimmunologic injury.

4.3 DERMIS

The dermis lies beneath the basement membrane and consists primarily of dense irregular connective tissue within a matrix of collagen, elastic, and reticular fibers and is embedded in an amorphous ground substance made up of various types of proteoglycans. The predominant cell types of the dermis are fibroblasts, mast cells, and macrophages. In addition, plasma cells, fat cells, chromatophores, and extravasated leukocytes are often found. Blood vessels, lymphatics, and nerves traverse through the dermis along with glandular structures such as sebaceous glands, sweat glands, and hair follicles. There are two types of sweat glands in man: eccrine and apocrine. The eccrine gland is found over the entire body, except for a few areas where the apocrine gland may dominate (e.g., axilla, areola, pubis, perianal, eyelid, and external auditory meatus). In contrast, the apocrine gland is found over the entire body surface in hairy mammals and most carnivores.

The papillary layer, the most superficial layer of the dermis, conforms to the stratum basale layer and consists of loose connective tissue that blends into the deeper reticular layer, which consists of dense connective tissue. The hypodermis or subcutaneous layer is beneath the dermis and anchors the dermis to the underlying muscle or bone.

4.4 REGIONAL AND SPECIES DIFFERENCES

Studies in dermatology, cutaneous pharmacology, and toxicology involve experiments in which skin from different animal species and body regions are utilized. However, differences in stratum corneum thickness or number of cell layers must not be overlooked because they may affect barrier function. Table 4.2 summarizes the thickness of the nonviable stratum corneum and viable epidermis and the number of cell layers from the back (thoracolumbar area) of nine species used in dermatology research (Monteiro-Riviere et al., 1990). This finding confirms that skin thickness of the back was different across these species suggesting that body site alone is not a sufficient factor to ensure successful interspecies extrapolations. For more detail information regarding thickness of other body site measurements of these nine species, see Monteiro-Riviere et al. (1990). Some studies report differences in human skin but the database has only been collected at a few specific body sites (Blair, 1968). Measurements have been done on the number of cell layers at different sites and ages in humans and showed considerable variation in different areas of the body (Southwood, 1955; Rushmer et al., 1966). In general, data on the thickness of the stratum corneum are limited. Studies with human skin show that the stratum corneum in a given region is variable in both thickness and number of cell layers and that the sample length of the stratum corneum measured from a region is not consistent in thickness and number of cell layers (Holbrook and Odland, 1974).

TABLE 4.2
Comparative Thickness of the Epidermis and Number of Cell Layers from the Back of Nine Species

	Epidermis (μm)	Stratum Corneum (μm)	Number of Cell Layers (μm)
Cat	12.97 ± 0.93	5.84 ± 1.02	1.28 ± 0.13
Cow	36.76 ± 2.95	8.65 ± 1.17	2.22 ± 0.11
Dog	21.16 ± 2.55	5.56 ± 0.85	1.89 ± 0.16
Horse	33.59 ± 2.16	7.26 ± 1.04	2.50 ± 0.25
Monkey	26.87 ± 3.14	12.05 ± 2.30	2.67 ± 0.24
Mouse	13.32 ± 1.19	2.90 ± 0.12	1.75 ± 0.08
Pig	51.89 ± 1.49	12.28 ± 0.72	3.94 ± 0.13
Rabbit	10.85 ± 1.00	6.56 ± 0.37	1.22 ± 0.11

Regional variations have been shown to affect percutaneous penetration in man (Feldman and Maibach, 1967; Maibach et al., 1971; Wester et al., 1980; Wester and Maibach, 1983). Studies with radiolabeled pesticides, parathion, malathion, and carbaryl were used to explore the permeability at 13 different anatomic sites in man. The palms and forearm showed a similar penetration rate but the abdomen and the dorsum of the hand had twice the penetration compared to the forearm (Maibach et al., 1971). Variations in percutaneous penetration of ^{14}C hydrocortisone demonstrate that the rate of absorption through back skin was more rapid than the flexor surfaces of the forearm (Feldman and Maibach, 1967). Additional studies using steady-state diffusion cells to investigate the absorption of phenol, methanol, octanol, caffeine, and aspirin through abdominal skin have shown that permeability of human abdominal skin within and between individuals was less variable than from other anatomic sites (Southwell et al., 1984). Similar studies have been conducted in other species. In the pig, absorption of topically applied parathion was greater for the back than the abdomen (Qiao et al., 1994). The extent and pattern of biotransformation were also different between these two sites (Qiao and Riviere, 1995). For parathion absorption, the ventral abdomen most closely resembles the human ventral forearm. The percutaneous absorption of methyl salicylate and the nerve agent VX was significantly greater when applied to the ear versus the epigastrium of pigs (Duncan et al., 2002). This finding questions the validity of using pig ears as an *in vitro* model to predict human absorption, and underscores the importance of anatomical differences in skin from different body regions on chemical absorption. Unfortunately, similar data are not available for many other compounds and species combinations.

Regional differences in total lipid content and lipid composition may occur within the stratum corneum at different anatomical sites. Sphingolipids and cholesterol are higher in the palmar and plantar stratum corneum than in the extensor surfaces of the extremities (Lampe et al., 1983). The distribution of lipids in nonkeratinized buccal epithelium is different than in keratinized areas due to the higher water permeability. Buccal epithelium contains glucosylceramides, acylceramides, small amounts of ceramides, but no acylglucosylceramides (Squier and Hall, 1985). In keratinized and nonkeratinized porcine oral epithelia, phospholipids are present in greater amounts than in the epidermis (Wertz, 1986). Also, there are differences in lipid composition in different species. Squalene is the major component in human skin, although most animal species have substantial amounts of diester waxes (Nicolaides et al., 1968). For an excellent review on the structure and function of mammalian epidermal lipids, see Wertz and Downing (1991).

Species differences in absorption for numerous chemicals have been well studied and adequately reviewed elsewhere (Wester and Maibach, 1975a,b, 1976, 1977). In general, the best animal models for human absorption are the domestic pig and the nonhuman primate. Evaluation of skin permeability was also performed on various animals by comparing the percutaneous penetration of nine radiolabeled compounds.

Statistically significant correlations to human data were obtained for the weanling pig and human skin–grafted nude mouse models. In contrast, significant correlations were not obtained in the hairless dog, pig skin–grafted nude mouse, and the nude mouse (Reifenrath et al., 1984).

Differences in the permeability of nicorandil, a coronary vasodilator, was determined in six different species (hairless mouse, hairless rat, guinea pig, dog, pig, and human), with the pig and human similar. It was suggested that the difference in permeability could be explained by the differences in species-specific skin surface lipids that may also affect the partitioning of nicorandil from the vehicle to the stratum corneum (Sato et al., 1991). These findings support the use of the pig as an optimal animal model for predicting human absorption.

Lipid extraction can have a profound effect by removing the essential lipids that are necessary for barrier function (Hadgraft, 2001; Monteiro-Riviere et al., 2001). The technique of altering the lipid composition has been applied to modulate skin permeability. Removal of lipids within the stratum corneum causes an increase in transepidermal water loss (TEWL) and also allows for an increase in the penetration of compounds. This enhancement of a compound is the basis for more efficient delivery of therapeutic compounds. Extraction of lipids from pig skin in three different body regions: the abdominal, inguinal, and back using three different solvent extraction procedures or tape stripping demonstrated that the mean total lipid concentration depended on the type of extraction solvents and body region. This was reproducible across sites and regions. Relative proportions of individual lipids (ceramides1-6, cholesterol, fatty acids, triglycerides, and cholesterol esters) extracted were similar across the three body regions, but higher concentrations of total lipids were extracted from the back (Monteiro-Riviere et al., 2001). Studies have also shown that there are regional differences in water content of human skin measured by Fourier transform near infrared (FT-NIR) spectroscopy. The results showed that these differences arise due to differences in depth, differences in specular reflection at the surface, and thickness of the stratum corneum (Egawa et al., 2006).

4.5 HAIR FOLLICLES

The basic architecture of the integument is similar in all mammals. However, structural differences in the arrangement of hair follicles and hair follicle density exist between domestic and laboratory animals. The hair density in pig and human is sparse compared to that of the rodent. The skin from the back of pigs and the abdomen of humans have 11 ± 1 hair follicles/cm^2, in comparison to the back of the rat with 289 ± 21, the mouse with 658 ± 38, and the hairless mouse with 75 ± 6 (Bronaugh et al., 1982). For a comprehensive review of hair follicle arrangement and microscopic anatomy of the integument in different domestic species, see Monteiro-Riviere (2006) and Monteiro-Riviere (1991).

Hair follicles, sebaceous glands, and sweat glands are often envisioned as special channels through the stratum corneum that facilitates absorption of topical compounds, thus bypassing the rate-limiting stratum corneum barrier. Controversy exists over the significance of these hair follicle pathways in percutaneous absorption. The comparative permeability of human and animal skin may be related to diffusion of compounds through appendages in the skin. Numerous studies have been designed to test this hypothesis. One must always remember that even when a compound traverses the skin via hair follicles, passage through the stratum corneum still occurs. It is probable that any increase in absorption attributed to the appendages probably results from the increased surface area seen in the attending invaginations of the stratum corneum, therefore areas covered with hair have a greater skin surface area available for transdermal absorption. Hair follicle delivery has been considered a way to develop treatments for hair follicle–associated diseases, gene therapy, and immunotherapy.

Hair follicle–rich areas such as the scalp, angle of jaw, postauricular area, and forehead have been shown to allow greater penetration of some pesticides (Maibach et al., 1971). The importance of hair follicles in percutaneous absorption was evaluated in a model of regrown skin without hair follicles dorsally on the hairless rat. Diffusion cell studies were used to compare the absorption of tritiated hydrocortisone, niflumic acid, caffeine, and *p*-aminobenzoic acid in intact- and appendage-free skin. These studies confirmed a higher rate of diffusion in intact skin and suggested that hair follicles acted as the major absorption pathway (Illel et al., 1991). Other investigators have also studied this phenomenon. Flow through organ culture studies were performed on normal-haired and hairless mice with benzo[a]pyrene and testosterone. The overall permeation of testosterone was greater than that of benzo[a]pyrene, and showed no strain differences. However, benzo[a]pyrene absorption was higher in the haired mice than the hairless mice.

Additional studies of three phenotypic hair-density variants, suggest that the permeability of both compounds was the highest in the haired phenotype, lowest in the hairless phenotype, and intermediate in the fuzzy-haired animal. They concluded that transappendageal penetration contributes significantly to overall skin absorption (Kao et al., 1988). Hence, regional distribution of skin appendages could influence absorption of some compounds. Absorption of estradiol and progesterone was studied on normal and appendage-free (scar) hairless rats to determine if differences were due to lack of appendageal structures or modification of blood flow. Concentration of both steroids was significantly higher in normal than in scar tissue (Hueber et al., 1994a). They also compared the absorption of estradiol, hydrocortisone, progesterone, and testosterone through scar skin (without hair follicles, sebaceous glands, and sweat glands) from the abdomen or mammary areas of humans. Again, absorption was significantly higher in normal than scar tissue. Based on these findings, hair follicles and sebaceous glands may constitute a route for penetration for these steroids (Hueber et al., 1994b). Another study tested the appendageal density and absorption of the vasodilator methyl nicotinate, on the forehead, forearm, and palms of

humans. Penetration was the greatest on the forehead, intermediate on the forearm, and least through the palms. They also concluded that there was a correlation between methyl nicotinate absorption and appendageal density (Tur et al., 1991). Other investigators have found that the penetration process of a compound is dependent on the phase of the hair growth cycle, sebum production, and the state of the follicular infundibulum (Lademann et al., 2001). However, there is another interpretation to these data. In areas with dense hair, limited interfollicular regions (areas without hair) of skin are present. Therefore, the compound appears to penetrate only through hair follicles. This factor, coupled with the increased stratum corneum surface area associated with the invaginations of follicles, may explain the enhanced penetration seen in hairy skin.

Studies have also shown that there are racial disparities in absorption in humans due to the follicular density and follicular reservoir that may play a role in the penetration of drugs and cosmetics. The hair follicle density of Asians is less than African Americans for the forehead region. Lower values were detected for volume, surface, follicular orifice, and hair shaft diameter on the thigh and calf regions for Asians and African Americans. The follicular volume was greater for Caucasians (Mangelsdorf et al., 2006). These types of differences must be considered when designing skin absorption studies among different ethnic populations. In summary, hair follicle density, stratum corneum thickness, number of cell layers, and lipid composition are important structural variables to be considered when comparing absorption across different body sites or species.

4.6 BLOOD FLOW

The complexity of blood vessels in the skin is limited to the dermis, for the epidermis is avascular. Large arteries arise from a network in the subcutaneous layer, which send some of their branches to the superficial and deep dermis. The superficial arteries traverse through the dermis and send smaller branches that supply hair follicles, sebaceous glands, and sweat glands. A network of smaller arteries, the rete subpapillare (horizontal plexus), run between the papillary and reticular layers. Small arterioles from this plexus supply the capillary loops (subepidermal plexus) in the dermal papillary layer. Beneath the basement membrane, capillary beds are present in the matrix of hair follicles and around sebaceous and sweat glands. In specific body sites (fingertips, toes, lips, and nose), alternative channels called arteriovenous anastomoses or shunts are present, which allow blood to be passed from the arteriole to the venule. When connective tissue surrounds such a vascular structure, it is referred to as a glomus, which functions in regulation of body temperature and peripheral blood circulation. For a complete understanding about the cutaneous vasculature, see Ryan (1991).

Most research models in dermatology, cutaneous pharmacology, and reconstructive surgery have been animals. It is important to be aware of the anatomic and physiologic differences in blood flow between species and sites within species before the variable of blood flow can be used to explain percutaneous absorption. In humans, laser Doppler velocimetry (LDV) is often used to assess cutaneous blood flow. LDV is an accepted noninvasive technique that assesses relative cutaneous capillary blood perfusion (Holloway and Watkins, 1977; Young et al., 1985; Fischer et al., 1983). It has been used to assess the vascular response in man to acute inflammation (Holloway, 1980; Ross et al., 1987; Serup and Staberg, 1985), heat (Holloway, 1980), ultraviolet light (Young et al., 1985; Frodin et al., 1988), corticosteroids (Bisgaard et al., 1986), nitroglycerin (Sunberg, 1984), minoxidil (Wester et al., 1984), to determine depths of superficial, deep dermal, and subdermal burns (Micheels et al., 1984; Alsbjorn et al., 1984), as well as to evaluate donor sites in reconstructive surgery (Goldberg et al., 1990).

Skin blood flow measurements using LDV at various sites in humans showed interindividual and spatial variations (Tur et al., 1983). The magnitude of cutaneous blood flow and epidermal thickness has been postulated to explain the regional differences in percutaneous absorption between body sites in man and animals. A comprehensive study comparing the histologic thickness (Table 4.2) and laser Doppler blood flow measurements (Table 4.3) was performed at five cutaneous sites (buttocks, ear, humeroscapular joint, thoracolumbar junction, and abdomen) in nine species (cat, cow, dog, horse, monkey, mouse, pig, rabbit, and rat) to determine the correlation of blood flow and thickness. These studies strongly suggested that LDV blood flow and skin thickness did not correlate across species and body sites but are independent variables that must be evaluated separately in dermatology, pharmacology, and toxicology studies (Monteiro-Riviere et al., 1990).

The role of the cutaneous vasculature was studied in the topical delivery of ^{3}H piroxicam, a nonsteroidal antiinflammatory drug. Dermal penetration of ^{3}H piroxicam gel was evaluated by *in vitro* diffusion cells and *in vivo* (pigs) at two different tissue beds: one that is vascularized by direct cutaneous and the other by musculocutaneous arteries. The *in vitro* fluxes were identical indicating a similar rate of stratum corneum and epidermal absorption, however more extensive and deeper tissue penetration was noted at the musculocutaeous sites. This suggests that the vascular anatomy is important in determining the extent of dermal penetration (Monteiro-Riviere et al., 1993). Other studies also implied that topical administration in male rats resulted in a high concentration of the drug in the underlying vasculature that could not be attributed to redistribution via the systemic circulation (McNeill et al., 1992). Thus, the cutaneous vasculature does not function as an infinite sink that removes all topically applied drugs to the systemic circulation (Riviere and Williams, 1992). This mechanism of drug delivery has been alluded by other investigators (Wada et al., 1982; Torrent et al., 1988; Guy and Maibach, 1983). Also, we have demonstrated that local modulation of the vasculature by coiontophoresis of vasoactive compounds could affect drug distribution to the underlying tissue (Riviere et al., 1991). All of these studies suggest a major role for the cutaneous

TABLE 4.3
Blood Flow Measurements of Comparative Species at Five Cutaneous Sites (Mean ± SE)

Species	BUT	EAR	HSJ	TLJ	VAB
Cat	1.82 ± 0.59	6.46 ± 2.30	1.86 ± 0.70	2.39 ± 0.35	6.19 ± 0.94

vasculature in modulating absorption and dermal penetration of some topically applied drugs.

4.7 AGING

The anatomical and physiological changes in skin associated with aging may also affect the barrier function. Some of the major problems that complicate the understanding of aged skin is the ability to differentiate actinically damaged from chronically aged or age-related changes due to environmental influences (e.g., chronic sun exposure, cold, wind, low humidity, chemical exposure, or physical trauma), maturation process (e.g., newborn to adult), diseases, or hormonal changes associated with menopause.

Aging skin is usually generalized by a wrinkled and dry appearance. However, the microscopic changes in the epidermis associated with aging include flattening of the epidermal–dermal junction, retraction of epidermal downgrowths, thinness, reduction in number and output of sweat glands, and a more heterogeneous basal cell population (Rapaport, 1973; Lavker, 1979; Hull and Warfel, 1983; Gilchrest, 1984; Kligman et al., 1985; Lavker et al., 1986, 1987; Kligman and Balin, 1989). Numerous ultrastructural changes have also been documented in the dermis of aged skin. These include changes in the architecture of the elastic fiber framework (Lavker, 1979; Montagna and Carlisle, 1979), dermal shrinkage (Evans et al., 1943), elastic fiber disintegration, thickening and clumping (Braverman and Fonferko, 1982a), progressive rise in the modulus of elasticity (Grahame and Holt, 1969), decrease in collagen content (Branchet et al., 1991), modification of collagen from fascicular to granular (Pieraggi et al., 1984), and a decrease in tensile strength (Vogel, 1983). Also, thickening of the vascular wall vessels (Braverman and Fonferko, 1982b), loss of melanocytes in the hair bulb, and fewer glands were observed (Gilchrest, 1984).

The general morphological organization and thickness of the stratum corneum in humans do not change with age (Lavker, 1979; Christophers and Kligman, 1965), but the lipid content and intercellular cohesion in the stratum corneum decrease with age (Leveque et al., 1984). Thin layer chromatography and photodensitometry were used to study interindividual differences in fatty acid composition of skin surface lipids. Both age and sex were significant factors (Nazzaro-Porro et al., 1979). Stratum corneum hydration parameters remain unchanged or slightly decreased with age (Potts et al., 1984). Premenopausal women tend to have smaller corneocytes than postmenopausal woman (Fluhr et al., 2001). All of these alterations may alter the clearance and absorption of transdermally absorbed compounds through and from the skin. This can best be illustrated with a few examples.

A dose response study of 14 different pesticides on young and adult female rats showed significant age-dependent differences in skin penetration in 11 pesticides (Hall et al., 1988). A decrease in dermal absorption of some chemicals in the aged may be due to morphological differences in blood flow (Christophers and Kligman, 1965). Studies in male rats, 1–24 months, and mice, 1–22 months of age, showed that blood flow in mice increased between 1 and 2 months, remained constant to 19 months, then increased at 22 months; but the blood flow in rats was constant except at 2 months. Also, the number of viable epidermal layers in mice was constant, while in rats it decreased with age. Epidermal thickness in both mice and rats decreased from 2 to 3 months. Dermal thickness decreased from 3 to 22 months in mice, and increased in rats from 1 to 2 months (Monteiro-Riviere et al., 1991). Other studies have shown a decrease in the dermal absorption of Evans blue dye in old rats as compared to middle-aged rats (Kohn, 1969). Cardiac output declines with age and the pattern of blood flow distribution also changes with the proportion of cardiac output received by the kidneys, skin, gastrointestinal tract, and liver decreasing in older rats (Yates and Hiley, 1979). Therefore, reductions in blood flow could alter the distribution of compounds to and from these tissues. Age difference in blood flow can occur and should be considered when evaluating cutaneous toxicity studies in different aged animals.

A decrease was observed in TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) and 4 PeCDF (2,3,4,7,8-pentachlorodibenzofuran) absorption in older rats compared to 10 weeks old rats (Banks et al., 1990). TCDD absorption decreased from 3 to 5 weeks in rats (Jackson et al., 1990). The decreased absorption of these compounds in older animals could be explained by decreased clearance from the application site due to reduced perfusion seen in rats older than 2 months. Maturational changes in the dermal absorption of TCDD in rats also indicated that TCDD is absorbed to a greater degree in young animals and a significant decrease in potential for systemic exposure occurs during maturation and aging (Anderson et al., 1993). Age-related differences in the absorption of 14 different pesticides studied in 1 and 3 months old rats showed an increase in some compounds and a decrease in others (Shah et al., 1987). Therefore, the physiological and physiochemical properties (e.g., lipophilicity, molecular size) of the compound may be as important in assessing percutaneous absorption in aged animals as anatomical or physiological differences. Other investigators studied the pharmacodynamic measurements of methyl nicotinate in aged individuals and showed no differences between young (20–34 years) and old (64–86 years) populations (Roskos et al., 1990). Studies with testosterone, estradiol, hydrocortisone, and benzoic acid in young controls (18–35 years), young-old (65–75 years), and old-old (>75 years) humans showed different patterns depending upon the compound. For estradiol, absorption in the old-old group was less than in the other two populations. For hydrocortisone and benzoic acid, absorption in the young was greater than both elderly groups. In contrast, testosterone was lowest in the young-old group (Roskos et al., 1986). These studies showed a tendency for decreased absorption with most compounds with advancing age.

Another study evaluating *tri-N*-propyl phosphate (TNPP) in *in vitro* human skin from various anatomic sites ranging from 3 to 57 years showed a decrease in permeability with increased age (Marzulli, 1962). Studies involving the percutaneous absorption of 2-*sec*-butyl-4,6-dinitrophenol (dinoseb) in relation to age and dosage in *in vitro* and *in vivo* rat skin showed that dermal absorption in young rats was less than in adults at all doses studied (Hall et al., 1992). These studies have many additional variables making simple extrapolations difficult. For example, hair follicle growth cycle and body site were significant factors in hydrocortisone absorption studies in rats (Behl et al., 1984). Many studies do not control for these factors. Therefore, in most studies conducted to date, age is an important multifaceted factor involving many biological processes (e.g., altered lipid composition, blood flow), which produce compound-dependent effects. These factors must be taken into account when interpreting any study.

4.8 DISEASES

Skin permeability may be increased or decreased depending on the condition of the skin. Impaired skin barrier function may be the cause of some dermatitis conditions. Common diseases such as psoriasis may influence absorption. Psoriasis may be defined as having an accelerated rate of epidermal cell replication, a decrease in tonofilaments and keratohyalin granules, a disordered, loosely and irregularly stacked stratum corneum, and tortuous and dilated capillary loops (Braverman et al., 1972). These abnormal capillaries (e.g., large lumen, fenestrations between endothelial cells, and multilayered basement membrane) may have an affect on blood flow to skin. In addition, intercellular ionic calcium distribution is different in psoriatic skin that could alter lipid permeability (Menon and Elias, 1991). For example, hydrocortisone has been shown to increase absorption in psoriatic skin (Schaefer et al., 1977; Zesch et al., 1975).

In addition, other skin diseases such as essential fatty acid deficiency and ichthyosis may have an effect on compound penetration. Epidermal barrier function is altered by abnormal lipid composition in noneczematous atopic dry skin (Fartasch et al., 1992). Any disease process that has altered any of the above mentioned anatomical factors would be expected to modulate chemical percutaneous absorption. The challenge to researchers is to define the specific factor that has the greatest impact on a specific chemical's toxicology or clinical efficacy.

4.9 CONCLUSIONS

This chapter should provide the reader with a brief introduction to the effects of anatomy on percutaneous absorption that is summarized in Figure 4.2. There are numerous factors, which must be taken into consideration when designing experiments or interpreting data. Many different processes such as aging, disease, or chemical damage may affect specific anatomical components of skin. Anatomy is a useful framework upon which to classify the various biological processes that may be affected. The critical anatomical variables that are important for influencing the absorption of compounds across the skin include those factors governing the length of the intercellular pathway (thickness, cell

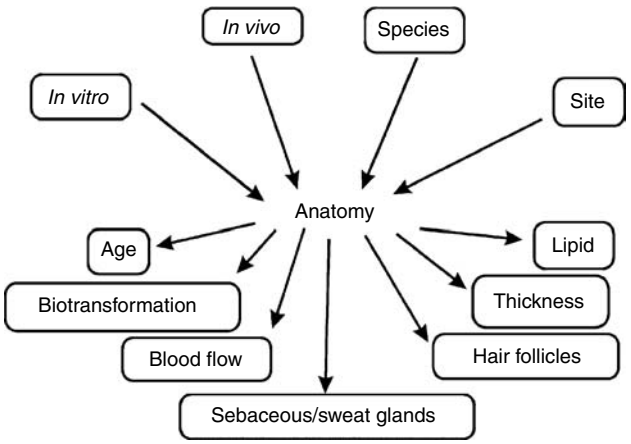

FIGURE 4.2 Overall summary depicting the anatomical factors that can influence absorption.

layers, cell size, and tortuosity), lipid composition of this medium, potential appendageal shortcuts (hair follicle density, sebaceous and sweat glands), and the nature and density of the underlying dermal circulation. A knowledge of how a process such as aging or disease affects each structure's integrity, then gives one a perspective on how the absorption of a chemical may be modified. Changes in these factors secondary to species, body regions, age, or disease would be expected to affect overall absorption. A major complication in most cases is that more than one component is altered and the effect observed is very dependent on the specific chemical's physiochemistry.

5.1 INTRODUCTION

Skin is an optimal interface for systemic drug administration. Transdermal drug delivery (TDD) is the controlled release of drugs through intact or altered skin to obtain therapeutic levels systematically and to affect specified targets for the purpose of, for example, blood pressure control, pain management, and others. Dermal drug delivery (DDD) is similar to TDD except that the specified target is the skin itself (Kydonieus and Wille, 2000). TDD has the advantages of bypassing gastrointestinal incompatibility and hepatic "first pass" effect; reduction of side effects due to the optimization of the blood concentration–time profile; predictable and extended duration of activity; patient-activated/patient-modulated delivery; elimination of multiple-dosing schedules thus enhancing patient compliance; minimization of inter- and intrapatient variability; reversibility of drug delivery allowing the removal of drug source; and relatively large area of application comparing with the mucosal surfaces (Kydonieus and Wille, 2000).

After nearly four decades of extensive study, the success of this technology remains limited, with many problems waiting to be solved, one of which is the challenge of low skin permeability hindering the development of TDD for macromolecules. To overcome the skin barrier safely and reversibly, while enabling the penetration of macromolecules, is a fundamental problem in the field of TDD and DDD.

Several technological advances have been made in the recent decades to overcome skin barrier properties (Smith and Maibach, 2005). Examples include physical means such as iontophoresis, sonophoresis, microneedles; chemical means using penetration enhancers (PE); and biochemical means such as liposomal vesicles and enzyme inhibition.

We overview physical and biochemical means of penetration enhancement and focus on the common chemical PEs. We discuss the classification and mechanisms of chemical PEs, its applications in TDD, and trends and development in penetration enhancement.

5.2 PHYSICAL PENETRATION ENHANCEMENT

Physical means of penetration enhancement mainly incorporate mechanisms to transiently circumvent the normal barrier function of stratum corneum (SC) and to allow the passage of macromolecules. Although the mechanisms are different, these methods share the common goal to disrupt SC structure to create "holes" big enough for molecules to permeate. Table 5.1 summarizes the commonly investigated technologies of physical penetration enhancement. Two of the better-known technologies are iontophoresis and sonophoresis, and the "holes" created by these methods are generally believed to be of nanometer dimensions permissive of transport of small drugs (Prausnitz, 2004). A new and exciting technology for macromolecule delivery is microneedle-enhanced delivery. These systems use arrays of tiny needlelike structures to create transport pathways of microns dimensions, and should be able to permit transport of macromolecules, possibly supramolecular complexes and microparticles. These systems have greatly enhanced (up to 100,000-fold) the penetration of macromolecules through

TABLE 5.1
Physical Methods of Penetration Enhancement

Method	Definition	Mechanism(s)	Examples of Drugs	References
Iontophoresis	The electrical driving of charged molecules into tissue by passing a small direct current through a drug-containing electrode in contact with skin	1. Electrical repulsion from the driving electrode drives charged molecules 2. The flow of electric current enhances skin permeability 3. Electroosmosis affects uncharged and large polar molecules	Calcitonin, transnail delivery of salicylic acid, transdermal delivery of peptides, proteins, and oligonucleotides	Santi et al. (1997), Narasimha (2007), Barry (2001), Miller et al. (1990), Mitragotri et al. (1995)
Electroporation	A method of reversibly permeabilizing lipid bilayers by the application of an electric pulse	Application of short (micro- to millisecond) electrical pulses of ~100–1000 V/cm create transient aqueous pores in the lipid bilayers	Methotrexate, timolol, fentanyl, tetracaine, nalbuphine, cyclosporin-A	Wong et al. (2005), Denet and Preat (2003), Hu et al. (2000), Sung et al. (2003), Vanbever et al. (1996a,b), Wang et al. (1998)
Sonoporation	Ultrasound mediated delivery of therapeutic agents into biological cells	1. Low energy frequency disturbs the lipid packing in SC by cavitation 2. Shock waves increase free volume space in bimolecular leaflets, thus enhance permeation	Insulin, cutaneous vaccination, transdermal heparin delivery, transdermal glucose monitoring, delivery of acetyl cholinesterase inhibitors for the treatment of Alzheimer's disease, treatment of bone diseases and Peyronie's disease, and dermal exposure assessment	Boucaud et al. (2002), Barry (2001), Vranic (2004)
Microneedle-enhanced delivery systems	A method using arrays of microscopic needles to open pores in SC, thus facilitating drug permeation	Bypass the SC and deliver drugs directly to the skin capillaries. Also has the advantage of being too short to stimulate the pain fibers	Oligonucleotide, insulin, protein vaccine, DNA vaccine, methyl nicotinate	Prausnitz (2004), Sivamani et al. (2005)

Source: Zhai, H. and Maibach, H.I., *Skin Pharmacol. Appl. Skin Physiol*., 14 (1), 2001. With permission.

skin (Barry, 2001), although offering painless drug delivery (Kaushik et al., 2001; Sivamani et al., 2005).

5.3 BIOCHEMICAL PENETRATION ENHANCEMENT

Biochemical means of penetration enhancement include using prodrug molecules (Sloan and Bodor, 1982), chemical modification (Choi et al., 1990), enzyme inhibition (Morimoto et al., 1992), and the usage of vesicular systems or colloidal particles (Mezei and Gulasekharam, 1980). Among these strategies, special formulation approaches based mainly on the usage of colloidal carriers are most promising. Liposomes (phospholipids-based artificial vesicles) and niosomes (nonionic surfactant vesicles) are widely used to enhance drug delivery across the skin. In addition, proliposomes and proniosomes, which are converted into liposomes and niosomes upon simple hydration are also used in TDD (Choi and Maibach, 2005). Generally, these colloidal carriers are not expected to penetrate into viable skin. Most reports cite a localizing effect whereby the carriers accumulate in SC or other upper skin layers (Barry, 2001).

More recently a new type of liposomes called transferosomes has been introduced (Planas et al., 1992; Cevc, 1996). Transferosomes consist of phospholipids, cholesterol and additional "edge activators"—surfactant molecules such as sodium cholate. The inventors claim that 200–300 nm-sized transferosomes are ultradeformable and squeeze through pores less than one-tenth of their diameter, and are thus able to penetrate intact skin. Penetration of these colloidal particles works best under *in vivo* conditions and requires a hydration gradient from the skin surface toward the viable tissues to encourage skin penetration under nonoccluded conditions.

In addition, ethosomes, which are liposomes high in ethanol content (up to 45%), penetrate skin and enhance compound delivery to deep skin strata or systematically. The mechanism suggested is that ethanol fluidizes both ethosomal lipids and lipid bilayers in the SC, allowing the soft, malleable vesicles to penetrate through the disorganized lipid bilayers (Touiton et al., 2000).

In general, six potential mechanisms of actions of these colloidal carriers were proposed (Barry, 2001):

1. Penetration of SC by a free drug process—drug releases from vesicle and then penetrates skin independently.
2. Penetration of SC by intact liposomes.

3. Enhancement due to release of lipids from carriers and interaction with SC lipids.
4. Improved drug uptake by skin.
5. Different enhancement efficiencies control drug input.
6. The role of protein requires elaboration.

5.4 CHEMICAL PENETRATION ENHANCERS (CPEs)

Substances that help promote drug diffusion through the SC and epidermis are referred to as penetration enhancers (PEs), accelerants, adjuvants, or sorption promoters (Pfister et al., 1990). PEs have been extensively studied given its advantages such as design flexibility with formulation chemistry, patch application over large area. PEs improve drug transport by reducing the resistance of SC to drug permeation. To date, none of the existing CPEs has proven to be ideal. In particular, the efficacy of PEs toward the delivery of high molecular weight drugs remains limited. Attempts to improve enhancement by increasing the potency of enhancers inevitably lead to a compromise on safety issues. Achieving sufficient potency without irritancy has proved challenging.

5.4.1 Classification of CPEs

The diverse physicochemical properties and variation in mechanisms of action of compounds investigated for their penetration enhancement effects made a simple classification scheme for PEs difficult to set up. Hori et al. (1990) proposed a conceptual diagrammatic approach based on Fujita's (1954) data for the classification of PEs. In this approach, they determined organic and inorganic values for PEs, and the resultant plot of organic versus inorganic characteristics grouped PEs into distinct areas on the diagram—area I encloses enhancers, which are solvents, area II designates PEs for hydrophilic drugs, and area III contains PEs for lipophilic compounds. However, Lambert et al. (1993) grouped most PEs into three classes: solvents and hydrogen bond acceptors (e.g., dimethylsulfoxide, dimethylacetamide, and dimethylformamide), simple fatty acids and alcohols, and weak surfactants containing a moderately sized polar group (e.g., Azone®, 1-dodecylazacycloheptan-2-one); whereas Pfister et al. (1990) classified PEs as either polar or nonpolar. To date, there is no consensus as to which classification to adopt. Table 5.2 classifies commonly investigated PEs based on the chemical classes to which the compounds belong (Barry, 1995). Only representative compounds are listed to avoid an exhaustive list. Note that a perfect classification is yet to be developed and the key lies in a comprehensive understanding of the mechanisms and the physicochemical parameters of CPEs.

5.4.2 Mechanism of CPEs

The mechanisms of action proposed for commonly seen CPEs are listed in Table 5.2. Basically, transdermal penetration of most drugs is a passive diffusion process (Hsieh, 1994). There are three major potential routes for penetration—appendageal (through sweat ducts or hair follicles with associated sebaceous glands), transcellular permeation through the SC, or intercellular permeation through the SC (Barry, 2001). The intact SC comprises the predominant route through which most molecules penetrate. On the other hand, despite its small available fractional area of 0.1%, the appendageal route, especially the follicular route, has recently received considerable attention and was found to be an important penetration pathway and a possible space for an intracutaneous reservoir (Schaefer and Lademann, 2001; Lademann et al., 2003; Otberg et al., 2004). Liposomal formulations have shown to be useful delivery systems for follicular drug targeting (Hoffmann, 1998), and transfollicular drug delivery seems promising for gene therapy and vaccination (Christoph et al., 2000; Hoffmann, 2000; Corsarelis, 2000; Hoffmann, 2005).

Kanikkannan et al. (2000) suggested three pathways for drug penetration through the skin: polar, nonpolar, and both. The mechanism of penetration through the polar pathway is to cause protein conformational change or solvent swelling; whereas the key to penetrate via the nonpolar pathway is to alter the rigidity of the lipid structure and fluidize the crystalline pathway. Some enhancers may act on both polar and nonpolar pathways by dissolving the skin lipids or denaturing skin proteins. However, Ogiso and Tanino (2000) proposed the following mechanisms for the enhancement effect: (a) an increase in the fluidity of the SC lipids and reduction in the diffusional resistance to permeants, (b) the removal of intercellular lipids and dilation between adherent cornified cells, (c) an increase in the thermodynamic activity of drugs in vehicles, (d) the exfoliation of SC cell membranes, the dissociation of adherent cornified cells and elimination of the barrier function.

Ogiso et al. (1995) also proposed examples of PEs with different relative enhancement capabilities due to differences in the chemical structure and other parameters. In their study, the relative ability to enhance transdermal penetration of indomethacin into hairless rat skin was studied. The results were summarized as follows (Chan, 2005):

Mechanisms	Comparison
Extraction of intercellalur lipids and dilations between cornified cells, permitting percutaneous passage of polar substances	1-dodecylazacycloheptane-2-one(Azone)>*n*-octanol>*d*-limonen>oleic acid>cineol
Increase in partitioning into skin	1-dodecylazacycloheptane-2-one>*n*-octanol>cineol>*d*-limonen>oleic acid>isopropyl myristate>monooleate
Increase in the fluidity of SC lipids and reduction in diffusional resistance	1-dodecylazacycloheptane-2-one>isopropyl mysirate>monoolein>oleic acid>cineol, sodium oleate
Increase in thermodynamic activity in vehicles	*n*-octanol>sodiumoleate>*d*-limonen>monoolein>cineol>oleyl oleate>isopropyl myristate

TABLE 5.2
Chemical Penetration Enhancers

Category and Examples	Cosolvent/Vehicle	Mechanism	Examples of Drugs (Ghosh et al., 1997)	Comment	References
Sulfoxides					
Dimethylsulfoxide (DMSO)		1. Increases lipid fluidity 2. Promotes drug partitioning	DMSO: theophylline, salicylic acid, hydrocortisone, testosterone, scopolamine, antimycotics, fluocinolone acetonide, flufenamic acid		Scheuplein and Blank (1971), Sekura and Scala (1988)
Decylmethylsulfoxide (DCMS)		Protein–DCMS interactions, resulting in a change in protein conformation, creating aqueous channels	DCMS: methotrexate, naloxone, pyridostigmine bromide, hydrocortisone, progesterone	DCMS enhances polar drug more effectively	
Alkanones					
N-heptane, *N*-octane, *N*-nonane, *N*-decane, *N*-undecane, *N*-dodecane, *N*-tridecane, *N*-tetradecane, *N*-hexadecane		Extensive barrier alteration of SC	Propanol, diazepam		Hori et al. (1991)
Alcohols					
Alkanol: ethanol (E), propanol, butanol, 2-butanol, pentanol, 2-pentanol, hexanol, octanol, nonanol, decanol, benzyl alcohol (BA) Fatty alcohol: caprylic, decyl, lauryl (LA), 2-lauryl, myristyl, cetyl, stearyl, oleyl, linoleyl, linolenyl alcohol		1. Low molecular weight alkanols (C≤6) may act as solubilizing agents 2. More hydrophobic alkanols may extract lipids from SC,* leading to increased diffusion	E: tacrine, metrifonate, dichlorvos, ketolorac, nitroglycerin, tazifylline, betahistine, cyclosporin A LA: buprenorphine		Tsuzuki et al. (1988), Friend et al. (1988), Ding et al. (2006), Liu et al. (2006), Aungst et al. (1986)
Polyols					
Propylene glycol (PG), polyethylene glycol (PEG), ethylene glycol, diethylene glycol, triethylene glycol, dipropylene glycol, glycerol (G), propanediol, butanediol , pentanediol, hexanetriol	43× enhancement of diazepam and 86× enhancement of midazolam maleate seen in PG and 5% Azone in a PG:E:water (2:2:1) vehicle	PG may solvate α-keratin and occupy hydrogen bonding sites, reducing drug-tissue binding	PG: 5-fluorouracil, tacrine, ketorolac, isosorbide dinitrate, clonazapem, albuterol, verapamil, betahistine, estradiol, dihydroergotamine, methotrexate, steroids, midazolam maleate, diazepam PEG: terbutaline G: diazepam, terbutaline, 5-fluorouracil	Inclusion of 2% Azone or 5% oleic acid to PG produced a more bioactive formulation	Mollgaard and Hoelgaard (1983), Herai et al. (2007)
Amides					
Urea, dimethylacetamide (DMA), diethyltoluamide, dimethylformamide (DMF), dimethyloctamide, dimethyldecamide		Urea: hydration of SC, keratolytic, creating hydrophilic diffusion channels DMA/DMF: (low concentration): partition to keratin, (high concentration): increase lipid fluidity, disrupt lipid packaging	Urea: ketoprofen, 5-fluorouracil DMA/DMF: griseofluvin, betamethasone 17-benzoate, caffeine	Urea analogues in PG enhanced permeability of 5-fluorouracil 6×	Aungst et al. (1986), Feldman and Maibach (1974)

Biodegradable cyclic urea: 1-alkyl-4-imidazolin-2-one			Indomethacin	Comparable to or better than Azone	Wong et al. (1988)
Pyrrolidone derivatives: 1-methyl-2-pyrrolidone (1M2P), 2-pyrrolidone, 1-lauryl-2-pyrrolidone, 1-methyl-4-carboxy-2-pyrrolidone, 1-hexyl-4-carboxy-2-pyrrolidone, 1-lauryl-4-carboxy-2-pyrrolidone, 1-methyl-4-methoxycarbonyl-2-pyrrolidone, 1-hexyl-4-methoxycarbonyl-2-pyrrolidone, 1-lauryl-4-methoxycarbonyl-2-pyrrolidone, *N*-methyl-pyrrolidone (NMP), *N*-cyclohexylpyrrolidone, *N*-dimethylaminopropylpyrrolidone, *N*-cocoalkypyrrolidone, *N*-tallowalkylpyrrolidone		Interact with both keratin in the SC and with lipids in the skin structure	1M2P: griseofulvin, theophylline, tetracycline, ibuprofen, betamethasone 17-benzoate NMP: prazosin		Aungst et al. (1986), Sasaki et al. (1991)
Biodegradable pyrrolidone derivatives: Fatty acid esters of *N*-(2-hydroxyethyl)-2-pyrrolidone					Lambert et al. (1993)
Cyclic amides: 1-dodecylazacycloheptane-2-one(Azone), 1-geranylazacycloheptan-2-one, 1-farnesylazacycloheptan-2-one, 1-geranylgeranylazacycloheptan-2-one, 1-(3,7-dimethyloctyl)azacycloheptan-2-one, 1-(3,7,11-trimethyldodecyl)azacyclohaptan-2-one, 1-geranylazacyclohexane-2-one, 1-geranylazacyclopentan-2,5-dione, 1-farnesylazacyclopentan-2-one	Azone: enhancer effect can be increased by use of cosolvent such as PG	Azone: 1. Affects lipid structure of SC 2. Increases partitioning 3. Increases membrane fluidity	Azone: 5-fluorouracil, antibiotics, glucocorticoids, peptites, clonazepam, albuterol, estradiol, levonorgestrel, HIV protease inhibitor (LB-71148), betahistine, dihydroergotamine	Azone: significant accelerant effects at low concentration (1–5%), can be applied undiluted to skin without significant discomfort, effective for both hydrophilic and hydrophobic drugs	Stoughton and McClure (1983), Okamoto et al. (1988), Zhou et al. (2005)
Hexamethylenelauramide and its derivatives					Mirejovsky and Takruri (1986)
Diethanolamine, triethanolamine					Mollgaard and Hoelgaard (1983)
Fatty acids					
Linear: linoleic(LIA), valeric, heptanoic, pelagonic, caproic, capric(CA), lauric(LAA), myristic, stearic, oleic(OA), caprylic Branched: isovaleric, neopentanoic, neoheptanoic, neononanoic, trimethyl hexanoic, neodecanoic, isostearic		Selective perturbation of the intercellular lipid bilayers OA: decreases the phase transition temperatures of the lipid, increasing motional freedom or fluidity of lipids	Naloxone, mannitol, betamethasone 17-benzoate, hydrocortisone, acyclovir, nitroglycerin OA: galanthamine, estradiol, levonorgestrel CA: buprenorphine, albiterol LAA: buprenorphine, betahistine	Among stearic, oleic, and linoleic acids, maximum enhancement was observed with linoleic acid	Aungst et al. (1986), (1989), Kogan and Garti (2006)

(*continued*)

TABLE 5.2 (continued)
Chemical Penetration Enhancers

Category and Examples	Cosolvent/Vehicle	Mechanism	Examples of Drugs (Ghosh et al., 1997)	Comment	References
Fatty acid esters					
Aliphatic: isopropyl *n*-butyrate, isopropyl *n*-hexanoate, isopropyl *n*-decanoate, isopropyl myristate (IPM), isopropyl palmitate, octyldodecyl myristate Alkyl: ethyl acetate (EA), butyl acetate, methyl acetate, methylvalerate, methylpropionate, diethyl sebacate, ethyl oleate		IPM: direct action on SC, permeating into liposome bilayers, increasing fluidity Aliphatic: increase diffusivity in the SC and the partition coefficient Alkyl: increase lipid fluidity (similar to DMSO)	IPM: galanthamine, ketorolac, chlorpheniramine, dexbrompheniramine, diphenhydramine, theophylline, pilocarpine, verapamil EA: levonorgestrel, 17β-estradiol, hydrocortisone, 5-fluorouracil, nefedipine		Sato et al. (1988), Friend et al. (1989)
Surfactants					
Anionic: sodium laurate, sodium lauryl sulfate, sodium octyl sulfate		Alter the barrier function of SC, allowing removal of water-soluble agents that normally act as plasticizers		Greater damage and permeation enhancement with anionic surfactants than with nonionic surfactants	Chowhan and Pritchard (1978), Gershbein (1979)
Cationic: cetyltrimethylammonium bromide, tetradecyltrimethylammonium bromide, octyltrimethyl ammonium bromide, benzalkonium chloride, octadecyltrimethylammonium chloride, cetylpyridinium chloride, dodecyltrimethylammonium chloride, hexadecyltrimethylammonium chloride	Significant increases in the flux of lidocaine from saturated systems in PG-water mixtures	Adsorb at interfaces and interact with biological membranes, causing damage to skin		Cationic surfactants are more destructive to skin than anionic surfactants	Gershbein (1979), Aoyagi et al. (1990), Tan et al. (1993)
Zwitterionic surfactants: hexadecyl trimethyl ammoniopropane sulfonate, oleyl betaine, cocamidopropyl hydroxysultaine, cocamidopropyl betaine					Zhang and Somasundaran (2006)

Nonionics:					
polyxamer (231,182,184), polysorbate (20,60), brij (30,93,96,99), span (20,40,60,80,85), tween (20,40,60,80), myrj (45,51,52), miglyol 840	Polysorbate 20 and 60 increased lidocaine flux in the presence of PG	Emulsify sebum, enhancing the thermodynamic activity of coefficients of drugs	Tween 80: ketoprofen Polysorbate 20,60: lidocaine		Aungst et al. (1986), Shen et al. (1976), Mahajour et al. (1993)
Bile salts:					
sodium cholate, sodium salts of taurocholic(TC), glycolic, desoxycholic acids			TC: elcatonin and vit D_3, estradiol and vit D_3		Carelli et al. (1993)
Lecithin					Kato et al. (1987)
Terpenes					
Hydrocarbons: D-Limonene, α-pinene, β-carene Alcohols: α-Terpineol, terpinen-4-ol, carvol Ketones: Carvone, pulegone, piperitone, menthone Oxides: Cyclohexene oxide, limonene oxide, α-pinene oxide, cyclopentene oxide, 1,8-cineole Oils: Ylang ylang, anise, chenopodium, eucalyptus		1. Increase diffusivity of drugs within SC due to disruption of intercellular lipid barrier 2. Open new polar pathways within and across the SC	5-Fluorouracil, aspirin, haloperidol	Hydrocarbon terpenoids were least effective; oxides moderately effective; and the alcohols, ketones, and cyclic ethers most effective accelerants of 5-fluorouracil permeation	Williams and Barry (1991), Hori et al. (1991), Lim et al. (2006)
Organic acids					
Salicylic acid and salicylates (including their methyl, ethyl, and propyl glycol derivatives), citric and succinic acid					Sugibayashi et al. (1988)
Cyclodextrins					
2-Hydroxypropyl-β-cyclodextrin (HPβCD), 2,6-dimethyl-β-cyclodextrin (DIMEB)	Higher penetration of liarzole in DIMEB with PG/oleic acid compared to HPβCD	Form inclusion complexes with lipophilic drugs and increase their solubility in aqueous solutions	Liarzole		Uekama et al. (1985), Frijlink et al. (1976)
Proprietary chemical enhancers					Chan (2005)
Alkyl-2-(*N*,*N*-disubstituted amino)-alkanoate ester (NexAct®), 2-(n-nonyl)-1,3-dioxolane (SEPA®)			Ibuprofen, ketoprofen, alprostadil, testoterone		

* SC: stratum corneum.

Furthermore, Kanikkannan et al. (2000) proposed that based on the chemical structure of PEs (such as chain length, polarity, level of unsaturation, and presence of specific chemical groups such as ketones), the interaction between the SC and PEs may vary, contributing to the different mechanisms in penetration enhancement. A comprehensive understanding of the mechanisms of action and a judicious selection of CPE would be helpful in the successful development of TDD and DDD products.

5.5 U.S. FOOD AND DRUG ADMINISTRATION (FDA)-APPROVED TDD

There has been an increased focus on the potential of transdermal drug delivery as evident from the increase in the number of patents as well as scientific publications on TDD systems. Many drugs have been evaluated for TDD in prototype patches, either *in vitro* permeation studies using mouse, rat, or human skin; or have reached varying stages of clinical testing. Examples are listed in Table 5.2. Despite a wide array of TDD systems undergoing research and development, only a small percentage of the drugs reaches the market successfully due to three limitations: difficulty of penetration through human skin, skin irritation and allergenicity, and clinical need. In addition, it is generally accepted that the best drug candidates for passive adhesive transdermal patches must be nonionic, low molecular weight (less than 500 Da), have adequate solubility in oil and water (log P in the range 1–3), a low melting point (less than 200°C), and are potent (dose is less than 50 mg/day, and ideally less than 10 mg/day) (Finnin and Morgan, 1999; Guy, 1996; Hadgraft, 1998). Given these operating parameters, the number of drug candidates, which fit the criteria may seem low. Nevertheless, with the development of novel technologies, such constraint may be overcome.

Since the introduction of a TDD for scopolamine in 1981, several new products have been introduced. The U.S. TDD market approached $1.2 billion in 2001 and was based on 11 drug molecules: fentanyl, lidocaine, prilocaine, nitroglycerin, estradiol, ethinyl estradiol, norethindrone acetate, testosterone, clonidine, nicotine, and scopolamine (Retail and Provider Perspective, 2001). Barry (2001) reported that 40% of drug delivery candidate products that were under clinical evaluation and 30% of those in preclinical development in the United States were TDD or DDD systems.

Examples of FDA-approved transdermal patches and their applications are in Table 5.3. Despite a plethora of candidate CPEs to choose from, all currently available TDD products adopt skin occlusion as the primary mechanism for penetration enhancement, perhaps due to its simplicity and convenience, and the following effects on SC (Zhai and Maibach, 2001a, 2002): an increase in SC hydration and a reservoir effect in penetration rates of the drug due to hydration, an increase in skin temperature from 32 to 37°C, and

TABLE 5.3
Examples of FDA-Approved Transdermal Patches, Their Applications, and the Mechanisms/Compounds Used for Penetration Enhancement

Drug	Application(s)	Example(s) of Commercially Available Product(s)	Penetration Enhancement Effect and Penetration Enhancers
Scopolamine	Motion sickness	Transderm scop	Occlusive effect
Fentanyl	Moderate to severe chronic pain	Duragesic	Occlusive effect
Lidocaine	Anesthesia	Lidoderm	Occlusive effect, urea, propylene glycol
Prilocaine	Anesthesia	EMLA anesthetic disc	Occlusive effect, polyoxyethylene fatty acid esters
Testosterone	Hormone replacement therapy	Androderm	Occlusive effect, glycerol monooleate
Estradiol/norethindrone acetate	Hormone replacement therapy	Combipatch	Occlusive effect, silicone, oleic acid, dipropylene glycol
Estradiol	Symptomatic relief of postmenopausal symptoms and prevention of osteoporosis	Alora, climera, esclim, vivelle, vivelle-dot	Occlusive effect Climera: fatty acid esters Vivelle: 1,3-butylene glycerol, oleic acid, lecithin, propylene glycol, dipropylene glycol Vivelle-dot: oleyl alcohol, dipropylene glycol
Norelgestromin/ethinyl estradiol	Contraception	Ortho evra	Occlusive effect, lauryl lactate
Nitroglycerin	Angina pectoris	Nitro-dur, nitrodisc, transderm-nitro	Occlusive effect, fatty acid esters
Clonidine	Hypertension	Catapres-TTS	Occlusive effect
Nicotine	Smoking cessation	Nicoderm CQ	Occlusive effect
Methyphenidate	Attention-deficit hyperactive disorder	Daytrana	Occlusive effect
Selegiline	Depression	Emsam	Occlusive effect
Oxybutynin	Urge/urinary incontinence	Oxytrol	Occlusive effect

the prevention of accidental wiping or evaporation (volatile compound) of the applied compound.

5.6 FUTURE TRENDS

The protective function of human SC imposes physicochemical limitations to the type of molecules that can traverse the barrier. As a result, commercially available products based on TDD or DDD have been limited. Various strategies have emerged over the last decade to optimize delivery. Approaches such as the optimization of formulation or drug-carrying vehicle to increase skin permeability do not greatly improve the permeation of macromolecules.

Sufficient data on chemical enhancers is available, so that the Smith textbook (1st and 2nd edition) provides extensive quantitative data (Smith and Maibach, 1995, 2005). Note that of the several dozen proposed enhancers suggested over 4 decades, few new chemical entities have received widescale usage. Dermatotoxicologic intolerance has been a major limitation. Dermatotoxicology 8th edition will provide a detailed explanation of some of the potential hazard with their long term use.

On the contrary, physical or mechanical methods of enhancing delivery have been more promising. Improved delivery has been shown for drugs of differing lipophilicity and molecular weight including proteins, peptides, and oligonucletides using electrical methods (iontophoresis, electroporation), mechanical (abrasion, ablation, perforation), and other energy-related techniques such as ultrasound and needleless injection (Brown et al., 2006).

Another strategy for penetration enhancement is to exploit the synergistic effects offered by combined techniques. Karande et al. (2004) reported the discovery of synergistic combinations of penetration enhancers (SCOPE), which allow permeation of 10 kDa macromolecules with minimal skin irritation using high-throughput screening method. Kogan and Garti (2006) also showed that the combination of several enhancement techniques led to synergetic drug penetration and decrease in skin toxicity. In essence, the possibilities seem endless in the field of TDD and DDD.

5.7 CONCLUSION

TDD would avoid problems associated with the oral route, as well as the inconvenience and pain associated with needle delivery; and has thus competed with oral and injection therapy for the accolade of the innovative research area for drug delivery. Yet there remains a paucity of candidates for TDD or DDD to be marketed. The reasons are twofold: (1) most candidate drug molecules have low permeation rates through the skin to ever reach clinically satisfactory plasma level; (2) risk of skin irritation and allergic contact dermatitis may be increased by skin occlusion (Zhai and Maibach, 2001b, 2002) or the application of potent PEs (Karande et al., 2004). The ideal characteristics of PEs include the following (Pfister et al., 1990):

- Be both pharmacologically and chemically inert
- Be chemically stable
- Have a high degree of potency with specific activity, rapid onset, predictable duration of activity, and reversible effects on skin properties
- Show chemical and physical compatibility with formulation and system components
- Be nonirritant, nonallergenic, nonphototoxic, and noncomedogenic
- Be odorless, tasteless, colorless, cosmetically acceptable, and inexpensive
- Be readily formulated into dermatological preparations, transdermal patches, and skin adhesives
- Have a solubility parameter approximating that of skin (i.e., 10.5 $cal^{1/2}cm^{3/2}$) (Sloan et al., 1986)

Future studies on the mechanisms of penetration enhancement, the metabolic processes of chemicals within the skin, skin toxicity, as well as the development of novel technologies will improve our knowledge on penetration enhancement. While the current TDD and DDD technologies still offer significant potential for growth, next-generation technologies will enable a much broader application of TDD to the biopharmaceutical industry.

6.1 INTRODUCTION

The percutaneous absorption of chemicals is most often studied using single chemicals applied to the surface of skin, often in a vehicle when solubilization is necessary. Exposure in most environmental and occupational scenarios occurs to combinations of chemicals. Similarly, most dermatological drugs are dosed in formulations composed of multiple additives. The difference is that in the pharmaceutical sector, components of a formulation are usually added for a specific purpose and their effects on drug absorption have been studied, or at least acknowledged. In environmental and occupational scenarios, the chemicals to which an individual is exposed are a function of their occurrence in the environment. The effect of one chemical, modulating absorption of a second mixture component, is not known. Risk assessments on topical exposure to chemical mixtures are presently an area of intense interest, but few quantitative approaches have been proposed.

The potential for chemical mixture interactions affecting systemic drug and chemical disposition and toxicity has been well recognized for many years and has been comprehensively reviewed elsewhere (Bliss, 1939; Yang, 1994; Pohl et al., 1997; Haddad et al., 2000, 2001; Borgert et al., 2001; Groten et al., 2001; Feron and Groten, 2002; Walker et al., 2005; Mumtaz et al., 2006). Similarly, the potential for drug–drug pharmacokinetic interactions has been recently recognized and debated in the context of the development of cassette dosing in drug discovery screening (White and Manitpisitkul, 2001; Christ, 2001; Singh, 2006). Despite this widespread acknowledgment of the importance of chemical interactions in systemic pharmacology and toxicology, little attention outside of the dermatological formulation arena has been paid to interactions that may occur after topical exposure to complex mixtures. The focus of this chapter is to provide a brief review into factors that should be considered when chemical mixtures are topically applied to skin.

6.2 LEVELS OF INTERACTION

The focus on any interaction is usually related to a compound of pharmacological or toxicological interest. The concern is then on how other chemicals in the mixture modulate the percutaneous absorption or dermatotoxicity of this chemical of interest. To clarify this discussion, we will refer to the compound of pharmacological or toxicological interest as the "marker" compound and all other substances present in the mixture as "components." In a simple binary mixture, the component would be the vehicle. It must be stressed that the purpose of selecting a component of a mixture as a marker compound does not confer special importance to this chemical relative to the other components present. It is purely an artificial construct to provide a frame of reference on which chemical interactions can be discussed. In many cases, multiple components may in fact be toxic or cause irritation.

Previously, we have presented a conceptual framework upon which the study of chemical interactions involved in compound percutaneous absorption can be based, termed mechanistically defined chemical mixtures (MDCM) (Baynes et al., 1996; Qiao et al., 1996; Williams et al., 1996). This approach assumes that components that are capable of modulating a marker's absorption or cutaneous disposition would result in an altered pharmacological or toxicological effect. Table 6.1 lists a series of levels in which chemical and biological interactions could occur.

The first potential for chemical–chemical interactions is on the surface of the skin. The types of phenomena that could occur are governed by the laws of solution chemistry, and include factors such as altered solubility, precipitation, supersaturation, solvation, or volatility; as well as physical-chemical effects such as altered surface tension from the presence of surfactants, changed solution viscosity and micelle formation (Idson, 1983; Williams and Barry, 1998; Barry, 2001; Moser et al., 2001; van der Merwe and Riviere, 2005). For some of these effects, chemicals act

TABLE 6.1
Levels of Potential Interactions after Topical Exposure to Chemical Mixtures

Surface	Chemical–chemical (binding, ion-pair formation, etc.)
	Altered physical-chemical properties (e.g., solubility, volatility, critical micelle concentration)
	Altered rates of surface evaporation
	Occlusive behavior
	Binding or interaction with adnexial structures or their products (e.g., hair, sweat, sebum)
Stratum Corneum	Altered permeability through lipid pathway (e.g., enhancer)
	Altered partitioning into stratum corneum
	Extraction of intercellular lipids
Epidermis	Altered biotransformation
	Induction or modulation of inflammatory mediators
Dermis	Altered vascular function (direct or secondary to mediator release)

independent of one another. However, for many the presence of other component chemicals may modulate the effect seen. Chemical interactions may further be modulated by interaction with adnexial structures or their products such as hair, sebum, or sweat secretions. The result is that when a marker chemical is dosed on the skin as a component of a chemical mixture, the amount freely available for subsequent absorption may be significantly affected. The primary driving force for chemical absorption in skin is passive diffusion that requires a concentration gradient of thermodynamically active (free) chemical. We have developed an *in vitro* membrane coated fiber (MCF) approach to quantitate the physical-chemical interactions seen in dosing solutions (Xia et al., 2005, 2006) that has promise to quantitatively assess the impact of such interactions on partitioning into skin.

The next level of potential interaction are those involving the marker or component chemicals with the constituents of the stratum corneum. These include the classic enhancers such as oleic acid, Azone®, or ethanol, widely reviewed elsewhere (Williams and Barry, 1998). These chemicals alter a compound's permeability within the intercellular lipids of the stratum corneum. Similarly, the partition coefficient between the drug in the surface dosing vehicle and stratum corneum lipids may be altered if chemical components of the mixture also partition and diffuse into the lipids and thus alter their composition. Organic vehicles on the surface of the skin may extract stratum corneum lipids that would alter permeability to the marker chemical (Monteiro-Riviere et al., 2001; Rastogi and Singh, 2001), a phenomenon seen with repeated topical exposure to jet fuels (Muhammad et al., 2005). Compounds may also bind to stratum corneum constituents forming a depot.

The next level of interaction would be with the viable epidermis. The most obvious point of potential interaction would be with a compound that undergoes biotransformation (Bronaugh et al., 1989; Mukhtar, 1992). A marker and component could interact in a number of ways, including competitive or noncompetitive inhibition for occupancy at the enzyme's active site, or induction or inhibition of drug metabolizing enzymes. Other structural and functional enzymes could also be affected (e.g., lipid synthesis enzymes), which would modify barrier function (Elias and Feingold, 1992). A penetrating marker or component could also induce keratinocytes to release cytokines or other inflammatory mediators (Luger and Schwarz, 1990; Allen et al., 2000; Monteiro-Riviere et al., 2002), which could ultimately alter barrier function in the stratum corneum or vascular function in the dermis. Alternatively, cytokines may modulate biotransformation enzyme activities (Morgan, 2001). A dermatopharmacokinetic scheme taking into account marker and a single-component (vehicle) compound penetration and potential interaction is depicted in Figure 40.7 of Chapter 40 of this book.

The final level of potential interaction is in the dermis where a component chemical may directly or indirectly (e.g., via cytokine release in the epidermis) modulate vascular uptake of the penetrated marker (Riviere and Williams, 1992; Williams and Riviere, 1993; Cross and Roberts, 2006). In addition to modulating transdermal flux of chemical, such vascular modulation could also affect the depth and extent of marker penetration into underlying tissues.

It must be stressed that interactions at all of these levels could occur simultaneously, and multiple components could be affecting marker penetration, as well as other component disposition in skin. These can optimally be teased apart using a hierarchy of experimental model systems, which are only responsive to specific levels of interactions. A scheme used in our laboratory to study these effects is depicted in Table 6.2. The important point to stress about this scheme is that when a chemical mixture absorption is being assessed, the biological complexity of the experimental model system must be sufficient to detect the interaction. It is the sum of all interactions that ultimately determines the mixture's effect on marker absorption or skin disposition.

6.3 EXAMPLES OF MIXTURE INTERACTIONS

The above conceptual framework for assessing the importance of chemical mixture interactions on a marker chemical absorption or cutaneous disposition is by no way unique.

TABLE 6.2
Experimental Model Systems Used to Assess Levels of Interactions

In Vitro Physical-Chemical Determinations	Solubility
	Viscosity
	Critical micelle concentration
	Partition coefficients
In Vitro Silicone Membrane Diffusion Cells or Membrane Coated Fibers (MCF)	*Above effects*
	Assess partitioning and diffusion through defined membrane
In Vitro Dermatomed Skin Diffusion Cells[a]	*Above effects*
	Partitioning and diffusion parameters through stratum corneum and viable epidermis
	Epidermal biotransformation
Ex Vivo Isolated Perfused Porcine Skin Flaps (IPPSF)	*Above effects*
	Vascular modulation
	Inflammatory mediators
	Dermal binding and metabolism
In Vivo Whole Animals or Humans	*All above effects*
	Systemic feedback operative

[a] Human and porcine skin (correlated to IPPSF and *in vivo*).

As mentioned earlier, many of these interactions have been defined in binary mixtures consisting of marker chemical and vehicle, and thus are often categorized as vehicle effects. The problems occur when the absorption of complex mixtures, such as environmental contaminants at waste sites (≈50) or hydrocarbon fuels (>200) are considered. Many "simple" occupational mixtures may contain upward of 5–10 compounds. Some interactions may be synergistic, others antagonistic. The result observed is a vectorial sum of all interactions. The principles of complexity and chaotic systems teach us that when simple systems are added together, emergent behavior may occur, which is not predictable from examining simpler systems with fewer components (Bar-Yum, 1997). We have demonstrated this lack of predictability when the behavior of single and 2×2 combinations of jet fuel additives did not predict the behavior of hydrocarbon marker absorption when all three additives were present (Baynes et al., 2001).

A number of investigators have probed nonvehicle type mixture effects on topical absorption. Reifenrath and coworkers (1996) demonstrated that exposure of skin to a complex chemical irritant (hydroxylammonium nitrate, triethanolammonium nitrate, water) resulted in enhanced skin permeability of subsequently applied benzoic acid using *in vitro* and *in vivo* models. Based on their own data and an interpretation of other irritant studies (Bronaugh and Stewart, 1985; Wilhelm et al., 1991), they concluded that *in vitro* and *in vivo* studies agree when alterations occur to the stratum corneum barrier. However, when irritants influence other aspects of cutaneous physiology (e.g., vesication, erythema), then the *in vivo* response may be exaggerated. A role of estradiol in modulating phenol absorption has been reported (Abou-Hadeed et al., 1998).

Our laboratory initially implemented the MDCM approach studying the effects of sodium lauryl sulfate (surfactant), methyl nicotinate (rubefacient), and stannous chloride (reducing agent) in aqueous mixtures containing either acetone or DMSO on the percutaneous absorption of parathion (Qiao et al., 1996) and benzidine (Baynes et al., 1996). These studies in parathion mixtures containing up to six components demonstrated significant modulation (11-fold) of marker compound absorption and skin penetration depending on the composition of the dosed mixture. Higher-level statistical interactions between mixture components were detected. Benzidine absorptions were modulated 10-fold. In both studies, some compounds tended to enhance absorption (sodium lauryl sulfate, DMSO) while others (stannous chloride) tended to retard absorption when present in a mixture. Methyl nicotinate blunted parathion absorptive flux and changed the shape of the absorption profile. The effects of some mixture components were most dramatically evidenced by changes in the absorption/skin deposition ratios. Stratum corneum barrier function as measured by transepidermal water loss in the benzidine study changed as a function of mixture composition (Baynes et al., 1997). These studies concluded that the percutaneous absorption and skin deposition of the marker compounds benzidine and parathion were significantly dependent upon the composition of the chemical mixture in which they were dosed. Compass plots (Figure 6.1), a novel graphical tool was developed to statistically evaluate and illustrate the interactions present in such complex mixtures (Budsaba et al., 2000).

Similar mixture interactions were detected in a study of pentachlorophenol (PCP) percutaneous absorption (Riviere et al., 2001), where PCP flux varied 12-fold depending on the mixture applied. These data are illustrated in Figure 6.2. In contrast, absorption of 3,3′,4,4′-tetrachlorobiphenyl (TCB) and 3,3′,4,4′,5-pentacholrobiphenyl (PCB) were minimal in this system under all exposure scenarios, again stressing the

central role that the individual chemical's properties have on their susceptibility to mixture interactions. A recent study clearly showed that the dermal absorption of the biocide triazine was enhanced when nickel or a nitrosamine (NDELA) was present in either a mineral oil- or synthetic aqueous propylene glycol–based cutting fluid (Baynes et al., 2005a), or when skin was preexposed to trichloroethylene (Baynes et al., 2005b).

Percutaneous absorption of topically applied permethrin and *N*,*N*-diethyl-*m*-toluamide (DEET), two chemical entities putatively involved in the Gulf War syndrome, was modulated by coexposure to one another, as well as simultaneous exposure to topical jet fuels, sulfur mustard or organophosphates (Baynes et al., 2002; Riviere et al., 2002a,b). The highest flux of labeled permethrin was observed when pyridostigmine and the organophosphate nerve agent simulant DFP were infused into the *in vitro* and *ex vivo* models, an experimental manipulation, which also blunted inflammatory mediator release simultaneously assessed (Monteiro-Riviere et al., 2003). This later observation highlights the importance of both topical and systemic chemical exposures to modulate absorption of marker compounds.

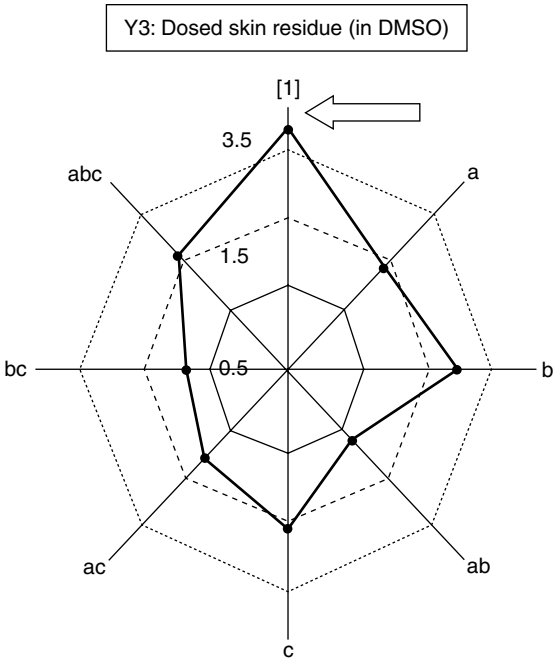

FIGURE 6.1 Compass plot illustrating a three-component chemical interaction. Mean (---) and confidence intervals (—) are depicted for all combinations of treatments a, b, and c. Points outside of this polygon (⇒) are significantly different.

6.4 A MODIFIED QSAR APPROACH TO QUANTITATE MIXTURE INTERACTIONS

Although studies such as those briefly reviewed above clearly demonstrate that mixture interactions occur, how does one quantitatively predict their impact on compound absorption? Significant progress has been made in predicting the dermal absorption or penetration of topically applied chemicals across skin using quantitative structure activity relationship (QSAR) models based on linear-free energy relations (LFER) that link penetrant molecular descriptors to skin permeability (k_p) (Potts and Guy, 1992; Abraham et al., 1999; Geinoz et al., 2004; Cronin, 2006). These efforts have employed chemicals applied to the surface of skin in

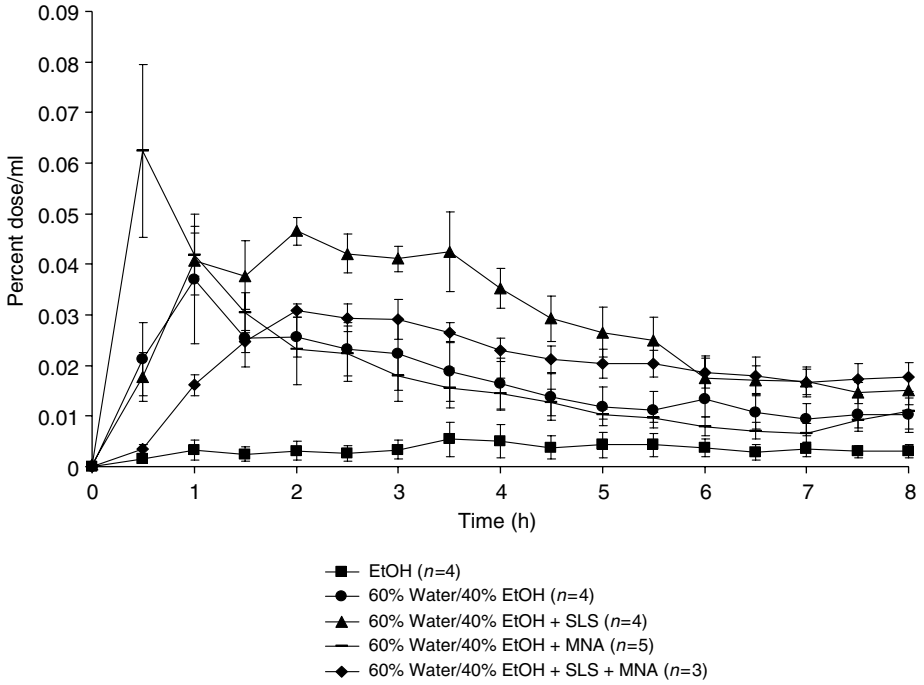

FIGURE 6.2 IPPSF perfusate absorption profiles of PCP (mean ± SEM).

single solvent or aqueous systems. The effects of mixture interactions have never been quantitatively addressed in the framework of QSPR models.

We have recently developed a hybrid LFER-based QSAR approach to predict the effect of mixture components on their absorption though porcine skin (Riviere and Brooks, 2005, 2007) based on the molecular descriptors for the chemical, modified by a mixture factor (MF), which accounts for the physicochemical properties of the vehicle/mixture components. We employed Abraham's LFER model as our base equation since it is representative of the dermal QSPR approaches presently available. Studies were conducted using *in vitro* porcine skin diffusion cells (Riviere and Brooks, 2005). The basic Abraham LFER model is

$$\log k_p = c + a\sum \alpha^H{}_2 + b\sum \beta^H{}_2 + s\pi^H{}_2 + rR_2 + vV_x \qquad (6.1)$$

where

k_p = Permeability constant for the diffusion cell experiments
$\Sigma\alpha^H{}_2$ = Hydrogen-bond donor acidity
$\Sigma\beta^H{}_2$ = Hydrogen-bond acceptor basicity
$\pi^H{}_2$ = Dipolarity/polarizability
R_2 = Excess molar refractivity
V_x = McGowan volume

To incorporate mixture effects, another term is added called the mixture factor (MF) yielding:

$$\log k_p = c + m\mathrm{MF} + a\sum \alpha^H{}_2 + b\sum \beta^H{}_2 + s\pi^H{}_2 + rR_2 + vV_x \qquad (6.2)$$

The parameters *c*, *m*, *a*, *b*, *s*, *r*, and *v* are strength coefficients coupling the molecular descriptors to skin permeability in the specific experimental system. The value for the MF is determined by examining the residual plot (actual – predicted log k_p) generated from Equation 6.2 based on molecular descriptors of the permeants as a function of the physical-chemical properties of the mixture/solvents in which they were dosed.

A large data set of 12 compounds in 24 mixtures were employed for a total of 288 treatment combinations. These data were previously analyzed and grouped into penetrants that were differentially modified by solvent–mixture combinations (van der Merwe and Riviere, 2006), an exercise which suggested the types of physical-chemical properties of the mixture components to analyze, including parameters of molecular size and volume, hydrogen bonding, p*K*a, Henry's law constant, polarizability, refractive indices, etc. We then computed a composite physical-chemical MF by weighting the component's physical-chemical parameter (e.g., refractive index) by its contribution to its MF based on the summation of the weight percentage of each of the bulk components in the mixtures for a particular parameter. Minor mixture components based on weight percentages, in this case the actual penetrant, did not materially contribute to the value of the MF for a specific treatment and could be excluded. To confirm selection of these specific parameters, principal component analyses of these descriptor's effects on k_p also yielded three groups of descriptors, which accounted for different patterns of variability seen.

Figure 6.3 depicts the predicted versus observed compound fluxes without (Figure 6.3A) and with (Figure 6.3B) a mixture factor included. These data clearly demonstrate the feasibility of using this approach to quantitatively gauge the impact of a mixture on compound absorption.

6.5 CONCLUSIONS

This brief review clearly demonstrates that dermal absorption of a chemical administered in a complex chemical mixture of even three to four components, cannot be easily predicted from simpler exposure scenarios unless the properties of the mixtures are included. In some cases, certain additives have consistent effects across mixtures (e.g., sodium lauryl sulfate, stannous chloride) due to a consistent mechanism of action. One approach to predict the effect of a complex mixture is to define the components based on their potential mechanism of action relative to modulating absorption. Use of multiple levels of experimental models facilitates this endeavor. Precise definition and quantitation of such interactions would allow for the development of complex interactive dermatopharmacokinetic models (Williams et al., 1996). However, the picture is not as clear as this conclusion implies. The effect of components on marker absorption is dependent on the chemical properties of the marker being studied, thus PCP behaved differently than PCB or TCB. Similarly, component effects on parathion and benzidine were different, an observation that is quantitated by the MF in the hybrid QSAR approach.

It is theoretically feasible that some mixture components, such as classical enhancers like oleic acid, might induce what amounts to a phase-transition in the stratum corneum lipids that would totally change the types of interactions seen with other mixture components. This would be an example of emergent behavior, a phenomenon that would make extrapolations from experimental studies or simpler mixture exposures problematic. Evidence of this was seen in the parathion mixture experiments where certain combination resulted in a great enhancement of treatment variance, an indicator that the system was no longer stable.

The risk assessment of topical chemical mixtures is a research and toxicological exposure paradigm that will become increasingly important as occupational and environmental problems become more common. Interactions should be defined in specific physical-chemical and biological terms so that methods to integrate findings across studies can be developed. Model systems should not be overinterpreted, and caution must be exercised when extrapolating from simple *in vitro* models up the ladder of biological complexity. The use of mathematical models is a powerful tool to link these studies across chemicals, mixtures, and experimental systems.

7.1 INTRODUCTION

The area of percutaneous absorption has been established as a significant part of dermatotoxicology. Human health risk assessment includes an estimate for percutaneous absorption where dermal exposure is involved. Some estimate of percent dose absorbed or steady-state absorption (flux) is included. Behind these generated numbers lies the question of validation. First, human exposure is a risk end point, and if a model is used, that model should be validated for humans *in vivo*. Second, there is the question of relevance of the particular risk assessment situation to the provided percutaneous absorption data. For example, is an absorption estimate derived over a long period of exposure applicable to a short exposure period? (There are some examples where this is not the case.) Also, multiple exposures (daily or weekly) can exceed single exposure estimates in some situations. Third, some limitations (lag time, lipophilicity) of the *in vitro* diffusion model are shown. Finally, the data showing skin delivery and percutaneous absorption of chemicals from clothing fabric are discussed. The overall interest is relevant and validates percutaneous absorption data and proper data interpretation.

7.2 SHORT-TERM EXPOSURE TO HAZARDOUS CHEMICALS

Exposure to hazardous chemicals in water during a bath or swim is on the order of 30 min to an hour. Some tasks at work or at home where exposure may occur can be of the same length of time. A hazardous spill is usually washed with soap and water within this time frame. The standard workday is 8 h, punctuated with breaks during this time period. Assessment of skin absorption in the laboratory is usually in the magnitude of 24 h, or some steady-state rate achieved in the course of 24+ h of exposure. Linearity in skin absorption is assumed, and the appropriate calculations to the desired time period are made.

Table 7.1 shows that the *in vivo* percutaneous absorption for a 24-h exposure is 51% for a dose of benzo[a]pyrene and 18.9% for a dose of DDT. To simulate short-term exposure,

TABLE 7.1
Short-Term Wash Recovery for Benzo[a]pyrene and DDT: 25-min Exposure versus 24-h Exposure

	Percentage Dose		
	Short Exposure (25 min), *In Vitro*		
Chemical	**Receptor Fluid**	**Skin**	**Long Exposure (24 h), *In Vivo***
Benzo[a]pyrene	0.00 ± 0.00	5.1 ± 2.1	51.0 ± 22.0
DDT	0.00 ± 0.00	16.7 ± 13.2	18.9 ± 9.4

Note: The chemical in acetone vehicle was dosed on human skin *in vitro*, then washed with soap and water after a 25-min period. The *in vivo* studies were a 24-h exposure with acetone vehicle dosing.

TABLE 7.2
Exposure of Human Skin to Cadmium in Water for 30 min Followed by Skin Surface Wash with Soap and Water and Then 48-h Perfusion with Human Plasma

	Percentage Dose	
Treatment	**Skin Content**	**Plasma Receptor Fluid**
30-min exposure only	2.3 ± 3.3	0.0 ± 0.0
30-min exposure followed by 48-h perfusion	2.7 ± 2.2	0.6 ± 0.8
Statistics	$p = .77$	$p = .04$[a]

Note: $n = 9$ (3 human skin sources × 3 replicates each). This study simulates a 30-min exposure of human skin to cadmium in water (swim, bath) followed by a soap-and-water surface wash. Cadmium is able to bind to human skin in the 30-min exposure time and then be absorbed into the body during the remainder of the day.

[a] Statistically significant difference.

TABLE 7.3
Effect of Exposure Time on Mercury Percutaneous Absorption *In Vitro* in Human Skin

	Percentage Dose	
Time/Treatment	**Receptor Fluid**	**Skin Content**
30 min only ($n = 9$)	0.01 ± 0.00[a]	5.5 ± 5.2[a,b]
30 min followed by 48-h perfusion ($n = 9$)	0.09 ± 0.05[a,b]	6.3 ± 4.9[a,b]
24 h ($n = 6$)	0.06 ± 0.03[b]	35.4 ± 15.2[a]

[a] Significant difference ($p < .05$ or greater).

[b] Nonsignificant difference.

human skin was dosed and the skin surface washed with soap and water after 25 min of dosing. The receptor fluid contained, as expected, no chemical. However, the skin was assayed and benzo[a]pyrene levels were at 5.1% and DDT levels were at 16.7% (the same as for 24-h exposure). In the short 25-min exposure, sufficient chemical had partitioned from the skin surface into the interior, or was so bound that soap and water wash did not remove the chemical (Wester et al., 1990).

In the course of studying cadmium skin absorption, short-term exposure to human skin *in vitro* was examined. This study simulated a 30-min exposure of human skin to cadmium in water (swim, bath) followed by a soap-and-water surface wash. Table 7.2 shows that with 30-min exposure alone, receptor fluid (human plasma) contained no cadmium (0.0%) but that skin content was 2.3% of the dose. To determine if cadmium would migrate from the skin into the plasma receptor fluid (and thus be a systemically absorbed chemical), some skin samples were further perfused for an additional 48 h. Some cadmium in the skin did migrate into the plasma perfusate (0.6%; statistically significant at $p = .04$) (Wester et al., 1992b).

Table 7.3 shows the effect of exposure time on mercury ($HgCl_2$) in water as percutaneous absorption *in vitro* in human skin. With 24 h of exposure, receptor fluid accumulation was 0.06%; however, skin content was 35.4%. Human skin has great attraction for mercury in water. Similar to the study just cited, mercury was applied to human skin for 30 min and the skin was washed with soap and water. Mercury was at low levels in receptor fluid (0.01%) but skin content was a robust 5.5%. Continued perfusion increased receptor fluid content to 0.09% (statistically significant difference $p < .05$). In other words, the mercury quickly partitioned into human skin, and then was slowly absorbed into the perfusate (body).

In each of the cases cited (DDT, benzo[a]pyrene, cadmium, mercury), the chemical exhibited a capacity to quickly partition into human skin with a short-term exposure of 30 min.

7.3 LAG TIME

There is a calculation from *in vitro* diffusion studies called the lag time. A line is drawn along an area of steady-state absorption to the abscissa (horizontal sequence of time) and the intercept with the abscissa is the lag time. This *in vitro* diffusion parameter should not be confused with the actual time that a chemical takes for percutaneous absorption *in vivo*. Table 7.4 gives the flux and lag time for hydroquinone *in vitro* percutaneous absorption in human skin dosed with a 2% hydroquinone cream. The lag time is 8 h. The same

TABLE 7.4
Parameters of *In Vitro* Hydroquinone Percutaneous Absorption in Human Skin

Treatment	Flux (μg/h cm²)	Lag Time (h)
HQ cream	2.94	7.99
HQ cream + inhibitor	2.93	8.03

Note: *In vivo* in human volunteers, hydroquinone is readily detected in blood within 30 min following topical application. The 8-h *in vitro* diffusion lag time has no relevance to the actual *in vivo* percutaneous absorption.

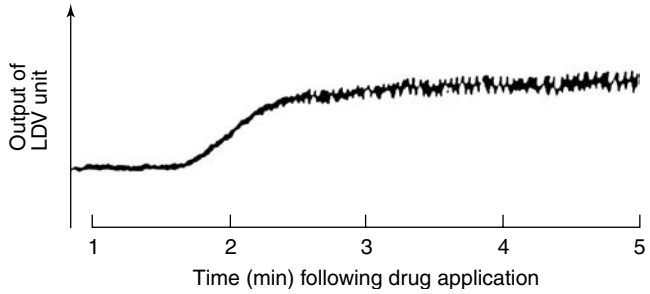

FIGURE 7.1 Laser Doppler velocimetry (LDV) measures human skin blood flow *in vivo*. Methyl nicotinate was able to penetrate and cause a pharmacological reaction in 2 min. This shows that *in vivo* percutaneous absorption can be rapid.

hydroquinone dose/vehicle was topically applied to human volunteers and hydroquinone was detected in blood within 30 min. Therefore, the 8-h *in vitro* diffusion lag time has no relevance to actual *in vivo* percutaneous absorption. The lag time is simply an artificial derivation of the *in vitro* diffusion system.

Laser Doppler velocimetry (LDV) is able to detect changes in human skin blood flow. Topical application of methyl nicotinate (a vasodilator) in human volunteers causes changes in skin blood flow within 2 min (Wester and Maibach, 1984) (Figure 7.1).

The end point for *in vivo* percutaneous absorption is the blood (systemic) in the microcirculation in the upper dermis at the epidermal junction. *In vitro* diffusion adds some dermis and solubility and detection sensitivity limits the process.

7.4 MULTIPLE EXPOSURES IN THE SAME DAY

On a historic and empiric basis, topical applications of hydrocortisone and other corticosteroids frequently use repeated, rather than single, bolus applications of drug to the skin. It is commonly assumed that multiple applications of hydrocortisone effectively increase its bioavailability and absorption. A long-term, multiple-dose rhesus monkey study by Wester et al. (1980) indicated that this was true. However, short-term experiments in the rhesus monkey by Wester et al. (1977) and long-term pharmacokinetic assays by Bucks et al. (1985) did not show an increase in hydrocortisone absorption following multiple dosing. An investigation was designed to determine if multiple-dose therapy (dosing the same site three times in the same day) would increase drug bioavailability in human skin. The study was done *in vivo* using male volunteers (from whom informed consent had been obtained) and *in vitro* with human skin. Hydrocortisone was in either a solvent (acetone) vehicle or in a cream base vehicle.

In each *in vivo* procedure in this crossover study, the subjects were healthy male volunteers, 25–85 years of age, from whom informed consent has been obtained. The treatments were performed on two adjacent sites on each forearm. Each site received a different treatment; each was performed 2–3 weeks apart, alternating forearms between the treatments to allow for systemic and dermal clearance of residual hydrocortisone and radioactivity. The dosing sequence was as follows:

Treatment	Dose per Application (μg/cm²)	Cumulative Dose (μg/cm²)	Total Vehicle Volume (μL)	
			Acetone	Cream
1[a]	13.33	13.33	20	100
2[b]	40.00	40.00	20	100
3[c]	13.33	40.00	60	100

[a] Single dose of 13.33 μg/cm², administered in 20 μL of vehicle.
[b] Single dose of 40.0 μg/cm², administered in 20 μL of vehicle.
[c] Three serial 13.33 μg/cm² doses each administered in 20 μL of vehicle (total 60 μg).

In vitro, three separate human donor skin sources with replicates per each experiment were used. Small cells were of the flow-through design with 1 cm² surface area. Buffered saline at a rate of 1.25 mL/h (1 reservoir volume) served as a receptor fluid. Human cadaver skin was dermatomed to 500 μm and stored refrigerated at 4ºC in Eagle's minimum essential medium. The skin was used within 5 days. This preservation/use regimen follows that used by the human skin transplant bank. Radiolabeled hydrocortisone in either acetone or cream base vehicle was applied to the skin per the study design.

Table 7.5 shows that *in vivo*, the multiple dose (×3) significantly increased hydrocortisone percutaneous absorption for acetone vehicle ($p < .05$) and for the cream vehicle ($p < .006$). Statistically, *in vitro* (Table 7.6), there was no difference with multiple dose; however, the trend was the same as with *in vivo*. Figures 7.2 and 7.3 show the enhanced absorption *in vivo* from the acetone vehicle and the cream vehicle.

This study suggests that triple therapy in humans may have some advantage (Melendres et al., 1992). If increased bioavailability is desired, then multiple-application therapy may be the answer, if patient convenience is not an issue. Our data suggest the possibility that increased bioavailability is related to reapplication of vehicle; hence, a case may be made for increasing hydrocortisone bioavailability merely by applying serial doses of vehicle to a previously applied single dose of hydrocortisone at the skin surface. Such an experiment would verify if the solvent–vehicle effect was the only component by which multiple application of hydrocortisone

TABLE 7.5
Predicted and Observed Hydrocortisone Absorption: *In Vivo*

		Hydrocortisone Absorbed (μg/cm²)	
Vehicle	**Dosing Sequence**	**Predicted**	**Observed**
Acetone[a]	13.3 μg/cm² × 1	–	0.056 ± 0.073
	40.0 μg/cm² × 1	0.168[e]	0.140 ± 0.136[c]
	13.3 μg/cm² × 1	0.168	0.372 ± 0.304[c]
Cream[b]	13.3 μg/cm² × 1	–	0.31 ± 0.43
	40.0 μg/cm² × 1	0.93[e]	0.91 ± 1.55[d]
	13.3 μg/cm² × 1	0.93	1.74 ± 0.93[d]

Note: Different volunteers were used for each formulation; therefore, comparison of absolute bioavailability across vehicle is not justified.

[a] $n = 6$; mean ± SD.

[b] $n = 5$; mean ± SD.

[c] Statistically different ($p < .05$), paired *t*-test.

[d] Statistically different ($p < .006$), paired *t*-test.

[e] 0.168 μg/cm² is 3 × the measured value of 0.056 μg/cm² is 3 × the measured value of 0.31 μg/cm².

TABLE 7.6
Predicted and Observed Hydrocortisone Absorption: *In Vitro*

		Hydrocortisone (μg/cm²)			
		Receptor Fluid		Skin	
Vehicle	**Dosing Sequence**	**Predicted**	**Observed**	**Predicted**	**Observed**
Acetone[a]	13.3 μg/cm² × 1	–	0.13 ± 0.05	–	0.87 ± 0.23
	40.0 μg/cm² × 1	0.39[b]	0.35 ± 0.22	2.61[b]	2.21 ± 2.05
	13.3 μg/cm² × 1	0.39	0.55 ± 0.75	2.61	2.84 ± 2.05
Cream[a]	13.3 μg/cm² × 1	–	0.53 ± 0.029	–	0.30 ± 0.24
	40.0 μg/cm² × 1	0.16[b]	0.23 ± 0.03	0.90[b]	0.86 ± 0.53
	13.3 μg/cm² × 3	0.16	0.27 ± 0.21	0.90	1.19 ± 0.43

[a] $n = 3$; mean ± SD.

[b] 0.39 μg/cm² is 3 × the measured value of 0.13 μg/cm²; 0.16 μg/cm² is 3 × the measured value of 0.053 μg/cm²; 2.61 μg/cm² is 3 × the measured value of 0.87 μg/cm²; 0.91 μg/cm² is 3 × the measured value of 0.30 μg/cm².

in acetone increased its bioavailability in human skin. The cream vehicle was equal in amount for each treatment. Reapplication of cream in triple therapy may have "activated" any hydrocortisone bound in the stratum corneum reservoir.

From a toxicological viewpoint, a question remains as to whether multiple exposures during the day will differ from a single continuous exposure. Also, will varying conditions affect absorption (sweat or rainfall "activating" the absorption system as suggested by increased vehicle situation)?

7.5 MULTIPLE DOSING: AZONE SELF-ENHANCED PERCUTANEOUS ABSORPTION

Azone (1-dodecylazacycloheptan-2-one) is an agent that has been shown to enhance percutaneous absorption of drugs. Azone is thought to act by partitioning into skin lipid bilayers and thereby disrupting the structure. An open-label study was done with nine volunteers (two males, seven females; aged 51–76 years) in whom Azone cream (1.6%; 100 mg) was topically dosed on a 5 × 10 cm area of the ventral forearm for 21 consecutive days. On day 1, 8, and 15, the Azone cream contained 47 μCi of [^{14}C] Azone. The skin application site was washed with soap and water after each 24-h dosing. Percutaneous absorption was determined by urinary radioactivity excretion. The [^{14}C] Azone was ring labeled [^{14}C]-2-cycloheptan. Radiochemical purity was >98.6% and cold Azone purity was 99%. Percutaneous absorption of the first dose (day 1) was 1.84 ± 1.56% (SD) of applied amount for 24-h skin application time. Day 8 percutaneous absorption, after repeated application, increased significantly ($p < .002$) to 2.76 ± 1.91%. Day 15 percutaneous absorption after continued repeated application stayed the same at

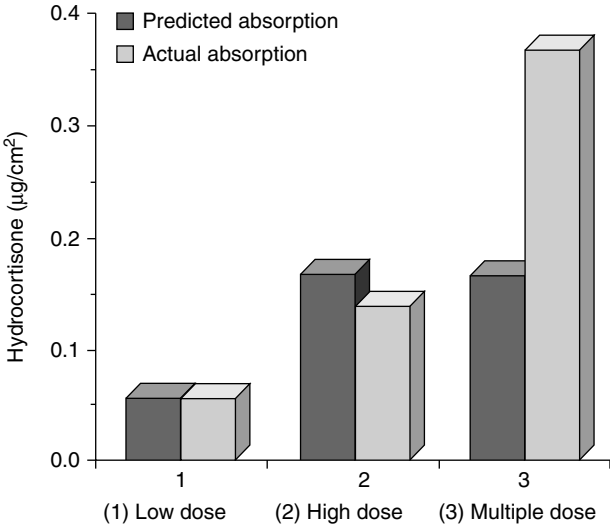

FIGURE 7.2 Hydrocortisone *in vivo* percutaneous absorption in human with acetone vehicle and single and multiple dosing. The multiple dosing (triple therapy) exceeded predicted absorption and was statistically ($p < .006$) greater than the single high dose.

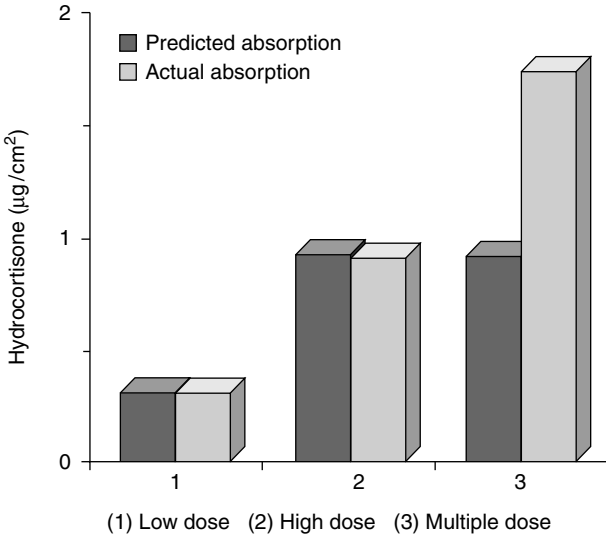

FIGURE 7.3 Hydrocortisone *in vivo* percutaneous absorption in human with cream vehicle and single and multiple dosing. The multiple dosing (triple therapy) exceeded predicted absorption and was statistically ($p < .006$) greater than the single high dose.

$2.72 \pm 1.21\%$. In humans, repeated application of Azone results in an initial self-absorption enhancement, probably due to its mechanism of action. However, steady-state percutaneous absorption of Azone is established after this initial change. Thus, Azone can enhance its own absorption as well as that of other compounds (Figure 7.4) (Wester et al., 1993b).

7.6 INDIVIDUAL VARIATION: *IN VITRO* HUMAN SKIN

It is well understood that chemical trials are designed with multiple volunteers to account for individual subject variation.

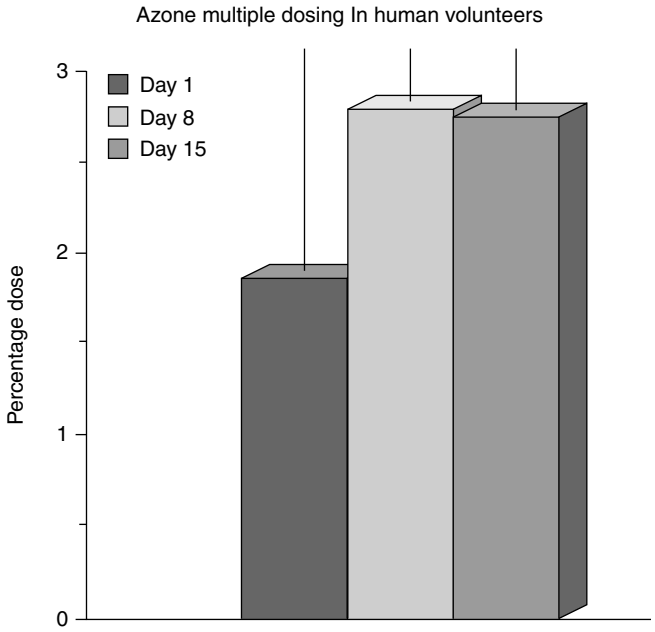

FIGURE 7.4 Azone *in vivo* in humans is able to enhance its own percutaneous absorption (day 1–8) until steady-state absorption is reached (day 1–15).

[b] $p = .42$ (nonsignificant; paired t-test).

This extends to *in vivo* percutaneous absorption where individual subject variability has been demonstrated (Wester and Maibach, 1985). This subject variation also extends to *in vitro* human skin samples (Wester and Maibach, 1991). Table 7.7 shows the *in vitro* percutaneous absorption of vitamin E acetate through human skin. Percent doses absorbed for two formulations, A and B, are shown for 24-h receptor fluid accumulation and for skin content (skin digested and assayed at 24-h time point). Assay of skin surface soap

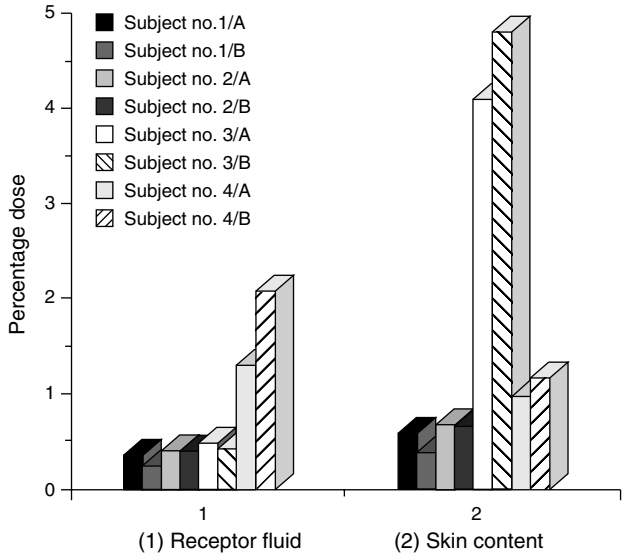

FIGURE 7.5 *In vitro* percutaneous absorption of vitamin E acetate in human skin. Note that individual variation is consistent between formulations A and B.

TABLE 7.8
Study Design for *In Vitro* Percutaneous Absorption

Human Skin Source	Treatments					
	A	B	C	D	E	F

4	X	X	X	X	X	X

Note: A–F can be separate treatment or replicates of treatments. If necessary or desired, human skin sources can be extended beyond 4.

and water washed at the end of the 24-h period gives dose accountability.

The two formulations were the same except for slight variation in pH. Statistically, there was no difference in absorption between the two formulations. However, a careful examination of the individual values in Table 7.7 shows consistency within individuals. Analysis of variance (ANOVA) for individual variation showed statistical significance for receptor fluid ($p = .02$) and skin content ($p = .000$) (Figure 7.5); therefore, when comparing treatments for *in vitro* percutaneous absorption, it is recommended that each treatment be a part of each skin source. Table 7.8 outlines a study based upon this.

7.7 MODELS: *IN VITRO* AND *IN VIVO*

Models are substitutes, and in the case of percutaneous absorption, the model substitutes for *in vivo* percutaneous absorption in humans. Models need to be validated, as shown for the rhesus monkey in Table 7.9. A popular substitute for humans *in vivo* is the use of human skin *in vitro*. Table 7.10

TABLE 7.9
***In Vivo* Percutaneous Absorption in Rhesus Monkey and Human (% Dose Absorbed)**

Compound	Rhesus Monkey	Human
2,4-Dinitrochlorobenzene	52 ± 4	54 ± 6

DDT	19 ± 9	10 ± 4
Retinoic acid	2 ± 1	1 ± 0.2
2,4-D	9 ± 2	6 ± 2

Note: These are data collected over the years from many laboratories. The rhesus monkey is a good animal model to predict potential percutaneous absorption in humans.

gives the *in vitro* percutaneous absorption of several chemicals, expressed as percent dose accumulated in receptor fluid for 24 h, and the skin chemical content at that time frame. For DDT, benzo[a]pyrene, chlordane, pentachlorophenol, and polychlorinated biphenyls (PCBs), there is negligible receptor fluid accumulation (Wester et al., 1990, 1992a, 1993b, 1993d). A basic rule on *in vitro* percutaneous absorption is that solubility of a chemical in receptor fluid should not be the limiting step. Table 7.11 shows that these chemicals have high log *P* values. For example, a log *P* of 6.91 (DDT) means that when DDT is introduced into an equal amount of octanol and water, 6,910,000 molecules will end up in the octanol and one molecule will be in the water. The stratum corneum is lipophilic, so there is a tendency for chemicals to stay in skin and not partition into water-based receptor fluid. In Table 7.10, the skin content of chemical is better than that of receptor fluid, and somewhat predictive of *in vivo* absorption, but not in all cases (pentachlorophenol, PCBs) (Wester et al., 1990, 1992a, 1992b, 1993a, 1993b, 1993d).

7.8 PERCUTANEOUS ABSORPTION FROM CHEMICALS IN CLOTHING

Chemicals in cloth cause cutaneous effects. For example, Hatch and Maibach (1986) reported that chemicals added to cloth in 10 finish categories (dye, wrinkle resistance, water repellancy, soil release, and so on) caused irritant and allergic contact dermatitis, atopic dermatitis exacerbation, and urticarial and phototoxic skin responses. This is qualitative information that chemicals will transfer from cloth to skin *in vivo* in humans. Quantitative data are lacking. Snodgrass (1992) studied permethrin transfer from treated cloth to rabbit skin *in vivo*. Transfer was quantitative but less than expected. Interestingly, permethrin remained within the cloth after detergent laundering.

In other studies (Quan et al., 1994), *in vitro* percutaneous absorption of glyphosate and malathion through human skin

Aroclor 1254	(high log P)

TABLE 7.12
***In Vitro* Percutaneous Absorption of Glyphosate and Malathion from Cloth through Human Skin**

Chemical	**Donor Conditions**	**Treatment**	**Percentage Dose Absorbed**
Glyphosate	1% Solution (water)	None	1.42 ± 0.25
	1% Solution on cloth	0 h	0.74 ± 0.26
	1% Solution on cloth	24 h	0.08 ± 0.01
	1% Solution on cloth	48 h	0.08 ± 0.01
	1% Solution on cloth	Add water	0.36 ± 0.07
Malathion	1% Solution (water/ethanol)	None	8.77 ± 1.43
	1% Solution on cloth	0 h	3.92 ± 0.49
	1% Solution on cloth	24 h	0.62 ± 0.11
	1% Solution on cloth	48 h	0.60 ± 0.14
	1% Solution on cloth	Add water/ethanol	7.34 ± 0.61

Note: Both glyphosate and malathion in solution (treatment = none) are absorbed through human skin. Glyphosate and malathion on cotton cloth show some absorption into skin, depending upon the time the chemical was added to cloth treatment = 0, 24, and 48 h). When the cloth was wetted (treatment = add water or add water/ethanol), the transfer of glyphosate and malathion from cloth to human akin was increased. This suggests that sweating, skin oil, or even rain may facilitate transfer of chemicals from cloth to skin.

was decreased when added to cloth (the cloth then placed on the skin) and this absorption decreased as time passed over 48 h (Table 7.12). It is assumed that with time the chemical will sequester into deep empty spaces of the fabric, (or some type of bonding is established between chemical and fabric. When water was added to glyphosate/cloth and water/ethanol to malathion/cloth, the percutaneous absorption increased malathion to levels from solution). This perhaps reflects clinical situations where dermatitis occurs most frequently in human sweating areas (axilla, crotch).

7.9 HUMAN *IN VIVO* PERCUTANEOUS ABSORPTION

7.9.1 Diazinon

Diazinon is an organophosphorus insecticide that, through general use, comes into contact with human skin. To investigate its percutaneous absorption, human volunteers were exposed for 24 h to ^{14}C-labeled diazinon applied in acetone solution (2 μg/cm^2) to the forearm or abdomen, or in lanolin wool grease (1.47 μg/cm^2) to the abdomen (Table 7.13).

TABLE 7.13
Percutaneous Absorption of Diazinon in Humans

Skin Site	Vehicle	Percutaneous Absorption (% of Dose)[a]
Forearm	Acetone	3.85 ± 2.16
Abdomen	Acetone	3.24 ± 1.94
Abdomen	Lanolin	2.87 ± 1.16

[a] Mean ± SD for six volunteers per group, calculated from human urinary ^{14}C disposition corrected for incomplete/other route excretion with the monkey urinary disposition after IV dosing.

Complete void urine samples were collected daily for 7 days. Percutaneous absorption ranged from 2.87 ± 1.16% (mean ± SD, $n = 6$) to 3.85 ± 2.16% of the applied amount, and there were no statistically significant differences with regard to site or vehicle of application. In rhesus monkeys, over the 7 days after IV dosing (2.1 μCi [^{14}C]diazinon, 31.8 μg), a total of 55.8 ± 68% ($n = 4$) of the dose was excreted in the urine, and 22.6 ± 5.2% was eliminated in the feces (78.4% total accountability). In *in vitro* percutaneous absorption studies with human abdominal skin, 14.1 ± 9.2% of the applied dose accumulated in the receptor fluid over 24 h of exposure to 0.25 μg/cm^2 (acetone vehicle). The calculated mass absorbed was the same (0.035 μg/cm^2) for both *in vitro* and *in vivo* absorption through human skin (Wester et al., 1993c).

7.9.2 Pyrethrin and Piperonyl Butoxide

To determine the human *in vivo* percutaneous absorption, a commercial formulation containing either [^{14}C]pyrethrin (3.8 mCi/mmol) or [^{14}C]piperonyl butoxide (3.4 mCi/mmol) was applied to the ventral forearm of six human volunteers (Table 7.14). The formulation contained 0.3% pyrethrin or 3.0% piperonyl butoxide. Spreadability studies showed that concentrations of 5.5 μg pyrethrin/cm^2 and 75.8 μg piperonyl butoxide/cm^2 (used in this study) would be consistent with levels found in actual use. The forearms were thoroughly cleansed with soap and water 30 min after application (as recommended for actual use). Percutaneous absorption was determined by urinary cumulative excretion following dose application. With a 7-day urinary accumulation, 1.9 ± 1.2% (SD) of the dose of pyrethrin and 2.1 ± 0.6% of the piperonyl butoxide applied was absorbed through the forearm skin. One hour after application, blood samples contained no detectable radioactivity. The percutaneous absorption of pyrethrin and piperonyl butoxide from the scalp was calculated to be 7.5% of the applied dose for pyrethrin and 8.3% for piperonyl butoxide. The calculated half-life of ^{14}C excretion was 50 h for pyrethrin and 32 h for piperonyl butoxide. The data should be of relevance to risk assessment where extrapolating animal data to humans (Wester et al., 1994b).

TABLE 7.14
Percutaneous Absorption of Pyrethrin and Piperonyl Butoxide from Human Forearm and Calculated from Human Scalp

	Dose Absorbed (%)			
	Pyrethrin		Piperonyl Butoxide	
Subject	Forearm	Scalp[a]	Forearm	Scalp[a]
1	1.4	5.6	2.8	1.2
2	1.6	6.4	1.8	7.2
3	2.0	8.0	2.8	11.2
4	0.6	2.4	1.8	7.2
5	1.6	6.4	1.4	5.6
6	4.1	16.4	1.8	7.2
Mean ± SD	1.9 ± 1.2	7.5 ± 4.7	2.1 ± 0.6	8.3 ± 2.4

[a] Scalp is assumed to have fourfold absorption greater than forearm.

TABLE 7.15
***In Vivo* Percutaneous Absorption of Isofenphos in Humans**

	Percentage Dose Absorbed[a]	
Subject	24-h Exposure	72-h Exposure
1	1.18	4.12
2	1.93	3.86
3	2.47	3.01
4	8.94	3.56
Mean ± SD	3.63 ± 3.58	3.64 ± 0.48

[a] Percentage dose absorbed = (urinary ^{14}C excretion for topical/urinary ^{14}C excretion for IV) × 100.

7.9.3 Isofenphos

Studies were done to determine the percutaneous absorption of isofenphos in human volunteers from whom informed consent had been obtained. *In vivo* absorption in humans was 3.6 ± 3.6% of applied dose for 24-h exposure and 3.6 ± 0.5% for 72-h exposure (Table 7.15). Skin wash recovery data showed that isofenphos evaporates from *in vivo* skin during the absorption process; the surface dose is minimal (<1%) by 24 h. Skin stripping showed no residual isofenphos in stratum corneum. This explains the similar absorption for 24- and 72-h prewash exposures. Skin surface recovery *in vivo* with soap and water was 61.4 ± 10.4% for the first dosing time (15 min). Time-recovery response declined with time to 0.5 ± 0.2% at 24 h. *In vitro* absorption utilizing flow-through diffusion methodology with human cadaver skin and human plasma receptor fluid gave 2.5 ± 2.0% dose absorbed, an amount similar to *in vivo* studies (Table 7.16). An additional 6.5 ± 24% was recovered in the skin samples (total of 9%). Skin surface wash at 24 h recovered 79.7 ± 2.2% and

TABLE 7.16
***In Vitro* Percutaneous Absorption of Isofenphos with Human Skin**

	Average Percentage Applied Dose[a]		
Human Plasma Receptor Fluid	**Skin**	**Surface Wash**	**Total**
2.5 ± 2.0	6.5 ± 2.4	79.7 ± 2.2	88.7 ± 4.6

[a] Mean ± SD for four replicates.

skin content was 6.5 ± 2.4% (total dose accountability of 88.7 ± 4.6%). Thus, isofenphos was available for absorption during the entire dosing period. Neither *in vitro* absorption nor *in vitro* evaporation studies predicted the potential skin evaporation of isofenphos. Published dermal studies in the rat had predicted isofenphos absorption at 47% of applied dose (12-fold greater than actual in humans). Subsequent toxicokinetic modeling predicted possible concern with the use of isofenphos. This is an example where the choice of the rat produced a nonrelevant absorption prediction. *In vivo* studies in human volunteers seem more relevant for predicting percutaneous absorption in humans (Wester et al., 1992c).

7.10 DISCUSSION

This chapter provides examples and discussion of information relating to relevance and validation of percutaneous absorption for risk assessment. The assessment of short-term exposure may be missed with some conventional calculations of percutaneous absorption such as conventional flux value (or modeled flux value) and lag time. *In vivo*, a chemical can rapidly partition into skin during a bath or swim (time period on the order of an hour or less). Interpretation of an artificial (due to *in vitro* diffusion system) lag time may eliminate that rapid uptake. Alternatively, a conventional flux rate, where linearity over time is scaled back to 30 min of exposure, may underestimate the actual exposure.

The other points raised in this chapter concern multiple exposures and absorption from nonformulated media (e.g., cloth/fabric). The question to be asked is, does the study design used to produce the (percutaneous absorption) data reflect the problem/risk assessment that is being investigated? A firmer understanding of these specific issues is needed, as well as more substantive methods of designing and interpreting clinically relevant situations.

8.1 IMPLICATION OF STRATUM CORNEUM LIPIDS IN PERMEABILITY BARRIER FUNCTION

Experiments performed in the early 1950s in which the effects of organic solvents on permeability of the skin were studied implicated stratum corneum lipids in the function of the permeability barrier (Berenson and Burch, 1951; Blank, 1952). However, little further progress was made until 1973, when two breakthroughs were reported. Through the use of electron-dense water-soluble tracers, Squier (1973) was able to demonstrate by transmission electron microscopy that the permeability barrier starts at the bottom of the stratum corneum, where the contents of the lamellar granules are extruded. These studies also indicated that all layers of stratum corneum contribute to barrier function. In this same year, Breathnach et al. (1973) demonstrated by freeze fracture electron microscopy that the intercellular spaces of the stratum corneum contain multiple stacked, broad lipid sheets. These findings were further elaborated by Elias and Friend (1975). In the scenario that emerged from this body of work, lipids accumulate in lamellar granules, and are extruded into the intercellular spaces in the upper granular layer. After extrusion, the short stacks of lipid lamellae are transformed into multiple broad lipid sheets, which fill most of the intercellular spaces throughout the stratum corneum. It is this lamellar lipid in the intercellular spaces that determines the permeability of the stratum corneum.

8.2 ALTERATION OF LIPIDS WITH DIFFERENTIATION

Basal keratinocytes, like most mammalian cells, contain phospholipids and cholesterol as the principal lipids; however, as epidermal keratinocytes undergo differentiation there are dramatic alterations of lipid composition (Yardley and Summerly, 1981). In addition to more phospholipids, the differentiating cells synthesize a great deal of ceramides, glucosylceramides, and cholesterol. In the final stages of the differentiation program, the phospholipids are broken down and the glycolipids are deglycosylated, leaving ceramides, cholesterol, and fatty acids as the principal lipids of the stratum corneum (Wertz and Downing, 1989a). These are the lipids that form the intercellular lamellae. It is remarkable that unlike most biological membranes, the intercellular lamellae do not contain phospholipids.

8.3 LAMELLAR GRANULES

Much of the lipid that accumulates during epidermal differentiation is packaged into lamellar granules (Landmann, 1988). This small organelle is round to ovoid in shape, approximately 0.2 μm in diameter, and consists of one or several stacks of lamellar disks surrounded by a bounding membrane. The lamellar disks are thought to be flattened lipid vesicles.

Several investigators have examined the lipid composition of isolated lamellar granules, and have found the major lipid classes to be phospholipids, cholesterol, and glucosylceramides (Wertz et al., 1984; Freinkel and Traczyk, 1985; Grayson et al., 1985). One unusual glycolipid associated with lamellar granules consists of 30- through 34-carbon ω-hydroxyacids amide linked to sphingosine with glucose β-glycosidically attached to the primary hydroxyl group of the long-chain base and linoleic acid ester-linked to the ω-hydroxyl group (Wertz and Downing, 1983a;

Abraham et al., 1985). The ω-hydroxyacyl portion of this molecule is of sufficient length to span a typical lipid bilayer, and it has been proposed that the linoleate could insert into an adjacent bilayer, thus riveting the two together (Wertz and Downing, 1982). This sort of interaction could promote the flattening and stacking of lipid vesicles to produce the stacks of disks found within the lamellar granules. It has also been suggested that only about one-third of the acylglucosylceramide is associated with the internal lamellae, while the other two-thirds is in the bounding membrane (Wertz, 1992, 1996).

8.4 LIPID ENVELOPE

When the bounding membrane of the lamellar granule fuses into the cell plasma membrane, much lipid including acylglucosylceramide is introduced to the cell periphery. At about this time, a thick band of protein is deposited on the inner aspect of the plasma membrane (Rice and Green, 1977, 1979; Mehrel et al., 1990), and this protein becomes cross-linked via isopeptide (Abernathy et al., 1977; Rice and Green, 1977) and disulfide linkages (Polakowska and Goldsmith, 1991). The glucose is removed from the acylglucosylceramide through the action of a glucocerebrosidase (Wertz and Downing, 1989b). The linoleate is removed and possibly recycled (Madison et al., 1989), and the remaining ω-hydroxyceramide becomes attached through ester linkages to the outer surface of the cross-linked protein (Wertz and Downing, 1987). The amount of this covalently bound lipid is just sufficient to provide a monomolecular coating over the entire surface of the cornified cell (Wertz and Downing, 1987; Swartzendruber et al., 1987). In the porcine model, there is one ω-hydroxyceramide that contains sphingosine as the base (Wertz and Downing, 1987); however, in human stratum corneum, there are two additional ω-hydroxyceramides. One of these contains 6-hydroxyceramide as the base component (Wertz et al., 1989; Robson et al., 1994), and the other contains phytosphingosine (Hill et al., 2006). It appears that transglutaminase 1 may be responsible for attachment of the ω-hydroxyceramide molecules to involucrin in the envelope (Nemes et al., 1999).

8.5 CHEMICAL STRUCTURES OF THE STRATUM CORNEUM LIPIDS

The first completely described epidermal ceramides were those from porcine epidermis (Wertz and Downing, 1983b). These ceramides comprised 50% of the mass of the stratum corneum lipids (Wertz and Downing, 1989a) and were fractionated into six chromatographically distinct fractions by thin-layer chromatography. Each fraction was analyzed by a combination of chemical, chromatographic, and spectroscopic methods, and one unique structural type of ceramide was found in each fraction. Accordingly, these ceramides were called ceramides 1 through 6, in order of increasing polarity. The least polar of the porcine ceramides, ceramide 1, is derived from the above-mentioned acylglucosylceramide, and may serve as a molecular rivet in stabilizing the multilamellar sheets within the intercellular spaces. Ceramide 2 consists of mainly 24- through 28-carbon fatty acids amide-linked to sphingosines. Ceramide 3 contains the same range of fatty acids, but they are here amide-linked to phytosphingosines. Ceramides 4 and 5 both contain α-hydroxyacids amide-linked to sphingosines. They differ in that ceramide 4 contains 24- through 28-carbon hydroxyacids, whereas ceramide 5 contains mainly the 16-carbon α-hydroxypalmitic acid. Ceramide 6 consists of α-hydroxyacids amide-linked to phytosphingosines. Cholesterol, a ubiquitous membrane lipid, comprises 25% of the stratum corneum lipid mass (Yardley and Summerly, 1981; Wertz and Downing, 1989a). The free fatty acids comprise 10% of the stratum corneum lipid (Yardley and Summerly, 1981; Wertz and Downing, 1989a), and like those from ceramides 2 and 3, are mainly 24- through 28-carbon saturates. It is noteworthy that with the exception of the linoleate tail of ceramide 1 for which a special function has been proposed, all of the aliphatic chains in the stratum corneum lipids are straight with no methyl branches or *cis* double bonds, and the polar head groups are minimal. These structural features should favor formation of highly ordered, probably gel phase membrane domains, and this expectation is supported by infrared (Potts and Francoeur, 1993), x-ray, and thermal studies (Bowstra et al., 1991).

As noted, the ceramide structures described in the previous paragraph were from porcine epidermis (Wertz and Downing, 1983b); however, all of the same ceramides are present in human epidermis (Wertz et al., 1985, 1987). The structures of the human stratum corneum lipids are presented in Figure 8.1. These lipids are shown in order of increasing polarity from top to bottom. One exception to this order occurs with the sixth and seventh listed ceramides, which comigrate. They have been separated only after being isolated as a mixed fraction, being acetylated, and being rerun in a different chromatographic system (Ponec et al., 2003). In addition to long-chain, saturated fatty acids, cholesterol, and the ceramides found in porcine stratum corneum, human stratum corneum contains four additional types of ceramides. Three of these contain 6-hydroxysphingosine as the base component (Robson et al., 1994; Stewart and Downing, 1999), and one is an acylceramide analogous to porcine ceramide 1 but with phytosphingosine as the base component (Ponec et al., 2003).

Because of the additional ceramides in human stratum corneum and the fact that they do not all separate into discrete chromatographic fractions, the nomenclature system based on chromatographic fraction numbers is no longer adequate. A system of ceramide nomenclature proposed by Motta et al. (1993) is increasingly coming into use. Within this system the amide-linked fatty acid is designated by N, A, or O, for normal fatty acids, α-hydroxyacids, and ω-hydroxyacids, respectively. Similarly, the base component

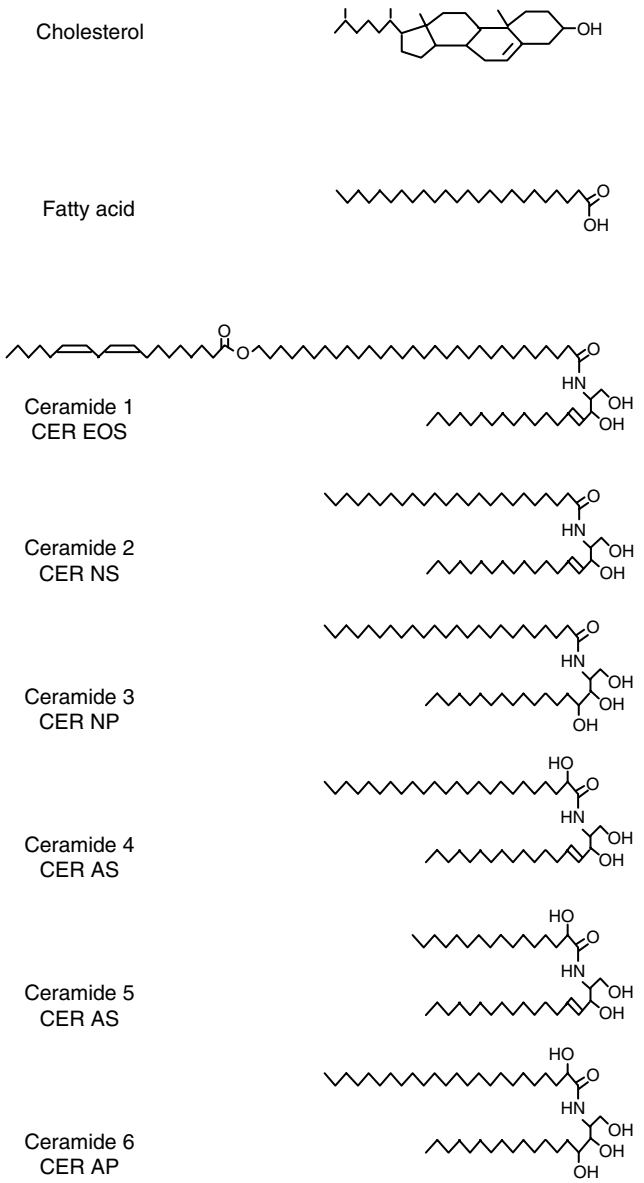

FIGURE 8.1 Representative structures of the major lipids from human stratum corneum. (From 6th edition.)

is designated as S, P, or H for sphingosine, phytosphingosine, and 6-hydroxysphingosine, respectively. If an ester-linked fatty acid is also present this is designated with a prefix E. The Motta nomenclature for each human ceramide is indicated in Figure 8.1.

8.6 ULTRASTRUCTURE OF THE INTERCELLULAR SPACES OF THE STRATUM CORNEUM

Although the intercellular lamellae of the stratum corneum could be detected by the freeze fracture method (Breathnach et al., 1973), this technique provides relatively little information. Until the recent introduction of ruthenium tetroxide as a postfixative for the preparation of samples (Madison et al., 1987), the intercellular lamellae could not be visualized by transmission electron microscopy, and it was proposed that the lipids were removed during sample processing (Elias et al., 1988). However, it is now known that this is not the case. The stratum corneum lipids, as appropriate for materials that interface with the external environment, are relatively chemically inert, and do not react appreciably with osmium tetroxide used for routine fixation. This difficulty was overcome by substitution of the stronger oxidizing agent, ruthenium tetroxide. With this reagent the intercellular lamellae can be routinely visualized as shown in Figure 8.2. In the nine-band pattern shown in the figure, the first lucent band adjacent to the electron-dense protein band of the cornified envelope is the covalently attached lipid. The paired bilayers are produced by edge-to-edge fusion of flattened lipid vesicles extruded from the lamellar granules (Landmann, 1988). The narrow lucent bands in the center of the nine-band pattern has been thought to be formed by eversion of linoleate chains from acylceramide molecules in the adjacent lamellae to form an interdigitated zipper-like central narrow lamella (Swartzendruber et al., 1989; Wertz, 1996). In this interpretation, space vacated by everted chains and remaining within the framework are filled in by free lipids. Essentially, the same model for the broad–narrow–broad repeat units has been arrived at independently in an attempt to explain the 13 nm repeat seen in x-ray diffraction studies (Bouwstra et al., 2000, 2002). This has been called the sandwich model and features trilaminar units with outer gel phase lamellae and a central narrow fluid lamella (Bouwstra et al., 2000, 2001).

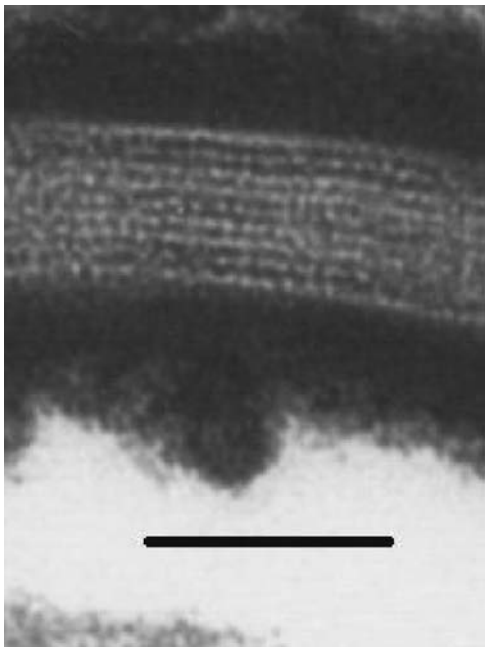

FIGURE 8.2 Transmission electron micrograph of stratum corneum after fixation with ruthenium tetroxide. Bar = 40 nm. (From 6th edition.)

In both of these broad–narrow–broad models of the intercellular lamellae, linoleate tails from the acylceramide molecules are thought to insert into the central narrow lamella with interdigitation. The remaining portion of the acylceramide molecules are thought to be in the outer lamellae. Thus, the acylceramides link the three lamellae together and fluidize the central lamella. In both models, the overall dimension of the trilaminar units is 13 nm. Recently, these models have been challenged (Hill and Wertz, 2003). Basically, it has been proposed that all three lamellae within the 13 nm trilaminar units are approximately 4.3 nm in thickness with acylceramide linoleates inserted into the central lamella. It was pointed out that this arrangement would result in relatively saturated outer lamellae and a concentration of double bonds from linoleate in the central lamellae. These double bonds would make the central lamella capable of reducing more ruthenium compared to the outer lamellae. This additional reduced ruthenium would accumulate beneath the planes of the polar headgroups of the central lamella, thus creating the false appearance of broad–narrow–broad lamellae. Strong support for this model comes from the application of cryo-transmission electron microscopy to the stratum corneum. This method avoids the artifacts associated with the use of chemical fixatives. It demonstrates intercellular lamellae in the stratum corneum that are uniform in thickness and are approximately 4.3 nm thick (Norlen, 2003). The nine-band pattern shown in Figure 8.2 and a similar six-band pattern are the most common arrangements seen between adjacent layers of cells in human stratum corneum using the ruthenium tetroxide method. Results obtained using cryo-transmission electron microscopy of vitreous, fully hydrated human epidermis suggest that the number of lamellae across the intercellular spaces may actually be greater (Norlen, 2003).

A single trilaminar unit with the typical broad–narrow–broad appearance is frequently seen between the ends of adjacent corneocytes. It has been suggested that the outer lamellae are the covalently bound hydroxyceramides and that the central lamella contains the sphingosine chains from these hydroxyceramides. It is proposed that the *trans* double bonds and additional hydroxyl groups from the long-chain bases again result in greater reduction of ruthenium within the central lamella resulting in a false impression of broad–narrow–broad lamellae (Hill et al., 2003).

Although the three-, six-, and nine-band patterns are the most frequent lamellar arrangements seen in normal epidermal stratum corneum when using the ruthenium tetroxide technique, the number and arrangement of lamellae is highly variable, and caution should be taken in comparing intercellular material in normal versus diseased or experimentally manipulated stratum corneum using this technique. The emergence and development of the cryo-transmission electron microscopic technique provides an alternative that appears less subject to artifacts.

It should be pointed out that the 13 nm trilaminar units can be reconstituted *in vitro* from either natural stratum corneum lipids (Kuemper et al. 1998) or from lipids of cholesterol, fatty acids, and suitable synthetic ceramides (de Jager et al., 2005). These reconstituted lamellae could be used for studies of physical properties, and given the availability of synthetic ceramides, a standardized model system could be established for *in vitro* studies on transdermal drug delivery.

9.1 INTRODUCTION

Chemical delivery/absorption into and through the skin is important in both dermato-pharmacology and dermato-toxicology. The human stratum corneum (SC) is the first layer of the skin, and constitutes a rate-limiting barrier to the transport of most chemicals across the skin (Blank, 1965). Chemicals must first partition into the SC before entering the deeper layers of the skin, the epidermis and the dermis, to reach the vascular system. Chemical partitioning proceeds much faster than complete diffusion through the whole SC, and the process quickly reaches equilibrium (Scheuplein and Bronaugh, 1983). In addition to binding within the SC, a chemical can also be retained within the SC as a reservoir (Zatz, 1993). Thus, understanding the process of chemical partitioning into the SC becomes important in developing an insight into its barrier properties and transport mechanisms.

Human SC has been used for decades as an *in vitro* model to explore both percutaneous absorption and the risks associated with dermal exposure (Surber et al., 1990; Potts and Guy, 1992). The human SC includes the horny pads of palms and soles (callus), and the membranous SC covers the remainder of the body (Barry, 1983). The traditional method of preparation is via physical–chemical and enzymological processes to separate the membranous layers of the SC from whole skin (Juhlin and Shelly, 1977; Knufson et al., 1985). However, it is time consuming and, in some cases, it is difficult to control the size and thickness of a sheet of SC. Moreover, it is often difficult to locate a suitable skin source.

Powdered human stratum corneum (PHSC) prepared from callus (sole) is thus substituted for the intact membranous SC. Podiatrists routinely remove and discard PHSC from the human foot, so it is easily obtained. The callus can be cut easily and quickly into smaller pieces, and ground with dry ice to form a powder. In our laboratory, PHSC particle sizes between 180 and 300 μm were selected with the aid of a suitable sieve. Because a corneocyte is only about 0.5 μm thick and about 30–40 μm long, the selected PHSC contains both intact corneocytes and intercellular medium structures, and thus retains its original physical–biochemical properties. Moreover, the greater surface area of the PHSC enhances solute penetration. In a typical experimental procedure, a test chemical in a transport vehicle—water—is mixed with the PHSC, and the mixture is incubated. After a predetermined time period, a solution is separated from the PHSC by centrifugation, and samples are measured (Hui et al., 2000).

This chapter reviews PHSC as an *in vitro* model for studying chemical interaction with human skin, with reference to studies conducted in our laboratory over the last decades. The results demonstrate that PHSC (callus) offers an experimentally easy *in vitro* model for the determination of chemical partitioning into the SC and may be useful in many skin research areas.

9.2 PHSC AND PHYSICAL–CHEMICAL PROPERTIES OF STRATUM CORNEUM

The callus is derived from human SC, and thus should retain some of its physical and chemical characteristics (Wester et al., 1987). SC lipid plays an important role in the determination of skin functions. However, the average lipid content of the SC varies regionally, from 2.0, 4.3, 6.5, to 7.2 weight percent of dry SC from plantar, leg, abdomen, and face, respectively (Lampe et al., 1983). Table 9.1 shows that the average lipid content of the dry PHSC samples derived from various regions was 2.29 ± 0.25 weight percent after extraction. This result is consistent with that in human plantar as determined by Lampe et al. (1983).

The water content of the SC is of importance in maintaining SC flexibility. Three possible mechanisms of water absorption or retention capacity of the SC have been suggested: (i) Imokawa et al. (1986) suggested that SC lipids play a critical role because their removal by the application of acetone/ether decreased absorption/retention capacity. (ii) Friberg et al. (1992), however, considered that protein might also play an important role in SC water retention. They found that the additional water absorbed after reaggregation of equilibrated lipids and proteins was equally partitioned between the protein and the natural lipid fraction of the human SC. (iii) Middleton (1968) considered that water-soluble substances were responsible for water retention and for most of the extensibility of the corneum. He found that powdered SC—but not the intact corneum extracted by water—exhibited lower water-retention capacity. He suggested that the powdering procedure ruptures the walls of the corneum cells and allows water to extract the water-soluble substances without a prior solvent extraction. We measured the water-retention capacities of untreated PHSC, delipidized PHSC (as the protein fraction), and the lipid content, by measuring the amount of [3H]-water (μg equivalent) per mg PHSC after equilibration. As shown in Table 9.1, no statistical differences ($p > 0.05$) were observed for untreated PHSC, delipidized PHSC, and the combination of delipidized PHSC and the lipid content. The PHSC can absorb up to 49% by weight of dry untreated PHSC (Table 9.1), which is consistent with literature reports. Middleton (1968) found that the amount of water bound to intact, small pieces, and powdered guinea-pig footpad SC was 40, 40, and 43% of dry corneum weight. Leveque and Rasseneur (1988) demonstrated that the human SC was able to absorb water up to 50% of its dry weight. Our results (Table 9.1) suggest that the protein domain of the PHSC plays an important role in the absorption of water. Depletion of the PHSC lipid content did not affect water retention (Hui et al., 1993).

9.3 PHSC AND CHEMICAL PARTITIONING

Table 9.2 shows the effect of varying initial chemical concentrations on the PC PHSC/w of these compounds (Hui et al., 1993). Under fixed experimental conditions—2 h incubation time and 35°C incubation temperature—the concentration required to attain a peak value of the partition coefficient varied from chemical to chemical. After reaching the maximum, increases in the chemical concentration in the vehicle did not increase the PC value; rather, it slightly decreased or was maintained at approximately the same level. This is consistent with the results of Surber et al. (1990a,b) on whole SC. Chemical partitioning from the vehicle into the SC involves processes in which molecular binding occurs at certain sites of the SC, as well as simple partitioning. Equilibration of partitioning is largely dependent on the saturation of the chemical binding sites of the SC

TABLE 9.1
Lipid Content and Water Uptake of Powdered Human Stratum Corneum

[b] PC PHSC/water represent the mean of each test ($n = 5$) ± SD (Hui et al., 1993).

(Surber et al., 1990a; Rieger, 1993). The results also indicate that, under given experimental conditions, the maximum degree of partitioning was compound specific. As the SC contains protein, lipids, and various lower molecular weight (MW) substances with widely differing properties, the many available binding sites display different selective affinities with each chemical. Thus, the degree of maximum binding or of equilibration varies naturally with molecular structure (Rieger, 1993). This result demonstrated that the solubility limit of a compound in the SC was important in determining the degree of partitioning, as suggested by Potts and Guy (1993). This view has been further supported by our recent study. PHSC incubated with six chemicals in saturated solution at three different pH ranges (1 ~ 3, 6 ~ 8, and 10 ~ 14), and percent-binding rate was then counted. Table 9.3 shows the result that the percent-binding rate of PHSC is correlated with the solubility of the test chemicals regardless of their MWs or p*K*a values. Moreover, an interesting finding is that when the pH value is lower (2 ~ 3), it seems to favor the binding rate for the chemicals with positive log *P*, whereas the higher pH value (9 ~ 13) favors those chemicals with negative log *P*. For chemicals with log *P* values near neutral, pH values do not affect the PHSC binding rate. On the basis of the solubility limit of a chemical, the absorption process of water-soluble or lipid-soluble substances was controlled by the protein domain or the lipid domain, respectively or a combination of two (Raykar et al., 1988). Since the lipophilicity of the lipid domain in the SC is much higher than that of water, a lipophilic compound would partition into the SC in preference to water. Thus, when water is employed as the vehicle, the PC PHSC/w increases with increasing lipophilicity of solute (Scheuplein and Bronaugh, 1983). Conversely, the protein domain of the SC is significantly more polar than octanol and governs the absorption of hydrophilic chemicals (Rayker et al., 1988). For very lipophilic compounds, low solubility in water rather than increased solubility in the SC can be an important factor (Scheuplein and Bronaugh, 1983). Moreover, in addition to partitioning into these two domains, some amount of chemicals may be taken into the SC as the result of water hydration. This is the "sponge domain," named by Raykar et al. (1988). They assume that this water, having the properties of bulk water, carries an amount of solute into the SC equal to the amount of solute in the same volume of bathing solution. Therefore, for hydrophilic compounds and some lower lipophilic compounds, the partitioning process may include both the protein domain and sponge domain.

9.4 PHSC AND PERCUTANEOUS ABSORPTION

To evaluate sensitivity of this in the *in vitro* PHSC model, we examined chemical partitioning into the PHSC, as well as that *in vitro* percutaneous absorption in human skin, and *in vivo* percutaneous absorption in the rhesus monkey. Table 9.4 shows that the *in vivo* percutaneous absorption of nitroaniline from surface water following 30 min exposure was 4.1 ± 2.3% of the applied dose. This is comparable with the 5.2 ± 1.6% for *in vitro* absorption with human cadaver skin and the 2.5 ± 1.1% bound to PHSC. Wester et al. (1987) suggest that this methodology—the systems tested, binding to PHSC, and *in vitro* and *in vivo* absorption—can be used to predict the burden on the human body imposed by bathing or swimming.

9.5 PHSC AND THE SKIN BARRIER FUNCTION

The barrier function of the SC is attributed to its multilayered wall-like structure in which terminally differentiated keratin-rich epidermal cells (corneocytes) are embedded in an intercellular lipid-rich matrix. Any physical factor or chemical reagent that interacts with this two-compartment

structure can affect the skin barrier function. Barry (1983) described how certain compounds and mechanical trauma can easily dissociate callus cells and readily dissolve their membranes. Thus the amount of protein (keratin) released from the SC after chemical exposure may be a measure of the solvent potential of the chemical. To evaluate this hypothesis, a test chemical in water is mixed with PHSC and incubated. After a predetermined time period, a solution is separated from the PHSC by centrifugation. The protein (keratin) content of the solution is then measured. Table 9.5 shows the amount of protein released from the PHSC after incubation with glycolic acid, sodium hydroxide, or water alone, at different time points. Sodium hydroxide has a pronounced ability to release protein from PHSC. This ability increases with increasing incubation time. The results suggest that the PHSC model constitutes a vehicle to probe the barrier nature of the SC and the chemical interactions with the PHSC.

9.6 PHSC AND DISEASED SKIN

PHSC has potential application in medical treatment. For instance, a set of vehicles can be screened to determine which vehicle most readily releases a given drug into the SC. This information would assist in the determination of the most effective approaches to drug delivery via the skin. Furthermore, diseases involving the SC can be studied using PHSC. An example in Table 9.6 is the partitioning of hydrocortisone from normal and psoriatic PHSC. In this case, we have shown that there is no difference in partitioning between normal and psoriatic PHSC. It should be noted that there is no difference between *in vivo* percutaneous absorption of hydrocortisone in normal volunteers and that in psoriatic patients (Wester et al., 1983).

9.7 PHSC AND ENVIRONMENTALLY HAZARDOUS CHEMICALS

The leaching of environmentally hazardous chemicals from soil and their absorption by the skin of a human body is a major concern. Knowledge of the extent and degree of such absorption will aid in determining the potential health hazards of polluted soil. Our laboratory's interest is in the potential percutaneous absorption of contaminants from soil. Soil can be readily mixed with PHSC, but centrifugation does not separate the two. However, centrifugation readily separates PHSC from any liquid, to varying degrees. Thus, the partition coefficients of various liquids may be determined relative to a common third liquid. These relative partitions can then be compared to those of other compounds and skin absorption values (Wester et al., 1992, 1993a,b) to evaluate the degree of hazard. We have determined such coefficients for several environmentally hazardous chemicals partitioning from soil into PHSC (Table 9.7).

9.8 PHSC AND CHEMICAL DECONTAMINATION

Our laboratory uses the PHSC model to determine which chemicals might be able to remove (decontaminate) hazardous chemicals from human skin. A contaminant chemical is mixed with PHSC, and the decontaminant effects of a series of possible decontaminants measured. The liquid decontaminant is mixed with contaminated PHSC and, after a predetermined time period, a solution is separated from the PHSC by centrifugation. The content of the solution is a measure of decontaminant's potential. This is shown in Table 9.8, which demonstrates that alachlor readily contaminates PHSC. Water alone removes only a small portion of the alachlor. However, a 10% soap solution removes a larger portion of the alachlor, and 50% soap solution removes most of it. Perhaps this is an elegant way to show that soapy water is effective in washing one's hands. However, it does illustrate the use of PHSC to determine the effectiveness of skin decontamination (Scheuplein and Blank, 1973).

TABLE 9.7
Partition Coefficients of Four Environmentally Hazardous Chemicals in PHSC/Water and Soil/Water

	Partition Coefficient	
Test Chemicals	**PHSC**	**Soil**
Arsenic	1.1×10^4	2.4×10^4

10% Soap and water wash	77.2 ± 5.7
50% Soap and water wash	90.0 ± 0.5

Note: [^{14}C]-Alachlor in Lasso EC formulation (1:20 dilution) mixed with powdered human SC, let set for 30 min, then centrifuged. SC wash with (1) water only, (2) 10% soap water, and (3) 50% soap and water.

9.9 PHSC AND ENHANCED TOPICAL FORMULATION

Macromolecules have attracted interest as potential drug entities, and as modulators to percutaneous delivery systems. Two macromolecular polymers (MW 2081 and 2565) were developed to hold cosmetics and drugs to the skin surface by altering the initial chemical and skin partitioning. The effect of these polymers on the partition coefficient of estradiol with PHSC and water was determined in our laboratory. As shown in Table 9.9, the polymer L had no effect on the estradiol PC between PHSC and water. The polymer H, however, showed a significant increase ($P < 0.01$) in log PC for estradiol concentrations of 2.8 and 0.25 mg/mL. This increase was dependent on the polymer concentration (Wester et al., 2002). The results suggest that the PHSC model can help in the development and selection of enhanced transdermal delivery systems.

9.10 PHSC AND QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIPS PREDICTIVE MODELING

Many experiments have been conducted to predict chemical partitioning into the SC *in vitro*. However, most were based on quantitative structure–activity relationships (QSARs)

TABLE 9.9
Effect of Two Polymers (L and H) on the Estradiol PC between PHSC and Water

[b] Statistically significantly different from control ($P < 0.05$).

or related chemicals to determine the partitioning process, and few studies focus on structurally unrelated chemicals. Since the range of molecular structure and physicochemical properties is very broad, any predictive model must address a broad scope of partitioning behavior.

This study assesses the relationship of a number of chemicals with a broad scope of physicochemical properties in the partitioning mechanism between PHSC and water. Uniqueness and experimental accuracy are added by using PHSC. The experimental approach is designed to determine how the PC PHSC/w is affected by (1) chemical concentration, (2) incubation time, and (3) chemical lipophilicity (or hydrophilicity), and other factors. These parameters are used to develop an *in vitro* model that will aid in the prediction of chemical dermal exposure to hazardous chemicals.

Figure 9.1 describes a smooth, partially curvilinear relationship between the log PC PHSC/w and the log PC o/w of a number of chemicals. The lipophilicities and hydrophilicities of compounds were defined as log PC o/w larger or smaller than 0, respectively. For lipophilic chemicals such as aminopyrine, hydrocortisone, malathion, atrazine, 2,4-D, alachlor, and PCB, the logarithms of PHSC/w partition coefficients are proportional to the logarithms of the octanol/water partition coefficients.

$$\begin{aligned} &\log \text{PC PHSC/w} = 0.59 \log \text{ PC o/w} - 0.72 \\ &\text{Student } t \text{ values}: 9.93 \\ &n = 7 \quad r^2 = 0.95 \quad S = 0.26 \quad F = 98.61 \end{aligned} \tag{9.1}$$

For hydrophilic chemicals such as theophylline, glyphosate, urea, glycine, and dopamine, the log PC PHSC/w values are approximately and inversely proportional to log PC o/w.

$$\begin{aligned} &\log \text{PC PHSC/w} = -0.60 \log \text{PC o/w} - 0.27 \\ &\text{Student } T \text{ values}: -4.86 \\ &n = 5 \quad r^2 = 0.88 \quad s = 0.26 \quad F = 23.61 \end{aligned} \tag{9.2}$$

However, the overall relationship of the PC PHSC/w of these chemicals and their PC o/w is nonlinear. This nonlinear relationship is adequately described by the following equation:

$$\begin{aligned} &\log \text{PC PHSC/w} = 0.078 \log \text{PC o/w}^2 + 0.868 \\ &\log \text{MW} - 2.04 \\ &\text{Student } T \text{ values}: 8.29 \qquad 2.04 \\ &n = 12 \quad r^2 = 0.90 \quad s = 0.33 \quad F = 42.59 \end{aligned} \tag{9.3}$$

The logarithm of MW gave a stronger correlation in this regression than MW ($T = 1.55$) itself. In Figure 9.1, the calculated log PC PHSC/w (Y estimate) values are compared to the corresponding observed values for these chemicals. As shown, the calculated values are acceptably close to the observed values. The correspondence with minimal scatter suggests that this equation would be useful in predicting *in vitro* partitioning in the PHSC for important environmental chemicals (Hui et al., 1993).

9.11 DISCUSSION

A new *in vitro* model employing PHSC (callus) to investigate the interaction between chemicals and human skin has been developed in our laboratory. The PHSC (callus) offers

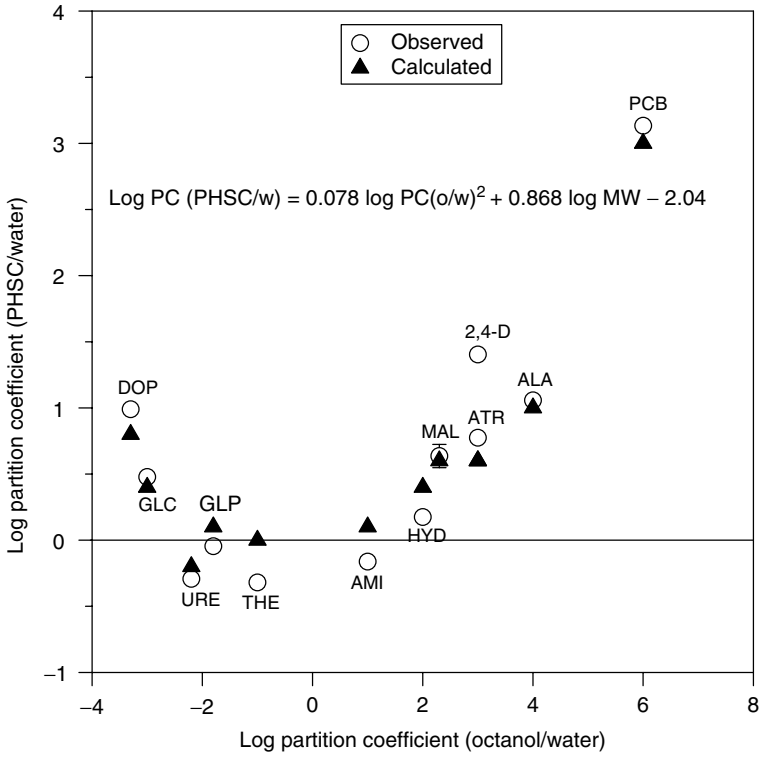

FIGURE 9.1 Correlation of the logarithm of SC/water partition coefficients (log PC sc/w) and logarithm of octanol/water partition coefficients of the 12 test chemicals. Open symbols are expressed as observed values and each represented the mean of a test chemical ± SD (n = 5). Close symbols are expressed as calculated values by the Equation 9.3. DOP = dopamin; GLC = glycine; URE = urea; GLP = glyphosate; THE = theophylline; AMI = aminopyrine; HYD = hydrocortisone; MAL = malathion; ATR = atrazine; 2,4-D = 2,4-dichlorophenoxyacetic acid; ALA = alachlor; PCB = polychlorinated biphenyls.

an experimentally easy *in vitro* model for the determination of chemical partitioning from water into the SC. Owing to the heterogeneous nature of the SC, the number and affinity of the SC binding sites may vary from chemical to chemical, depending upon molecular structure. For most lipophilic compounds, the PC PHSC/w were governed by the lipid domain, whereas PCs of the more hydrophilic compounds are determined by the protein domain and possibly, by the sponge domain (Raykar et al., 1988). These relationships can be expressed by the log PC PHSC/w of these chemicals as a function of the corresponding square of log PC o/w and log MW (Equation 9.3), which is useful in predicting various chemical partitionings into the SC *in vitro*. However, a disadvantage in using the human callus is that it may display some differences in water and chemical permeation when compared to membranous SC (Barry, 1983).

This chapter has summarized a variety of potential applications for PHSC, ranging from basic science to applications in medicine and environmental impact studies. PHSC, imagination, and a balanced study design can add to scientific knowledge.

10 Sensitive Skin

Harald Löffler, Caroline Weimer, Isaak Effendy, and Howard I. Maibach

CONTENTS

10.1 A Self-Reported Sensitive Skin 95
10.2 Problems with Enhanced Skin Susceptibility 96
10.3 Definition of Terms Concerning Skin Susceptibility 98
References 98

"Sensitive skin" is a term for several skin problems, which is widely used particularly by numerous skin patients, the media, and the drug and cosmetic companies. Today, hardly any cosmetic preparation without the label "for sensitive skin" can be found. Indeed, what is "sensitive skin?"

For many patients, sensitive skin stands in general for allergic reactions to common contact allergens, for example, nickel.[1,2] Their main problems are eczematous skin reactions by contact (e.g., in costume jewelry), or by ingestion in food, followed by hematogenic eczema.[3,4]

Other patients who are particularly affected by the problem of sensitive skin are atopic individuals or patients with a disrupted epidermal barrier function.[5–9] These individuals develop dermatitis caused by numerous triggers. Exogenous triggers (e.g., chemical or mechanical irritation, allergens, climatic conditions, wrong skin care, nutrition) are for these patients as relevant as endogenous ones (e.g., psychological stress, endogenous eruption, predisposition to dry, xerotic skin).[9–11] The atopic individual describes his skin in the symptom free intervals as a sensitive skin, which can be transformed by a combination of the mentioned triggers to a clinical visible atopic eczema. Indeed, many patients with acute eczematous problems complain about sensitive skin. This is so far understandable, since all kind of eczema are frequently accompanied by a skin barrier disruption leading to the so-called sensitive skin, since due to this barrier disruption even slight irritations (handwashing) may lead to a clinical visible skin reaction (e.g., worsening of the underlying dermatitis).[12] Such a skin reaction may concern individuals with rosacea, irritant dermatitis, nummular eczema, and exsiccation eczema as well.[13]

Other groups complaining about sensitive skin are subjects with nonvisible skin changes, or with a normal unimpaired skin. But, these individuals claim about skin symptoms after otherwise harmless affections of the skin, like the use of cosmetics, sun, wind, and clothes. However, some claim about sensitive skin even without any known about exogenous influences (Table 10.1).

Hence, a closer definition of the term sensitive skin is needed to avoid the mix-up of different entities of skin diseases and skin nondiseases.[14] The first group with sensitive skin indeed shows clinical signs, which can be detected by visual evaluation or by measurement of skin physiological parameters. Their complain concern all manifestations (clinical signs) of dermatitis and can be accompanied by any of the symptoms (Table 10.1). However, there is also a group complaining about sensitive skin without any clinical detectable skin changes (only the second row of Table 10.1).

10.1 A SELF-REPORTED SENSITIVE SKIN

The explanation for the visible symptoms in a group claiming about sensitive skin is founded in their skin precondition (e.g., dermatitis) and is mostly manifested in any degree of skin irritation. While nonvisible symptoms of other group are hard to explain, they are important for epidemiology: The number of individuals stating their skin as "sensitive" is amazingly high and is estimated at 50% with a clear dominance of women.[15] A very common statement of these individuals is that they have discomfort when using some cosmetic products.[15] It is anyhow very hard to verify such complaints using objective reproducible methods. Recently, we investigated whether sensitive skin is a result of a different anatomic or biophysical skin conditions (which can be evaluated by bioengineering methods) or, perhaps, the consequence of a different perception of skin sensations.[16]

We found in a questionnaire dealing with various influencing factors concerning skin susceptibility and skin sensitivity, which was completed by 420 volunteers, that in accordance to the study of Willis,[15] almost 50% of the volunteers estimated their skin sensitivity as strong or severe. However, the reason for their sensitive skin is hard to define. One reason may be an atopic constitution.

Indeed, we found a significant correlation between sensitive skin and atopy score. Hence, the subgroup of atopic patients is included in the group of volunteers with sensitive skin to a great extent. The majority of the volunteers with a sensitive skin had, however, no atopic constitution. But nearly any possible "trigger" such as sheep wool,

Lichenifications	
Hyperkeratosis	

cosmetics, soaps, deodorants, perfume, or sun rays are suspected to worsen their sensitive skin. Interestingly, the skin susceptibility to sun rays was told to be enhanced, but there was no correlation to the skin type according to Fitzpatrick. It seems that, without any differentiation, every proposed influence was chosen by people with a self reported sensitive skin, however, the objectivability is missing.

Mostly, subjective terms were used to describe the problem with sensitive skin like the feeling of tension, burning, or reddening. Exactly defined and objectivable skin problems, like eczema, were not associated with the degree of sensitive skin. This again underlines the diversity between subjects with visible symptoms, like eczema, and patients with subjective nonvisible skin problems. This is supported by other investigators who also found a poor correlation between objective skin findings and subjective complaints about skin symptoms.[17]

In accordance to these findings, no changes in biophysical functions have been found in the group with the sensitive skin, neither basal nor after sodium lauryl sulfate (SLS) testing. In general, there was no correlation between the degree of self-estimated skin sensitivity and every single measured parameter. It therefore seems that the "sensitive skin" is a nonobjectivable estimation, probably influenced by the individual education and even more by the mass media. Furthermore, it seems indeed to be fashionable to have a sensitive skin, particularly for women and men in "modern society."[17]

These findings could be backed up by a study of Aramaki and co-workers. Aramaki et al.[18] investigated a population, which is known to have a very sensitive skin, namely Japanese individuals. Aramaki found that skin irritability tested by a SLS irritating test is the same between Germans and Japanese, but in a stinging test one could observe that the Japanese felt stinging immediately, whereas German women felt stinging somewhat later. The reason for these findings may be due to the assumption that Asian skin is more permeable to water than European skin and that several chemicals, like benzoic acid, caffeine, and acetylsalicylic acid showed an increase in percutaneous absorption in Asians relative to Caucasians,[19] but we also know that there is a certain difference in the culture and education between Japan and Germany. In Japan, the femininity is more desirable for women than in western countries, leading to a desirable, vulnerable, and female behavior. In this, the female role expectation of a dainty woman is expected to have a sensitive skin with problems with many cosmetics. However, it is hard to say whether the sensitive skin of Japanese women is caused by different cultural assessment of discomfort or by differences in penetration speed.

Even in these considerations about sensitive skin in Japanese and German women, the mix-up between different meanings of sensitive skin has become obvious. Is sensitive skin objective or subjective? Which parameters will define it? Hence, a better definition of all kinds of skin susceptibility is needed. The higher incidence of adverse skin effects against cosmetics is probably founded in a different perception of the skin.

Although previously changes in biophysical skin functions in the elderly have been found,[20] there was no correlation between complaints about sensitive skin and age of the subjects. This indicates, that the estimation of a sensitive skin is a complaint independent of age.

However, there are certain arguments that a sensitive skin does exist. One is the finding that individuals with a sensitive skin might be detectable by a stinging test and rather not by a skin irritation test. In contrast, there are lots of individuals who state their skin as sensitive but react normal in the stinging test and SLS patch test.

10.2 PROBLEMS WITH ENHANCED SKIN SUSCEPTIBILITY

Another group, which is particularly affected by the problem of sensitive skin, are patients who have a disrupted epidermal barrier function, for example, atopic patients or other groups with chronic eczematous skin. This group is likely to develop further eczema, often contact allergies.

In earlier years there was the impression that an allergic contact dermatitis could be caused by minimal doses of allergens. However, it has been shown that not only in the elicitation but also in the sensitization process, the concentration of the allergen per area is a crucial point. White et al.[21] have shown that the sensitization to dinitrochlorobenzene (DNCB), a potent sensitizer, only occurs, when a defined concentration threshold is reached. The explanation for this phenomenon was seen in the irritant feature of DNCB. Only if DNCB was applied in a concentration that a distinct irritant reaction was achieved, the sensitization process could take place. This irritation is therefore accepted as the "danger" signal necessary for each sensitization.[22,23] Mostly, the hapten itself can induce this danger signal because we know that almost every known relevant allergen is also an irritant. But if the hapten has a very low irritability, high concentrations are necessary for the sensitization. If lower concentrations are applied, the danger signal can be induced by additional substances. Experimentally, it has been shown that the vehicle of the hapten can induce this danger signal, so that the hapten itself does not necessarily have an irritant activity.[24] The coadministration of, for example, SLS,

a model irritant, with a hapten increases the chances of successful sensitization. Furthermore, when DNCB in a very low concentration is applied for sensitization, the accumulation of Langerhans cells in the draining lymph node and the proliferative response by draining lymph node cells can be increased by coadministration of the irritant SLS. This raised immunological activity can be compared to the one induced by DNCB alone in higher concentrations.[25] It can be assumed, that in these higher concentrations the irritant feature of DNCB is sufficient enough to induce a strong immunological reaction.

In metals, the coadministration of an irritant plays an important role, too. By the various attempts to sensitize mice against the common allergen nickel, it is known, that a simple injection or application of $Ni(II)Cl_2$ does not induce sensitization.[26] However, when applied together with an irritant, the experimental sensitization to $Ni(II)Cl_2$ can be successful.[27] A possible explanation for this observation is that the Ni-ion is altered in an inflamed skin. Phagocytes, which are activated by irritants produce oxidants like hypochloride (OCl^-) and hydrogen peroxide (H_2O_2), which are able to generate Ni(III) and Ni(IV) from Ni(II).[28,29] In this higher oxidation state, nickel contains a far higher chemical reactivity and it becomes able to sensitize naive T cells. Hence, the inflammation induced by an irritant does alter the nickel–hapten, so that a sensitization is possible. The same mechanism can be found for gold. When gold (I)—a weak sensitizer—is oxidized to gold (III), the sensitization capacity is raised enormously.[30,31] The impact on oxidation to the sensitizing capacity of allergens is generally known. Especially the dramatic effect of air-oxidation to various allergens (terpenes, fragrances, ethoxylated surfactants) has been investigated over the past years.[32–34]

But which cells are responsible for the initiation of the danger signal?

Today, the keratinocytes are in the focus of attention. It has been shown, that after stimulation by irritants (like SLS, DMSO, croton oil, and phorbol myristate acetate) keratinocytes produce a number of cytokines, for example, TNF-alpha, IL1-alpha, IL1-beta, IL-8.[35–39] But even the irritant property of Nickel is sufficient enough to induce such a cytokine release by keratinocytes.[40] TNF-alpha does of course induce an unspecific proinflammatory response by activation of T cells, macrophages, and granulocytes; it activates the expression of cellular adhesion molecules and the release of further cytokines.[41] More important in our context is the ability to activate Langerhans cells. TNF-alpha down-regulates E cadherin and induces the production of type-IV collagenase (MMP-9), so that the Langerhans cells can migrate more easily in the local lymph node.[42,43]

Moreover, TNF-alpha induces the up-regulation of MHC class-I and -II molecules, increasing the possibility of presentation of an allergen. As a consequence, TNF receptor p75 knockout mice are hardly sensitizable,[44] and anti-TNF-alpha antibodies or recombinant soluble receptors were able to block the sensitization.[45,46] Besides the known IL1-beta production (which is induced by irritants), the TNF-alpha production by keratinocytes seems to be a crucial point in the activation of the Langerhans cell migration,[47] and therefore in the concept of a danger signal (Table 10.2). An interesting theory is that in the absence of such a danger signal, the contact of the allergen with immunologic competent cells might induce tolerance.[21,22,48,49] This absence can be achieved by a very low dose of the allergen, so that the irritancy of the allergen is too small to induce any unspecific reaction, while the immunologic (allergenic) effect is still present. At this moment, the immunologic reaction might lead to tolerance. Experimentally, this was shown in mice by various groups;[50–53] the confirmation in humans is still missing.

In principle, the same danger signal may be necessary for elicitation and sensitization. Even the cytokine profile apparent at sensitization is very similar to that at elicitation; TNF-alpha and IL-1 are of highest relevance.[54] Often, the irritant property of the allergen may be sufficient enough to induce this danger signal. But if the allergen is applied on nonirritated skin in a concentration that no irritant reaction is induced, no allergic reaction takes place. The elicitation of an allergic response can then be achieved by coadministration of an irritant,[54] like SLS.[55,56] For the clinical practice, it is of highest relevance that in an irritated skin, the danger signal is already present. It means that a hapten does not have to induce the danger signal in the skin and therefore even a much lower concentration of the hapten is necessary for the sensitization and elicitation of an allergic dermatitis. Hence, especially patients with an irritant or atopic dermatitis have a much higher risk of developing a further skin sensitization and an additional allergic contact dermatitis. This association was assumed by epidemiological studies.[57,58]

For individuals with an enhanced skin susceptibility (more precisely, with an irritable skin), which is apparent as recurrent eczematous reactions, this danger signal–hypothesis is of highest relevance. They are in danger to develop more and more sensitizations during the course of an eczematous skin reaction, because once the reaction is induced, the danger signal is present due to the persistent inflammation. Further contact to the allergen may maintain this reaction, even when the concentration of the relevant allergen is below the concentration, which would normally be needed for the elicitation of the reaction (Table 10.2).

TABLE 10.2
Danger Signal and Its Cellular Mechanism

Danger Signals for Initiation of an Allergy: Irritation	Cellular Mechanism
High concentration of an allergen[21]	Up-regulation of MCH I and II, increased possibility of presenting an allergen[44]
Coadministration of an irritant[27]	Unspecific inflammation
Oxidation of metals[30,31]	Increased accumulation and activation of LCs in the draining lymph node[42,43]
Preirritated skin and epidermal disruption	Keratinocytes producing TNF alpha, IL1-beta, IL-8[36–39,59]

TABLE 10.3
Definition of Terms Concerning Skin Susceptibility

Term	Definition	Findings
Sensitive skin	Individuals, who stated their skin as more sensitive than average	None
Irritable skin	Individuals, who objectively develop a stronger skin reaction to an allergen than average	Enhanced values of bioengineering evaluation methods
Stinger	Individuals, who react reproducible positive in a test with a sensation inducing chemical	Reproducible positive skin stinging-test

10.3 DEFINITION OF TERMS CONCERNING SKIN SUSCEPTIBILITY

Concerning the various discussed mechanisms of sensitive skin, it becomes obvious, that the term sensitive skin has to be used very differentiated.

We propose the following classification of skin irritancy (Table 10.3):

People with sensitive skin are only individuals who stated their skin as sensitive. There is no possibility to prove the statement with objective methods, because the skin may have normal biophysiological skin parameter.

If such individuals react repeatedly to a skin test with sensation induced by chemical irritants (like lactic acid), they are identified as "stinger." It can be assumed that these individuals have indeed an increase in unpleasant skin sensations after use of otherwise well-tolerated skin products.

Moreover if individuals do have a high susceptibility to allergens or irritants because of a pre-irritated skin, which can be measured objectively by bioengeneering methods, they can be identified as individuals with an irritable skin.

This classification might be of relevance in discriminating individuals with a higher risk to develop skin irritation, particularly on the hands.[7,60–62]

With this classification it can be stated that there is neither any significant correlation nor any significant coincidence between individuals with a sensitive skin and individuals with an "irritable skin." Only a minority of individuals with a sensitive skin or an irritable skin can be identified as stingers.[63–66] Hence, if the patient is stating, "I have a very sensitive skin," he does not give you any important information, but solely telling you that he takes a lot of care of his skin.

11.1 INTRODUCTION

The skin is a seemingly impermeable barrier with its primary function to protect against entry of foreign agents into the body. Nevertheless, intact skin may be used as a route of administration for systemic delivery of simple potent drug molecules through a transdermal patch. In fact, recent literature suggests that the transdermal route now competes with oral administration as the most successful innovative research area in drug delivery, as 40% of current drug products under clinical evaluation are transdermal (Barry, 2001). The first U.S.-approved transdermal patch was introduced in 1981 for scopolamine. In the past two decades, another nine drugs have been introduced to the U.S. market, namely nitroglycerin and clonidine for cardiovascular disease, nicotine for smoking cessation, fentanyl for chronic pain, estradiol with or without levonorgesterel or norethisterone for hormone replacement, estradiol with norelgestromin for hormonal contraception, testosterone for hypogonadism (Hogan and Cottam, 1991), lidocaine for postherpetic neuralgia, and oxybutynin for detrusor hyperactivity, and most recently selegiline to treat major depressive disorder. Many more transdermal drug delivery systems (TDDS) are currently under investigation, including products to treat Parkinson's disease, Alzheimer's disease, and skin cancer (Benson, 2005) (Table 11.1).

11.2 PERCUTANEOUS DRUG ABSORPTION

The skin's uppermost layer of epithelium, the stratum corneum (SC), is the rate-limiting barrier to percutaneous drug transport. In fact, it is significantly more impermeable than the gastrointestinal, vaginal, nasal, buccal, or rectal epithelial barriers. Consequently, the daily dose of drug that can be delivered is only 5–10 mg, thereby limiting this route to the most potent of drugs. Drug molecules may penetrate the SC through three potential pathways: directly across the SC, through the sweat ducts, or via the hair follicles and sebaceous glands (also known as the appendages). Prior experimentation has suggested that the follicular route comprises only 1/1000 of the entire skin surface area, and therefore most skin penetration systems focus on enhancing penetration directly across the SC.

The SC is comprised of a multilayered brick and mortar structure of keratin-rich corneocytes in an intracellular matrix of fats, including long chain ceramides, free fatty acids, triglycerides, cholesterol, and sterol/wax esters. It was traditionally thought that hydrophilic chemicals diffuse within the aqueous regions near the outer surface of intracellular keratin filaments while the lipophilic chemicals diffuse through the intercellular routes, through the lipid matrix between the filaments. This is a gross oversimplification, and more recent data suggest that the intercellular route is the major pathway for

TABLE 11.1
Transdermal Delivery Systems

Active Drug	Duration of Application	Matrix or Membrane	Typical Formulations
Nitroglycerin	12–24 h (depending upon brand)	Matrix	0.1, 0.2, 0.4, 0.6, or 0.8 mg/h
Clonidine	1 week	Membrane	0.1, 0.2, or 0.3 mg/day
Nicotine	24 or 16 h	Membrane or matrix	21, 14, or 7 mg/day or 15 mg in 16 h
Fentanyl	72 h	Membrane	1.25, 2.5, 5, 7.5, or 10 mg/h
Estradiol	3 days to 1 week (depending upon brand)	Matrix	0.025, 0.0374, 0.05, 0.075, or 0.1 mg
Estradiol/levonorgestrel	1 week	Matrix	0.045 mg estradiol and 0.015 mg levonorgestrel per day
Estradiol/norethindrone acetate (NETA)	3–4 days	Matrix	0.05 mg estradiol and between 0.14 and 0.25 mg NETA per day
Norelgestromin/ethinyl estradiol (EE)	7 days	Matrix	150 mcg norelgestromin, 20 mcg EE per day
Testosterone	24 h	Membrane	2.5–5 mg/day
Lidocaine	12 h, usually three patches at a time	Matrix	Three patches yield 64 ± 32 mg/12 h
Oxybutynin	3–4 days	Matrix	3.9 mg/day
Selegiline	24 h	Matrix	6 or 9 or 12 mg selegiline in 24 h

both lipophilic and hydrophilic chemicals. Therefore, most penetration enhancement techniques aim to alter the structure or manipulate the solubility of the lipid domain (Benson, 2005; Elias and Friend, 1975; Bodde, 1991).

Once a drug is able to cross the SC, it is relatively easy to permeate the deeper epidermal and dermal layers and become systemically absorbed. The epidermis is comprised of cells with a greater degree of hydration allowing faster diffusion of drug. In addition, Langerhans cells, the antigen-presenting cells of the skin, present in the epidermis are the target of transdermal vaccines. Small vessels in the dermis allow for distribution of drug to the systemic circulation. The lymphatic network in the dermis is responsible for removal of transdermally applied drugs, although this has not been studied extensively.

The challenge in transdermal drug delivery is systemic absorption in a safe, controllable, and therapeutic fashion without permanently reducing the efficacy of the skin barrier (Berti and Lipsky, 1995). Rate and extent of drug absorption must be tightly controlled to successfully achieve these goals. Factors such as the thickness of the SC in a body region (Ya-Xian et al., 1999) (SC is thicker on the palmar and plantar regions and thinner on the postauricular, axillary, and scalp) and formulation of vehicle are instrumental in designing the appropriate patch. In general, drugs that have been successfully designed for a transdermal system are small, of low molecular weight, high potency, and of moderate lipophilicity (because they must get through the hydrophilic epithelial and dermal layers) (Ogiso and Tanino, 2000; Kalia and Guy, 2001).

11.3 TRANSDERMAL DRUG DELIVERY DEVICES

There are currently two types of transdermal drug delivery devices—matrix-controlled and membrane (reservoir)-controlled (Figures 11.1 and 11.2) (Ranade, 1991). The matrix-controlled device incorporates a drug-in-polymer matrix layer between frontal and backing layers, where the matrix binds to the drug and controls its rate of release from the skin. In the reservoir system, there is a rate-controlling membrane present between the drug matrix and the adhesive layer, which controls the rate of drug release. In both systems, the rate of drug permeation is greater than the permeation rate across the skin. This provides drug uptake at a predetermined rate that is independent of patient skin variability (Ansel and Allen, 1999).

The advantage of the membrane-controlled system is that it provides a true constant (zero-order) release of drug from the system, irrespective of the amount of drug remaining in the patch. In the matrix system, the rate of release is dependent on the matrix bound to the drug. As drug is depleted from the system, there is a slight decline in the release rate when using the matrix system. This is because drug in the surface layers has already permeated and the remaining drug must diffuse a longer distance through the matrix to penetrate the skin. With well-designed matrix systems this rate is insignificant. A disadvantage of the reservoir system is that drug molecules may saturate the rate-controlling membrane and thereby cause a "burst effect," whereby the patch initially releases too much drug into the system and potentially causes toxicity. Of course, the burst effect may be advantageous for drugs that normally exhibit a long lag time between patch application and therapeutic effect (Ranade and Hollinger, 1996; Kydonieus, 1992).

11.3.1 Advantages of Transdermal Drug Delivery

Transdermal drug delivery avoids the gastrointestinal and hepatic first-pass metabolism and thereby increases drug

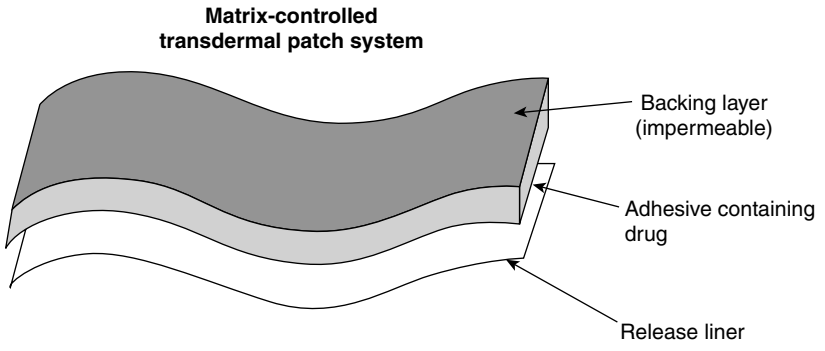

FIGURE 11.1 Matrix-controlled device.

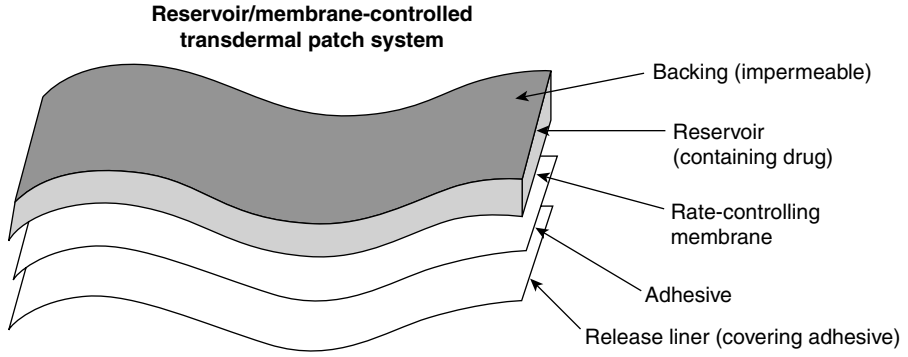

FIGURE 11.2 Membrane-controlled device.

bioavailability in comparison to oral formulations. Another important advantage of the TDDS is the elimination of the generally observed "peaks" and "valleys" in the plasma drug concentration profile observed in patients receiving oral drug delivery formulations (Kydonieus, 1992). With the appropriate TDDDS the drug input rate into the bloodstream can be controlled to stay in the therapeutic region, potentially avoiding toxic or sub-therapeutic drug plasma levels. In addition, transdermal systems also reduce the frequency of drug administration and some allow for multiday continuous drug delivery. These factors may improve patient compliance (Bronaugh and Maibach, 1999).

11.3.2 Disadvantages of Transdermal Drug Delivery

The main disadvantage of the use of transdermal drug delivery is in its limitations. The SC is an excellent barrier and therefore only small; highly potent molecules with moderate lipophilicity will be candidates for transdermal delivery (Bronaugh and Maibach, 1999). In addition, there is the potential for a long lag time between patch application and effect of drug, which is a disadvantage when immediate drug action is needed. Depending upon the circumstance, it may be necessary to supplement with oral medication during the initial patch application. Other disadvantages include variable intra- and interindividual percutaneous absorption efficiency, variable adhesion to different skin types, and a limited time that the patch can be affixed. Finally, TDDS are currently only developed when conventional administration has serious limitations. This is because transdermal systems are costly and involve complex technology to develop.

11.4 VARIABLE INTRA- AND INTERINDIVIDUAL PERCUTANEOUS ABSORPTION EFFICIENCY

Transdermal systems are designed to account for intra- and interindividual differences that affect the percutaneous absorption of the drug. Interindividual differences include age and ethnicity. It is well established that the skin of neonates and the elderly is more permeable than middle-aged adults. Additionally, there is evidence to suggest that Caucasian skin is more permeable than black skin (Astner, 2006). Intraindividual differences include body site and skin status or condition. The scrotal skin, mucous membranes, and eyelids are the most permeable to drugs, while the chest/back, buttocks, and upper arms/legs are areas of relative impermanence. Other skin conditions that increase permeability include hydrated skin, irritated or broken skin, thermal burns, warmer skin, and eczematous skin (Wikosz, 2003). To minimize such potential differences, transdermal manufacturers will specify the skin site, duration of time, and age range for which they recommend using their product.

11.5 ADVERSE REACTIONS TO TRANSDERMAL SYSTEMS: GENERAL

The adverse reactions due to transdermal systems may be classified into two broad categories: local irritation due to the patch itself or a systemic and immunologic reaction to the components of the patch (Maibach, 1992).

11.5.1 Local Effects

11.5.1.1 Occlusion

TDDS are occlusively applied to the skin for 1–7 days (Brown and Langer, 1988). Occlusion enhances skin hydration by allowing eccrine sweat glands and water vapor to accumulate on the skin's surface (Hurkmans et al., 1985). Hydration not only enhances skin absorption of compound but may also lead to adverse effects, such as miliaria rubra, caused by sweat duct occlusion. In miliaria rubra, sweat infiltrates below the epidermis and results in pruritic erythematous papulovesicles (Hurkmans et al., 1985). Generally, the miliaria rubra is limited to the application site and is resolved within 1 day. Treatments for miliaria rubra include topical steroids to reduce the associated itching, and increased fluid intake to maintain homeostasis in the body. To prevent miliaria from occurring, transdermal patches are not reapplied to the same site following a 1–7 day course. Transdermals should not be given for more than 7 days at a time.

11.5.1.2 Erythema

Transient mild to moderate erythema occurs in most patients. Removal of the pressure-sensitive adhesive is responsible for the erythematous skin response (Fisher, 1984).

11.5.1.3 Irritant Contact Dermatitis

There is an increased risk of developing irritant contact dermatitis (ICD) proportional to the increased occlusive period of the patch. Additionally, irritant dermatitis may occur if the transdermal system is repeatedly applied to the same skin site.

11.5.1.4 Miscellaneous

Scopolamine patches have been implicated in causing anisocoria in several patients when they are inadvertently transferred to another site (Carlston, 1982; McCrary and Webb, 1982). A nitroglycerin disk was implicated in causing a second-degree burn on a patient's chest, in one case report (Murray, 1984). Person-to-person transfer of transdermal therapeutic systems may cause toxicity in the recipient (Wick et al., 1989). This is most likely to occur when the TTD has been applied for a long time to one site. The longer the application period of the TDDS, the lower the skin adhesion and the more likely the system will become dislocated inadvertently.

11.6 SYSTEMIC/IMMUNOLOGIC

The most common type of hypersensitivity reaction to the TDDS is an allergic contact dermatitis. Generally, the reaction is in response to a component of the drug or the adhesive background in the transdermal system (Nieboer et al., 1987); the reaction is prevalent during any stage of drug use. Lanolin, a vehicular ingredient in many of the transdermal ointments, is one of the primary accountable agents. Patches applied to thin-skinned areas, such as the postauricular region (scopolamine) or the scrotal area (testosterone) are more likely to cause ACD. Sensitization is also promoted in response to local irritation (resulting from prolonged occlusion) as well as oily, inflamed, broken, calloused or occluded (Dwyer and Forsyth, 1994; Nieboer et al., 1987) skin. Lack of patient compliance with regard to applying the patch to the designated site, applying the patch for a designated period of time, or rotating patch application sites may also lead to skin sensitization. The skin hypersensitivity reaction is generally manifested as a rash accompanied by redness, burning, itching, heat, and swelling. If the reaction persists, the therapeutic system should be discontinued.

11.7 PROPHYLACTIC MEASURES TO DECREASE ACD INCIDENCE

Allergic contact dermatitis from TDDS is one of the limiting factors in patient compliance. Some prophylactic measures that should/are being taken to decrease the incidence of ACD include limiting patch application time and rotating the patch site. Improved predictive tests of sensitization should be developed for each of the therapeutic systems. In the development of clonidine, standard predictive tests indicated that it was not an allergen; however, when marketed, many users developed allergic contact dermatitis. Currently, mouse strains are being developed as an alternative to the standard guinea pig model (Kalish et al., 1996). Robinson and Cruze used guinea pig models and a local lymph node assay (LLNA) in mouse models to aid in the detection of weak allergens (Robinson and Sozeri, 1990). Through vitamin A supplementation and the introduction of chronic conditions, they were able to detect contact sensitization of clonidine in both mice and guinea pigs. Other predictive models have analyzed the electrophiles within various haptens, such as scopolamine and clonidine and their relationship with nucleophilic groups of skin protein to form antigens (Benezra, 1991). Contact sensitization from transdermal *d*-chlorpheniramine and benzoyl peroxide was reduced when hydrocortisone was coadministered (Amkraut et al., 1996). Additionally, when applied prior to the transdermal patch, ion channel modulators, such as ethacrynic acid, have been found to prevent sensitization in mice (Kalish et al., 1997; Wille et al., 1999). The potential role of corticosteroids and ion channel modulators in the prevention of contact sensitization from Transdermal therapeutic system (TTS) should be further investigated and better defined. Additionally, minimizing reapplication to the same application site (Hogan and Cottam, 1991) and maintaining caution when performing oral provocation tests (Vermeer, 1991) would help to reduce the induction of allergic contact dermatitis among TTS users.

11.8 ACTIVE TRANSDERMAL DRUG DELIVERY AND PENETRATION ENHANCERS

The advantages associated with TTS, including avoidance of the first-pass metabolism, elimination of "peaks and valleys," and improved patient compliance, have led to continual interest

in the development of new transdermal systems. Some transdermal systems that may be available in the United States in the near future include insulin (Sen et al., 2002) and asthma (Kato et al., 2002) medication.

The current transdermal delivery systems are useful for delivering small, lipophilic molecules through the skin. However, there are many compounds that do not meet these requirements. New techniques are being developed to allow the transfer of hydrophilic, charged drugs through the skin. "Active" transdermal drug delivery involves utilizing external driving forces on the SC to allow penetration of the molecule of interest (Barry, 2001).

Electrically assisted methods include iontophoresis, phonophoresis, electroporation, magnetophoresis, and photochemical waves. Iontophoresis passes an electric current through the skin and thereby provides the driving force to enable penetration of ions into the skin (Singh et al., 1995). The development of transdermal insulin (Rastogi and Singh, 2002), dexamethasone (Nirschl, 2003), naproxen (Baskurt, 2003), and others may require the use of iontophoresis. Phonophoresis utilizes ultrasound energy to enhance drug penetration. Higher-frequency energy not only enables greater penetration but is also associated with greater adverse events. Electroporation uses strong, brief pulses of electric current to punch holes in the SC. These holes close 1–30 min following the electrical stimulus (Banga and Prausntiz, 1998). Electroporation coupled with iontophoresis may be helpful in the delivery of some drugs (Badkar et al., 1999). This technique is currently being studied to eventually allow transdermal delivery of drugs such as metoprolol (Vanbever, 1994) and heparin (Prausnitz, 1995). The application of high-gradient magnetic fields and vibrational forces to biological systems is termed magnetophoresis. Magnetophoresis may be effective in the delivery of terbutaline sulfate (TS), a drug widely used for the treatment of acute and chronic bronchitis patients (Narasimha and Shobha Rani, 1999). Laser-induced stress waves, known as photochemical waves, may also benefit drug delivery. More recently, ultrasound or sonophoresis has been studied *in vitro* to increase the permeability of drugs such as insulin and aldosterone (Mitragotri, 2001).

Hydrating agents and chemical enhancers (Smith and Maibach, 1995) also increase pore size to enhance drug delivery. Moisturizers are the primary hydrating agents. There are numerous chemical enhancers, including benzalkonium chloride, oleyl alcohol, and alphaterpineol (Monti et al., 2001; Sinha and Kaur, 2000). Transdermal delivery may be most improved by utilizing a combination of chemical enhancers and electrically assisted devices (Terahara et al., 2002).

Structurally based techniques have recently been developed to actively increase drug permeability. The SC may be removed or bypassed utilizing ablation and thus increasing drug permeability. Microneedles and jet-propelled particles are two relatively new techniques for physically increasing drug permeability. Microneedles are used to create a physical pathway through the upper epidermis and thereby increases skin permeability. The needles are approximately 150 mcm length and 80 mcm diameter, and are fabricated onto arrays. The needles penetrate the SC and epidermis without reaching nerve endings present in the upper dermis and are thereby painless. Recent experimentation suggests that this technology has allowed greater than fourfold increase in drug permeability (Figure 11.3).

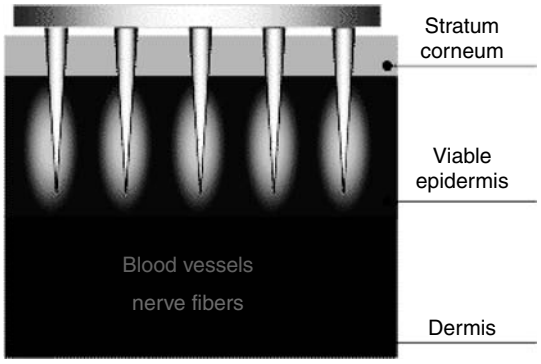

FIGURE 11.3 Microneedle technology.

The transdermal jet-injectors propel drug molecules into the skin through the production of a high-velocity jet of compressed gas (usually helium) that accelerates through the nozzle of the injector device, carrying its drug particles. The injectors are currently being studied for the injection of macromolecules, as well as in the delivery of DNA or protein vaccines into the epidermis (Cross, 2004; Dean, 2003).

Although passive transdermal systems have been on the market for more than 20 years, active transdermal systems are still not available for clinical use. In the next few years, we await the development of new passive transdermal products and the onset of clinical studies utilizing active transdermal techniques to promote drug permeability.

12.1 INTRODUCTION AND HISTORICAL PERSPECTIVES

The skin is the largest organ in the human body and has long been used as a site for administration of therapeutic agents for localized pharmacological actions (Kastrip and Boyd, 1983). Drug delivery through the skin for systemic effects, though limited, is a well-established branch of pharmaceutics. The stratum corneum, the outermost layer of the skin offers excellent barrier properties to applied substances thus limiting the number of drug candidates for passive transdermal delivery to usually small, potent, and lipophilic compounds. Physical and chemical techniques have been used to improve the permeability of the skin to applied substances. Dermal iontophoresis is one of such physical techniques.

A Greek physician, Aetius, first prescribed shock from electric fish for the treatment of gout more than 1000 years ago and since then the use of electric current to introduce drugs into the body has intrigued scientists. Iontophoresis was first introduced by Pivati to treat arthritis in the 1740s (Licht, 1983) and Palaprat claimed in 1833 to have been able to deliver iodine directly to tissues by means of electric current (Jones, 1907).

Iontophoresis may be defined as the facilitated transport of ions of water-soluble salts across membranes under the influence of an applied electric field. The technique temporarily lost its importance partly because it was not well understood and partly due to safety considerations. Earlier, Munch demonstrated the systemic application of this technique in 1879, when strychnine delivered under the positive electrode in

rabbit killed the animal within 15 min of current passage. Leduc (1900) described some of the earliest systematic experiments outlining the usefulness of iontophoresis in systemic drug delivery. He placed a solution of strychnine sulfate (positively charged strychnine ion) in the positive electrode (anode) of an iontophoresis setup on one rabbit with the negative electrode filled with water and a solution of potassium cyanide (negatively charged cyanide ion) in the negative electrode (cathode) of a setup on another rabbit with the positive electrode filled with water. The animals were connected and when a constant current of 40–50 mA was applied, both animals died due to strychnine and cyanide poisoning, respectively. In a subsequent experiment, reversing the polarity of the delivery electrodes (i.e., strychnine in the cathode and cyanide in the anode), neither animal died demonstrating that in the first case, the electric current delivered the lethal ions.

Since the early years, there has been a resurgence of interest in iontophoresis. Gibson and Cooke (1959) used iontophoretic delivery of pilocarpine to induce sweating and the procedure is now used for the diagnosis of cystic fibrosis, a method still used in modern medicine for the routine diagnosis of cystic fibrosis even in children and neonates (Santos et al., 2005; Ahn et al., 2005; Mackay et al., 2006). Iontophoresis has been used for the treatment of palmoplantar hyperhydrosis. In addition to this and other local applications of the technique, the present focus of research and development efforts on iontophoresis is for systemic drug delivery. With interest in controlled drug delivery surfacing in the last two decades, and the inability to deliver a great number of drugs especially proteins and peptides passively, iontophoresis appears to be particularly attractive and holds great commercial promise for noninvasive rate-controlled transdermal drug delivery for a wide array of drugs including hydrophilic, charged, and high molecular weight compounds all of which would not permeate the skin by passive diffusion.

12.2 THEORY

Biological tissues including skin consist of membrane barriers made up of lipids and proteins. Transport through these membranes is better suited to unionized than ionized compounds. Many potential drug candidates are ionized at skin pH (4–5) and cannot therefore be transported across membranes passively. As stated previously, the stratum corneum provides an excellent barrier to transport across the skin. In addition, passive diffusion depends on a concentration gradient across the membrane. Membrane transport of drugs can be facilitated by the application of an external energy source (active transport).

Iontophoresis by utilizing electric current provides an excellent source of this external energy. It operates on the general principles of electricity, i.e., opposite charges attract and like charges repel. Thus, if the drug of interest is cationic, for delivery across the skin it is placed in the anode reservoir. When a voltage is applied, the positively charged drug is repelled from the anode through the skin and into the systemic circulation. Conversely, an anionic drug is placed in the cathode reservoir. The transport of polar neutral and uncharged molecules (Gangarosa et al., 1980; Sims and Higuchi, 1990; Banga, 1998; Bath et al., 2000) as well as high molecular weight cations (Pikal, 1992) can also be facilitated by iontophoresis by the process of current induced convective water flow also known as electroosmosis. Electroosmosis may in fact be the major underlying mechanism in iontophoretic delivery of proteins and peptides. In addition to the major mechanisms of electro-repulsion and electroosmosis, the application of electric current may itself directly increase passive diffusion across the skin by reversibly disorganizing skin lipids and proteins. Figure 12.1 is an illustration of an iontophoretic setup.

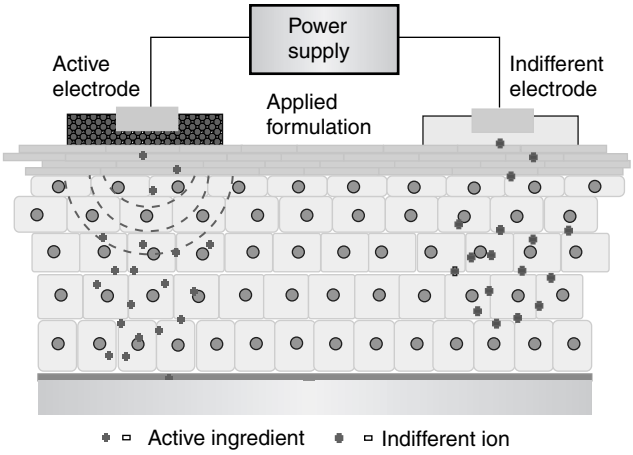

FIGURE 12.1 A schematic depiction of the basic principles of transdermal iontophoresis showing drug repulsion from the active electrode toward the indifferent electrode and into the skin upon passage of current. (From Daniels, R. Skin Care Forum, Online Issue 37, 7, 2004. With permission.)

In this section, the underlying principles of iontophoretic transport will be described briefly. The Nernst–Planck flux equation as applied in iontophoresis provides that the flux of an ion across a membrane under the influence of an applied charge is due to a combination of iontophoretic (electrical potential difference), diffusive (increased skin permeability induced by the applied field), and electroosmotic (current-induced water transport) components (Schultz, 1980).

$$J_{ion} = Je + Jp + Jc \tag{12.1}$$

where *Je* is the flux due to electrical potential difference and is given by:

$$Je = \frac{ZiDiF}{RT} Ci \frac{\partial E}{\partial x} \tag{12.2}$$

and *Jp* is the flux due to passive delivery and is given by:

$$Jp = KsDs \frac{\partial C}{\partial x} \tag{12.3}$$

and *Jc* is the flux due to electroosmosis or convective transport and is given by:

$$Jc = kCsI \tag{12.4}$$

where

Zi = valence of the ionic species
Di = diffusivity of the ionic species, i in the skin
F = Faraday constant
T = absolute temperature
R = gas constant
$\partial E, \partial x$ = electrical potential gradient across the skin
Ci = donor concentration of the ionic species
Ks = partition coefficient between donor solution and stratum corneum
Ds = diffusivity across the skin
$\partial C, \partial x$ = concentration gradient across the skin
Cs = concentration in the skin
I = current density
k = proportionality constant

(Chien et al., 1990).

In iontophoretic drug delivery, the major contribution to the overall flux of a compound would be due to electrical potential gradient (electromigration). The contribution to the flux due to electroosmosis is likely to be small (Srinivasan et al., 1989) and Roberts et al. (1990) have suggested that only about 5% of the overall flux is due to convective solvent flow. In the anodal iontophoresis of lidocaine hydrochloride, electromigration was shown to contribute approximately 90% of the total flux (Marro, et al., 2001a). Electroosmosis is always in the direction as the flow of the counterions. Human skin is negatively charged at pH above 4 and the counterions are positive ions and therefore, electroosmotic flow would occur from anode to cathode.

The Goldman constant field approximation is used to facilitate the integration of Equation 12.1 to give an enhancement factor E (relative to passive flux) which is given by (Srinivasan et al., 1989):

$$E = (Flux_{\text{ionto}} / Flux_{\text{pass}}) = \frac{-K}{1-\exp(K)} \tag{12.5}$$

where

$$K = \frac{ZiF\Delta E}{RT} \tag{12.6}$$

At high voltages, deviations from the predictions based on Equation 12.5 have been known to occur (Srinivasan et al., 1989; Kasting and Keister, 1989).

While the Nernst–Planck equation when applied to iontophoresis describes the flux of a drug through a membrane under the influence of applied potential, Faraday's law describes flux in terms of electric current flowing in the circuit. Applying Faraday's law therefore, the mass of substance transported in an aqueous solution is proportional to the charge applied (this is the product of current and time). The flux of a compound transported across the skin (J_{trans}) is thus given by:

$$J_{\text{trans}} = \frac{t}{zF} I \tag{12.7}$$

where

t = transport number of the compound
z = charge on the drug
F = Faraday's constant and is equal to 96,500 C/mole
I = current density (A/cm^2).

In iontophoresis, all ions in a formulation as well as ions in the skin carry a fraction of the applied electric current. The most important ions for consideration, are however, those of the drug of interest with transport number t, which is defined as the fraction of the total current carried by the drug and is given by:

$$t = \frac{z^2 mc}{\sum_i z_i^2 m_i c_i} \tag{12.8}$$

where

z = charge of the drug
m = ionic mobility
c = concentration of the ion and
i = all the ions in the system.

In theory, therefore, if the mobility of a drug in the skin is known, the iontophoretic flux can be predicted. In practice, however, it is not easy to estimate the skin mobility of a drug and free solution mobility is thus usually used as an approximation (Singh et al., 1997). The efficiency of iontophoretic drug delivery is therefore governed by both thermodynamics and electrochemistry being influenced by a combination of valency, polarity, mobility of the ionic species, formulation composition, and electrical duty cycle.

12.3 IONTOPHORESIS DEVICES AND EXPERIMENT PARAMETERS

12.3.1 *In vitro*

In the early stages of the revival of iontophoresis, relatively simply techniques were employed for the delivery of small molecules. Examples include Molitor (1943); Burnette and Marrero (1986); Bellantone et al. (1986); Masada et al. (1989); Green et al. (1991); Thysman et al. (1991); and Chang and Banga (1998). Usually these involve modifications of the two-compartment *in vitro* passive diffusion set-up. Two electrodes connected to a power supply are used, and in some instances, one is inserted in each compartment separated by the mounted skin and voltage or current measurements are made between the electrodes. In other instances using vertical flow through diffusion cells, a horizontally mounted

piece of skin separates the positive and negative electrode chambers with the epidermal side of the skin from the receptor phase bathing the dermal side.

A four-electrode potentiostat system designed to maintain a constant voltage drop across a membrane in a two-chamber diffusion cell has been described by Masada et al. (1989). As with passive diffusion studies, the whole assembly is kept at 37°C with the aid of a constant-temperature water bath to maintain the skin surface temperature at 32°C.

In all constructs, the receiver compartment medium is usually stirred with the aid of magnetic bar stirrers. The electrodes usually consist of platinum wires or silver/silver chloride. Cationic drugs are placed under the anode electrode in the donor compartment with the cathode in the receiver compartment and the opposite is true of anionic drugs. Pulsed or constant current may be applied.

Regardless of the type of electrodes and cells used, the same principles and transport mechanisms apply. Bellatone et al. (1986) demonstrated that diffusion cell type had little impact on the diffusion of benzoate ions across hairless mouse skin. Similarly, Kumar et al. (1992) have shown that cell design was not a factor in the delivery of an analog of growth hormone releasing factor *in vitro* across hairless guinea pig skin by iontophoresis.

Furthermore, iontophoresis has been combined *in vitro* with other enhancement techniques (physical or chemical) such as skin penetration enhancers as in skin pretreatment with oleic acid or oleic acid added to the drug formulation for the delivery of piroxicam (Gay et al., 1992); sodium lauryl sulfate or cetrimide to the donor in the delivery of Acyclovir (Lashmar and Manger, 1994); skin pretreatment with surfactant or a suspension of elastic liquid-state vesicles for the delivery of Apormorphine (Junginger, 2002); ethanol or a combination of terpenes and ethanol for the delivery of Insulin (Pillai and Panchagnula, 2003); terpenes for the delivery of Buspirone hydrochloride (Al-Khalili et al., 2003); lipid extraction for the delivery of insulin (Rastogi and Singh, 2002); electroporation for the delivery of Timolol and Atenolol (Denet et al., 2003) and 5-fluorouracil (Fang et al., 2004); laser treatment for the delivery of 5-fluorouracil (Fang et al., 2004); and liposomes and liposomes and electroporation in the delivery of estradiol (Essa et al., 2004).

12.3.2 *In vivo*

Devices used in iontophoresis are designed for rate-controlled delivery of therapeutic agents. The devices used *in vivo* vary in complexity from those that use household current to battery-and-rheostat type to modern electronic circuit devices (Singh and Maibach, 1993). Essentially, they consist of a power source to provide current, anode, and cathode reservoirs. The reservoir electrodes usually consist of a small metal plate over which a moist material preferably a pad or gauze is overlaid and this portion comes in direct contact with the skin. During use, an indifferent electrode (without drug) is placed some distance from the active electrode. Regardless of design, the most important considerations in choosing an iontophoretic device include safety and comfort of patients, cost, ease of operation, reliability, size, and therefore, portability.

Generally, they are operated at a constant voltage allowing the current to be varied for patient comfort and compliance over a given period. As with *in vitro* apparatuses, various devices have been described for use in iontophoresis *in vivo* (Molitor and Fernandez, 1939; Barner, 1961; Rapperport et al., 1965). Rattenbury and Worthy (1996) described systems used in the U.K. Hidrex (Gessellschaft für Medizin and Technik, Wuppertal, Germany) has been described by Hölzle and Alberti (1987). Phipps et al. (1989) described a custom-made battery operated device with two hydrogel electrodes for *in vivo* delivery of pyridostigmine. These devices deliver direct steady current, which have been postulated to be responsible for skin irritation arising from iontophoresis due to continuous electric polarization. To minimize this, others advocate devices delivering pulsed current such as have been used to administer catecholamines to dogs (Sanderson et al., 1987). In furtherance of this argument, two delivery systems using pulsed direct current have been described, one being the advance depolarizing pulse iontophoretic system (ADIS-4030) designed to continuously deliver drugs under constant pulsed current application (Okabe et al., 1986). The other, the transdermal periodic iontophoretic system (TPIS) delivers pulsed direct current with combinations of frequency, waveform, on/off ratio, and current density, for a programed treatment duration (Chien et al., 1990).

Available in the United States is a portable battery operated power supply unit called a Phoresor® (Dermion Drug Delivery Research, Salt Lake City, Utah, USA) and it is suitable for home use.

The US Food and Drug Administration has categorized iontophoretic devices into those for specialized uses (Class II) and others (Class III) (Tyle, 1986). These include Drionic® (General Medical Company, Los Angeles, CA, USA), Macroduct (Wescor Inc., Logan, UT, USA), Iontophor-PM (Life-Tech Inc., Houston, TX, USA), Model IPS-25 (Farrall Instruments Inc., Grand Island, NE, USA), Electro-Medicator (Medtherm Corporation, Huntrille, AL, USA), Dagan® (Dagan Corporation, MN, USA), and Desensitron II® (Parkell, Farmingdale, NY, USA).

12.4 CHOICE OF ELECTRODE MATERIALS IN IONTOPHORESIS

Platinum electrodes or patches consisting of zinc/zinc chloride or silver/silver chloride electrodes are used. The choice of electrode material depends on several factors including good conductivity, malleability, and the ability to maintain a stable pH. In addition, the electrodes should not produce gaseous by-products and must be safe to be used on the skin. Silver/silver chloride electrodes also referred to as reversible electrodes are made from a metal in contact with solution of its own ions (Boucsein, 1992) and are the most commonly

used as they satisfy these requirements. At the anode, silver under the influence of an applied electric field is oxidized and reacts with chloride to form silver chloride. At the cathode, silver chloride is reduced to silver with the liberation of chloride ions. These electrodes are thus stable. They should however be thoroughly cleaned after use and rinsed with distilled water. When not in use for prolonged periods, it is advisable to store the electrodes dry.

Platinum electrodes though used are less desirable in some situations than silver/silver chloride electrodes because with prolonged use of platinum electrodes, there is oxidation of water to oxygen gas and hydronium ions. This was demonstrated by Phipps et al. (1989) in anodal delivery of lithium across hydrogel membranes. The efficiency of delivery achieved using platinum electrodes was 20% compared to 37% when silver anode was used instead.

Careful selection of the electrode used to deliver a particular drug is also important. For instance, dexamethasone sodium phosphate can be delivered under the anode electrode by electroosmosis. However, considering that electroosmosis contributes a small fraction to the overall iontophoretic transport of any given drug, cathodal iontophoresis should therefore be considered. It is in fact known that the delivery efficiency of dexamethasone sodium phosphate by iontophoresis from the cathode is far greater than from the anode. It has been suggested that for monovalent ions with Stoke's radii larger than 1 nm, electroosmotic flow may be the dominant transport mechanism. In addition, for large anions or negatively charged protein, electroosmotic flow from the anode may be more efficient than cathodal electromigration (Pikal, 2001).

12.5 ANIMAL MODELS

The ultimate goal of any research done in the field of iontophoresis is the application in humans for drug delivery. For obvious reasons, animals and not human subjects are the first choice for experimental purposes. There is no consensus as to which of the animal models used in passive uptake studies is suitable for iontophoresis. Hairless mouse has been the most commonly used model (Bellantone et al., 1986). Other models that have been investigated include hairless guinea pig (Walberg, 1970), dog (McEvan-Jenkinson et al., 1974), furry rat (Siddiqui et al., 1987), pig (Monteiro-Riviere, 1990), hairless rat (Thysman and Preat, 1993), and rabbit (Lau et al., 1994; Anigbogu et al., 2000). Phipps et al. (1989) found no differences in the fluxes of lithium and pyridostigmine through human, pig, and rabbit skin *in vitro*. There is, therefore, the need to establish which model closely resembles human skin for both penetration and toxicological studies. Recently, Marro et al. (2001) evaluated the suitability of porcine skin as a model for human skin in iontophoretic studies by comparing the anode-to-cathode and cathode-to-anode delivery of mannitol through both skin types at different pH. They concluded that the isoelectric points 4.4 for pig skin and 4.8 for human skin were close enough and that pig skin showed the same pH-dependent perselectivity for mannitol as did human skin and would, therefore, be an appropriate model for human skin.

12.6 PATHWAYS OF ION TRANSPORT

The predominant pathway for ion transport through the skin remains controversial. Appendages: sweat ducts and hair follicles are thought to be the major pathway for iontophoretic transport through the skin (Grimnes, 1984; Burnette, 1989). This is obviously so in the use of pilocarpine for the diagnosis of cystic fibrosis. Abramson and Gorin (1940) showed that charged dyes delivered iontophoretically produced a dotlike pattern on human skin and the dots were identified as sweat glands. Papa and Kligman (1966) observed a direct link between methylene blue staining of the skin and the location of sweat ducts. Monteiro-Riviere et al. (1994) demonstrated the appendageal pathway for the iontophoretic delivery of mercuric chloride across pig skin *in vivo*. Cullander and Guy (1991) using a vibrating probe electrode identified the largest currents to be in the area of residual hairs. Laser scanning confocal microscopy has been used to elucidate the pathway for the iontophoretic transport of Fe^{2+} and Fe^{3+} ions (Cullander, 1992) as being the sweat glands, hair follicles, and sebaceous glands. Based on these and other studies, the sweat ducts and glands, however, appear to be more important than hair follicles in the transport of ions through the shunts. A schematic of the routes of ion transport across the skin is shown in Figure 12.2.

It is however not correct to assume that all charged transport takes place through the appendages. Walberg (1968) demonstrated that Na^+ and Hg^{2+} could penetrate through guinea pig skin in areas devoid of sweat glands and hair follicles. Millard and Barry (1988) compared the iontophoretic

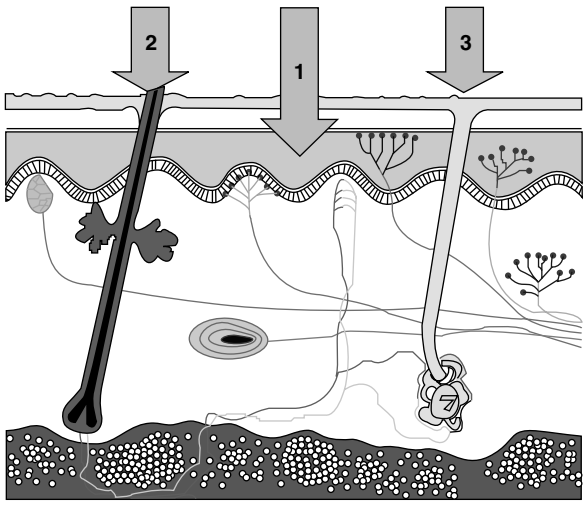

FIGURE 12.2 An illustration showing possible pathways of permanent transport across human skin either through: (1) intact stratum corneum, (2) the hair follicles with interconnected sebaceous glands, or (3) the sweat glands. (From Daniels, R. *Skin Care Forum*, Online Issue 37, 3, 2004. With permission.)

delivery of water and glutamic acid through full thickness human skin and shed snakeskin, which is largely devoid of sweat glands and hair follicles. Iontophoresis was shown to increase the delivery of both materials through snakeskin. Sharata and Burnette (1989) showed that mercuric and nickel ions can diffuse passively between the keratinocytes. Jadoul et al. (1996) concluded from results of fourier transform infrared spectroscopy (FTIR) and small angle x-ray scattering (SAXS) studies on isolated rat and human cadaver skin following prolonged *in vitro* iontophoresis that iontophoresis transport is related to lipid bilayer stacking disorganization.

12.7 FACTORS AFFECTING IONTOPHORETIC DRUG ADMINISTRATION

Several factors come into play when considering iontophoresis for drug delivery. These include the physicochemical properties of the drug in question: the charge, molecular size, and concentration; formulation parameters: choice of vehicle, pH range in which drug is ionic, presence of competing or parasitic ions, viscosity, or mobility (Maurice and Hughes, 1984). Others include physiologic considerations such as appropriate skin site for application; instrumentation, e.g., type of current source, pulsed or constant, and current density. This list is by no means exhaustive but includes some of the more critical factors, which will be considered briefly in this section.

12.7.1 pH

Transdermal iontophoresis achieves the transport of drug molecules into and through the skin under the influence of an applied electric field. This means that the drug candidate should be charged to allow for delivery in therapeutically relevant levels through the skin. The optimum pH for delivery of a drug by iontophoresis is that at which it exists predominantly in the ionic form. This has been demonstrated by Siddiqui et al. (1985, 1989). The pH of peptides, proteins, and other amphoteric substances characterized by their isoelectric point is of particular significance i.e., a pH above which the molecule is anionic and below which it is cationic. For instance, the skin permeability of insulin has been shown to be greater at a pH below its isoelectric point (Siddiqui et al., 1987). Furthermore, the pH gradient encountered in the skin is an important factor in iontophoretic transport. The pH of the skin ranges from 4 to 6 on the outside to about 7.3 in the viable tissues. If, at any time, the drug encounters an environment in which it becomes uncharged, its transport becomes impeded. Thus, for a molecule to be delivered efficiently by iontophoresis, it must remain charged during its transport into and through the skin. For proteins and peptides, iontophoretic transport may be limited to those with isoelectric points below 4 or above 7.3.

12.7.2 Molecular Size

The molecular size of the compound of interest is crucial in predicting the efficiency of its iontophoretic delivery (Srinivasan et al., 1989, 1990; Yoshida and Roberts, 1993). Generally, monovalent positively charged drugs are delivered with greater efficiency by iontophoresis than monovalent negatively charged anions. This has been ascribed to the net negative charge on the skin. The greater the molecular size, the lower the permeability coefficient. Nevertheless, high molecular weight proteins and peptide drugs with molecular weight 3000–5000 Da have been delivered effectively by iontophoresis. As advances in the electronic devices used in iontophoretic drug delivery have evolved, researchers have focused efforts on the delivery of macromolecules ranging from small molecules such as oligonucleotides (Van der Geest et al., 1996; Brand et al., 1998; Davies et al., 2003) to genes (Asahara et al., 1999) and large peptides such as Insulin, MW 3–7 K Da. (Rastogi and Singh, 2002; Kumar et al., 2004).

12.7.3 Concentration

The concentration of the drug in the formulation also affects the flux achieved by iontophoresis. There abound in the literature insurmountable evidence that increasing the concentration of drug in the donor compartment increases proportionately, the flux of the compound e.g., Arginine–Vasopressin (Lelawongs et al., 1989), butyrate (DelTerzo et al., 1989), and diclofenac (Koizumi et al., 1990). A linear relationship between concentration of the drug in the donor solution and flux has been established for gonadotropin releasing hormone (GnRH) and sodium benzoate with flux increasing linearly with increasing concentration (Bellantone et al., 1986). With some drugs, however, increasing the concentration in the donor solution beyond a certain limit appears not to further increase the flux. This was demonstrated for methylphenidate, the steady-state flux of which was found to increase with concentration up to 0.1M (Singh et al., 1997). It was shown recently that increasing the concentration of methotrexate in hydrogels did not further improve the effectiveness of delivery by iontophoresis (Alvarez-Figueroa and Blanco-Méndez, 2001).

12.7.4 Competing Ions

The fraction of current carried by each type of ion in solution is called the transference or transport number. When a migrating ion carries 100% of the current through the membrane, its rate of transport is maximal and its transport number is unity. To control the pH of the donor solution, buffers are often employed. The buffers, however, introduce extraneous ions, which may be of different type but are of the same charge as the drug ion. These are called co-ions and are usually more mobile than the drug ion. The co-ions reduce the fraction of current carried by the drug ion thus resulting in a diminished transdermal flux of the drug. In a recent publication, Mudry et al. (2006) demonstrated the reduction in transport numbers of all cations by addition of co-ions, the magnitude of which was highly dependent on the mobility as well as the molar fraction of the ions. Some workers also employ antioxidants and antimicrobials which

themselves contain co-ions. In addition to these, co-ions can also be introduced from reactions occurring at the electrodes if, for example, platinum is the conducting material. Hydrolysis of water occurs resulting in the generation of hydronium ion at the anode and hydroxyl ion at the cathode. Reducing the amount of competing ions in the drug donor solution will increase the transport efficiency of the drug ions but as there are also endogenous ions in the skin, e.g., sodium, potassium, chloride, bicarbonate, and lactate, which carry an appreciable fraction of the ionic current (Phipps and Gyory, 1992), the transport number of any drug will always be less than unity. Marro et al. (2001b) concluded that the mole fraction of drug relative to competing ions of similar polarity was the determinant of the extent to which it can carry charge across the skin during iontophoresis.

12.7.5 Current

A linear relationship has been established between the iontophoretic fluxes of a number of compounds and the current applied. Examples include lithium (Phipps et al., 1989), thyrotropin releasing hormone (Burnette and Marrero, 1986), mannitol (Burnette and Ongpipattanakul, 1987), gonadotropin releasing hormone (Miller et al., 1990), verapamil (Wearley and Chien, 1989). Tissue distribution of phosphorus following iontophoretic delivery was shown to be proportional to current density (O'Malley and Oester, 1955). This relationship between skin flux and applied current is closely related to fall in skin resistance. As shown in Figure 12.3, the greater the applied current, the lower the steady state skin resistance achieved (Anigbogu et al., 2000). This relationship is, however, seen not to be linear at current densities above 2 mA/cm^2. The rate of transfer of ketoprofen from skin to cutaneous blood in rats was found to be proportional to applied electric current with the enhancement ratios compared to passive delivery being 17 and 73 respectively for 0.14 and 0.70 A/cm^2 (Tashiro et al., 2000). Zhu et al. (2002) reported less skin to skin variability using constant conductance alternating current compared to conventional constant direct current iontophoresis. Plasma and tissue levels of diclofenac sodium in rabbit were found to be proportional to applied current density (Hui et al., 2001) and at up to 0.5 mA/cm^2 of current for six hours in the presence of drug, rabbit skin showed no significant irritation. Overall, therefore, in theory, since the current can be easily modulated, the amount of drug transportable across the skin can be increased by increasing the electric current applied. In practice, however, the limiting factor especially in humans is safety, comfort, and acceptability. The upper limit of current tolerable to humans is thought to be 0.5 mA/cm^2 (Abramson and Gorin, 1941; Ledger, 1992). Increasing the surface area of the electrodes allows for increasing current and, therefore, improving the delivery of some drugs. This is, however, not a linear relationship and may not apply to all drugs (Phipps et al., 1989). In terms of skin barrier properties, it has recently been suggested that the fall in skin impedance following iontophoresis does not necessarily represent damage to the barrier but rather is a response to the relevant electrical potential and ion concentration gradients involved in iontophoresis (Curdy et al., 2002). Kanebako et al. (2002), evaluated the relationship between skin barrier function and direct current applied by measuring short-term resistance. In addition, they demonstrated that the distance between two electrodes affect the barrier function due to the localization of current density in the adjacent electrode. In a follow study (Kanebako et al., 2003), assessed the effect of electrode distance, boundary length, and electrode shape on skin barrier function and percutaneous absorption during iontophoresis. They found that a distance of 2 mm between electrodes decreased skin barrier function and surrounded electrode types were more effective in reducing skin barrier function than paired types.

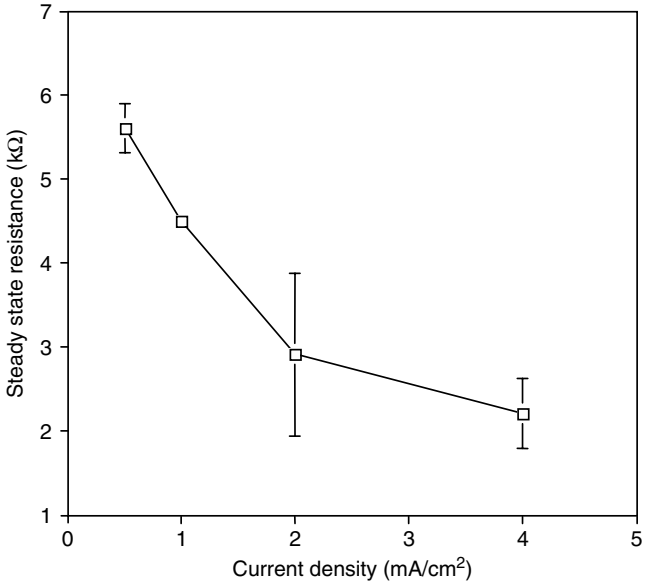

FIGURE 12.3 Apparent steady-state skin resistance as a function of current density. Area of Application = 1cm^2, Duration = 1h, Electrolyte in patch = 0.15M NaCl, pH = 7. (From Anigbogu et al., *Int. J. Pharm*., 200, 203, 2000. With permission.)

12.7.6 Species, Sex, and Site

Iontophoretic deliveries of lithium and pyridostigmine have been found to be comparable in pig, rabbit, and human skin (Phipps et al., 1989). Burnette and Ongpipattanakul (1987) found the iontophoretic fluxes of sodium chloride and mannitol through thigh skin from male and female cadavers to be comparable. Successive iontophoretic delivery of iodine through the same knee in a human volunteer resulted in a constant uptake (Puttemans et al., 1982). Iontophoresis, therefore, decreases the intra- and intersubject variability as well as the influence of site usually observed with passive diffusion. Further studies need to be done, however, to establish the degree to which factors such as race, age, skin thickness, hydration, and status of the skin (healthy or diseased) affect iontophoretic drug delivery. Skin tolerability to electric current appears to be species dependent. Rabbit, which is normally reactive to applied chemicals and is used commonly

in Draize skin irritation test tolerated 1 mA/cm^2 current for up to 1 h without irritation as opposed to human skin for which the upper limit is 0.5 mA/cm^2 (Anigbogu et al., 2000). The same study, however, found skin irritation in rabbit to be tied to applied current density or treatment duration with currents greater than 1 mA/cm^2 applied for periods of 30 min or greater or 1 mA/cm^2 for application times greater than 1 h. In further assessing rabbit skin as a suitable *in vitro* and *in vivo* model for human skin iontophoresis experiments, Nicoli and coworkers (2003) measured the sodium transport number at different pH values for the bathing solution and thus estimated the isoelectric point (IP) of rabbit ear skin to be 2–3. They validated their method by evaluating the transport of mannitol, a model drug through rabbit skin. Applying the same method, they also obtained the same values for human skin, numbers lower than previously reported (Rein, 1924; Marro et al., 2001a). They defined the electroosmotic flow associated with the transport of mannitol at physiologic pH to be in the anode-to-cathode direction. Subsequently, with the same electroosmotic and electrorepulsive contributions to the flux of lidocaine, a model hydrophilic drug observed for human skin and rabbit ear skin, Nicoli et al. concluded that rabbit ear skin is a suitable model for human skin in iontophoretic drug delivery.

Using cellulose membrane as barrier and thus further eliminating inter- and intra-sample variations that could occur with biological membranes, Tiwari and Udupa (2003a) investigated the various parameters affecting iontophoretic transport of ketoralac, a potent nonnarcotic analgesic and anti-inflammatory drug *in vitro*. Their results indicated that increasing drug concentration and current density increased the transport of ketorolac across the membrane while the presence of extraneous ions or increase in the viscosity of the vehicle decreased drug flux and variations in pH from 5.6 to 8 did not influence drug transport. Using glucose as a model nonionizable drug for comparison to evaluate mechanisms of iontophoretic transport of ketorolac, they showed that the total flux of ketorolac resulted from a combination of passive diffusion and electro transport with negligible contribution from electroosmosis. Tiwari and Udupa (2003b) also compared the transdermal transport of ketorolac across full thickness rat skin by iontophoresis and passive diffusion. They investigated electrical, device-related, and the physicochemical factors associated with iontophoretic drug delivery. Iontophoresis resulted in a flux of ketorolac 60 times greater than that achieved by passive diffusion. Increasing the loading dose of drug resulted in a nonlinear increase in the flux of ketorolac. Increasing the ionic strength of the donor solution from 0.06 to 1 M resulted in a sevenfold decrease in the achieved drug flux. Silver–silver and platinum electrodes transported ketorolac with the same efficiency and continuous current was more efficient in the transdermal transport of ketorolac than pulsed current. Pretreatment with ethanol did not increase the flux further by either passive diffusion or iontophoresis i.e., flux by iontophoresis was 60 times greater than for passive transport. Pretreatment with ultrasound followed by either procedure achieved the same flux level as ethanol pretreatment. Pretreatment with D-limonene in ethanol or D-limonene in ethanol and ultrasound significantly enhanced the iontophoretic transport of ketorolac compared to passive diffusion with or without the same pretreatment. Of all the variations in iontophoretic parameters investigated by Tiwari and Udupa, the combined pretreatment of skin with ethanolic D-limonene and ultrasound produced the greatest percutaneous flux of ketorolac.

12.7.7 Continuous versus Pulsed Current

Whether pulsed or continuous direct current should be used, is one of the controversies that exist in the field of iontophoresis. Continuous direct current causes skin polarization with time and this reduces the efficiency of delivery. This can be avoided by using pulsed direct current i.e., direct current delivered periodically. During the "off-period," the skin becomes depolarized returning to near its original state. Chien and co-workers (1989) applying the same current density (0.22 mA/cm^2) over the same 40 min period, were able to deliver twofold level of vasopressin *in vivo* in rabbits using pulsed current from the TPIS described earlier compared to the Phoresor system which delivers constant direct current. They also showed a peak plasma insulin level in 30 min in diabetic rabbits using TPIS (1 mA, 40 min) compared to 1–2 h for the Phoresor system (4 mA, 80 min). Ion transport using pulsed current may, however, be affected by the frequency. If the frequency is high, the efficiency of pulsed delivery is reduced (Bagniefski and Burnette, 1990). While Lui et al. (1988) observed a greater blood glucose reduction in diabetic rats using 2 kHz compared to 1 kHz, Haga et al. (1997) found no significant difference in the decrease in blood glucose levels when frequency was changed from 1 to 2 kHz, in the same species. Pillai et al. (2004) investigated factors affecting the optimization of electronic parameters for the iontophoretic delivery of insulin as a large model peptide. They concluded high flux could be achieved by modulating current density and duration, either low current strength for long duration or high current strength for short duration. Their study further showed that for extended current application, periodic current application was preferable to continuous current application to achieve comparable or higher drug flux. More studies need to be done to explain these discrepancies in results from different studies. Pulsed direct current was shown to be more efficient in delivering two decapeptides, Nafarelin, and LHRH with a greater portion of both drugs intact compared to continuous current (Raiman et al., 2004).

12.7.8 *In vitro–In vivo* Correlation

Recently, we compared the pharmacokinetic and local tissue disposition of diclofenac sodium delivered by iontophoresis and intravenous (IV) infusion (Hui et al., 2001). As shown in Figure 12.4 within 30 min of turning on the current, same plasma concentration was achieved by a 0.2 mA/cm^2 current as the IV infusion. The IV infusion at later time points

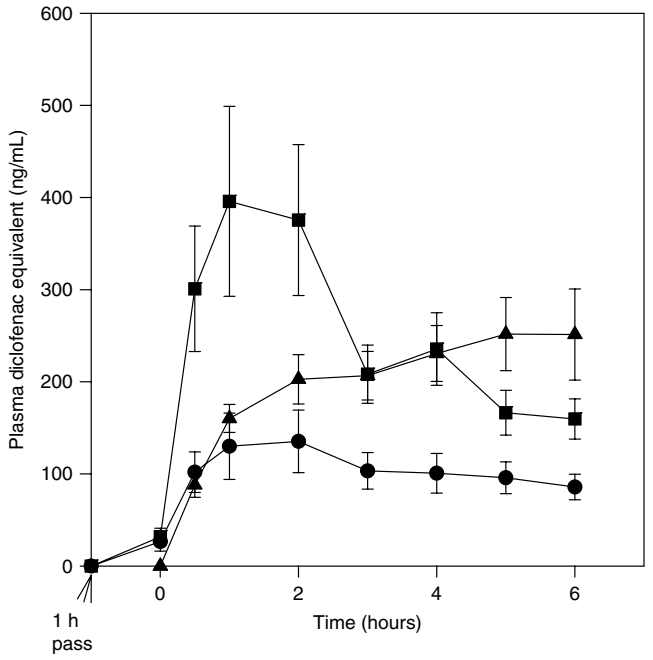

FIGURE 12.4 Plasma Diclofenac sodium concentrations (mean ± SEM, n = 4) over time in rabbit following IV infusion (Dose = 1.25 mg at 0.2 mg/h) and transdermal iontophoresis (Donor concentration =7 mg/mL; pH = 7.4. Key: ▲ IV infusion, ● 0.2 mA/cm^2, ■ 0.5 mA/cm^2. (From Hui et al., *J. Pharm. Sci*., 90, 1272, 2001. With permission.)

produced plasma concentrations surpassing iontophoresis under this conditions at all other time points up to 6 h. Whereas, iontophoresis of diclofenac sodium at 0.5 mA/cm^2 achieved superior plasma concentration than IV infusion from the time the current was initiated till the end of the treatment period. The peak plasma concentration observed between 1–2 h during six hours of iontophoresis was 132 and 371 µg/L with current densities of 0.2 and 0.5 mA/cm^2, respectively. The iontophoretic delivery rates calculated using the C_{max} values from the iontophoresis results and clearance values from the IV infusion data were 0.027 and 0.074 mg/(cm^2/h) for 0.2 and 0.5 mA/cm^2, respectively. The *in vivo* delivery efficiency for diclofenac sodium in rabbit was 0.15 mg/mA.h, a value double that of unpublished data obtained *in vitro* with hairless mouse skin. Bearing in mind differences in experimental conditions and species differences, the *in vitro* and *in vivo* data appear realistic. More studies need to be done in this area.

12.8 ADVANTAGES OF IONTOPHORESIS

Considering the complexity of iontophoresis compared to traditional dosage forms such as tablets, liquids, injections, ointments, and even passive transdermal patches, it must have advantages to enjoy a resurgence of interest.

Transdermal iontophoresis shares many of the advantages of passive transdermal drug delivery including the bypass of hepatic first-pass metabolism, avoidance of gut irritation, controlled drug delivery, and ease of termination of drug-input when necessary. An important consideration is patient compliance. The dosage regimens of many pharmacologic agents available for delivery through other routes pose a challenge to patients. An example is the need to be taken with or without food, dosing frequency (e.g., to be taken every 4–6 h) etc. In addition, the injectable route is particularly uncomfortable to many patients. In fact, Voight et al. (2002) demonstrated that columb-controlled iontophoresis (CCI) was a safe and efficient method of ocular aspirin administration in rabbits and, therefore, could be useful for the treatment of several underlying ocular diseases associated with prostaglandin activity in the eyes such as retinal detachment, diabetic neuropathy and retinopathy of prematurity, scleritis, episleritis, allergic conjunctivitis, and cystoid macular edema without the associated side effects e.g., gastric bleeding, aspirin-induced asthma, hepatotoxicity, platelet dysfunction associated with IV injection. Many drugs, which are available for systemic therapy cannot be delivered through many of the existing traditional dosage forms as they are subject to extensive hepatic first-pass metabolism and variable gut absorption. Many drugs including new biotech drugs (proteins, peptides, and oligonucleosides) (Meyer, 1988; Merino et al., 1997) and local anesthetics such as lidocaine (Gangarosa, 1981), which would have to be injected to derive maximum benefit, have been delivered efficiently using iontophoresis.

Since the rate of drug delivery is generally proportional to the applied current, the rate of input can, therefore, be preprogramed on an individual basis (Banga and Chien, 1988). The controllability of the device would eliminate the peaks and troughs in blood levels seen with oral dosing and injections. Patients can titrate their intake of drugs as required.

12.9 PROBLEMS ASSOCIATED WITH IONTOPHORESIS

Only a fraction of the charge introduced in iontophoresis is delivered suggesting that iontophoresis is not necessarily as efficient as theoretically proposed (Sage and Riviere, 1992).

Of more serious consideration, however, are the unwanted skin effects of iontophoresis arising from the system itself or drug formulation. Typically, side effects of iontophoresis with low voltage electrodes properly used are minimal; nevertheless, must be considered. These include itching, erythema, edema, small punctate lesions, and sometimes burns. A slight feeling of warmth and tingling is generally associated with iontophoresis (Kellog et al., 1989; Zeltzer et al., 1991; Ledger, 1992; Maloney et al., 1992). Erythema is also commonly reported and is thought to arise from skin polarization associated with continuous direct current. To minimize this, pulsed direct current has been advocated. Electric shock can occur when high current density is directed at the skin. To minimize this, the current should be increased slowly from zero to the maximum desired current level acceptable to the patient. Similarly, at the end of the procedure, current should

be returned from the maximum to zero in a stepwise manner. The effect of current on nerve fibers is thought to be responsible for the itching, tingling, and erythema.

The histological and functional changes that occur in animal skin following iontophoresis have been studied. Under similar delivery conditions (i.e., drug concentration, current density, and duration) as are used in humans, Moteiro-Riviere (1990) studied structural changes in porcine skin following iontophoresis of lidocaine. Light microscopy revealed epidermal changes. He, however, noted that similar changes were not observed following iontophoresis of other compounds suggesting the effects were largely due to the lidocaine rather than the electric current. Cho and Kitamura (1988) iontophoresing lidocaine through the tympanic membrane of the guinea pig, observed a loss of adhesion of the epidermis to underlying connective tissue and retraction of noncornified epidermal cells. Jadoul et al. (1996) used FTIR and SAXS to study isolated rat skin and human skin from cadaver following prolonged iontophoresis. While FTIR revealed transient increases in the hydration of the outer layers of the stratum corneum but no increase in lipid fluidity, SAXS showed that iontophoresis induced a disorganization of the lipid layers. This was also reversible within days of the procedure. Using wide-angle x-ray scattering (WAXS), the authors did not find evidence either of modification of the intralamellar crystalline packing of lipids or of keratin.

The answer to what should be the upper limit of current tolerable to humans is not very straight forward, as what may be just discernible to one patient may be uncomfortable to another. Generally, however, 0.5 mA/cm^2 is cited (e.g., Abramson and Gorin, 1941; Banga and Chien, 1988; Ledger, 1992). Molitor and Fernandez (1939) found that the greater the surface area of the electrode, the larger the tolerable current but the relationship is curvilinear. Small punctate lesions are associated with electric current traveling through a path of least resistance into the skin. Common sense thus dictates that iontophoresis should not be used on skin showing signs of damage. Pain and burns arising from iontophoresis are linked to electrochemical reactions, which occur at the electrodes and involve the electrolysis of water to generate hydronium and hydroxyl ions resulting in pH changes (Sanderson et al., 1989). Much earlier, however, Molitor and Fernandez (1939) using continuous flow electrodes, which did not generate hydroxyl and hydronium ions and, therefore, did not produce any pH changes, showed that burns could not solely be related to pH changes.

Erythema is the most common side effect associated with iontophoresis and could be due to nonspecific skin irritation such as occur with the delivery of an irritant drug. Erythema may be due to a direct effect of electric current on blood vessels or current induced release of histamine, prostaglandins, or other neurotransmitters leading to local vasodilatation of the affected area. It has also been suggested that electric current can stimulate specific classes of noiceptors, the C-fibers causing them to release the potent vasodilators, substance P, and calcitonin gene-related peptide (CGRP) (Brain and Edwardson, 1989; Dalsgaard et al., 1989). Whatever the cause of the erythema, it is usually transient and not associated with any permanent changes in the skin.

Delayed-type contact sensitivity to components of the iontophoresis system, electrodes, and electrode gels (Fisher, 1978; Zugerman, 1982; Schwartz and Clendenning, 1988), or to the drug being delivered (Teyssandier et al., 1977; Holdiness, 1989) has been reported.

Another consideration in choosing iontophoresis for drug delivery is cost. Iontophoresis requires a power source to supply electrical energy. Even though the power requirement for a unit delivery may be small, repeated applications would require a considerable investment in battery supply. Better batteries than those currently used need to be developed.

An important consideration in the use of iontophoresis for drug delivery especially for unstable compounds is whether they are delivered intact or degraded. This has recently been addressed by Brand et al. (2001) who delivered antisense, phosphorothioate oligonucleotides into rats by iontophoresis. They were able to measure the decline in CYP3A2 levels suggesting that the antisense agent was successfully delivered in sufficient therapeutic amounts and intact. Raiman et al. (2004) compared the effect of constant and pulsed iontophoresis on the delivery and stability of LHRH and Nafarelin in human skin. They observed that pulsed direct current was more efficient in the transport of both compounds across human epidermis compared to constant current with the percentage of intact LHRH delivered being slightly higher with pulsed current with five degradation products detected for either method. With Nafarelin, however, the peptide was delivered completely intact using pulsed current with no degradation products detected in the receiver medium. A more stable analog of LHRH acting as a superagonist has also been used in place of hormone to ensure that clinically relevant amounts of the drug is delivered intact across full thickness hairless mouse skin (Miller et al., 1990).

Even though proteolytic activity is considerably less in the skin compared to the oral mucosa, biotransformation of drugs nevertheless, occurs in the skin and can be an important issue to be considered in iontophoresis. Enzymatic degradation of proteins and peptides during iontophoresis has indeed been reported (Steinstrasser and Meckle, 1995). The coapplication of protease inhibitors is one way of reducing enzymatic degradation of peptides and has been addressed as illustrated in the successful *in vivo* nasal delivery of vasopressin in rats and salmon calcitonin across rat skin *in vivo* (Morimoto et al., 1991, 1992).

Iontophoresis is contraindicated in patients with high susceptibility to applied currents and in patients with known hypersensitivity to the drug in question. Iontophoresis should be avoided in patients with electrically sensitive implants such as pace makers. To improve acceptability by both prescribers and patients, more studies need to be done in the field of iontophoresis to minimize unwanted side effects and improve safety.

12.10 DIFFERENTIAL CLINICAL DIAGNOSES, CURRENT AND FUTURE TREATMENT MODALITIES USING IONTOPHORESIS

Lim et al. (2004) compared the response of normal subjects and patients with chronic heart failure (CHF) to iontophoresed Urotensin II (U-II), a vasoactive peptide. They observed that while normal subjects exhibited a dose-related skin microvasculature vasodilator response to U-II measured by the laser Doppler velocimeter, in contrast, patients with CHF exhibited a dose-related vasoconstrictor response. They, therefore, concluded that in addition to the direct effects of U-II on the myocardium, it may contribute to the increased peripheral vascular tone characteristic of CHF and therefore, its blockade may be a target in the treatment of CHF.

Because injection of local anesthetics at sites of dermatologic procedures in children is not viewed positively due to the pain and fear associated with injections, iontophoresis has been explored as a viable option by different groups of investigators. A few of the studies and the findings are detailed here. In a randomized, cross over study, Galinkin et al. (2002) compared local anesthesia achieved by lidocaine iontophoresis and a eutectic mixture of local anesthetics (EMLA®) in 26 patients, ages 2–16 years requiring multiple venous cannulation. During the third session, each patient received his or her preferred method of anesthesia, and pain during venipuncture was assessed by the patients, parents, investigator, and technician performing the blood draw using a 100 mm visual analog scale (VAS). The observers also used the Eastern Ontario pain scale to rate the children's pain. They concluded that both methods, iontophoresis of lidocaine or EMLA provided the same level of pain relief for insertion of IV catheters and, therefore, that lidocaine iontophoresis would be a useful noninvasive method of achieving dermal anesthesia for venous cannulation.

Zempsky and Parkinson (2003) performed a prospective, double blind placebo controlled assessment of iontophoresis of 2% lidocaine with 1:100,000 epinephrine in 60 children, ages 4–16 years requiring dermatologic procedures. Of the 31 pediatric patients that received lidocaine, only two required supplemental anesthesia compared to 27 of the patients who received placebo ($p < 0.001$). The lidocaine treated patients reported a significantly lower pain on the Oucher pain scale following their procedure ($p < 0.001$). The parents and investigators also rated the pain lower ($p < 0.001$). Erythema and blanching that was observed on the treated sites in 58 of the 60 patients resolved within 1 h post treatment. Using the Northstar ionotophoretic drug delivery system (IDDS), Kearns et al. (2003) delivered Lidocaine in children, 5–10 years using a current of 1.78 mA. Local anesthesia was achieved in 10 min compared to 40–60 min normally achieved by eutectic mixtures of anesthetics and EMLA cream. In addition, no skin irritation was observed for up to 24 h following iontophoresis and no subject reported any pain or discomfort with this method of lidocaine delivery. With minimal systemic bioavailability of lidocaine in all subjects (10 ng/mL) and excellent tolerability, they concluded that IDDS was suitable for clinical use in pediatrics. The conclusion from these studies is that iontophoresing lidocaine is a safe, well-tolerated method of topical anesthesia in pediatric patients before dermatologic procedures.

With the obvious potential advantages of ocular iontophoresis over traditional ocular drug delivery methods e.g., drops and ointments including the ability to rapidly deliver a broad range of drugs including large peptides and oligonucleotides beyond the anterior segment of the eye, Parkinson and co-workers (2003) investigated the tolerance of ocular iontophoresis in healthy volunteers. Using Ocuphor™ hydrogel drug delivery applicators, they transclerally iontorephesed isotonic balanced solution in 24 male and female subjects, in a three-period crossover study in which 16 subjects received 0 mA and 2 DC currents from a choice of 0.1, 0.5, 1, 2, 3, 4 mA for 20 min. Six subjects received either 3 mA for 20 min or 1.5 mA for 40 min (equivalent to 60 mAmin total charge). Using a subjective VAS and an objective ophthalmic assessment before and up to 22 h following treatment, to evaluate safety and tolerance of the treatment parameters they found a good tolerance and no clinically significant ophthalmic changes occurring with 0–3 mA current delivery for 20 min or 1.5 mA current application for 40 min. Two of the four subjects exposed to 4 mA current for 20 min reported a burning sensation under the applicators, which resolved by 22 h postdosing.

Eljarrat-Binstock and colleagues (2004) performed ocular delivery of gentamycin by iontophoresis, from a drug-loaded disposable hydroxyethyl methacrylate (HEMA) hydrogel, with an applied current of 1 mA for 1 min in rabbit eye. The study used three control groups consisting of animals with mock iontophoretic treatment for 1 min i.e., no current applied, animals given subconjunctival injection of 0.25 mL of 40 mg/mL gentamycin solution, and animals treated with topical eye drops of fortified gentamycin (1.4%) applied every 5 min for 1 h. They measured gentamycin levels in the cornea and aqueous humor by fluorescence polarization immunoassay. Peak concentrations of gentamycin in the cornea and aqueous humor were achieved at 0 and 2 h respectively following iontophoresis. The levels of gentamycin following a single iontophoretic treatment were 12–15 times higher than from injection or topical instillation and were much higher still for mock iontophoresis. Therapeutic concentrations of gentamycin were maintained for 8 h following cessation of current. This suggests that short duration iontophoresis has potential application for increasing the penetration of antibiotics and other drugs to the anterior portions of the eye and maintaining therapeutic levels of drug at the desired target for long periods of time. Further work done by Raiskup et al. (2006) using a solid hydrogel made from HEMA cross-linked with ethyleneglycol dimethacrylate (EGDMA) as a probe to deliver gentamycin into rabbit by iontophoresis by applying 1.5 mA current for 60 s compared to eye drops with 1.4% gentamycin, observed high drug concentrations in the sclera and in the retina and in the sclera four hours after transscleral

iontophoresis, with the lowest concentration observed in vitreous fluid. They concluded that HEMA/EGDMA hydrogels are promising for more efficient ocular iontophoresis of gentamycin.

Transcleral methylprednisolone (solumedrol) iontophoresis was used successfully to treat severe acute corneal graft rejection (Halhal et al., 2003). Treatment consisted of solumedrol iontophoresis under topical anesthesia using a current of 1.5 mA for 3 min, once a day for 3 days. Topical corticoid therapy using dexamethasone was reduced to three drops per day. Ocular iontophoresis was well tolerated with no patient complaints and no observed side effects. The therapeutic efficacy of solumedrol iontophoresis in corneal rejection was assessed by the achievement of corneal transparency, visual acuity, and measurement of corneal inflammation parameters, which had all cleared.

Intraocular retinoblastoma is treated by systemic chemotherapeutic delivery of carboplastin. In addition to significant morbidity and mortality associated with systemic carboplastin, it may be associated with future occurrences of cancer in pediatric patients because of mutation at the RB-1 gene. Hayden et al. (2004) explored coulomb-controlled ocular iontophoretic delivery of carboplastin (5 mA/cm^2 for 20 min) as an alternative and safer direct delivery of the drug using a single IV infusion of carboplatin and a single subjunctival injection of carboplastin in New Zealand white rabbits as controls. Analyses of the retina, choroids, vitrous humor, and optic nerve showed that iontophoresis resulted in significantly higher levels of carboplastin compared to both IV injection and subconjunctival injection of the drug. In addition, much higher systemic plasma concentrations of carboplastin were achieved following IV injection than by subconjunctival injection and coulomb-controlled iontophoresis with no ocular toxicity observed following the later methods of delivery. They thus, concluded that iontophoresis might offer a means of delivering high levels of the cytotoxic drug directly to target tissues for the clinical treatment of retinoblastoma with concomitant reduction in the systemic exposure.

Khan et al. (2003) iontophoresed Acetylcholine (ACH) and sodium nitroprusside (SNP), in 145 normal healthy children aged 11–14 years and measured skin microvasular responses by laser Doppler imaging. They divided the subjects into a quintile, based on 2-h postfeeding glucose levels. The subjects in the upper glucose quintile expressed significantly lower vasodilation to ACH and SNP than those in the lower quintile. In some of the children, the macrovascular function was negatively associated with abnormal adiposity. In addition, they found that waist to hip ratio and fasting insulin resistance was higher in the upper quintile than the lower quintile. Fasting triglyceride were also greater in the upper quintile than the lower. Their overall conclusion is that risk factors for adult cardiovascular disease begin to cluster much earlier in life in normal children and these may have important consequences for the risk of developing artherosclerosis later in life. Thus, screening much earlier in life by iontophoresing ACH and SNP and measuring microvascular response, and taking preventative actions in otherwise normal looking children will bode well for their health as adults.

In a separate study, using iontophoresis, Koïtka and coworkers (2004) explored the causative mechanism for the prevalence of foot ulcers in diabetics. They iontophoresed two agonists, ACH and SNP and compared the cutaneous blood flow in normal and diabetic patients using Laser Doppler flowmetry and found that while normal subjects had pressure induced vasodilation at the foot level, it was largely absent in diabetic patients. They postulated that the absence of cutaneous vasodilator response to progressive pressure strain might be related to interactions between changes in unmyelinated C fibers and the endothelium and, therefore, relevant in the high prevalence of foot ulcers in diabetics.

Iodide was applied in two groups of patients suffering from dry eye syndrome or keracojunctivitis sicca, 16 of them by iontophoresis and 12 patients without current for a total of 10 days (Howarth-Winter et al., 2005). The study used 0.5% sodium iodide solution of pH 8 at which the iodide ions were negatively charged. Since the treatment was over an extended period of time, for safety purposes, a lower current, 0.2 mA applied for 7 min. Based on the significantly greater improvement in clinical symptoms and reduced frequency of use of artificial tears observed in the patients that received iontophoresed iodide, versus the noniontophoresed group, the researchers concluded that iontophoresis was a safe and effective method of dry eye syndrome. Leboulanger et al. (2004) evaluated reverse iontophoresis as a noninvasive alternative method of monitoring lithium ion *in vivo* in bipolar and schizo-affective disorder patients in place of blood measurements. They extracted lithium and other cations (sodium, potassium, and calcium) from 23 bipolar and schizo-affective patients over a 2-h period with an applied current of 0.8 mA and accurately assayed all cations by ion chromatography with blood samples drawn from the same patients serving as controls. Normalization of the lithium flux with that of sodium, which served as an internal standard allowed them to correctly calibrate the method with the amount of lithium ion extracted being proportional to the serum concentration. Nicoli and Santi (2006) were able to measure Amikacin, a model aminoglycoside antibiotic with broad spectrum Gram-negative activity, delivered by anodal iontophoresis at the cathode by reverse iontophoresis, suggesting that if fully developed and optimized, this might offer an accurate means of monitoring the antibiotic topically applied.

Sakamoto et al. (2004) topically iontophoresed antisense oligonucleotide for mouse interleukin [IL-10 (AS6)] onto lesions on mouse skin with established dermatitis of a human atopic dermatitis model (NC/Nga mice). 30% of the applied dose of AS6 penetrated the skin and was distributed in the epidermis and upper dermis resulting in decreased levels of mRNA and protein of IL-10 in the lesions of NC/Nga mice, with IL-4 levels unaffected. Repeated applications of AS6 inhibited IL-10 production and resolved the skin lesions. Though the precise mechanism(s) by which inhibition of IL-10 resolves skin lesions is unknown, the study demonstrated that this may facilitate the

treatment of atopic dermatitis in human subjects and further contribute to the knowledge of the disease etiology.

12.11 APPLICATIONS OF IONTOPHORESIS IN DERMATOLOGY

In the past, iontophoresis was found useful in local delivery of pharmacologic agents. Iontophoresis has been used for the treatment of various dermatologic conditions including lupus vulgaris using zinc. Before the advent of antibiotics, infections were treated by the iontophoresis of metals e.g., the treatment of streptococcal infections with copper sulfate. Other conditions that have benefited from the use of iontophoresis include lichen planus, scleroderma, plantar warts, hyperhydrosis, infected burn wounds, and achieving local anesthesia. Even though Botulinum toxin type A has recently been added to the treatment algorithm for axillary or palmoplantar hyperhydrosis (Lowe et al., 2002; Lauchli and Burg, 2003), because of the pain and cost associated with the treatment, iontophoresis with its long established safety history, remains an inexpensive and popular treatment choice especially for palmoplantar hyperhydrosis (Karacoc et al., 2002; Thomas et al., 2004; Haider and Solish, 2005). Bursitis and other musculoskeletal conditions have been treated with iontophoresed corticoids (Harris, 1982). Summaries of dermatologic applications of iontophoresis have been made by Sloan and Soltani (1986) and Singh and Maibach (1994), Rai and Srinivas (2005). Of greater interest in this era is the use of iontophoresis for controlled systemic drug delivery and for targeting deep tissue penetration. Recently, "reverse iontophoresis" involving the extraction of material from the body for the purposes of clinical chemistry has been described (Guy, 1995; Guy et al., 1996). Although glucose is not charged, iontophoresis can markedly increase its passage across the skin by electroosmosis (Merino et al., 1997; Tierney et al., 2000) and this has been applied for the noninvasive monitoring of diabetics' blood sugar levels (Tamada et al., 1995; Svedman and Svedman, 1997; Tierney et al., 2001a,b; Potts et al., 2002). In addition to drug delivery, with the availability of sensitive assay methods, iontophoresis is thus being touted as a diagnostic tool. The "Glucowatch® Biographer" was in fact approved by the Food and Drug Administration in 2001 and launched in the United States in April 2002. Sieg et al. (2004a,b) explored the concept of calibration-free glucose monitoring using sodium ion as an internal standard with aims of improving the reverse iontophoresis method of assessing glycemia in diabetics employed in the Glucowatch technology. They found that the glucose ions extracted iontophoretically, reflected the blood glucose concentration profiles and that sodium extraction was essentially constant mirroring the known constant systemic concentration of sodium in contrast to the variation in extracted potassium ions observed in about two-thirds of the study population. They concluded that calibration with a blood sample was not necessary in using sodium ion as an internal standard in blood glucose monitoring. Recurrence of cold sores has been attributed to difficulties in getting sufficient drug amounts to the infected tissues. Morrel et al. (2006) performed a multicenter placebo controlled clinical trial in which they explored a low voltage iontophoretic delivery of 5% acyclovir as well as topical application in 200 patients with an incipient cold sore outbreak at the erythema or papular/edema lesion stage. The results demonstrated that the outbreak was aborted at a significantly quicker pace in subjects that received active iontophoresis than the vehicle group. The investigators suggested that iontophoresis should be further investigated for the treatment of herpes labialis.

12.12 DEVICES APPROVED OR AWAITING APPROVAL

Iomed's Iontocaine (Numby stuff®), a mixture of 2% lidocaine HCl and epinephrine 1:100,000 (0.01 mg/mL) in the phoresor iontophoresis system was approved in 1995 and is indicated for local dermal anesthesia during local surgeries. Empi Dupel® electrodes approved as a device by the FDA and not in association with any active, has been used since 1992 by sports medicine practitioners for localized tissue delivery of dexamethasone and other corticosteroids for the relief of acute local inflammatory and other sports injury related conditions. With the approval of the Glucowatch Biographer, it is more likely in the future that iontophoresis will be used as a diagnostic tool for other disease conditions. Vyteris is awaiting approval for an iontophoresis device to deliver lidocaine for anesthesia in children (Cleary, 2003). The Vyteris device has the advantage of being prefilled with drug and is current controlled, thus reducing irritation and inducing a rapid onset of action, achieving local anesthesia in 10 min (Rhodes, 2002). ALZA Corporation, a division of Johnson & Johnson received marketing authorization from the European commission to market its IONSYS™ in the European Union (PR Newswire, 2006). This is the first compact (weight: 15 g, dimensions, $3.3'' \times 1.9''$), noninvasive patient-activated transdermal system (PATS) delivering 40 µg/dose of fentanyl hydrochloride, a narcotic analgesic over a 10 min period for use in patients with acute postoperative pain. Patients can initiate for up to 6 doses/h for up to 24 h from the time of first dosing or a maximum of 80 doses, whichever comes first (Koo, 2005). Scale up and launch of the product is expected in 2007. ALZA having originally submitted an NDA for licensure of IONSYS in the United States to the FDA in September 2003 and receiving an approvable letter in mid 2004 had since resubmitted an NDA for the device in November 2005 (Medical Letter, 2006) and received approval for marketing the device on May 23, 2006 (Reuters, 2006).

12.13 CONCLUSIONS

Strides in the biotech industry will continue to result in a large number of drugs, many of which would be proteins,

peptides, and oligonucleotides, most of which at present can only be delivered by the injectable route. In addition, many of the old drugs already in use have the same dosage form requirements with its associated problems. Iontophoresis provides an attractive alternative to the existing dosage forms in delivering these drugs both for local as well as systemic indications. The fact that it could allow for a programmable rate-controlled delivery of drugs makes it particularly attractive. Considerable progress has been made in hydrogel technology and the world of formulation science as well as in microelectronics and battery technology, all of which have been harnessed in improving iontophoresis technology. With high throughput low-cost manufacturing capability, many controllable, miniaturized, iontophoretic devices have been fabricated and are available for the iontophoresis delivery of many suitable drug candidates. The recent approval of IONSYS for iontophoretic delivery of fentanyl by both EU- and US regulatory bodies, will more than likely bolster the development efforts being made by many companies in this area. It is not far reaching to predict that the medical world should expect many more marketing approvals for iontophoretic delivery systems for drugs of serious therapeutic consequences in the not too distant future.

Like any new technology, research will continue to better define and fine-tune the parameters to better maximize the safety, acceptability, and efficiency of iontophoresis as a routine dosage form.

13.1 CLINICAL ASPECTS

Irritant contact dermatitis occurs when chemicals or physical agents damage the surface of the skin. The clinical presentation is highly variable and depends on many factors including amount and strength of the irritant, length and frequency of exposure, environmental factors, and skin susceptibility. In addition to the typical clinical features of dermatitis, the clinical presentations may change according to the physicochemical nature of the irritant concerned (Table 13.1). Ulcerative lesions can develop from skin contact with strong acids or strong alkalis like calcium oxide, calcium hydroxide, sodium hydroxide, sodium metasilicate, sodium silicate, potassium cyanide, and trisodium phosphate. Compounds of beryllium, arsenic, or cadmium are also capable of inducing ulcerations. Chrome ulcers are the most common type of cutaneous ulcers induced by irritants. Solvents such as acrylonitrile and carbon bisulfide as well as gaseous ethylene oxide are examples of contactants that may induce ulceration in certain occupations. Cutaneous ulcers

TABLE 13.1
Clinical Features That May Suggest the Etiology of Irritant Contact Dermatitis

Ulcerations	Strong acids, especially chromic, hydrofluoric, nitric, hydrochloric, sulfuric. Strong alkalis, especially calcium oxide, sodium hydroxide, potassium hydroxide, ammonium hydroxide, calcium hydroxide, sodium metasilicate, sodium silicate, potassium cyanide, trisodium phosphate. Salts, especially arsenic trioxide, dichromates. Solvents, especially acrylonitrile, carbon bisulfide. Gases, especially ethylene oxide, acrylonitrile
Folliculitis and acneiform	Arsenic trioxide, glass fibers, oils and greases, tar, asphalt. Chlorinated naphthalenes, polyhalogenated biphenyls, and others.
Miliaria	Occlusive clothing and dressing, adhesive tape, ultraviolet, infrared, aluminum chloride
Pigmentary alterations	Hyperpigmentation, any irritant or allergen, especially phototoxic agents such as psoralens, tar, asphalt, phototoxic plants, and others. Metals, such as inorganic arsenic (systemically), silver, gold, bismuth, mercury. Radiation, ultraviolet, infrared, microwave, ionizing. Hypopigmentation, *p-tert*-amylphenol, *p-tert*-butylphenol, hydroquinone, monobenzyl ethyl hydroquinone, monomethyl hydroquinone ether, *p-tert*-catechol, *p*-cresol, 3-hydroxyanisole, butylated hydroxyanisole, 1-*tert*-butyl-3, 4-catechol, 1-isopropyl-3, 4-catechol, 4-hydroxypropriophenone
Alopecia	Borax, chloroprene dimers
Urticaria	Numerous chemicals, cosmetics, animal products, foods, plants, textile, woods
Granulomas	Keratin, silica, beryllium, talc, cotton fibers, bacteria, fungi, parasites, and parasite parts

develop from the direct corrosive and necrotizing effect of the chemical on the living tissue. Exposed areas, where both friction and chemical irritation are associated, are most susceptible for ulcers; minor preceding trauma in the exposed skin increases the risk. The ulcers tend to be deeper, with an undermined thickened border, and the exudate under the covering crusts predisposes to infection. Cutaneous granulomas are considered a variant of irritant contact dermatitis, caused by a biologically inactive substance inoculated into the skin, where macrophages respond with phagocytosis to the foreign body inoculation, and even giant cells may be seen (Epstein, 1983). A granuloma appears as a focal, tumid lesion persisting chronically in its primary site. It is subjectively symptomless. Powders, lead, and metals such as metallic mercury, beryllium, and silica are examples of substances that elicit toxic skin granulomas (Kresbach et al., 1971).

The actual types of irritant contact dermatitis, with reference to major characteristics in the clinical appearance, are listed in Table 13.2.

TABLE 13.2
Clinical Classification of Irritation

Irritation	Onset	Prognosis
Acute (primary) irritant dermatitis	Acute, often single exposure	Good
Irritant reaction	Acute, often multiple exposures	Good
Delayed acute irritant dermatitis	Delayed, 12–24 h or longer	Good
Subjective irritation	Acute	Excellent
Suberythematous irritation	Slowly developing	Variable
Cumulative irritant contact dermatitis	Slowly developing (weeks to months)	Variable
Traumiterative dermatitis	Slowly developing (weeks to months)	variable
Traumatic irritant dermatitis	Slowly developing following trauma	Variable
Pustular and acneiform dermatitis	Moderate-slow developing (weeks to months)	Variable
Exsiccation eczematoid	Moderate-slow developing (weeks to months)	Variable
Friction dermatitis	Moderate-slow developing (weeks to months)	Variable

13.1.1 Acute Irritant Dermatitis (Primary Irritation)

When exposure is sufficient and the offending agent is potent, such as acids or alkaline solutions, classic symptoms of acute skin irritation are seen. Contact with a strong primary irritant is often accidental, and an acute irritant dermatitis is elicited in almost anyone independent of constitutional susceptibility. This classic, acutely developing dermatitis usually heals soon after exposure. The healing of acute irritant dermatitis is described as a *decrescendo phenomenon,* where the irritant reaction quickly peaks and then immediately begins to heal upon removal of irritant. In unusual cases the dermatitis may persist for months after exposure, followed by complete resolution. The availability of the material Safety Data Sheet and data from the single-application Draize rabbit test combined with activities of industrial hygienists and other informed personnel greatly decreased the frequency of such dermatitis in industry. Further educational efforts and appropriate industrial engineering should make this form of irritation a rarity.

13.1.2 Delayed, Acute Irritant Contact Dermatitis

Some chemicals like anthralin (dithranol), benzalkonium chloride, and hydrofluoric acid are chemicals, which may elicit a retarded inflammatory response, so that inflammation is not seen until 8–24 h or more after exposure (Malten et al., 1979; Lovell et al., 1985) (Table 13.3). Except for the delayed onset, the clinical appearance and course resemble those of acute irritant contact dermatitis. The delayed acute irritant

TABLE 13.3
Chemicals Inducing Delayed Acute Irritation

Anthralin
Bis(2-chloroethyl)sulfide
Butanedioldiacrylate
Dichloro(2-chlorovinyl)arsine
Epichlorhydrin
Ethylene oxide
Hydrofluoric acid
Hexanedioldiacrylate
Hydroxypropylacrylate
Podophyllin
Propane sulfone

dermatitis, because of its delayed onset, is often confused with allergic contact dermatitis; appropriately performed diagnostic patch tests easily separate the two.

13.1.3 Irritant Reaction

Individuals extensively exposed to irritants, in the first months of exposure, often develop erythematous, chapped skin on the dorsum of the hands and fingers. This irritant reaction (Fregert, 1981; Griffiths and Wilkinson, 1985; Hjorth and Avnstorp, 1986) may be considered a preeczematous expression of acute skin irritation. It is frequently seen in hairdressers and variable wet work-performing employees repeatedly exposed. Repeated irritant reactions sometimes lead to contact dermatitis, with good prognosis, although chronic contact dermatitis may also develop.

13.1.4 Subjective/Sensory Irritation

Subjective irritation is experienced by some individuals ("stingers") in contact with certain chemicals (Frosch and Kligman, 1982; Lammintausta et al., 1988b; Jourdain et al., 2005). Itching, stinging, or tingling is experienced, for example, from skin contact with lactic acid, which is a model for no visible cutaneous irritation. The threshold for this reaction varies between subjects, independent of susceptibility to other irritation types. The quality as well as the concentration of the exposing agent is also important, and neural pathways may be contributory, but the pathomechanism is unknown. Some sensory irritation may be subclinical contact urticaria. Screening raw ingredients and final formulations in the guinea pig ear swelling test (Lahti and Maibach, 1985) or the human forehead assay allows us to minimize the amount of subclinical contact urticaria. Although subjective irritation may have a neural component, some studies suggest an altered baseline biophysical parameters representing a trend toward barrier impairment (Seidenari et al., 1998). Additionally, the blood vessel may be more responsive in "stingers" than in nonstingers (Lammintausta et al., 1988b; Berardesca et al., 1991a). At least 10% of women complain of stinging with certain facial products; thus, further work is needed to develop a strategy to overcome this type of discomfort.

13.1.5 Suberythematous Irritation

In the early stages of skin irritation, subtle skin damage may occur without visible inflammation. As a correlate of no visible irritation, objectively registered alterations in the damaged epidermis have been reported (van der Valk et al., 1985; Lammintausta et al., 1988b; Charbonnier et al., 2001). Common symptoms of suberythematous irritation include burning, itching, or stinging. Consumer dissatisfaction with many chemicals may result from exposure to this low-grade irritation; thus, the patient feels more than the physician observes. It is customary in Japan to screen new chemicals, cosmetics, and textiles for subtle signs of stratum corneum damage, employing replicas of stratum corneum (the Kawai method) (Kawai, 1971).

13.1.6 Cumulative Irritant Dermatitis

Multiple subthreshold skin insults induced by repeated applications of weak irritants may lead to cumulative cutaneous irritation. In cumulative cutaneous irritation, the frequency of exposure is too high in relation to the skin recovery time. Acute irritant skin reaction is not seen in the majority of patients, but mild or moderate invisible skin changes. Repeated skin exposures and minor reactions lead to a manifest dermatitis when the irritant load exceeds the threshold for visible effects. The development of a cumulative irritant dermatitis was carefully documented by Malten and den Arend (1978) and Malten et al. (1979). Classic signs are erythema and increasing dryness, followed by hyperkeratosis with frequent cracking and occasional erythema. Cumulative irritant dermatitis is the most common type of irritant contact dermatitis. This syndrome may develop after days, weeks, or years of subtle exposure to chemical substances. Variation in individual susceptibility increases the multiplicity of clinical findings. Delayed onset and variable attack lead to confusion with allergic contact dermatitis. To rule out allergic etiology, appropriate diagnostic patch testing is indicated. Models of cumulative irritant dermatitis have been developed (Freeman and Maibach, 1988; Widmer et al., 1994).

13.1.7 Traumiterative Irritant Dermatitis

Traumiterative irritant dermatitis, in the older German literature ("traumiterative" = traumas repeating) (von Hagerman, 1957; Agrup, 1969), is a consequence of too frequent repetition of one impairing factor. This syndrome and cumulative irritant dermatitis are very similar clinically.

13.1.8 Traumatic Irritant Dermatitis

Traumatic irritant dermatitis develops after acute skin trauma. The skin does not completely heal, but erythema, vesicles or vesicopapules, and scaling appear. The clinical course later

resembles nummular (coin-shaped) dermatitis. This may occur after burns or lacerations and after acute irritant dermatitis: It may be compounded by a concurrent allergen exposure. The healing period is generally prolonged. Often these patients are considered to have a factitial dermatitis because of a healing phase followed by exacerbation. Although factitial (unnatural) aspects may occur in some patients, this peculiar form of irritation appears to be a disease *sui generis*. Its chronicity and recalcitrance to therapy provides a challenge to both patient and physician. We have no information explaining why the occasional patient develops this phenomenon, and how this patient differs from the general population. Many such patients are considered factitial in origin if the dermatologist is unaware of the syndrome.

13.1.9 Pustular and Acneiform Irritant Dermatitis

Pustular and acneiform irritant dermatitis may develop from exposure to metals, oils and greases, tar, asphalt, chlorinated naphthalene, and polyhalogenated naphthalene (Wahlberg and Maibach, 1981, 1982; Fischer and Rystedt, 1985; Dooms-Goossens et al., 1986). In occupational exposure, only a minority of subjects develop pustular or acneiform dermatitis. Thus, the development of this type of irritant contact dermatitis appears to be dependent on both constitutional and chemical factors. Cosmetic dermatitis commonly assumes this morphology.

13.1.10 Exsiccation Eczematoid

Exsiccation eczematoid is seen mainly in elderly individuals during the winter months, when humidity is low. Patients suffer from intensive itching, and their skin appears dry with ichthyosiform scaling. The condition is thought to be due to a decrease in skin surface lipid and persistence of both peripheral and nonperipheral corneodesmosomes in the upper stratum corneum (Simon et al., 2001). In severe cases, a reduction of skin content of amino acid due to low profilaggrin biosynthesis was found (Horii et al., 1989).

13.1.11 Friction Dermatitis

This is sometimes seen on the hands and knees in the workplace, and results from frictional trauma. The syndrome has been characterized by Susten (1985).

13.2 EXTERNAL FACTORS

The variable clinical response to primary irritants is attributed to factors such as chemical characteristics of the irritants, physical nature, binding capacity, polarity, exposure time, cumulative effect with other irritants and environmental conditions.

13.2.1 Irritants

Many chemicals qualify as irritants when the exposing dose is high (Kligman and Wooding, 1967). Increasing the concentration of a compound may change the pattern of the response; sodium lauryl sulfate (SLS) and croton oil induce erythema with low concentrations and bullae with high concentrations (Bjornberg, 1968). Quantitative differences in the skin response to different concentrations of SLS were also noted (Agner et al., 1990; Aramaki et al., 2001; Loffler et al., 2001). It is believed that the biological effect of a substance depends on the amount of the molecules (molarity) rather than the total mass of the molecules (concentration) (Tupker, 2003). In addition, the absorbed dose may vary when the substance is suspended in different vehicles (Cooper, 1985; Gummer, 1985). The solubility of the irritant in the vehicle and the inherent irritancy of the vehicle have an impact on each reaction (Flannigan and Tucker, 1985).

13.2.2 Exposure

The effective tissue dose depends on application time and duration on and in the skin.

Long time of exposure and large volume increase penetration, thus, greater response may be expected (Aramaki, 2001). If exposure is repeated, the recovery from previous exposure(s) affects the subsequent response. Sometimes a shorter, repeated exposure leads to a lengthened recovery period (Malten and den Arend, 1978). This was demonstrated in experimental studies with dimethyl sulfoxide (DMSO), where intermittent application led to a different response as compared with one lengthened application (Lammintausta et al., 1988a). Skin may adapt to topical irritants through accommodation. A single exposure can induce resistance to subsequent exposures in the form of an adaptive downregulation of the inflammatory response or by changes in the stratum corneum lipids (Guin, 1991; Kawai, 1991; Wahlberg, 1992; Widmer et al., 1994; Heinemann, 2005). However, in a recent study adaptive hyposensitivity was not observed after long-term repetitive irritant exposure (Branco, 2005). These experimental observations are consistent with the multiple clinical appearances of cumulative irritant dermatitis.

13.2.3 Multiple Simultaneous Exposures

Simultaneous or subsequent exposure may lead to an additive effect and increased reaction, although each chemical alone would elicit only a minor reaction, or none (Fluhr et al., 2005a,c). However, subsequent exposure may lead to a decreased response. For instance, exposure to a detergent and then to a soap led to a weaker response than exposure to a detergent alone. The detergent was washed away by the subsequent soap exposure (Malten, 1981). Similarly, exposure to benzalkonium chloride, a cationic surfactant, and then to sodium dodecyl sulfate (SDS), an anionic surfactant, resulted in a milder irritant reaction (McFadden et al., 2000). However, when SLS and toluene were concurrently applied, significantly stronger effects were noted than twice daily application of SLS or toluene alone (Wigger-Alberti et al., 2000). No synergistic effect and limited additive effect were found with serial application of 0.5% SLS and *n*-propanol (Kappes et al., 2001). Tandem application of ascorbic acid, acetic acid, and NaOH

with SLS led to additive effects (Fluhr et al., 2004). In contrast, combined exposure to fruit acids and SLS did not enhance cumulative skin irritation *in vivo* (Schliemann-Willers et al., 2005). A "crossover" phenomenon between two distinct irritants has been suggested. The serial application of SLS retinoic acid (RA) caused considerably stronger erythema, more scaling, higher transepidermal water loss (TEWL) values, and decreased stratum corneum hydration than the serial application of RA/SLS or the individual components alone (Effendy et al., 1996; Ale et al., 1997). A pharmacological synergism or antagonism between the compounds may explain this phenomenon. Alternatively, the effects of one agent may result in a change in the kinetics of the percutaneous penetration of the other. Sometimes the outcome of multiple, subsequent, or simultaneous exposures is unexpected (Lammintausta et al., 1987a) and rules must be sought (Pittz et al., 1985).

13.2.4 Environmental Factors

Low humidity enhances irritability; testing the skin with irritants produced more and stronger reactions during the winter when the weather was cool, windy, and dry (Hannuksela et al., 1975; Agner and Serup, 1989; Basketter et al., 1996b; Leggat and Smith, 2006). Temperature may affect the skin response to irritants, warm temperatures are generally more damaging than cool temperatures. Warm temperature increased skin irritation induced by surfactant (Berardesca, 1995), and *in vitro* penetration of SLS was also increased with increasing the temperature (Emilson et al., 1993). Furthermore, it was shown that exposure to 43°C citral perfume led to primary irritation which continued even after 48 h, while the reaction to the same perfume at 23°C was reduced 3 h after exposure (Rothenborg et al., 1977). It is well known that water temperature influences the irritant capacity of a detergent. Higher ionic content and higher temperature were found to be determinative for the irritant potential (Clarys, 1997). Exposure to local heat sources together with detergents represents a common workplace situation. Warm airflow at different temperatures increased SLS-induced barrier disruption (Fluhr et al., 2005d). While, in a short-term model, cold temperatures were found to have a protective effect on the development of irritation (Fluhr et al., 2005b). Changes in temperature may be an important means for prevention of irritant contact dermatitis (Ohlenschlaeger, 1996). UVB diminished immediate reactions induced by phenol and DMSO and delayed reactions from SLS and DMSO (Larmi et al., 1989). Occlusion enhances stratum corneum hydration and often increases percutaneous absorption and acute irritation. In contrast, it compromises skin barrier function by impairing passive TEWL at the application site. Thus, skin reactions frequently become stronger when the chemical is applied under occlusion (van der Valk et al., 1989a), providing a humid environment that minimizes evaporation and makes the stratum corneum more permeable. Gloves and clothing increase the susceptibility for irritant dermatitis. Frequent changes of these articles is important to minimize the humid and occlusive environment. Occlusion alone may produce cytological damage to the skin that had been termed *hydration dermatitis* by Kligman. Stratum corneum lipids are implicated as an important determinant in water-retaining properties and the barrier function. A seasonal comparison of the total lipid amounts extracted from the stripped stratum corneum revealed an increased level in the summer, while the levels of ceramides were slightly increased in the winter compared with the summer (Yoshikawa et al., 1994).

Tree-Sawing particles
Wool
Plastics, dry
Particles from plants
Stone particles in mining

13.2.5 Airborne Irritation

Airborne irritation dermatitis is located most commonly in exposed skin areas, such as the face, hands, and arms (Lachapelle, 1986). Volatile chemicals and dusts are common sources of exposure, but even sharp particles in dust may induce lesions (Table 13.4). Airborne irritation is a type of exposure in which physical sources of irritation frequently exacerbate the response with an additive influence. For instance, sunlight, wind, and cold air are additive to chemical exposure. Depending on the occupational situation, multiple environmental and occupational irritants may induce airborne irritation (Dooms-Goossens et al., 1986).

13.3 PREDISPOSING FACTORS

13.3.1 Methodological Aspects

Identification of subjects at risk for irritant dermatitis by screening tests is desirable to adjust the preventive measures. Individual susceptibility to chemicals has been studied by documenting the skin reactivity to model irritants, by measuring the intensity of the wheal created by DMSO, and the time required to raise a blister (minimal blistering time [MBT]) after cutaneous application of ammonium hydroxide solution

(Frosch, 1985). Stinging has been also studied with certain test substances (e.g., lactic acid, capsaicin) (Frosch and Kligman, 1982; Jourdain et al., 2005). Methods for quantifying inter and intraindividual differences in stratum corneum barrier function were also described. High correlation between subjects developing increased water loss and propensity for SLS damage after application of sodium hydroxide was found (Wilhelm et al., 1990), and recently a visual assessment method which determines subject irritant threshold, studying the relationship between SLS irritant threshold and TEWL measurements of normal skin and SLS patch tests, was described (Smith et al., 2004). An increased baseline TEWL in patients with acute and healed irritant contact dermatitis or eczema was also noted (Effendy et al., 1995; Kuzmina et al., 2003). Later on, an association between reactivity to an irritant and the likelihood of positive elicitation reactions to lower hapten concentrations was noted (Smith et al., 2002). These simple approaches provided a first step toward a preemployment test for irritant dermatitis potential. A genetic marker of irritant susceptibility in normal individuals was also described. In this study, an association of tumor necrosis factor (TNF) α gene polymorphism at position –308 with susceptibility to irritant dermatitis was noted (Allen et al., 2000). However, despite important steps taken in the investigation of the pathogenesis of irritant contact dermatitis, no experimental design has proved entirely successful for the clinical evaluation of individual susceptibility.

The main factors that influence individual proclivity are age, race, sex, site, history of dermatitis, and genetic background.

13.3.2 Regional Anatomic Differences

Skin permeability is variable in different skin sites, being generally greatest in thin skin areas (Cronin and Stoughton, 1962; Feldmann and Maibach, 1967a,b; Wester and Maibach, 1985, 1989; Tur et al., 1985). Corresponding association between permeability, skin thickness, and skin irritation is expected, but direct correlation is lacking. Regional variations were noted in the whealing response to DMSO, and in the time for blister formation (MBT) after topical ammonium hydroxide application (Frosch and Kligman, 1982). Both tests showed the mandibular area to be the most reactive, followed by the upper back, forearm, lower leg, and palm. With DMSO whealing, the forehead was more sensitive than the back, the antecubital area reaction preceded that of the rest of the upper extremity, and the wrist was more sensitive than the leg. Patch tests with the irritant benzalkonium chloride and a number of allergens produced maximal reactivity in the upper back (Magnusson and Hersle, 1965), particularly in the middle scapula (Flannigan et al., 1984). The greater reactivity may be related to pressure in this area when sleeping (von Hornstein and Kienlein-Kletschka, 1982; Gollhausen and Kligman, 1985). TEWL measurements after exposure to SLS revealed the thigh to be the most vulnerable site followed by the upper arm, abdomen, upper back, dorsal and volar forearm, postauricular, and ankle, with the palm as the least vulnerable location (Cua et al., 1990). Recently, human scalp irritation was compared to that of the arm and back. Results indicated that the back was most sensitive to SLS treatment (Zhai et al., 2004). Later on regional and age-related differences in the human face were examined in two age groups. In both age groups, one with an average age of 25.2 ± 4.7 years and another with an average age of 73.7 ± 3.9 years some significant differences between the regions of the face were detected. The younger group showed higher changes in TEWL than the older group in all the areas studied, but only in the chin and nasolabial area were the differences statistically significant (Marrakchi and Maibach, 2006). When the volar surface of the forearm was studied the potential for irritation increased from the wrist to the cubital fossa (van der Valk, 1989b). Vulvar skin was significantly more reactive than the forearm to benzalkonium chloride (17%) and maleic acid (20%) (Britz and Maibach, 1979; Oriba et al., 1989). No differences were found between vulvar and forearm skin when SLS was applied at various concentrations (Elsner et al., 1990). However in clinical occupational dermatology, it is often noted that male genitalia are affected in occupational irritant dermatitis. Since cutaneous irritant responses to various irritants might be mediated by distinctly different pathophysiological pathways, regional susceptibility to diverse irritants vary accordingly (Patrick et al., 1985). Additionally, stratum corneum barrier properties have been associated with stratum corneum lipid composition, regions with higher neutral lipids and lower sphingolipids are generally associated with superior barrier properties (Lampe et al., 1983). Certain "inherent" differences between different skin sites in irritation reactivity may also exist.

13.3.3 Age

The threshold for skin irritation is decreased in babies, who develop dermatitis from irritation that usually does not occur in adult skin (Jordan and Blaney, 1982). Except for structural and functional immaturity of infant's skin, other factors (intestinal *Candida albicans,* low frequency of diaper changes) are contributory (Seymour et al., 1987). Children below the age of 8 years are generally considered more susceptible to skin irritation (Mobly and Mansmann, 1974; Epstein, 1971; Fisher, 1975), irritation susceptibility gradually decreases after this age. Maibach and Boisits (1982) define this database; unfortunately, despite extensive chemical exposure of infants and children, experimental evidence is lacking because of methodological problems and limited data. Studies in newborn infants showed high and variable TEWL in the first 4 h after birth settling to a constant level thereafter (Rutter, 1978), and newborn term infants have less TEWL than adults (Cunico et al., 1977). No differences in baseline TEWL were demonstrable between young and old individuals (Thune et al., 1988; Roskos, 1989; Wilhelm and Maibach, 1989). However, elderly subjects reacted to skin irritants less sharply and more slowly than younger individuals (Grove et al., 1981; Lejman et al., 1984; Schwindt et al., 1998; Robinson, 2002; Marrakchi and Maibach, 2006), the difference was particularly significant in sites characterized by low TEWL under basal conditions

TABLE 13.5
Cutaneous Sodium Lauryl Sulfate Irritation Potential: Age and Regional Variability

(Cua et al., 1990) (Table 13.5). When pre and postmenopausal women were compared, age-related differences were apparent in the forearm skin, but not the vulva (Elsner et al., 1990). A corresponding alteration occurred with regard to cutaneous reactivity to allergens. With ammonium hydroxide skin tests, older subjects had a shorter reaction time (MBT), whereas the time needed to develop a tense blister was longer (Frosch and Kligman, 1977), and a longer time was also needed for the absorption of a wheal elicited by saline injection (Kligman, 1976). Age-associated alterations in skin reactivity may be related to altered cutaneous penetration, although contradictory results have been reported (Christophers and Kligman, 1965; Tagami, 1971; DeSalva and Thompson, 1965; Guy et al., 1985; Roskos et al., 1990). Alterations in structural lipids (Elias, 1981), in cell composition (Gilchrest et al., 1982) and renewal (Baker and Blair, 1968; Roberts and Marks, 1980), are reported in association with structural alteration (Montaga and Carlisle, 1979; Holzle et al., 1986). Finally, the effects of stratum corneum hydration on irritancy potential is probably noncontributory, baseline capacitance did not differ between age groups on most regions (Cua et al., 1990).

13.3.4 Race

Ethnic differences in skin physiology and pathophysiology exist (Berardesca and Maibach, 1988c; Berardesca et al., 1991b; Berardesca and Maibach, 1996). Results based on traditional visual grading suggest that blacks have less-irritable skin than Caucasians (Weigand and Gaylor, 1974; Andersen and Maibach, 1979). Use of alternative evaluative techniques, including laser Doppler flowmetry (LDF), and TEWL tend to support this conclusion. However, when SLS was applied to untreated, preoccluded, and predelipidized skin, blacks had higher TEWL levels than Caucasians in the preoccluded state (Berardesca et al., 1988a). This finding contradicts the hypothesis that blacks are less susceptible to irritation. However, no significant differences were noted between black and Caucasian subjects in LDV measurements after application of methyl-nicotinate (Gean et al., 1984: Guy et al., 1985), or irritation with SLS (Berardesca et al., 1988a). Similarly, fluorescence excitation spectroscopy demonstrated no differences in the hyperproliferative response after irritant exposure, and indicated similar kinetics for 15 Caucasian and 15 African-American patients tested (Astner et al., 2006). Baseline TEWL measurements were significantly higher in Asian and black subjects compared with white subjects. No baseline differences were seen between black and Asian subjects (Kompaore et al., 1993). No difference was found in this parameter when African black subjects were compared with white European subjects or among other racial groups studied (DeLuca et al., 1983; Pinnagoda et al., 1990). Blacks and Hispanics showed higher TEWL responses to SLS (Berardesca et al., 1988a,b) and *in vitro* TEWL differences between blacks and whites have also been reported (Wilson et al., 1988). In a similar study, Chinese have been found to be more sensitive than Malaysians but no significant differences were found between Chinese and Indians or between Malaysians and Indians (Goh and Chia, 1988). Rapaport using a 21-day cumulative irritation test protocol found among the Japanese subjects generally greater cumulative irritation scores for 13 of the 15 irritants tested (Rapaport, 1984). Subsequent studies using acute and cumulative skin irritation tests in Caucasian and Asian populations failed to confirm a consistent trend. No significant differences were seen between Caucasian and Chinese subjects exposed to chemicals of varying irritation potency under a 4-h patch test (Robinson, 2000). Japanese subjects showed a tendency to respond faster than the Caucasian subjects at several chemical exposure time points in the acute irritation test, and in the cumulative irritation test only with the lowest concentration of SDS (Robinson, 2000). When the same study was repeated among

the same populations, no differences were seen in the acute and cumulative skin irritation responses between the Japanese and Caucasian subjects. However, Chinese subjects showed a heightened response to acetic acid after 4 h of exposure, and a slower and less-severe response in the cumulative irritation test compared to Caucasian and Japanese subjects (Robinson, 2000). Later on, Caucasian and Japanese women were tested with a range of irritant materials. The acute irritation response tended to be greater in the Japanese panel, and this was statistical significant with the stronger irritants. In the cumulative irritation test the Japanese compared to Caucasian panellists showed a higher response only with the weaker irritants, however, the results were not significant (Foy et al., 2001). When Japanese subjects were tested to cosmetic products and topical tretinoin cream, a high level of intolerance was also noted (Ishihara et al., 1986; Tadaki et al., 1993). An international dose–response study with the anionic surfactant SLS at different concentrations was conducted under Unilever's direction. In this study, the German population tended to be the most responsive and the Asian population was not more reactive than the Caucasians (Basketter et al., 1996b). Similarly, Robinson analyzed skin reactivity in different human subpopulations. Results were compiled from nine acute irritation patch-test studies, conducted at three test facilities over a 5-year period. For three irritant test chemicals, 20% SDS, 100% decanol, and 10% acetic acid, an increased reactivity for Asian versus Caucasian subjects was noted (Robinson, 2002). However, studying populations in different geographic locations and at different times of the year creates difficulties in the interpretation of the data. The different studies indicate that there is little evidence of statistically significant differences in the irritant response among Caucasian, black, and Asian groups, and there is no consensus on whether race contribute as an endogenous factor in the development of irritant contact dermatitis.

13.3.5 Gender

There is a common perception that women are more prone to skin irritation than men (Agrup, 1969; Lantinga et al., 1984; Rystedt, 1985), yet, when four irritants were compared, male subjects were found to be directionally or significantly more reactive than females to each of the irritants tested (Robinson, 2002). In line with this experimental observation is the result of a multicenter study of the German contact dermatitis research group, where irritant reaction to SLS was somewhat increased in males (Uter et al., 2004). However, differences between males and females were not experimentally documented in most studies (Bjornberg, 1975; Lammintausta et al., 1987b; Goh and Chia, 1988; Meding, 2000). The increased occurrence of irritant contact dermatitis in females may be related to the more extensive exposure to irritants and wet work. A minimal relationship between gender and constitutional skin irritability is supported by the fact that the female preponderance in the irritant contact dermatitis populations does not hold true for all geographic areas (Olumide, 1987).

13.3.6 Previous and Preexisting Skin Diseases

It has been suggested that existing dermatitis irrespective of which type may enhance skin reactivity to various irritants (Bjornberg, 1968). Skin response to SLS was statistically significantly increased in atopics compared to controls, when evaluated by visual scoring and skin thickness (Agner, 1991). Increased water loss with detergent patch tests and several other irritants was also reported (van der Valk et al., 1985; Tupker et al., 1990; Goh, 1997). However, when 20% SDS, 35% cocotrimethyl ammonium chloride, and 10% hydrochloric acid were tested, a higher reaction of atopic skin was found only to 20% SDS, but not to 35% cocotrimethyl ammonium chloride and 10% hydrochloric acid (Basketter et al., 1996a). Different concentrations of SLS were also tested, a higher percent of positive results and a significantly greater intensity of response were noted in the atopic dermatitis group than in controls; the same result was demonstrated in atopic allergic rhinitis patients without dermatitis (Nassif et al., 1994). The responsiveness to SLS was not increased in patients with chronic or healed dermatitis (Agner, 1991). Later on, the relative reactivity of an apparently normal skin in atopic and nonatopic groups was studied. SLS was applied at a range of concentrations and exposure times. At various time points, the irritation response was measured by visual assessment, chromametry, LDF, and TEWL. Using all of the methods of assessment, the reactions in atopics were similar to or a little less than those seen in nonatopics (Basketter et al., 1998). Hannuksela and Hannuksela data suggested that different methods of application, like open application and plastic chamber, may produce dichotomous results (Hannuksela and Hannuksela, 1995). The enhanced irritant susceptibility in atopic dermatitis at least in part is explained by constitutional factors. Patients with atopic dermatitis are alleged to have defective skin barrier function, both in irritated and normal looking skin. Itchy and dry atopic skin has been connected with an increased risk for developing hand dermatitis (Lammintausta and Kalimo, 1981; Rystedt, 1985). Reduced capacity to bind water has been related to atopic skin (Werner et al., 1982), which in noneczematous sites demonstrates greater TEWL than does nonatopic skin, and stratum corneum water content may even be increased (Finlay et al., 1980; Al Jaber and Marks, 1984; Gloor et al., 1981). Furthermore, keratinocytes of atopic dermatitis patients after a nonspecific stimulation produced higher levels of TNF-α and interleukin (IL)-1 compared to nonatopics (Pastore et al., 1998). Ichthyosis vulgaris is sometimes seen in association with atopic dermatitis; in ichthyosis vulgaris, patients' irritant reactivity has been shown to be increased to alkali irritants (Ziierz et al., 1960). Seborrheic skin has not been shown to possess increased susceptibility to skin irritants; reports and interpretations are contradictory (Holland, 1958; Vickers, 1962; von Hornstein et al., 1986). However, exposure to SLS induced significantly greater blood flux in patients with seborrheic dermatitis (Cowley and Farr, 1992). Clinical experience suggests that some increased irritability is associated with a seborrheic constitution in

certain subjects. This may be true in certain geographic areas, where environmental humidity is low in the winter in relation to the cold temperatures.

Different methods have been used in studies on skin irritability in psoriatic individuals. These studies revealed decreased and increased irritant reactivity (Kingston and Marks, 1983; Maurice and Greaves, 1983; Lawrence et al., 1984; MacDonalds and Marks, 1986) when anthralin (dithranol) irritancy was the main interest. Psoriatic skin is particularly irritable in certain individuals (Epstein and Maibach, 1985), and the development of psoriatic lesions in irritation sites (Koebner phenomenon) is often seen. In the presence of eczema, the threshold for skin irritation is decreased (Mitchell, 1981; Bruynzeel et al., 1983; Bruynzeel and Maibach, 1986; Agner, 1991). A whole-body examination of employees sometimes reveals nummular lesions or other constitutional eczema symptoms. Such a clinical finding may suggest increased skin irritability in different locations. Pompholyx (dyshidrosis) type dermatitis is harmful. As a constitutional eczema, it probably increases skin irritability in general. These patients often have difficulty wearing gloves, since phompholyx is made worse by occlusion. A history of contact dermatitis may be important when susceptibility to irritant contact dermatitis is evaluated (Nilsson et al., 1985; Lammintausta et al., 1988a). Although increased irritability exerted by the preexisting dermatosis was hard to demonstrate, further improvement of methodological equipment in the bioengineering industry should make this possible (Lammintausta et al., 1988a; Santucci et al., 2003).

13.3.7 Genetic Background

Irritant dermatitis is a multifaceted disease and the mechanisms underlying susceptibility to skin irritants are not clearly understood. However, a growing body of evidence suggests that immunologic mechanisms may also in part underlie the pathogenesis of irritant contact dermatitis. As different irritants with different chemical properties of molecules produce different effect on epidermal structures, it seems likely that there are many routes by which irritant dermatitis may arise. However, all irritants bear in common the same pathophysiological changes including skin barrier disruption by chemical stimuli or mechanical trauma, cellular epidermal damage and release of proinflammatory mediators particularly cytokines, all of which are interlinked. Disruption of the barrier leads to release of cytokines such as IL-1 α, IL-1 β, and TNF-α. Furthermore, when the barrier is disrupted, the entry of chemicals into the epidermis is facilitated, leading to structural changes in keratinocytes and further cytokine release. Among the proinflammatory cytokines which have been found to be released are IL-1 α, TNF-α, IL-6, IL-8, granulocyte–macrophage colony-stimulating factor (GM-CSF), and T-cell-derived cytokines, including IL-2 and interferon-γ (Wood et al., 1992; Ulfgren et al., 2000). As TNF-α plays a key role in inflammation, it seems likely that factors affecting the production of TNF-α may account for the degree of the irritation response and the interindividual variations. Allen et al. investigated the relationship between polymorphism in the TNF-α-chain gene and responses to irritants. In this study, an association of TNF-α gene polymorphism at position −308 with susceptibility to irritant dermatitis was noted (Allen et al., 2000). This is the first description of a genetic marker for irritant susceptibility in normal individuals, and further studies to support this result are needed.

13.4 SUMMARY

The mechanisms by which various chemicals elicit irritant dermatitis are not clearly understood. While strong irritants quickly elicit signs and symptoms of dermatitis, weak irritants may not. The severity of the dermatitis is highly variable and depends on the amount and strength of the irritant, length and frequency of exposure, environmental factors, and skin susceptibility. The main factors that influence individual proclivity are age, race, sex, site, history of dermatitis, and genetic background. Thus, age-associated alterations in cutaneous reactivity are expected; however, the subject requires more investigation. Conflicting findings have been reported comparing skin response to irritants in Caucasian, black, and Asian groups, and there is no consensus on whether race contribute as a factor in the development of irritant contact dermatitis. There is a common perception that women are more prone to skin irritation than men, yet, in recent studies male sex was identified as a relatively weak but significant risk factor for the occurrence of irritant dermatitis. It has been suggested that preexisting dermatitis irrespective of which type may enhance skin reactivity to various irritants. However, the role of preexisting dermatitis in the response to irritants resulted quite marginal in most of the studies. It seems that regional variations in skin irritation do exist and further studies to support these result are needed. Identification of subjects at risk for irritant dermatitis by screening tests is desirable. A recent description of a genetic marker of irritant susceptibility in normal individuals seems promising.

14.1 INTRODUCTION

Systemic contact dermatitis is an inflammatory skin disease that may occur in contact-sensitized individuals when these persons are exposed to the hapten orally, transcutaneously, intravenously, or by inhalation. The entity can be present with clinically characteristic features or be clinically indistinguishable from other types of contact dermatitis. Contact sensitization to ubiquitous haptens is common. In a recent Danish population-based study, 15.2% reacted to one or more of the haptens in the standard patch-test series (Nielsen et al., 2001). The total number of individuals at risk of developing a systemic contact dermatitis reaction is therefore large. Systemic contact dermatitis from medicaments is a well-established entity. There is increasing evidence for similar reactions from plant derivatives and metals such as nickel (Hindsén et al., 2001).

The first description of systemic contact dermatitis can probably be ascribed to the pioneering British dermatologist Thomas Bateman (Shelley and Crissey, 1970). His description of the mercury eczema called eczema rubrum is similar to what we today describe as the baboon syndrome.

Eczema rubrum is preceded by a sense of stiffness, burning, heat, and itching in the part where it commences, most frequently the upper and inner surface of the thighs and about the scrotum in men, but sometimes it appears first in the groins, axillae or in the bends of the arms, on the wrists and hands, or on the neck.

In this century, the systemic spread of nickel dermatitis was described by Schittenhelm and Stockinger (1925) in Kiel. By patch testing nickel-sensitive workers with nickel sulfate, they observed the spread of dermatitis and flares in the original areas of contact dermatitis. Similar clinical features have been seen in large groups of carefully evaluated nickel-sensitive patients Marcussen (1957); Calnan (1956). The literature on systemic contact dermatitis is now comprehensive. Reviews include Veien et al. (1990), Menné et al. (1994), and Veien and Menné (2006); Fisher (1986); Cronin (1980).

14.2 IMMUNOLOGY/MECHANISM

Systemic contact dermatitis may start a few hours or 1–2 days after experimental provocation, suggesting that more than one type of immunological reactions are involved. The local flare-up reaction has been studied experimentally in both humans and in animals. Christensen et al. (1981) studied flare-up reactions in 4- to 7-week-old positive nickel patch tests in five nickel-sensitive patients after oral provocation with 5.6 mg nickel. The histology was that of acute dermatitis. Direct immunofluorescence examination for deposits of IgG, IgA, IgM, complement 3, and fibrinogen was negative. A few sensitized T cells can remain in the skin for months (Scheper et al., 1983; Yamashita et al., 1989). Systemic exposure to haptens can activate sensitized T cells in sites of previous contact dermatitis and initiate the inflammatory response.

A patient had parthenium dermatitis that was aggravated during stays in an area of India where parthenium grew profusely. Inhalation of material from fresh parthenium plants resulted in aggravation of the dermatitis without respiratory symptoms (Mahajan et al., 2004).

The investigation of lymphocyte subsets in the gastrointestinal mucosa and in blood before and after oral challenge with nickel in nickel-sensitized women showed a reduction of CD4+ cells, CD4+CD45Ro+ cells, and CD8+ cells in the peripheral blood of women with evidence of systemic contact dermatitis. Oral challenge with nickel induced maturation of naive T cells into memory cells that tended to accumulate in the intestinal mucosa (di Gioacchino, 2000).

Jensen et al. (2004) found a reduction of the number of CLA+ CD45Ro+ CD3 and CLA+ CD45Ro+ CD8 but not CLA+ CD45Ro+ CD4 in the peripheral blood of nickel-sensitive patients after oral challenge with nickel.

Following the removal of a metal joint prosthesis containing cobalt, CD4 T-cell clones reacted to cobalt but not to nickel (Thomssen et al., 2001).

Möller et al. (1998) challenged 10 gold allergic patients with an intramuscular dose of gold and saw a flare-up of 1-week-old gold patch-test reactions in all of them. Five also experienced a maculopapular rash, and four had transient fever. Plasma levels of TNF-α, IL-1 ra, and sTNF-R1 and C-reactive protein were increased, particularly in those with fever.

In a later study of 20 gold and 28 nickel-allergic patients challenged orally with nickel and gold in a double-blind, double-dummy fashion, 3 of 9 nickel-sensitive patients reacted to 2.5 mg nickel, while none reacted to gold. Six of 10 gold-allergic patients reacted to 10 mg gold sodium thiomalate, none of them reacted to nickel. TNF-R1 was increased in the plasma of nickel-sensitive patients challenged with nickel, while TNF-R1, TNF-α, and IL-1 were increased in gold-sensitive patients challenged with gold (Möller et al., 1999a).

In a study of 42 patients with systemic contact dermatitis from *Toxicodendron*, it was suggested that a toxic rather than a specific immune reaction might be responsible (Oh et al., 2003).

The mechanism behind skin symptoms unrelated to previous contact dermatitis sites has been minimally evaluated. Veien et al. (1979) investigated 14 patients with positive nickel patch tests and severe dermatitis. All were challenged orally with 2.5 mg nickel. After 6–12 h, five developed widespread erythema. No clinical dermatitis developed in the erythematous areas. In a passive immunodiffusion assay, three of the five demonstrated precipitating antibodies in their sera against a nickel–albumin complex. The same phenomenon was observed by Polak and Turk (1968a,b) in chromium-sensitized guinea pigs. As in humans, the response started 6–8 h after a chromate injection. Histopathology 24 h after the challenge showed a marked dilatation of the capillaries in the upper dermis. The authors suggested that circulating immune complexes were the triggering mechanism.

Van Hoogstraten et al. (1992) demonstrated antigen-specific tolerance to nickel and chromate in guinea pigs. Administration of the allergens to the oral mucosa proved the most effective means of inducing tolerance. Prior to this study, the same author conducted a retrospective clinical study of the risk of nickel sensitization from pierced ears in patients who did or did not wear dental braces. It was shown that fewer cases of nickel sensitization were seen when dental braces were fitted before ear piercing than when the braces were fitted after ear piercing (Van Hoogstraten, 1991). These findings have been confirmed by Mørtz in a study of 13–15-year-old girls (Mørtz, 1999).

It has also been shown that giving repeated oral or sublingual doses of nickel to nickel-sensitive patients gradually reduces the severity of flares of dermatitis seen after oral challenge with nickel (Sjövall et al., 1987); Morris (1998); Panzani et al. (1995) or reduces circulating lymphocytes reacting to nickel (Bagot et al., 1999). It is possible that the repeated doses of nickel decrease the intestinal absorption of the metal (Santucci et al., 1994).

Hyposensitization to poison ivy was observed in 9 of 13 poison ivy-sensitive workers who were exposed to dust from cashew nut shells. The route of hyposensitization was thought to be gastrointestinal from swallowed dust (Reginella et al., 1989).

A patient was successfully hyposensitized to *Parthenium hysterophorus* by the oral route of exposure (Srinivas et al., 1988).

Twenty parthenium-sensitive patients were hyposensitized orally for 12 weeks with ether extracts of parthenium. Fourteen completed the procedure and improved. Six stopped due to aggravation of their dermatitis. Seven of the fourteen were followed for a year. Four of them had recurrences within 2 months (Handa et al., 2001).

Two patients with chrysanthemum dermatitis were successfully hyposensitized using chrysanthemum juice for 21 days. Aggravation of the dermatitis was seen initially in both patients. The patients remained clear of dermatitis for more than 2 years (Mori et al., 2000).

14.3 CLINICAL FEATURES

The clinical symptoms related to systemic contact dermatitis are summarized in Table 14.1. The symptoms usually appear exclusively on the skin, but general symptoms are occasionally

TABLE 14.1
Clinical Aspects of Systemic Contact Dermatitis Reactions

Dermatitis in areas of previous exposure
Flare-Up of previous dermatitis
Flare-Up of previously positive patch-test sites
Skin symptoms in previously unaffected skin
Vesicular hand eczema
Flexural dermatitis
The baboon syndrome
Maculopapular rash
Vasculitis-like lesions
General symptoms
Headache
Malaise
Arthralgia
Diarrhea and vomiting

seen. Knowledge of the clinical symptoms stems from clinical observations and experimental oral challenge studies.

Flare-up reactions in the primary site of dermatitis or previously positive patch-test sites raise the suspicion of systemic contact dermatitis (Ekelund and Möller, 1969; Christensen and Möller, 1975; Menné and Weismann, 1984; Hindsén et al., 2001). Flare-up of previously positive patch-test sites following ingestion of the hapten is a fascinating and specific sign of systemic contact dermatitis. It is seen in relation to systemic contact dermatitis from medicaments and in experimental oral provocation studies. Such flares of patch-test sites have not been a feature of the clinical spectrum of systemic contact dermatitis. This symptom is hapten specific and can be seen years after the original patch testing. Christensen et al. (1981) and later Hindsén et al. (2001) examined the specificity of this symptom in nickel-sensitive individuals. Positive patch tests to nickel and to the primary irritant sodium lauryl sulfate were made on previously unaffected skin areas. After several weeks, the individuals were given an oral nickel dose. A flare of dermatitis was seen at the nickel patch-test site, but not at the site of irritant dermatitis.

Vesicular hand eczema (pompholyx or dyshidrotic eczema) (Veien and Menné, 2000), a pruritic eruption on the palms, volar aspects and sides of the fingers, and occasionally the plantar aspects of the feet, presents with deep-seated vesicles and sparse or no erythema. If the distal dorsal aspects of the fingers are involved, transversal ridging of the fingernails can be a consequence. Recurrent, vesicular hand eczema is a common clinical manifestation of hand eczema and can have many different causes. It is a frequent symptom seen in systemic contact dermatitis.

Erythema or a flare of dermatitis in the elbow or the knee flexures is a common symptom of systemic contact dermatitis (Wintzen et al., 2003). It is difficult to distinguish from the early lesions of atopic dermatitis. Flexual psoriasis can be a Köbner phenomenon associated with systemic contact dermatitis.

The baboon syndrome (Andersen et al., 1984) is a well-demarcated eruption on the buttocks, in the genital area and in a V shape on the inner thighs with a color ranging from dark violet to pink. It may occupy the whole area or only part of it. Nakayama et al. (1983) described the same syndrome as mercury exanthema. Lerch and Bircher (2004) added acute, generalized exanthematous pustulosis to the syndrome. Based on case stories, the patients may have had systemic contact dermatitis. Even extensive patch testing fails to confirm the diagnosis of systemic contact dermatitis in some patients who present with features of the baboon syndrome.

A nonspecific maculopapular rash is often part of a systemic contact dermatitis reaction. Even cases of vasculitis presenting as palpable purpura have been seen (Veien and Krogdahl, 1989).

In relation to oral provocation with nickel or medicaments, general symptoms such as headache and malaise have occasionaly been seen in sensitized individuals. In neomycin- (Ekelund and Möller, 1969) and chromate-sensitive patients (Kaaber and Veien, 1977), oral provocation with the hapten has caused nausea, vomiting, and diarrhea. A few patients have complained of arthralgia. The available information on the general symptoms observed in relation to the systemic contact dermatitis reaction is anecdotal and deserves systematic documentation.

14.4 MEDICAMENTS

14.4.1 Antibiotics

Neomycin and bacitracin are widely used topical antibiotics. Contact allergy to these compounds is particularly frequent (4–8%) in patients with leg ulcers. Ekelund and Möller (1969) challenged 12 leg-ulcer patients sensitive to neomycin with an oral dose of the hapten. Ten of the twelve had a reaction. Five had flares of their original dermatitis; six had flares at the sites of previously positive patch tests. Three developed vesicular hand eczema for the first time. Four experienced various gastrointestinal symptoms. Some surgeons use oral neomycin prior to colon surgery. Even if neomycin is poorly absorbed from the gastrointestinal tract, severe systemic contact dermatitis might occur in neomycin-sensitive individuals (Menné and Weismann, 1984).

Contact sensitivity to penicillin was previously common, and flares of dermatitis have been seen in sensitized persons following exposure to traces of penicillin in milk (Vickers et al., 1958). Contact sensitivity and systemic contact dermatitis caused by penicillin can still occur after the topical use of the drug in the middle ear, in the peritoneum during abdominal surgery (Andersen et al., 1984), or after occupational exposure. Tagami et al. described a patient with toxic epidermal necrolysis after the systemic administration of ampicillin and reviewed 10 other patch-test proven cases of dermatitis of similar morphology caused by various medications (Tagami et al., 1983).

Penicillin, ampillin/amoxicillin, and erythromycin have been described as causes of systemic contact dermatitis with baboon-like clinical features (Llamazares, 2000; Goossens et al., 1997).

The baboon syndrome caused by drugs was reveiwed by Hausermann et al. (2004). Approximately 100 cases were reviewed. Most cases were caused by antibiotics.

Systemic contact dermatitis was seen in nurses occupationally sensitized to streptomycin (Wilson, 1958) when attempts were made to induce tolerance by subsequent systemic exposure to the drug.

During World War II, sulfonamides were used extensively for the treatment of wounds. Later systemic use of sulfonamides in sensitized individuals caused dose-dependent flares of dermatitis. The persons who had the most pronounced reactions were those most sensitive to sulfonamides (Park, 1943).

Systemic contact dermatitis caused by pristinamycine and gentamicin has also been described (Bernard et al., 1988; Ghadially and Ramsay, 1988).

14.4.2 Antihistamines

The pharmacological effectiveness of topically applied antihistamines is questionable. Antihistamines derived from ethanolamine and ethylenediamine are the most common contact-sensitizing antihistamines in the United States

(Fisher, 1976). Ethylenediamine-based antihistamines may elicit systemic contact dermatitis in patients sensitized to ethylenediamine. Aminophylline, which contains theophylline and ethylenediamine, may elicit reactions in ethylenediamine-sensitized patients (Provost and Jilson, 1967; Guin et al., 1999; Walker and Ferguson, 2004).

Much of the knowledge in this field is based on anecdotal therapeutic accidents. In view of the large number of persons who are contact sensitized to ethylenediamine, incidents of systemic contact dermatitis to ethylenediamine derivatives must be considered rare.

14.4.3 *para*-Amino Compounds

Sidi and Dobkevitch-Morrill (1951) studied cross-reactions between *para*-amino compounds. Systemic reactions were seen after oral challenge with procaine in sulfonamide-sensitive patients, after challenge with *p*-aminophenylsulfamide in procaine-sensitive patients, and after challenge with *p*-aminophenylsulfamide and procaine in *p*-phenylenediamine-sensitive patients.

Oral challenge with the sulfonyl urea hypoglycemic drugs in patients sensitized to *para*-amino compounds (sulfanilamide, *para*-phenylenediamine, and benzocaine) resulted in flare-up reactions in sulfanilamide-sensitive patients, but not in *para*-phenylenediamine and benzocaine-sensitive patients (Table 14.2). Oral challenge with tartrazine (20 mg) and saccarine (150 mg) in patients sensitized to *para*-amino compounds and sulfonamide did not produce any flare-up reactions (Angelini and Meneghini, 1981; Angelini et al., 1982).

14.4.4 Corticosteroids

Contact allergy to glucocorticoids is not uncommon in patients with eczematous skin diseases (Lauerma, 1992). The frequency seems to vary from center to center depending on local prescribing habits, degree of patient selections, and the diagnostic method used.

Patch testing with topical corticosteroids has not yet been standardized with regard to patch-test concentrations and vehicles. Intradermal testing may offer additional diagnostic possibilities.

Patients sensitized to hydrocortisone may react with systemic contact dermatitis when provoked orally with 100–200 mg hydrocortisone (Lauerma et al., 1991; Torres et al., 1993). These authors also investigated whether cortisol produced in the adrenals (i.e., hydrocortisone) could provoke systemic contact dermatitis. In a placebo-controlled study, a patient was challenged with an adrenocorticotropic hormone (ACTH) stimulation test. A skin rash similar to that seen after oral hydrocortisone developed after 8 h.

Räsänen and Hasan (1993) studied five patients who developed rashes when treated with systemic or intralesional hydrocortisone. They recommend patch testing and intradermal testing to make the diagnosis of systemic hydrocortisone sensitivity and, if these tests fail, an oral challenge.

Whitmore (1995) reviewed 16 studies with a total of 24 patients who had systemic contact dermatitis from corticosteroids. Typical clinical features were exanthema, localized dermatitis, generalized dermatitis, and purpura. Onset was often hours to days following ingestion of the corticosteroids.

As a part of her thesis on corticosteroid allergy, Isaksson (2000) challenged 15 budesonide-sensitive patients with 100 and 800 μg budesonide or placebo by inhalation. Four of seven challenged with budesonide had reactivation of previously positive patch-test sites as well as papular exanthema or a flare-up of previous dermatitis.

Pirker et al. (2003) saw an anaphylactoid reaction after inhalation of budesonide in a patient who was contact sensitized to budesonide. In another study, a betamethasone-sensitive patient developed baboon syndrome after the oral administration of betamethasone (Armingaud et al., 2005).

TABLE 14.2
Oral Challenge with Sulfonyl Urea Hypoglycemic Drugs in Sulfanilamide-Sensitive Patients

Substance	Allergen Dose (mg)	Duration of Treatment	Response
Carbutamide	500	Single exposure	7/25
Tolbutamide	500	Single exposure	3/11
Chlorpropamide	500	Single exposure	1/20

14.4.5 Miscellaneous Medications

Antabuse (tetraethylthiuram disulfide) is of particular interest, since it can cause systemic contact dermatitis in three ways. Antabuse is used in the manufacture of rubber as a fungicide and in the treatment of chronic alcoholism. In patients sensitized to thiurams from the use of rubber gloves, systemic exposure to Antabuse can give rise to systemic contact dermatitis (Pirilä, 1957). Subcutaneous implantation of Antabuse led to contact sensitization in two patients. Subsequent oral challenge with the hapten produced a flare-up reaction in one of the two patients (Lachapelle, 1975). A similar patient was described by Kiec-Swierczynska et al. (2000). Severe recall dermatitis of the penis was seen in a thiuram-sensitive patient after Antabuse treatment. He had been sensitized by the use of a rubber condom (Fisher, 1989). Antabuse also induces a systemic contact reaction by an entirely different mechanism. As Antabuse and its metabolites are strong metal-chelating substances, they can cause systemic contact reactions in nickel- and cobalt-sensitive patients via a pharmacological interaction in a dose-dependent manner (Kaaber et al., 1979, 1983; Veien, 1987c; Klein and Fowler, 1992).

Experimental oral challenge with 1 mg nickel before and during disulfiram treatment of a nickel-allergic patient showed greatly increased urinary nickel excretion during disulfiram treatment. A corresponding flare-up of dermatitis was seen (Hindsén et al., 1995).

The antitumor antibiotic mitomycin C is used for the treatment of superficial bladder cancer. Colver et al. (1990) demonstrated delayed-type hypersensitivity in 13 of 26 patients who

had received mitomycin installations by applying the allergen as a patch test (Colver et al., 1990). de Groot and Conemans (1991) reported six cases where intravesical administration of the drug resulted in a systemic contact dermatitis reaction including vesicular eczema of the hands and feet and dermatitis of the buttocks and genital area. A more widespread rash was eventually seen.

Calkin and Maibach (1993) reviewed delayed hypersensitivity to drugs and mentioned several patients who had positive patch tests to drugs and reactions to oral challenge with the same substances.

Other medications associated with systemic contact dermatitis are listed in Table 14.3.

TABLE 14.3
Medicaments That Have Caused Systemic Contact Dermatitis

Acetylsalicylic acid (Hindson, 1977)
Aminophylline
5-Aminosalicylic acid (Gallo and Parodi, 2002)
Amlexanox (Hayakawa et al., 1992)
Ampicillin
Antihistamines
Butylated hydroxy anisole (BHA), butylated hydroxy toluene (BHT)
Cinchocaine (Erdmann et al., 2001)
Clobazam (Machet et al., 1992)
Codeine (de Groot and Conemans, 1986)
Corticosteroids
Diclofenac (Alonso et al., 2000)
Dimethyl sulfoxide (Nishimura et al., 1988)
Ephedrine (Audicana et al., 1991)
Epsilon-Aminocaproic acid (Villarreal, 1999)
Erythromycin (Fernandez Redondo, 1994)
Estradiol (Gonçalo et al., 1999)
Gentamycin
Hydromorphone (de Cuyper and Goeteyn, 1992)
Hydroxyquinoline (Ekelund and Möller, 1969)
Immunoglobulins (Barbaud et al., 1999)
8-Methoxypsoralen (Ravenscroft et al., 2001)
Mitomycin C
Neomycin
Norfloxacin (Silvestre et al., 1998)
Nystatin (Lechner et al., 1987; Cooper et al., 1999)
Panthothenic acid (Hemmer et al., 1997)
Parabens (Kleinhans and Knoth, 1979)
Penicillin (Panhans-Gross et al., 1999)
Phenobarbitol (Pigatto et al., 1987)
Pristinamycine
Pseudoephedrine (Tomb et al., 1991; Sánchez et al., 2000)
Pyrazinobutanzone (Bris et al., 1992)
Resorcinol (Barbaud et al., 2001)
Streptomycin
Sulfonamides
Tetraaethylthiuram disulfide (Antabuse®)
Vitamin B_1 (Hjorth, 1958)
Vitamin C (Metz et al., 1980)

Note: Only references not mentioned in the text are given in the table.

14.5 NICKEL

Contact sensitivity to nickel is common, particularly among young females (Nielsen and Menné, 1992). Nickel-sensitive individuals seem to run an increased risk of developing hand eczema, particularly of the vesicular type (Wilkinson and Wilkinson, 1989). Christensen and Möller (1975) showed that oral intake of nickel induces a systemic contact dermatitis reaction in nickel-sensitive individuals. This observation led to intense research in the area of nickel dermatitis and systemic contact dermatitis (Menné and Maibach, 1991; Fowler, 1990).

Daily nickel intake varies from 100 to 800 μg (Biego et al., 1998; Ysart et al., 2000). The highest nickel content is found in vegetables, nuts, whole wheat or rye bread, shellfish, and cocoa. Nickel exposure from drinking water, air pollution, and cigarettes is usually negligible, although exceptions occur (Grandjean et al., 1989).

Certain makes of electric kettles and coffee machines and some glazed tea mugs may release significant amounts of nickel (Berg et al., 2000; Ajmal et al., 1997). Stainless steel cooking utensils contribute little to total nickel intake (Flint and Packirisamy 1995). Intravenous fluids may be contaminated with 100–200 μg Ni/L (Sunderman, 1983).

Only 1–10% of ingested nickel is absorbed. Nickel absorption varies greatly. Ingestion of 12 μg Ni/kg 1 h prior to eating a 1400 kJ portion of scrambled eggs gave a 13-fold higher serum concentration of nickel compared with the simultaneous ingestion of nickel and scrambled eggs (Nielsen, 1999). Both fecal and urinary nickel excretion can be used as parameters of systemic nickel exposure. The nickel concentration in sweat is high, ranging from 7 to 270 μg Ni/L (Grandjean et al., 1989; Hohnadel et al., 1973; Christensen et al., 1979).

Christensen and Möller (1975) challenged 12 nickel-sensitive female patients with an oral dose of 5.6 mg nickel given as nickel sulfate. Nine of the patients developed flares of the dermatitis with crops of vesicles on the hands. The reaction appeared within 2–16 h after ingestion. This observation has been confirmed (Table 14.4), and there is a marked dose–response relationship. Only a few nickel-sensitive patients react to oral doses of less than 1.25 mg of nickel, while most react to doses of 5.6 mg. A positive challenge test includes one or more of the previously described symptoms.

The flares seen at former nickel patch-test sites are also dose-dependent (Jensen et al., 2003) and are correlated to the intensity of the previous patch-test reaction and to the length of time since patch testing (Hindsén, 2001).

It is interesting that a previously seen statistical association between hand eczema and nickel sensitivity was no longer present 7 years after a ban on nickel content in items intended for close contact with the skin was introduced in Denmark in 1991 (Nielsen et al., 2002).

Hindsén et al. (1994) suggested that atopics absorb nickel more readily than nonatopics and that systemic nickel dermatitis should be looked for in atopics with nickel allergy.

There was rapid elimination of nickel in the urine after i.m. injection of nickel in hamsters, while elimination after

TABLE 14.4
Challenge Studies in Nickel-Sensitive Patients with an Oral Dose of Nickel Given as the Sulfate

cutaneous application of nickel was slow. Keratinocytes retained nickel much longer than did fibroblasts (Lacy et al., 1996).

The clinical implication of these findings is uncertain (Burrows, 1992; Möller, 1993). The nickel doses used in the challenge studies often exceed the amount of nickel in a normal daily diet. In experimental studies, we have often observed flare-up reactions at sites of previously positive nickel patch tests. This phenomenon has not been observed in clinical practice. After oral challenge with 0.6–5.6 mg nickel typically given as nickel sulfate, a nonphysiologically high concentration of urinary nickel was observed on the days following the challenge (20–200 μg Ni/L). In two studies (Menné and Thorboe, 1976; de Yongh et al., 1978) involving a small number of patients, higher nickel excretion in the urine tended to be related to active hand dermatitis, but the urinary nickel levels were much lower than the concentrations measured on the days following oral nickel challenge.

These observations do not exclude the possibility that systemic exposure to nickel is important for the chronicity of hand eczema related to nickel sensitivity. Undoubtedly, the daily nickel intake will sometimes exceed 0.6 mg, and two of five patients reacted to this dose in a study carried out by Cronin et al. (1980). A rather unpleasant diet with a high nickel content has been shown to increase the activity of chronic nickel dermatitis (Nielsen et al., 1990). A diet with low nickel content may diminish the activity of hand eczema in some nickel-sensitive patients (Veien et al., 1993b), and a flare of hand eczema has been seen in patients who abandoned such a diet (Veien et al., 1985a).

Dietary intervention controlled the dermatitis of 44 of 112 nickel-sensitive patients, and all except one patient who responded to the diet reacted to a placebo-controlled oral challenge with 2.23–4.47 mg nickel. The clinical manifestations were pruritic dermatoses, atopic dermatitis, and urticaria (Antico and Soana, 1999).

The inhalation of nickel while working in an electroplating plant caused a nickel-sensitive man to develop a widespread rash that cleared after disulfiram treatment and a low-nickel diet (Candura et al., 2001).

A nickel-sensitive woman who took two ampoules Oligosol® per day or the equivalent of a daily intake of 145.2 μg nickel/day had generalized dermatitis that cleared when Oligosol was discontinued (el Sayed et al., 1996). A study by Christensen et al. (1999) showed that Danish nickel-sensitive patients had lower serum nickel than controls. This appeared to be because the diet of the former had a lower nickel content.

If nickel is given intravenously to nickel-sensitive patients, 1–3 μg can elicit a severe systemic contact dermatitis reaction. This has been observed in patients treated with intravenous

infusions through cannulas that released traces of nickel and in patients treated with hemodialysis (Stoddard, 1960; Smeenk and Teunissen, 1977; Olerud et al., 1984; Raison-Peyron et al., 2005). This difference between oral and intravenous challenge doses indicates that very small variations in the amount of nickel in the skin may cause flares of dermatitis.

Nickel binds to a variety of naturally occurring proteins and amino acids (Nieboer et al., 1984). Thus, flares of dermatitis in nickel-sensitive patients may not always be caused by increased oral exposure to nickel but could be elicited by metabolic and pharmacological reactions. Interaction between nickel and zinc formed the basis for an open treatment trial in which 15 nickel-sensitive patients participated. The dermatitis of most of the patients for whom this assay was carried out improved or cleared, and their urinary nickel excretion was reduced (Santucci et al., 1999).

There may be cross-reactivity between nickel and palladium. Hindsén et al. (2005) challenged nickel- and palladium-sensitive patients with an oral dose of nickel in a placebo-controlled trial. More flare-up reactions were seen at sites of previously positive patch test to nickel and palladium following oral challenge with nickel than after ingestion of the placebo. This difference was statistically significant. Reactions at cobalt patch-test sites were also seen after oral challenge with nickel, but these were less frequent.

14.6 CHROMIUM, COBALT, AND OTHER METALS

Sidi and Melki (1954) suggested that oral dichromate ingestion in chromate-sensitive patients might be of importance for the chronicity of their dermatitis. This hypothesis has been tested in the studies listed in Table 14.5. Fregert (1965) challenged five chromate-sensitive patients with 0.05 mg chromium given as potassium dichromate. Within 2 h they developed severe vesiculation of the palms. One of the patients experienced acute exacerbation of generalized dermatitis. Schleiff (1968) observed flares of chromate dermatitis in 20 patients challenged with 1–10 mg potassium dichromate contained in a homeopathic drug. Some of the patients also experienced flares in previously positive dichromate patch-test sites.

Kaaber and Veien (1977) studied the significance of the oral intake of dichromate by chromate-sensitive patients in a double-blind study. Thirty-one patients were challenged orally with 2.5 mg chromium given as potassium dichromate and a placebo tablet. Nine of the eleven patients with vesicular hand eczema reacted with a flare of dermatitis within 1 or 2 days but did not react to the placebo. Three patients experienced vomiting, abdominal pain, and transient diarrhea after the chromate challenge, but not after challenge with the placebo.

A systemic contact dermatitis reaction to chromium has been seen after inhalation of welding fumes containing chromium (Shelley, 1964), after the ingestion of a homeopathic drug (van Ulsen et al., 1988), and after a nutritional supplement with chromium picolate (Fowler, 2000).

Compared to chromium and nickel, cobalt is well absorbed from the gastrointestinal tract. This makes cobalt-sensitive individuals candidates for further study of the possible existence of systemic contact dermatitis caused by this metal (Veien et al., 1987a). In a double-blind study, six of nine patients with positive patch tests to cobalt reacted to oral challenge with 1 mg cobalt given as 4.75 mg cobalt chloride (Veien et al., 1995). Most of the patients had recurrent vesicular hand dermatitis. Glendenning (1971) observed a 49-year-old housewife with persistent eczema of the palms and isolated cobalt allergy. After the removal of metal dentures made of a cobalt–chromium alloy (Vitallium), the dermatitis cleared. The patient had not had symptoms of stomatitis. After removal of the prostheses, she noticed a return of her appetite, the loss of which had been a definite symptom during the entire disease period.

Flare of cobalt dermatitis has been seen as a recall phenomenon in chronic alcoholics treated with tetraethylthiuram disulfide (Menné, 1985).

Systemically aggravated contact dermatitis has been caused by aluminium in toothpaste in children who have been sensitized to aluminium in vaccines (Veien et al., 1993a).

There have been several reports of widespread exanthema or multiforme-like erythema in patients with positive patch tests to mercury compounds (Nakayama et al., 1984). Vena et al. (1994) described nine such patients, seven of whom also had systemic symptoms such as malaise, pyrexia, and leukocytosis. The sensitization was induced by an antiparasitic

TABLE 14.5
Challenge Studies in Chromate-Sensitive Patients with an Oral Dose of Chromium Given as Potassium Dichromate

powder that was thought to cause systemic contact dermatitis after inhalation. Mercury in homeopathic medicine caused baboon syndrome in a 5-year-old girl (Audicana et al., 2001). Another route of systemic exposure is via dental treatment following the drilling of amalgam fillings. Following such treatment, a widespread maculopapular rash was seen in one mercury-sensitive patient (Aberer, 1993), two patients developed nummular dermatitis (Adachi et al., 2000), while another had flexural dermatitis (White and Smith, 1984) and one also had a flare of dermatitis at the site of a 4-week-old patch test to mercury (Veien, 1990). Flexural dermatitis is another manifestation of systemic dermatitis in mercury-sensitive patients. A baboon-like syndrome has also been seen (Pambor and Timmel, 1989; Faria and de Freitas, 1992; Zimmer et al., 1997).

A careful study of the concentration of mercury in saliva, feces, blood, plasma, and urine showed increased levels of mercury in saliva, blood, and feces during the first week after the removal of amalgam fillings. After removal of all the amalgam fillings, plasma Hg concentrations fell to 40% of the pretreatment level (Ekstrand et al., 1998).

Systemic contact dermatitis from implanted metals is rare with the currently employed technology within orthopedic surgery.

Case reports indicate that systemic contact dermatitis may still occur in a sensitized patient after the insertion of a metal prosthesis. Giménez-Arnau et al. (2000) reported widespread dermatitis in a nickel- and cobalt-sensitive woman whose aortic aneurism was repaired with a stent containing nickel and titanium.

A nickel-sensitive man developed vesicular hand dermatitis after his ankle fracture was repaired with plates containing 14% nickel. The dermatitis improved after the plate was removed (Kanerva and Förström, 2001).

Orthodontic appliances have been seen to cause urticaria and dermatitis in nickel-sensitive persons (de Silva and Doherty, 2000; Kerosuo and Kanerva, 1997; Fernández-Redondo et al., 1998). In some nickel-sensitive patients, the diagnosis has required oral challenge with the metals nickel, cobalt, and chromium (Veien et al., 1994a).

Gold has become a common contact allergen in several centers. Möller et al. (1996) challenged 20 gold-sensitive patients with sodium thiomalate or placebo. One of ten who received the active compound experienced flare-up of a previous contact dermatitis site. All 10 patients experienced a flare-up of their previous gold patch-test sites, and several patients had toxicoderma-like symptoms. In a later study, Möller et al. (1999b) saw a flare-up of previously positive gold patch-test sites and transient fever in five of the five gold-sensitive patients. Russell et al. (1997) reported three patients who developed lichenoid dermatitis after drinking liquor containing gold.

14.7 OTHER CONTACT ALLERGENS

Kligman (1958a) attempted to hyposensitize persons with *Rhus* dermatitis by giving increasing amounts of the allergen in oral doses. Half of the moderately to severely sensitive patients experienced either pruritus or a rash; 10% of the patients experienced flares of their dermatitis at sites of previously healed contact dermatitis. Flares of vesicular hand eczema and erythema multiforme were rare. Pruritus ani occurred in 10% of the highly sensitive individuals. Severe systemic contact dermatitis was described in *Rhus*-sensitive patients who had eaten cashew nuts (Ratner et al., 1974). The allergen in cashew nut shells cross-reacts with the poison ivy–allergen, which explains the reactions (Kligman, 1958b).

Sporadic cases of cashew nut dermatitis caused by the presence of shell fragments among edible nuts have been described. A case of perianal dermatitis occurred after the ingestion of cashew nut butter (Rosen and Fordice, 1994). A baboon-like eruption occurred 36 h after the ingestion of a pesto sauce containing cashew nuts (Hamilton and Zug, 1998).

The lacquer tree contains antigens related to those found in poison ivy and cashew nuts. Thirty-one patients with systemic contact dermatitis were seen following the ingestion of lacquer. A widespread erythematous, maculopapular eruption was the most common clinical symptom. Some patients experienced abdominal pain, nausea, vomiting, and chills (Park et al., 2000).

Systemic contact dermatitis has been seen in patients sensitive to balsam of Peru, which contains naturally occurring flavors. The perfume mixture may be a better indicator of sensitivity to spices than balsam of Peru (van der Akker et al., 1990). Hjorth (1965) observed systemic contact dermatitis in balsam of Peru–sensitive patients who had eaten flavored icecream and orange marmelade. Veien et al. (1985b) challenged 17 patients sensitive to balsam of Peru with an oral dose of 1 g of balsam of Peru. Ten patients reacted to balsam of Peru and one to a placebo.

Hausen (2001a) reviewed 102 patients sensitive to balsam of Peru. Ninety-three reacted to one or more of 19 constituents. Eight who had reactions to coniferyl benzoate and benzyl alchohol had systemic contact dermatitis. Three of these patients had hand eczema and three had widespread dermatitis.

Based on questionnaires mailed to the patients 1–2 years after the initiation of diet treatment, Veien et al. (1996a) reviewed 46 balsam-sensitive patients who had been asked to reduce their dietary intake of balsams. Sixteen of 22 (73%) who had reacted to 1 g balsam of Peru in a placebo-controlled oral challenge had benefit from a low-balsam diet compared to 3 of 10 (30%) who had shown no reaction to the oral challenge. Nine of fourteen (64%) who were placed on a low-balsam diet, but who were not challenged orally, benefited from a low-balsam diet.

Salam and Fowler (2001) studied 71 perfume and balsam-sensitive patients retrospectively. The dermatitis of 21 of 45 patients who followed a low-balsam diet improved or cleared. The most common sites of dermatitis were the hands, face, and anogenital region. The most commonly implicated foods were tomato, citrus, and spices.

Niinimäki (1995) challenged 22 patients orally with balsam of Peru in a placebo-controlled study. Eight patients reacted to balsam of Peru but not to the placebo, while four

reacted to both balsam of Peru and the placebo or only to the placebo. Aggravation of vesicular hand eczema was the most common clinical response. Similarly, Niinimäki (1984) challenged 71 patients sensitive to balsam of Peru with spices. Seven had positive reactions to the challenge. Most had vesicular hand eczema.

A 56-year-old woman had dermatitis on the fingers of both hands, and patch testing showed a + reaction to balsam of Peru and a +++ reaction to coniferyl benzoate. Her hand eczema cleared after she stopped smoking and drinking 3 L of Coca-Cola® per day (Hausen, 2001b).

The dermatitis of two balsam of Peru–patients cleared after a reduction in the intake of plant extracts (le Sellin, 1998), and the hand eczema of a patient sensitive to balsam of Peru cleared after a low-balsam diet was followed. The latter diagnosis was confirmed by oral challenge with balsam of Peru (Pfutzner et al., 2003).

A patient sensitive to balsam of Peru and to rosin experienced a flare of hand eczema and widespread dermatitis after dental work involving the filling of a root canal with rosin (Bruze, 1994).

Dooms-Goossens et al. (1990) described systemic contact dermatitis caused by the ingestion of spices in a patient with a positive patch test to nutmeg and in two patients sensitive to plants of the composita family after the ingestion of laurel. Sesquiterpene lactones found in compositae caused systemic contact dermatitis in a patient following the ingestion of lettuce (Oliwiecki et al., 1991).

Goldenrod in an oral medication (Urodyn®) caused systemic contact dermatitis in a 52-year-old man (Schätzle et al., 1998).

German chamomile tea caused a widespread eruption and anal pruritus in a 26-year-old woman who was sensitive to sesquiterpene lactone (Rodríguez-Serna et al., 1998) and caused recurrent facial dermatitis in another patient (Rycroft, 2003).

Inhalation of the allergen costus resinoid caused a baboon-like eruption in a sesquiterpene lactone-sensitive woman (le Coz and Lepoittevin, 2001).

A 45-year-old man developed widespread dermatitis after the ingestion of tea tree oil to which he had previously had a positive patch test (de Groot and Weyland, 1992).

Kava extract caused systemic contact dermatitis in one patient (Suss and Lehmann, 1996).

Garlic has been shown to cause systemic contact dermatitis with vesicular hand eczema as the clinical manifestation. The dermatitis could be reproduced by placebo-controlled oral challenge (Burden et al., 1994). Ingestion of garlic has also caused systemic contact dermatitis in the elbow flexures and periorbitally (Pereira et al., 2002).

Cutaneous reactions following the ingestion of alcoholic beverages were reviewed by Ophaswongse and Maibach (1994). Both immediate- and delayed-type hypersensitivity reactions causing systemic contact dermatitis were described. One patient became sensitized to ethanol in an estrogen transcutaneous delivery system. She developed widespread exanthema after the ingestion of alcoholic beverages (Grebe et al., 1993).

The antioxidant butylated hydroxyanisole, which is used both in cosmetics and in foods, can cause systemic contact dermatitis (Roed-Petersen and Hjorth, 1976), as can substances as diverse as formaldehyde (Bahmer and Koch, 1994) and ethyl ethoxymethylene cyanoacetate (Hsu et al., 1992).

Preservatives such as sorbic acid have caused systemic contact dermatitis presenting clinically as hand eczema (Raison-Peyron et al., 2000; Dejobert et al., 2001).

Parabens have been suspected as the cause of systemic contact dermatitis. However, only 2 of 14 paraben-sensitive patients experienced flares of their dermatitis after placebo-controlled oral challenge with 200 mg methyl and propyl parahydroxybenzoate. Both patients who reacted to the challenge had vesicular hand eczema (Veien et al., 1996b).

14.8 RISK ASSESSMENT-ORIENTED STUDIES

While the risk of systemic contact dermatitis from drugs can be assessed, it is more difficult to carry out similar studies on ubiquitous contact allergens such as metals and naturally occurring flavors. In spite of intensive research on the significance of orally ingested nickel in nickel-sensitive individuals, we are unable to give firm advice concerning the oral dose that would represent a hazard for the wide range of nickel-sensitive individuals. Many variables, such as the route of administration, bioavailability, individual sensitivity to nickel, interaction with naturally occurring amino acids, and interaction with drugs must be considered. A number of as yet unknown factors could influence nickel metabolism. Furthermore, immunological reactivity to nickel can change with time and can be influenced by sex hormones and the development of tolerance. It is important to recognize that this area of research is extremely complex and that much well-controlled research is still needed.

Jensen et al. (2006) performed a modified meta-analysis of the theoretical risk of systemic contact dermatitis after the oral administration of nickel in nickel-sensitive patients. The conclusion was that only a minority of nickel-sensitive patients is at risk of systemic contact dermatitis after the ingestion of nickel in food.

With regard to medicaments, it is possible to perform well-controlled oral challenge studies in sensitized individuals. The beta-adrenergic blocking agent alprenolol is a potent contact sensitizer. Ekenvall and Forsbeck (1978) identified 14 workers employed in the pharmaceutical industry who were contact-sensitized to this compound. Oral challenge with a therapeutic dose (100 mg) led to a flare in one worker, who experienced pruritus and widespread dermatitis.

Merthiolate is a preservative widely used in sera and vaccines. Förström et al. (1980) investigated 45 merthiolate contact-sensitive persons to evaluate the risk of a single therapeutic dose of 0.5 mL of a 0.01% merthiolate solution given subcutaneously. Only 1 of the 45 patients developed a systemic contact dermatitis reaction. Aberer (1991) did not observe any reactions in a similar study involving 12 patients.

Maibach (1987) studied a group of patients who had discontinued the use of transdermal clonidine because of

dermatitis. Of 52 patients with positive patch tests to clonidine, 29 were challenged orally with a therapeutic dose of the substance. Only one patient reacted with a flare-up at the site of the original dermatitis.

Propylene glycol is used as a vehicle in topical medications and cosmetics and as a food additive. Propylene glycol is both a sensitizer and a primary irritant. Hannuksela and Förström (1978) challenged 10 contact-sensitized individuals with 2–15 mL propylene glycol. Eight reacted with exanthema 3–16 h after the ingestion.

14.9 DIAGNOSIS

Systemic contact dermatitis can occur in patients who are contact sensitized to haptens if these patients are then exposed systemically to the same hapten. The number of persons who will actually react to a systemic exposure depends on the dose administered and for nickel to the strength of the patch-test reaction and the time elapsed since patch testing (Hindsén, 2001). Break-down products like formaldehyde from aspartame may cause systemic contact dermatitis (Hill and Belsito, 2003).

According to the available literature, particularly from experimental nickel challenge studies and challenge studies with medicaments, the dose needed to produce such systemic contact dermatitis reactions is relatively large. The number of patients with systemic contact dermatitis seen in clinical practice is low compared to the number of patients with allergic and irritant contact dermatitis (Veien et al., 1987b). In spite of the fact that systemic contact dermatitis is relatively rare, it is important to identify this type of reaction to provide optimal management of the individual patient. The diagnosis rests upon patch testing and oral-challenge studies. Severe reactions are exceptional. To our knowledge, severe or lethal anaphylactic reactions have not occurred after accidental or experimental oral challenge of patients with allergic contact dermatitis.

References 156

Contact dermatitis, an inflammatory skin disease characterized by itching, redness, and skin lesions, is caused by skin contact with either an irritant or an allergenic chemical. Acute irritant contact dermatitis arises on initial contact with an adequate concentration of a direct-acting cytotoxic chemical. Whereas, allergic contact dermatitis (ACD) usually arises following more than one skin contact (induction and elicitation) with an allergenic chemical. The skin response of ACD is delayed, immunologically mediated, and consists of varying degrees of erythema, edema, and vesiculation. In the Gell and Coombs system (1968), it is classified as a cell-mediated, tuberculin-like, Type IV allergy.

The best known example of ACD is the linear vesicular skin response that is often seen hours after contact with poison ivy, at which time itching is a prominent symptomatic feature.

Allergenic chemicals penetrate the skin as small molecules (usually $<$400 MW), and they are incompletely allergenic (haptens) until they bind to protein and form a complete allergen.

In ACD, the first significant exposure to a haptenic chemical activates the immune system (induction) and sensitizes the skin. After sensitization (which takes a few days to a few weeks), subsequent antigenic exposures result in the evocation of an altered ("allergic") skin response (elicitation), that is, one that is more pronounced than the original response. For sensitization to take place, the allergenic chemical must first penetrate the skin, so that it can reach and interact with key elements of the underlying immune system. A certain level of allergen entry must be achieved that represents a threshold for triggering the immune system. The threshold can be reached following a single skin exposure to a sufficiently high amount or concentration of allergenic chemical, or after contact with a large area of skin, or as a consequence of repeated skin applications.

Once the allergenic chemical has abrogated the horny barrier layer of skin and entered the viable layer of the epidermis, it makes contact and binds with Langerhans cells. These are dendritic cells that direct the allergen to a regional lymph node where interaction with T lymphocytes is followed by replication of sensitized T lymphocytes and expansion of the sensitized T-lymphocyte population, completing the induction phase of the sensitization process.

In the sensitized individual, the next contact with the allergenic chemical results in the elicitation of a hypersensitive skin response that is due to a reaction between circulating sensitized lymphocytes and allergen at the skin site where allergen has entered the living epidermis.

The term allergy was coined by von Pirquet in 1910; however, our present understanding of events of the sensitization process probably began to unfold after the patch test was developed by Jadassohn (1895). This test was intended to clinically duplicate contact allergy on a small scale by applying a suspect chemical to the skin of a sensitized patient (under occlusion) to confirm its allergenic potential.

The next important episode involved the passive transfer of immediate-type allergy by the Prausnitz-Kustner reaction (1921). This consisted of injecting blood serum from an allergic person into the skin of a normal person, making the injected site reactive to the injected allergen.

Landsteiner and Jacobs (1936) demonstrated that delayed-type reactions could be induced by intradermal injection of certain allergens.

Another important finding was that of Landsteiner and Chase (1942) that lymphocytes become sensitized during the development of ACD.

Other early historical events were reviewed in the 50th anniversary issue of the *Journal of Allergy and Clinical Immunology* (Allergy, 1979).

The development of predictive and diagnostic human and guinea pig tests for skin sensitization focused further attention on ACD (Schwartz, 1941), as did regulatory and legal requirements for evaluating drug and cosmetic safety (Draize, 1959).

Early in the study of ACD, humans were the primary investigative test species. Later, guinea pigs were added as the animal model of choice. More recently the mouse has been used extensively.

Concordance of developments in genetics and molecular biology, based on mouse studies, with the entry of the mouse as a test species for ACD potential led ultimately to the finding that cytokines play a role in both irritant dermatitis and ACD. A detailed interpretation of cellular and molecular events of ACD is given in Sauder and Pastore (1993).

Entrance of an irritant or allergenic chemical into the epidermis signals the release of a cascade of cytokines from

affected keratinocytes, suggesting a key role for keratinocytes in these inflammatory processes. It is not yet clear how cytokines differ qualitatively and quantitatively during ACD and irritant reactions, but this is likely to be an important area of future research.

While foundations for the overall picture of events of ACD appear secure, the future may unhinge some present interpretations of the details.

Keratinocytes comprise the main cellular composition of the human epidermis. They are involved in synthesis of various cytokines during both normal and abnormal cell functions. Cytokines are regulatory proteins that mediate cell communication, and include interleukins, growth factors, colony-stimulating factors, and interferons. When keratinocytes are damaged during contact with irritant or allergenic compounds, various inflammatory elements, including cytokines, adhesion molecules, and chemotactic factors, are released (Barker et al., 1991; Kupper, 1989). Current research interest in this area has sparked a continuously expanding literature.

A number of studies have been conducted to investigate the activation sequence following keratinocyte damage. In one such study (Willis et al., 1989), 10 healthy human volunteers were patch tested with six structurally unrelated irritants, and their skins were biopsied 48 h later and examined by light and electron microscopy. Keratinocytes were damaged in distinctly different patterns, and mononuclear cells were the predominant infiltration response.

It is virtually impossible to distinguish irritant dermatitis from ACD with precision, on gross and even microscopic inspection. Recently, Brasch et al. (1992) reported an attempt to find a distinction between the two dermatides. Topically applied sodium lauryl sulfate (SLS), an irritant chemical, was administered to seven sensitized subjects along with the allergenic chemical, on two separate test skin sites, to produce experimental irritant and allergic contact dermatitis on a small scale. Both skin sites responded similarly in clinical appearance, histology, and immunohistology. A large battery of monoclonal antibodies directed against numerous surface, intracellular, and nuclear antigens failed to uncover a difference between the irritant and the allergic sites by these immunostaining techniques.

The finding that cytokines are released during the ACD process opens the way to the ultimate development of a specific test to differentiate ACD from irritant dermatitis (Enk and Katz, 1992; Paludan and Thestrup-Pederson, 1992).

Some commonly encountered allergens that have been reported by members of the North American Contact Dermatitis Research Group during diagnostic studies of clinical patients include (Storrs et al., 1989) balsam of Peru, benzocaine, benzoyl peroxide, black rubber paraphenylenediamine mix, caine mix minus benzocaine, carba mix, cinnamic alcohol, cinnamic aldehyde, dibucaine, cyclomethycaine sulfate, epoxy resin, ethylenediamine dihydrochloride, eugenol, formaldehyde, hydroxycitronellal, imidazolidinyl urea, isoeugenol, lanolin alcohol, mercapto rubber mix, mercaptobenzothiazole, neomycin sulfate, nickel sulfate, oak moss, *p*-tertiary butylphenol formaldehyde resin, potassium dichromate, *p*-phenylene diamine, quaternium-15, rosin (colophony), tetracaine, thimerosol, and thiuram rubber mix.

Vehicle and preservative allergens include ammoniated mercury, benzophenone, 2-bromo-2-nitropropane 1, 3-diol (bronopol), captan, chloroacetamide, *p*-chloro-*m*-cresol, chloroxylenol, diazolidinyl urea, dichlorophene, DMDM hydantoin, Kathon CG, paraben mix, polythylene glycol, *o*-phenylphenol, propylene glycol, sorbic acid, and Tween 85.

Cosmetic injury reports to the Office of Cosmetics and Colors, FDA (1988–1993), are similar to preceding years when fragrances and preservatives were established as the most common sensitizers in cosmetics.

Among the newer preservative chemicals that may sensitize are methyldibromoglutaronitrile and phenoxyethanol (Euxyl K 400). Dibenzoyl methanes in addition to PABA (*para*-aminobenzoic acid) are among the newer sunscreens that are potential allergens (Brancaccio, 1992). Furthermore, glyceryl monothioglycolate is a sensitizer in hair products; nicotine is in transdermal therapeutic systems; and corticosteroids such as hydrocortisone are of increasing concern as sensitizers (Brancaccio, 1992).

Natural rubber latex, now widely used in surgical gloves and in condoms, is producing allergic reactions in epidemic proportions.

Additional useful information relating to the allergenic potential of specific chemicals is published in other scientific journals.

The Cosmetic Ingredient Review Committee of the Cosmetic, Toiletry and Fragrance Association has published 22 special issues of the *Journal of the American College of Toxicology* that contain information on skin sensitization and other safety data on cosmetic ingredients beginning in 1982.

The Research Institute for Fragrance Material has published sensitization data on chemicals that have been proposed for use as fragrance ingredients and are in *Food and Chemical Toxicology*.

Lachapelle (2003) provides an efficient premise on diagnostic skin testing. Maibach (2001) dermatotoxicologic assayz. Wahlberg (2003) summarizes common exposures to the more frequently patch tested chemicals.

16.1 INTRODUCTION

Contact dermatitis is one of the most common skin diseases, with a great socio-economic impact (Uter et al., 1998). As the outermost barrier of the human body, the skin is the first to encounter chemical and physical agents from the environment. According to the pathophysiological mechanisms involved, two major types of contact dermatitis may be recognized, that is, irritant contact dermatitis (ICD) and allergic contact dermatitis (ACD).

The basis for a diagnosis of either ICD or ACD is mainly established by considering the morphology of the clinical lesions, assessing the relationship between the putative exposure and the time course of the dermatitis, as well as performing appropriate diagnostic patch testing. Differentiating between ICD and ACD is frequently difficult in the clinical setting. This represents a considerable predicament, in view of the high frequency of these entities and their impact on the patient's quality of life. Discriminating between allergens and irritants is also crucial in toxicological research and major efforts have been made to identify morphological, immunohistochemical, and immunological changes, allowing for a clear-cut distinction between the effects of allergens and irritants.

Such information will enhance our understanding of the molecular processes involved in ICD and ACD and may provide a mechanistic basis for designed refined *in vivo* and *in vitro* models to be applied in toxicological testing.

16.2 PATHOGENETIC MECHANISMS

Several authors have demonstrated that ACD and ICD may have clinical, histological, and immunohistochemical similarities (Lammintausta and Maibach, 1990; Brasch et al., 1992; Scheynius et al., 1984). However, the immunobiological mechanisms that underlie both types of response were thought to be fundamentally different.

ACD requires the activation of antigen specific–acquired immunity leading to the development of effector T cells, which mediate the skin inflammation. The cutaneous inflammatory response in ACD is dependent on the activation and clonal expansion of specific allergen-responsive T lymphocytes. In contrast, ICD has been defined as a local inflammatory reaction, following a single or repeated exposure to an irritant, which is an agent producing a direct toxic insult to the cutaneous cells (Mathias and Maibach, 1978). Irritant damage to the skin induces abnormalities of epidermal proliferation and differentiation and activation of the skin innate immunity. Epidermal cells injured by irritants release eicosanoids, cytokines, and growth-enhancing factors, which are potent chemoattractants for leukocytes and may induce T-cell activation via antigen-independent pathways (Barker et al., 1991; Nickoloff and Naidu, 1994; McKenzie and Sauder, 1990). The immune cascade is then activated independently of the antigen presentation pathway, by the induction of proinflammatory mediators that directly recruit and activate T lymphocytes, without the induction of antigen-specific memory T cells (Baadsgaard and Wang, 1991; Hunziker et al., 1992). Following T-cell activation and lymphokine release, the cellular events and inflammatory response in ACD and ICD seem to be comparable (Ulfgren et al., 2000; Effendy et al., 2000; Brand et al., 1997; Gawkrodger et al., 1986; Brasch et al., 1992).

Therefore, the distinction between ICD and ACD becomes progressively blurred, and it is now apparent that allergic and irritant contact reactions have at least partially overlapping pathophysiology and share common effector pathways (Brand et al., 1996; Effendy et al. 2000; Mohamadzadeh et al., 1994).

Moreover, many chemicals that are capable of behaving as contact allergens also have irritant properties, frequently disregarded because their allergenic potential dominates their toxicity profile. Indeed, it is believed that irritancy promotes allergic sensitization to some degree, even if the mechanisms underlying this interaction are only partially known. The "danger signal" hypothesis (Matzinger, 1998) suggests that the immune responses can be augmented by danger signals released by tissues undergoing stress, damage, or abnormal death. In this context, an antigenic signal will produce sensitization only in the presence of a danger signal; in its absence tolerance will occur. Irritancy may represent a danger signal for the immune system as direct toxic damage of dendritic cells (DC) or other cells (principally keratinocytes) will trigger cytokine release predisposing to allergic sensitization (Gallucci and Matzinger 2001; McFadden and Basketter, 2000). In fact, as most contact allergens have irritant properties, both the antigenic and danger signals may arise from the hapten (Smith et al., 2002).

The majority of haptens bear lipophilic residues, which enable them to cross through the stratum corneum (SC) barrier, and electrophilic residues, which are responsible for the covalent bonds to the nucleophilic residues of cutaneous proteins (Lepoittevin and Leblond, 1997). T lymphocytes recognize haptens as structural entities bound covalently to, or by complexation to, peptides anchored in the grooves of major histocompatibility (MHC) class I and class II molecules. The antigen able to activate hapten-specific T cells is then a haptenated peptide (Martin et al., 1992).

The pathophysiology of contact sensitization (CS) has been classically divided into two distinct phases, that is, the sensitization phase and the elicitation phase. The sensitization phase, also referred to as afferent phase or induction phase of CS, was believed to occur at the first significant contact of skin with the sensitizing substance, which leads to the generation of allergen-specific T cells. The hypothesis of the first contact of a chemical being sensitizing for the host may be accurate for strong allergens; however, ACD to moderate or weak allergens almost never occurs after the first contact but may take years of permanent skin exposure to develop.

The haptens capable to induce CS are low molecular weight chemicals that are not immunogenic by themselves, and need to bind to epidermal proteins that can act as carrier molecules. The ability of a hapten to induce sensitization relies on two distinct properties. Through their proinflammatory properties, haptens activate the skin innate immunity and deliver signals responsible for inducing the maturation and migration of cutaneous DC. Through their binding to amino acid residues they modify self-proteins and induce the expression in the skin of new antigenic determinants. Haptens are loaded by DC and are expressed as haptenated peptides in the groove of MHC class I and class II molecules at the cell surface. Hapten-bearing DC migrate from the skin to the regional lymph node where specific CD8+ and CD4+ T lymphocytes are primed in the paracortical area. T cells proliferate and emigrate out of the lymph nodes to the blood where they recirculate between the lymphoid organs and the skin.

In the elicitation phase, also known as efferent or challenge phase of CS, the challenge of sensitized individuals with the same hapten leads to the apparition of ACD/CS in 24/72 h. Haptens diffuse in the skin and are uptaken by skin cells, which express MHC I and II/haptenated peptide complexes. Specific T lymphocytes are activated in the dermis and the epidermis, and trigger the inflammatory process responsible for the cutaneous lesions. Recent studies have demonstrated that CD8+ cytotoxic T lymphocytes are the main effector cells of CHS to strong haptens and that they are recruited early after challenge before the massive infiltration of leucocytes, which contain the downregulatory cells of CHS, found in the CD4+ T-cell subset.

16.2.1 Cytokine Profiles

Cytokines, a family of inducible glycoproteins, play a fundamental role in triggering and developing the inflammatory processes occurring in the skin. Therefore, several studies have investigated the cytokine expression in allergic and irritant reactions, in an effort to provide insight about the underlying pathogenic mechanisms operating in both types of inflammatory responses. Until now, the results have been contradictory and have not provided unambiguous differentiation (Table 16.1).

After skin contact, irritants such as sodium lauryl sulfate (SLS) impair the SC barrier (De Jongh et al., 2006; Fartasch, 1997; Willis et al., 1989) and produce a direct toxic effect on the keratinocytes. In response to these effects, preformed cytokine interleukin-1α (IL-1α) is released from the SC and keratinocytes as the first step in the inflammatory cascade. IL-1α stimulates other keratinocytes and fibroblasts to produce and release more IL-1α, as well as other proinflammatory cytokines such as IL-1β, IL-6, IL-8, and tumor necrosis factor-α (TNF-α), which may play a role in the migration and activation of inflammatory cells (Boxman et al., 1996). The triggered cytokine cascade results in the inflammatory response induced by irritants. Hoefakker et al. (1995) attempted to elucidate whether there was a difference in the cytokine profiles in allergic and irritant patch-test reactions, especially at the same time of final reading in diagnostic patch testing. Local cytokine profiles in skin biopsies from allergic reactions to epoxi resin (1%) and formaldehyde (1%), and irritant reactions to SLS (10%) and formaldehyde (8%) were determined by *in vivo* immunohistochemistry. The allergic and irritant patch-test reactions showed similar levels of expression of the Th1 cytokines IL-2 and interferon-γ (IFN-γ) in the dermis, confirmed by probe-based detection of IL-2 mRNA and IFN-γ mRNA.

In cultured human keratinocytes, different irritants, namely SLS, phenol, and croton oil, as well as the allergen dinitrofluorobenzene (DNFB) induced the production and intracellular accumulation of IL-8 (Wilmer et al., 1994). Similarly, the expression of IL-8 gene by human keratinocytes was significantly increased by SLS and the allergens DNFB and 3-*n*-pentadecylcatechol (Mohamadzadeh et al., 1994). Ulfgren et al. (2000) observed that the cytokine

profile in irritant reactions to SLS and contact allergic skin reactions to nickel 6 h after challenge was similar. At 72 h, the dermal cells expressed IL-1α, IL-1β, IL-2, IL-4, IL-6, and IL-10 in both types of inflammatory reactions. However, two differences were observed. Staining for the IL-1 receptor antagonist was more prominent in the dermis at the late stages of the allergic reaction, and the inflammatory mononuclear infiltrate showed a more prominent IFN-γ staining in the irritant reactions. Pichowski et al. (2000) studied the mRNA expression for IL-1β in blood-derived dendritic cells, cultured in the presence of DNFB, SLS, or vehicle. This cytokine plays a major role in the induction phase of ACD (Enk et al., 1993b) and was shown to upregulate MHC class II molecule expression on Langerhans cells (LC) *in situ* to produce recruitment of inflammatory cells and to induce adhesion molecules related to leukocyte–endothelial adhesion. A two- to threefold increase in IL-1β mRNA was observed in cells derived from three of eight DNFB-treated donors, whereas SLS treatment did not induce IL-1β mRNA expression in the cells of any of the donors investigated. In contrast, Brand et al. (1996) demonstrated that the protein levels of IL-1β in human skin lymph increased in the course of both irritant and allergic contact dermatitis and therefore do not allow to discriminate between them.

Using an *in situ* hybridization technique, Flier et al. (1999) detected mRNA expression for the chemokine IFN-γ-inducible-protein-10 (IP-10), as well as the related CXC chemokine receptor-3 (CXCR3) activating chemokines, macrophage migration inhibitory factor (Mif), and IP-9 in contact allergic reactions, but not in SLS-induced irritant reactions. Additionally, up to 50% of the infiltrating cells in ACD expressed CXCR3, the cognate receptor for IP-10, Mif, and IP-9, which is nearly exclusively expressed on activated T cells. In contrast, CXCR3 expression was found in only 20% of irritant reactions. The differential expression of IP-10 in human ICD and ACD is consistent with the results of previous studies in mice (Enk and Katz, 1992; Enk et al., 1993a) and suggests that this chemokine intervene in the generation of the inflammatory infiltrate in ACD, but not in SLS-induced irritant reactions. In addition, intercellular adhesion molecule 1 (ICAM-1) expression by keratinocytes was only found in allergic reactions correlating with chemokine expression (Flier et al., 1999). Similarly, Verheyen et al. (1995) and Vestergaard et al. (1999) reported that ICAM-1 expression in keratinocytes can be found in allergic patch test reactions but only rarely occurred in irritant reactions induced by SLS or croton oil. These results support the conception that ICAM-1 plays a role in the specific immune response by facilitating the antigen presentation or lymphocytic infiltration. However, upregulation of ICAM-1 expression by keratinocytes, in correlation with expression of lymphocyte function antigen-1-positive leukocytes, was also observed in SLS-induced reactions (Willis et al., 1991), indicating that ICAM-1 may play a role in irritant reactions. Similarly, Verheyen et al. (1995) reported that ICAM-1 expression by endothelial cells and also mononuclear cells could be induced in both irritant and allergic reactions.

Brand et al. (1997) observed that the IL-10 levels in lymph derived from irritant reactions and primary sensitization of ACD were similar to those obtained from normal skin, remaining below 4.4 pg/mL. In contrast, the IL-10 levels increased manifold, both in the primary allergic reaction (928.5 pg/mL) and the elicitation of ACD (124 pg/mL). In addition, the IL-10 mRNA signal was markedly stronger in lymph and epidermal blister cells from the elicitation reactions as compared to the signal in lymph cells derived from normal skin and from the primary sensitization of allergic reactions. Similarly, Ryan and Gerberick (1999) observed stronger mRNA expression of IL-10, IL-4, and IL-2 in allergic patch-test reactions to poison ivy compared to irritant reactions induced by SLS.

The number of infiltrating cells was larger in biopsies from allergic reactions induced by nickel sulfate than in irritant reactions induced by SLS. However, at the single-cell level, the expression of VLA (very late antigens), lymphocyte function-associated antigen-1 (LFA-1), CD44, and intercellular adhesion molecule-1 (ICAM-1) was similar in both groups. The endothelial cells in allergic reactions showed a stronger expression of vascular cell adhesion molecule-1 (VCAM-1), endothelial leukocyte adhesion molecule-1 (ELAM-1), and ICAM-1 compared to irritant reactions (Wahbi et al., 1996).

In summary, even if cytokines play a fundamental role in the pathogenic mechanisms of inflammatory skin diseases, present knowledge of the complex interactions of cytokines and cellular targets does not allow for identification of a specific "fingerprint" pattern of cytokine production that clearly distinguishes allergic from irritant reactions.

16.3 HISTOLOGY AND IMMUNOHISTOCHEMISTRY

Cellular changes that take place during the development of ACD and ICD, including modifications in the morphological appearance, proliferative state, and cell kinetics, have been evaluated in an attempt to discriminate between both disorders.

ICD shows much greater histological pleomorphism than ACD (Table 16.2). Irritants produce a wide range of histopathological changes as a consequence of their different mechanism of action and chemical interaction with the skin components. Lesions will also vary according to concentration of the irritant, type and duration of the exposure, and individual reactivity of the skin (Lachapelle, 1995; Willis et al., 1992, 1988; Patrick et al., 1985). Acute allergic reactions are characterized by dermal inflammatory infiltrates around the dilated venules of the superficial plexus, edema, and spongiosis. The inflammatory infiltrate in the epidermis adopts a focal distribution (Avnstorp et al., 1987) and constitutes microvesicles. If the process evolves more slowly, the spongiosis propels the epidermis to become hyperplastic. Subacute ACD lesions of ACD become less spongiotic and more psoriasiform. In chronic lesions of ACD there is almost no spongiosis. Rubbing and scratching will cause lichenification with thickening of the epidermis and hyperkeratosis. ICD also shows a perivascular inflammatory infiltrate in the dermis. In epidermis, the inflammatory infiltrate characteristically adopts a nonfocal, diffuse distribution. There may be some spongiosis, but it is habitually associated with ballooning of epidermal cells (intracellular edema), a phenomenon characterized by abundant, pale-staining cytoplasm of keratinocytes. In addition, the intraepidermal vesicles often develop into vesiculo-pustules and there is dermal and epidermal infiltration of neutrophilic granulocytes (Avnstorp, 1988). Strong irritants may induce necrosis of keratinocytes. Chronic ICD is usually indistinguishable of chronic ACD, showing acanthosis and hyperkeratosis.

It has been suggested that spongiosis may be specific of allergic reactions. In a comparative light microscopic study, early allergic patch-test responses (6–8 h after challenge) were characterized by follicular spongiosis, although clinically equipotent irritant reactions induced by SLS showed no significant changes (Vestergaard et al., 1999). However, spongiosis has been observed after challenge with

TABLE 16.2
Histological and Histochemical Differences between ICD and ACD

	ICD	ACD
Histology	Epidermis: Moderate spongiosis, intracellular edema, exocytosis spread, diffuse distribution of the inflammatory infiltrate in epidermis	Spongiosis with microvesicles predominates
	Occasionally, neutrophil-rich infiltrates	Focal distribution of the inflammatory infiltrate the epidermis
	Pustulation and necrosis may develop. Greater pleomorphism	Pustulation is rare
CD1+Langerhans cells	Decreased	Initial decrease in number, then increase
Immunohistochemistry	CD4+ T cells predominate, some CD8+ T cells	CD4+ T cells predominate, some CD8+ T cells
	In activated state (IL-2 expression)	In activated state (IL-2 expression)
	Increased expression of ICAM-1 by keratinocytes (the results from different studies have been conflictive)	Increased expression of ICAM-1 by keratinocytes
	Increased expression of HLA-DR by keratinocytes (the results from different studies have been conflictive)	Increased expression of HLA-DR by keratinocytes
Epidermal volume (proliferation)	Increase in epidermal volume at 24 h after challenge. Proliferating epidermal cells reach a peak 4 days after challenge. Keratin 16 and involucrin expression in the epidermis increased rapidly after challenge reaching a peak after 3 days and fading thereafter	Increase in epidermal volume at 72 h after challenge. Keratin 16 and involucrin expression in the epidermis increasing more slowly reaching a peak 4 days after challenge

other irritants such as benzalkonium chloride, croton oil, and dithranol (Willis et al., 1989).

Avnstorp et al. (1988) selected 17 histological variables for establishing the differential diagnosis between irritant and allergic reactions. In ACD reactions, the focal disposition of the inflammatory infiltrate in epidermis was found to be significantly different from the widespread distribution in ICD reactions. Necrosis was a significant feature in the diagnosis of irritant reactions, as it was in the presence of neutrophilic granulocytes in the dermal stroma. Statistical analysis by correlation of the selected variables provided a diagnostic specificity of 87% and a sensitivity of 81% for allergic reactions. In irritant reactions the specificity was 100%, but the sensitivity was only 46%. By multiple regression analysis, an index could be calculated: $4 \times$ necrosis $- 3 \times$ edema $- 2$. Subzero values denoted irritancy, while values above zero indicated allergy.

Both allergic and irritant challenges induce epidermal proliferation; however, the dynamics are different. Irritant reactions to SLS induced a statistically significant increase in epidermal volume at 24 and 72 h after challenge, compared to 0 and 6 h ($p < 0.003$ and $p < 0.001$, respectively), whereas the increase in the epidermal volume in allergic reactions to nickel sulfate was not noted until 72 h after challenge, compared to 0, 6 ($p < 0.001$), and 24 h ($p < 0.004$) (Emilson et al., 1998). Le et al. (1995) observed that challenge with the irritant SLS induced a higher and earlier increase in the number of cycling epidermal cells, and the maximum proliferation was reached 4 days after challenge. In comparison, allergic reactions showed a gradual increase in proliferating cells until a peak was attained on day five. Similarly, the expression of keratin 16 (K16), a molecule that is present in the suprabasal epidermis under hyperproliferative conditions, and involucrin, a marker of terminal differentiation, increased rapidly following challenge with SLS, reaching a peak after 3 days and fading thereafter, while allergic reactions exhibited a more delayed response reaching a maximum after 4 days. A positive CD36 (OKM5) expression was found both in irritant and allergic patch tests (Vestergaard et al., 1995). It has been postulated that there may possibly be a connection between OKM5 expression in the stratum granulosum and the proliferative state of the epidermis (Willis et al., 1991).

Concerning the cells of the inflammatory infiltrate, identical composition of peripheral T lymphocytes, associated with peripheral HLA-DR positive macrophages and LC, is observed in ICD and ACD (Scheynius et al., 1984; Ferguson et al., 1985; Brasch et al., 1992; Ranki et al., 1983). In the lymphocyte population, helper/induced T lymphocytes exceed the number of suppressor/cytotoxic cells in both types of reaction (Scheynius et al., 1984; Avnstorp et al., 1987). The number of infiltrating cells was larger in biopsies from allergic reactions induced by nickel sulfate than in irritant reactions induced by SLS. However, the kinetics of the cell responses, the phenotypes of the inflammatory cells, their allocation, and spatial relationship was comparable (Scheynius, 1984). Similar findings were reported by Gawkrodger et al. (1986), although slight differences in the spatial distribution between both types of reactions were observed. Dermal infiltrates were larger in the allergic reactions, but epidermal invasiveness was greater in the irritant reactions. Using laser scanning microscopy and indirect immunofluorescence, Emilson et al. (1998) evaluated the epidermal expression of HLA-DR and the invariant chain reactivity associated with antigen processing and presentation in allergic and irritant reactions. No significant change in the epidermal volume of HLA-DR reactivity was found in both types of reactions, nor was any significant change in the epidermal volume of invariant change reactivity in the allergic reactions. In the irritant reactions, however, there was a significant decrease in the epidermal volume of invariant chain reactivity from 24 to 72 h. Also, 72 h irritant reactions had a significantly lower epidermal volume of invariant chain reactivity compared to allergic reactions. This decline might reflect an epitope-induced alteration by irritants or a downregulated biosynthesis of the invariant chain due to variance in local cytokine production between both types of inflammatory reactions.

Using confocal and electron microscopy, Rizova et al. (1999) showed that freshly isolated human LC preincubated with contact sensitizers internalized the HLA-DR molecules, preferentially in lysosomes situated near the nucleus, whereas the irritant-treated or -untreated LC internalized these molecules in small prelysosomes located near the cell membrane.

16.4 ALLERGENS AND IRRITANTS IN IMMUNOTOXICOLOGY TESTING

During the past two decades growing interest arose in developing improved toxicological methods for differentially diagnosing contact allergic reactions from contact irritant reactions in humans. The majority of tests for predicting allergenicity of chemicals use guinea pigs or mice with biphasic protocols, comprising a sensitization phase (induction) and an elicitation phase (challenge) (Buehler, 1965; Magnusson and Kligman, 1969; Maurer et al., 1980). In guinea pig models, such as the guinea pig maximization test, Buehler's occluded patch test, or the optimization test, contact reactivity is assessed mainly by a subjective local erythema score and determined by the frequency of animals exhibiting a positive response. In the challenge-induced mouse ear–swelling test (MEST), induration is the predominant feature of the positive allergic reaction. To avoid false–positive results, challenge must be performed with a concentration of the test material that is unable to provoke skin irritation in nonsensitized controls. It is possible, therefore, with highly irritant materials that the concentrations selected for challenge are below those necessary to elicit a contact hypersensitivity reaction. More recently, the murine local lymph node assay (LLNA) was described as an alternative method for the detection of moderate or strong contact sensitizers. In contrast to guinea pig models and the MEST, the LLNA is based upon the detection of a primary immune response as a function of the cell proliferation in the draining lymph nodes after epicutaneous exposure to materials (Kimber et al., 1986; Kimber and Weisenberger, 1989; Basketter et al., 1991, 1994).

Although the LLNA was first described to selectively detect allergic skin immune responses, recent studies showed that many irritant compounds like sodium dodecyl sulfate (SDS), chloroform/methanol, triton X-100, croton oil, benzalkonium chloride, salicylic acid, dimethyl sulfoxide, among others, also induce node cell proliferation not distinguishable from the results with low-grade or moderate irritants (Montelius et al., 1994; Ikarashi et al., 1993; Homey et al., 1998). Therefore, irritant substances could be wrongly classified as allergens, or the allergenicity of substances with both allergenic and irritant properties could be overestimated.

To differentiate the cellular and molecular events elicited by allergens and irritants, Sikorski et al. (1996) performed a phenotypic analysis of lymphocyte subsets in the draining lymph nodes after topical treatment. The expression of CD3, CD4, CD8, and B220 was evaluated by flow cytometry. The allergens oxazolone and trinitro-chloro-benzene (TNCB) and the irritant benzalkonium chloride increased the total number of T and B lymphocytes in comparison with vehicle. In allergen-treated mice, a preferential increase in B lymphocytes, as seen by an increase in B220+ cells, was apparent in comparison with those treated with irritant and vehicle. This increase was consistently more prominent when stronger sensitizers or higher concentrations were used. Specific markers of antigen-induced T-cell activation were also examined (Gerberick et al., 1997). CD62L (L-selectin) and CD44 (H-CAM) expression was selectively modulated after treatment with the contact allergen TNCB when compared with the irritant benzalkonium chloride or the vehicle control. Mice treated with dinitro-chlorobenzene (DNCB) also had an increase in the percentage of CD4+ cells expressing $CD62L^{lo}CD44^{hi}$ that were dose dependent and peaked at 72 h after the final allergen treatment. In addition, increases in the percentage of CD8+ cells expressing $CD62L^{lo}CD44^{hi}$ were observed with allergens, including DNCB, oxazolone, and hexylcinnamic aldehyde, but not with irritants (Gerberick et al., 1997). Homey et al. (1998) observed that topical treatment with allergens (1% oxazolone) strongly induced the activation markers CD25 and CD69 on CD4+ and CD8+ lymph node cells, whereas irritants (croton oil) induced only marginal upregulation. Furthermore, treatment with oxazolone resulted in an expansion of I-A+/B220+ and a significant upregulation of CD69 on I-A+ lymph node cells. In contrast, croton oil treatment resulted in only a minor increase of both I-A+/B220+ and CD69/I-A+ lymph node cell subpopulations. Differences were considered to be qualitative rather than quantitative, since the analyses were performed with oxazolone and croton oil concentrations that induced comparable lymph node cells count indices. The upregulation of CD69 on I-A+ lymph node cells, confirming antigen-specific sensitization, was the most prominent marker for differentiation between the reaction patterns of oxazolone and croton oil. Phenotypic analyses of the CD69/I-A+ lymph node cells revealed them to be predominantly B220+ cells. Thus, examination of cellular phenotypic changes by flow cytometry demonstrates to be valuable in differentiating between allergic and irritant responses in the draining lymph nodes of mice.

Further criteria for the differentiation between allergens and irritants using a modified LLNA were proposed by Homey et al. (1998). They postulated that contact allergens induce activation and proliferation of skin-draining lymph node cells with only marginal skin inflammation, whereas irritants predominantly induce skin inflammation and, as a result, generate lymph node cell proliferation. Therefore, a differentiation index (DI) was developed considering the relationship between local draining lymph node activation (calculated as a percentage of the maximal increase in lymph node cell count index) and skin inflammation (calculated as a percentage of maximal ear swelling). DI values >1 indicated an allergic reaction pattern, whereas DI values <1 denoted an irritant response. The sensitizing potential of oxazolone was clearly confirmed eliciting a DI ranging from 2.5 to 16.6 in three different experiments. In contrast, the irritant croton oil produced a DI varying from 0.7 to 0.8 (Homey et al., 1998).

An increased understanding of the immunologic events that mediate and regulate allergic and irritant skin responses may provide a mechanistic basis for development of more objective and accurate *in vivo* and *in vitro* models of immunotoxicology testing.

16.5 CLINICAL DIAGNOSIS

Irritant dermatitis is not a single clinical entity but rather a heterogeneous spectrum of disorders (Table 16.1) with diverse pathophysiology and a broad range of clinical and histological features (Berardesca, 1997). The diagnosis of acute ICD to strong skin irritants agents is usually straightforward, because of the rapid onset of skin lesions after exposure points to the causative agent. However, subacute or chronic contact dermatitis frequently appears as an eczematous condition without a readily apparent cause. In these circumstances, the clinician must go through a decision process to discriminate among ICD, ACD, and other eczematous conditions. Differentiation between chronic ICD and ACD is frequently impossible on the basis of macroscopic or microscopic morphology (Table 16.2). The clinical picture in both conditions may include erythema, edema, lichenification, vesicles, bullae, oozing excoriations, scaling, and hyperkeratosis. Pustules, necrosis, and ulceration may be seen after contact with strong irritants, whereas they are rarely observed in ACD. Vesiculation, edema, and oozing are usually more prominent in ACD. Symptoms of ICD may include burning, pain, itching, stinging, soreness, and discomfort. Pruritus is the cardinal symptom in ACD. ICD lesions are usually sharply demarcated and confined to the contact area; while in ACD, lesions are poorly circumscribed and frequently disseminated. However, ICD lesions may disseminate depending on the characteristics of the exposure. Irritant reactions were believed to be unspecific and reproducible in all exposed subjects, in contradistinction with the uniqueness and specificity of allergic reactions. Yet, different irritants produce inflammation by different mechanisms and through d ifferent mediators. The effects of irritants on cutaneous targets depend on several factors such as the type of chemical, concentration, mode of exposure, concomitant environmental

factors, and individual susceptibility (Lammintausta et al., 1987; Berardesca and Maibach, 1988; Lammintausta and Maibach, 1988; Wilhelm and Maibach, 1990; Patil and Maibach, 1994; Judge et al., 1996; Rietschel, 1997). Irritant thresholds and dose responses vary considerably among individuals when tested with a low concentrated or mild irritant and also in the same individual over time (Judge et al., 1996).

Concerning the timing of the dermatitis, features that claimed helpful in distinguishing irritant dermatitis include cutaneous reaction upon first exposure—at least with potent irritants—and rapid onset of dermatitis after exposure. In ACD, two phases are required: an induction phase, during which sensitization is acquired; followed by elicitation of a cutaneous inflammatory reaction in subsequent exposures. Usually, the induction phase does not result in clinical skin lesions, probably due to the low numbers of responder T lymphocytes present. Subsequent challenges, resulting in clonal T-cell expansion and representation of the antigen to already primed (memory) T cells, may induce an enhanced inflammatory response eliciting the clinical dermatitis. However, a potent allergen may induce both sensitization and elicitation phases through a single exposure. Acute ICD develops rapidly after exposure, while ACD lesions usually appear 24–96 h after the last exposure to the causative agent, depending on the characteristics of the sensitizer, the conditions of exposure, and the individual susceptibility.

Patch testing is applied to make the distinction between ACD and ICD in clinical settings. The morphology and kinetics of the response is important when assessing patch-test reactions. The irritant reaction usually reaches its peak quickly after exposure, and then starts to heal; this is called the *decrescendo* phenomenon. Allergic reactions are characteristically delayed, reaching their maximum at approximately 72–96 h (*crescendo* phenomenon). However, some irritants may elicit a delayed inflammatory response, and visible inflammation is not seen until 24 h or even more after exposure (Malten et al., 1979; Bruynzeel et al., 1982; Lammintausta and Maibach, 1990; Reiche et al., 1998).

16.6 CONCLUSIONS

The current understanding of mechanisms of both irritant and allergic dermatitis does not allow for establishing pertinent and practical criteria for a clear-cut differentiation between them. Although the pathways for ICD and ACD are distinctly defined, there seems to exist an overlapping and interconnected cellular and molecular network between both types of contact dermatitis. Therefore, differences between irritants and allergens are more conceptual than verifiable.

Further understanding of the molecular pathways in contact dermatitis would be significant in dermatological practice, as well as in clinical and toxicological research.

A better comprehension of the immunologic events that mediate and regulate allergic and irritant skin responses may provide opportunities for development of more objective and accurate methods in clinical practice and toxicological research.

17.1 INTRODUCTION

Occupational contact dermatitis (OCD) is an inflammatory skin disorder resulting from cutaneous contact with materials primarily associated with the workplace. OCD is an important medical and occupational health problem, with incidence rates ranging from 24/100.000 to 170/100.000 (Cherry et al., 2000; Diepgen and Coenraads, 1999; Mathias and Morrison, 1988). Of work-related cases involving the skin, 90–95% will involve contact dermatitis (Lushniak, 2003; Mathias et al., 1990). Actually, most cases of contact dermatitis treated by physicians are in some way work related. OCD can be broadly classified into irritant and allergic. However, OCD is often multifactorial, and the different contributory factors can be difficult to ascertain. The reported frequency of occupational allergic contact dermatitis (OACD) and occupational irritant contact dermatitis (OICD) in different studies varies, depending on differences in how occupational diseases are notified and recognized, the specific characteristics of the occupation, the comprehensiveness of the workplace investigation, and the medical examination, including the accuracy of diagnostic patch testing.

Medical management has had little impact on clinical outcome in OCD, and most studies report persistent disease in 33–81% of the individuals (Emmett, 2003; Kanerva et al., 1995). Establishing suitable therapeutic and preventive measures requires an accurate diagnosis and the identification of all causal or contributing agents. A more comprehensive approach to prevention and management, based on rational criteria, is required to substantially reduce the burden of OCD.

17.2 DIAGNOSIS OF OACD

The diagnosis of OACD depends on patient history, dermatitis pattern, occupational exposure history—including hazard identification, estimation of dermal exposure, and risk characterization—and comprehensive diagnostic patch testing. It involves two crucial elements: (1) recognizing the existence of an occupational exposure and (2) assessing whether that exposure can be linked to the expression of the dermatitis process as a cause or substantial contributive factor. Even though exposure to an occupational allergen is the essential factor, whether or not this exposure will finally result in clinical dermatitis, depends on additional circumstances, therefore, the rational work-up should include the analysis of all predisposing and contributory factors.

17.2.1 Clinical History

The first step in establishing a work exposure as the cause of contact dermatitis is to take a detailed clinical and occupational history (Table 17.1). A dermatitis that clears or improves substantially during a 2–3 week break from work and recurs within a few days of the return to work strongly suggests an occupational origin. OACD tends to recede over a period of 3 or more weeks after the contact allergen is withdrawn. Significant improvement in the course of a few days away from work may occur with weak irritant reactions, but it is improbable with allergic reactions. Often OACD improves more slowly than OICD when the occupational exposure ceases and recurs faster (in a few days) when exposure is restored. Contrarily, irritant dermatitis to several weak

TABLE 17.1
Clinical History for the Assessment of OACD

Clinical characteristics of the dermatitis
- Time of onset and possible relationship with the occupation
- Characteristics of initial lesions and clinical evolution
- Dermatitis area corresponding to exposure site and occupational gestures
- Dermatitis morphology suggesting specific allergens

Time relationship to occupation. Effect of holidays and time-off work

History of occupational exposure
- Job description. Occupational gestures and characteristics of the working milieu
- Potential allergens and irritants in the working environment
- Characteristics of the exposure: dose, frequency, site
- Concomitant exposure factors: temperature, humidity, occlusion, friction, etc.
- Personal protective measures at work (gloves, masks, barrier creams)

Other workers similarly affected

History of nonoccupational exposure
- Domestic products: cleanser, detergents
- Skin care products, fragrances, nail and hair products
- Pharmaceutical products (prescription and over the counter)
- Personal protective measures at home (gloves)
- Jewelry, clothing
- Homework and hobbies

Special variants on exposure
- Photoexposure
- Indirect contact (fomites, connubial exposure)
- Airborne contact

History of previous dermatitis, atopy, and other skin/general diseases
- Past contact dermatitis (occupational or not)
- Previous patch testing
- Other exogenous or endogenous dermatitis: atopic dermatitis, stasis dermatitis, psoriasis, sensitive skin
- Atopy (asthma, rhinoconjunctivitis)

Family atopy and other skin diseases

irritants, that is, cumulative irritant contact dermatitis, usually requires many weeks to reappear when exposure is reestablished. A time course of 2–4 days between exposure and recurrence is suggestive of contact allergy. However, the elicitation time depends on the characteristics of the sensitizer, intensity of exposure, and degree of sensitivity. Contact allergic reactions will not appear until at least 2 weeks after the sensitizing exposure in a new worker—or following the introduction of a new allergen in the working environment—since this is the minimum sensitization period for most allergens. In contrast, reactions to strong irritants do not require an induction period and may appear within minutes to hours after the first exposure. Usually, several exposures are required for an OACD to develop. Weak irritants may mimic the effect of allergens, inducing dermatitis after a series of exposures.

Clinical history should investigate all possible sources of allergenic exposure in the workplace and should also scrutinize nonoccupational sources, comprising hobbies and domestic exposures: for example, personal skin care products and fragrances, medicaments, clothing, and accessories. Sometimes, even when a comprehensive history has been taken, the source of allergenic exposure remains concealed. Many times patients fail to recognize a causal allergen when the exposure is infrequent or sporadic. In addition, exposure may be indirect, that is, the contact may be airborne, ectopic, connubial, or through a contaminated item. Furthermore, some sources of allergenic exposure remain hidden due to insufficient chemical identification in many household or industrial products.

Finally, clinical history should provide insights in differentiating OACD from other exogenous or endogenous dermatoses, such as atopic dermatitis or psoriasis.

17.2.2 Clinical Examination

OACD is usually characterized by eczematous inflammation. However, it is frequently difficult to distinguish OACD from other forms of dermatitis, especially irritant contact dermatitis on the basis of exclusive morphological criteria. No pathognomonic clinical signs and symptoms can unambiguously discriminate between allergic and irritant contact dermatitis, although vesiculation and pruritus are more frequent in the former. To further complicate the matter, most allergens also have irritant properties, and many times dermatitis is the result of both irritancy and allergy. Sometimes, clinical examination may reveal an occupational "mark" that points out to a specific occupational exposure. Most of the time, the physician must rely on the pattern of distribution and general characteristics of the dermatitis to determine the causative agent. For instance, eczematous lesions affecting the exposed areas of the face, eyelids, and skin folds are commonly observed in airborne dermatitis from fumes, dusts, or other airborne particles. Compromise of the dorsal aspects of the hand and fingers, and especially, the finger webs is frequently observed in wet work occupations. However, the original pattern of the dermatitis is frequently modified by secondary dissemination, secondary infection, treatment etc., requiring a sensitive diagnostic approach.

17.2.3 Patch Testing

The strongest evidence that an allergic contact dermatitis is of occupational origin is a positive patch test to a nonirritating concentration of a chemical found in the workplace, which plausibly could come into contact with the areas of dermatitis. Habitually, the patch-test evaluation of subjects with suspected OACD starts with one of the standard screening series of allergens, such as the one proposed by the International Contact Dermatitis Research Group (ICDRG) (Lachapelle et al., 1997), supplemented by additional series tailored for specific occupations, as well as any other allergen that may be associated with the clinical situation. Testing with additional allergens depending on the exposure and specific occupations gives a substantial number of additional positive reactions (Menné et al., 1992). Also, testing with substances used by the patient in the workplace is often required. Many of these nonstandard occupational materials have irritant properties, and special caution should be exerted when testing with them. Besides producing false-positive irritant reactions, the

injudicious use of undiluted industrial substances in patch testing increases the risk of active sensitization.

As a rule, patch testing should be performed with the highest nonirritating concentration of the chemical. When possible, information about appropriate concentrations and vehicles for nonstandardized substances should be obtained. If no information can be found, an open (unoccluded) test should be done using a low concentration of 0.1–2.0% of the putative substance(s) in a nonirritant vehicle (water, petrolatum, etc.). If no irritation appears with increasing dosage, an occluded test may be performed. It is advisable to incorporate a dose–response assessment performing the patch test with serial dilutions of the substance.

False-negative reactions are especially treacherous since the cause of the dermatitis may be missed. Many times, false-negative reactions are due to methodological or technical problems; for example, insufficient occlusion and other technical flaws, concurrent treatment with corticosteroids, and failure to perform delayed readings. However, in occupational dermatology, the most significant cause of false-negative reactions is the failure of the patch test to reproduce the actual conditions of the occupational exposure: (1) sweating and mechanical trauma experienced at work may not be adequately reproduced in patch testing; (2) the allergen concentration in the products obtained from the workplace may be insufficient to elicit an allergic patch-test reaction following a single application, but enough to produce an OACD after multiple occupational exposures; (3) insufficient cutaneous penetration of the allergen: allergens are applied on normal skin in patch testing, but, in the real life situation, a pre existent work-related irritant dermatitis may predispose to the development of contact allergy. When patch-testing results are negative, but the suspicion of OACD persists, it is helpful to carry out additional tests, such as a repeated open application test (ROAT), a provocative use test (PUT) (Nakada et al., 2000; Villarama and Maibach, 2004), or testing with product's extracts. Occasionally, photopatch testing should be performed to rule out the possibility of photosensitization to an occupational substance. Contact urticaria to work-related materials is also possible, since immediate contact reactions may lead to dermatitis. This association is especially important in workers exposed to latex gloves and also in the food industry. Immediate hypersensitivity testing is mandatory when contact urticaria or protein contact dermatitis is suspected.

17.2.4 Assessment of Clinical Relevance

The fact that contact allergy to one or several allergens has been reliably demonstrated by careful patch testing does not guarantee that these allergens are responsible for the patient's dermatitis. It must be established whether or not the responsible allergen is relevant to the dermatitis, either as a primary cause or as an aggravating factor. Our goal in assessing relevance is to ascertain the putative responsibility of a particular allergen to the clinical circumstance. In this sense, the exposure to the incriminated allergen may explain the dermatitis entirely, that is, "complete relevance," but dermatitis with a multifactorial background frequently occurs.

Assessing the relevance of a positive patch-test reaction is often complicated and involves many confounding factors. "Evaluating the relevance of a reaction is the most difficult and intricate part of the patch test procedure, and is a challenge to both dermatologist and patient. The dermatologist's skill, experience and curiosity are crucial factors" (Wahlberg, 1995). If an allergen produces a patch-test reaction and the patient is exposed to circumstances in which skin contact with occupational materials known to contain the allergen is likely to occur, relevance is considered possible. If a PUT or a ROAT with the product to which the patient is in contact—and it is known to contain a sufficient amount of the allergen to elicit the dermatitis—produces a positive response, relevance can be considered certain. Absolute proof of relevance is often unattainable, and many times a positive reaction is judged nonrelevant because of insufficient environmental information. Frequently, it is difficult to substantiate the presence of the allergen in the patient's environment. This may be due to the complexity in detecting certain allergens or to insufficient knowledge about the composition of different products. As a consequence, the relevance scores for different allergens vary; the easy the identification of the source of an allergen, the higher the relevance scores (Ale and Maibach, 1995).

Guidelines for assessment of relevance have been proposed (Table 17.2). Assessment starts with a comprehensive clinical history and physical examination and should be supplemented by a rigorous environmental evaluation,

TABLE 17.2
Suggested Guidelines for the Assessment of Relevance

1. Revise the clinical history
   - Reinterrogate the patient in light of the test results
2. Look for all possible sources of allergen exposure
   - Perform a workplace visit
   - Consider all possible types of exposure: direct, indirect, sporadic, concealed, etc. Consider cross-reacting substances
   - Obtain information from "lists" of allergens, databases, products' manufacturers, etc.
   - Perform chemical analysis of suspected products
3. Assess the sensitization potential of the substance
   - Obtain data from predictive tests, structure/activity analysis, and epidemiological studies
4. Assess all exposure parameters
   - Concentration of the substance in the suspected product
   - Route of exposure
   - Specific site of contact and possible presence of skin damage or dermatitis in the contact area
   - Intensity of exposure (i.e., dose, duration, frequency, and total surface area)
   - Simultaneous exposure factors: humidity, occlusion, temperature, mechanical trauma
5. Perform additional testing procedures with the suspected allergen(s), products brought by the patient presumably containing the suspected allergen or product's extracts

TABLE 17.3
Testing Procedures for the Assessment of Relevance

1. Testing with the suspected allergen(s)
   - Sequential patch testing
   - Repeated open application test (ROAT) or provocative use test (PUT)
     - on normal skin
     - on slightly damaged or previously dermatitic skin
2. Testing with products suspected to contain the responsible allergen
   - Patch testing (using suitable vehicle and appropriate concentration, frequently starting with highly diluted substances)
   - ROAT (similar as stated earlier, using proper vehicle and adequate concentration)
   - PUT (typical product use)
   - Testing in normal controls (if necessary)
3. Testing with product's extracts
   - Similar to 2
4. Testing with cross-reacting allergens and products suspected to contain them
   - Similar to 1

TABLE 17.4
Exposure Assessment in OACD

Characteristics of the suspected substance or product
- Assessment of the hazardous potential of the substance or product
  - Data procurement from predictive assays for delayed hypersensitivity (e.g., quantitative structure–activity relationship, murine local lymph-node assay, guinea pig sensitization test, and human skin sensitization assays)
  - Data from epidemiological studies
- Assessment of the physicochemical properties of the substance (i.e., pH, solvent properties, hygroscopicity, oxidizing capacity, substantivity, binding capacity, and wash-and-rub resistence to removal)
- Concentration of the substance

Characteristics of the exposure
- Routes of exposure
  - Skin exposure: specific cutaneous sites, previous skin damage
  - Other routes: respiratory, gastrointestinal
- Intensity of exposure
  - Dose
  - Duration
  - Frequency (periodicity)
  - Specific site of contact and area of exposure
- Concomitant exposure factors (i.e., wet work, occlusion, temperature, humidity, and mechanical trauma)

investigating the existence of exposure to the putative agent, characteristics of this exposure, and possible concurrent factors. Visiting the patient workplace enables the physician to obtain a comprehensive picture of the real conditions at the working environment, bringing many details into clinical significance. Additional tests such as testing with product's extracts, ROAT, PUT, etc. may prove valuable in establishing a definite causative relationship (Ale and Maibach, 1995; Marrakchi and Maibach, 1994) (Table 17.3). The positive patch-test reactions for which clinical relevance cannot be established may represent false-positive results. However, much too frequently they represent true-positive reactions, wherein the patient fails to recall a significant exposure or the clinician omits to retrieve the pertinent historical data, to trace the responsible environmental exposure, or to perform the appropriate tests. Relevance has been defined as the capability of an information retrieval system to select and redeem data appropriate to a patient's need (Lachapelle, 1997).

17.2.5 Assessment of Exposure

Exposure assessment is an important analytical tool in occupational dermatology for evaluating the likelihood and extent of actual or potential exposure of workers to the source of a chemical hazard. The field of exposure assessment has developed significantly in the past 15 years, and exposure assessment techniques are now available, which can significantly improve the quality of epidemiologic and health risk assessment studies (Jayjock, 1998). Better quantitative exposure components can now be incorporated into these studies, such as measuring the concentration of many chemicals to which workers are exposed, cataloguing the various exposure pathways and routes, and identifying typical values, which can be used in the exposure calculations. In addition, a number of exposure assessment models are available for estimating personal exposure to certain chemicals of concern in both the workplace and the general population. The goal of exposure science is to identify and characterize "real world" contacts with exogenous materials and uptake in the body of toxic materials that can cause acute or chronic health effects. Exposure science is predominantly observational, performed in the field within normal living and working situations. The knowledge obtained can then be used in computer models for generalization to other populations including people deemed to be at higher risk. The conclusions drawn from these studies allow the evaluation of public health and environmental policy options for effective reduction or prevention of exposure.

Industrial exposures generally occur via the dermal or respiratory routes. Gastrointestinal exposure may result from contaminated hands or handling of foods, but it is uncommon in occupational settings. Direct skin contact with the causative agent represents the most relevant route of exposure for occupational dermatitis. Additionally, dermatitis may result following inhalation in a sensitized worker. Likewise, induction of skin sensitization may result in subsequent heightened respiratory responsiveness following inhalation exposure (Arts et al., 2006).

It is essential to be informed about the hazardous properties of all the suspected occupational substances, including their intrinsic sensitizing capacity, as well as their physicochemical properties (Table 17.4). The sensitizing potential of occupational or consumer products regularly follows a stepwise approach that may involve structure–activity evaluations (Hostynek et al., 1996), analytical assessments, preclinical skin sensitization testing (e.g., the murine local lymph node assay (Basketter and Cadby, 2004; Dearman et al., 1999;

Kimber et al., 2001), guinea pig sensitization tests (Maurer et al., 1994), confirmatory clinical testing (e.g., the human repeat insult patch test [HRIPT], human maximization tests) (Schneider and Akkan, 2004), and benchmarking of resulting data against similar substances and product types (Gerberick and Robinson, 2000). In addition to the intrinsic properties of the substance, quantitative data regarding exposure and other concomitant factors should be evaluated, including: (1) specific cutaneous site and total area of exposure (Upadhye and Maibach, 1992), (2) existence of skin damage or dermatitis in the contact area, (3) duration and periodicity of the exposure, (4) concentration and dose of the causative agent, and (5) additional exposure factors (Table 17.2). Cutaneous site and total area of exposure are significant factors in determining the skin penetration of the substances (Wester and Maibach, 1985). Skin damage or irritation may result in a higher cutaneous permeability and a significant reduction of the no-effect level for a specific compound. Therefore, the clinical scenario will often show that an OACD is preceded by an OICD. The intensity of the exposure, that is, dose, duration, frequency, and total area of exposure is a significant factor. Sensitization and subsequent dermatitis may result from a single exposure to a very strong allergen. However, repeated exposures are usually required before sensitization occurs. Contact allergy is a dose-related phenomenon, and there is a threshold surface concentration of the allergen required to induce sensitization or elicitation of the response (Basketter et al., 1997; Boukhman and Maibach, 2001; Kimber et al., 1999; Marzulli and Maibach, 1976). Reported results suggest that especially relatively high concentrations can induce sensitization, and that prevention of such concentrations will prevent workers from developing occupational allergies. The threshold concentration for the elicitation of allergic skin reactions in sensitized subjects is generally lower than the threshold to induce sensitization (Scott et al., 2002). Therefore, it is important to consider the low threshold levels for elicitation for recommendation of health-based occupational exposure limits. Despite the observation of dose–response relationships and no-effect levels, due to a number of uncertainties, no definite conclusions can be drawn about absolute threshold values for allergens with respect to sensitization and elicitation reactions in the skin, as well as the respiratory tract. In predictive tests, it was observed that the threshold of elicitation decreases as the doses used to induce the sensitization increase, making difficult to establish clear threshold doses below which allergic responses are not seen (Hostynek and Maibach, 2004). Besides, most predictive tests are generally intended to detect the potential of a chemical to induce skin or respiratory allergy at relatively high doses. As a result, these tests do not provide information of dose–response relationships at lower doses such as those observed in occupational situations. In addition, dose–response relationships and threshold values for occupational allergens have been obtained by a broad variety of test methods using different techniques, for example, intradermal exposure, topical exposure, and inhalation exposure at the workplace or different endpoints (Arts et al., 2006; Robinson et al., 2000). Therefore, standardized and validated dose–response test methods are urgently required to be able to recommend safe exposure levels for allergens at the workplace.

17.3 CONCLUSION

As stated earlier, assessing OACD frequently represents a complex and multifaceted procedure. A rational work-up includes eight consecutive steps as follows:

1. Identification of occupational exposure to sensitizing substance(s).
2. Demonstration of time relationship between the occupational exposure and the clinical course of dermatitis.
3. Physical characteristics of the dermatitis consistent with the occupational exposure regarding the morphology and localization.
4. Nonoccupational exposure excluded (not present or irrelevant).
5. Positive patch test with the sensitizer in appropriate vehicle and concentration.
6. Positive PUT or ROAT with the sensitizing materials: allergens, allergen-containing products, or product's extracts.
7. Identification of the sensitizer in the suspected occupational products in sufficient concentration to elicit the dermatitis.
8. Clearing of the dermatitis when the allergen is removed from the occupational environment or the exposure is substantially decreased.

Nonsingle criterion provides sufficient evidence for the probable occupational origin of allergic contact dermatitis. OCD is often of multifactorial origin, and it is difficult to determine the relative significance of the various contributing factors. Diagnosis of OACD requires a high index of suspicion and knowledge of the worker's environment, as well as a judicious clinical evaluation including comprehensive skin testing. The correct diagnosis and identification of the occupation-related allergen improves the primary, secondary, and tertiary preventive strategies for OACD. If undiagnosed, the disease may persist and deteriorate, resulting in permanent disability to the worker.

With a better knowledge of the chemical environment and more advanced test techniques, it is probable that more cases of contact dermatitis will eventually demonstrate to have an occupational allergic component. Also, epidemiologic animal and human studies are necessary to determine the capacity of the chemicals used in industry to induce OACD. It is necessary to standardize the predictive tests to compare results among laboratories and to predict the potential for sensitization. Exposure–effects relationships should be established with increased certainty to recommend safe exposure levels for allergens at the workplace. The above guidelines can provide a simplified rational approach for assessing OACD until more information is forthcoming.

18.1 INTRODUCTION

Human skin is exposed to a number of chemicals and drugs throughout our entire lives. Following percutaneous absorption, a chemical and or its metabolites may cause toxicity locally or in another organ, distant from the point of entry. Although not generally appreciated, some chemicals are more toxic, at least in animals, when applied topically rather than orally. Furthermore, many compounds are absorbed to a greater degree from the skin than gastrointestinal (GI) tract, and whole body exposure can produce systemic absorption up to grams of material. This chapter focuses on the limited epidemiologic material available and depends mostly on case reports. Many compounds dermally absorbed are capable of producing systemic side effects whose occurrence and severity depends largely on the many factors that can affect the absorption of topically applied compounds (both physiological/pathological condition of the skin and physicochemical properties of the compound). The majority of reports for systemic toxicity have been from industrial chemicals/agrochemicals and occupationally these probably have the greatest potential hazard after dermal exposure.

18.2 FACTORS AFFECTING PERCUTANEOUS ABSORPTION

18.2.1 Integrity of the Barrier

The stratum corneum layer of the epidermis is a major barrier to percutaneous absorption. Anything that alters the structure or function of the stratum corneum will affect epidermal absorption. The integrity of this barrier is reduced by any inflammatory process of the skin, such as any form of dermatitis or psoriasis, which may result in increased percutaneous absorption. Similarly, removal of the stratum corneum by stripping or damage by alkalis, acids, etc. will increase absorption.

18.2.2 Physicochemical Properties of the Substance

Percutaenous absorption is affected by the relative water/lipid solubility of the drug and the comparable solubility of the drug in its vehicle and in the stratum corneum. For a chemical to penetrate through the skin into the systemic circulation, it requires both a degree of lipophilicity (to facilitate its entry into the stratum corneum) and hydrophilicity (to aid its passage through the viable epidermis and dermis). Other factors such as molecular weight, molecular volume, and melting point will also be important determinants.

18.2.3 Occlusion

The penetration of some compounds can be increased by the use of an occlusive covering, up to 10-fold or more. This can be due to increased water retention in the stratum corneum, increased blood flow, increased temperature, and increased surface area after prolonged occlusion (skin wrinkling). Occlusion also prevents the accidental wiping off or evaporation (for volatile compounds), hence maintaining a higher local concentration on the skin surface.

18.2.4 Vehicle

The greater the affinity of a vehicle for the drug it contains, the lesser the expected percutaneous absorption will be. The physical properties of vehicles, especially the degree of occlusion they produce, affect percutaneous absorption, as discussed above (e.g., grease). Structural or chemical damage to the barrier layer can also affect the absorption rate; vehicles such as dimethyl sulfoxide cause greatly increased percutaneous absorption due to stratum corneum damage. In general, a higher concentration of the drug in its vehicle enhances penetration. Enhanced solubility produces greater thermodynamic activity yielding greater flux.

Extensive evidence on factors affecting penetration has been published.[1–3]

18.2.5 Anatomical Site

Regional differences in permeability of skin largely depend on the thickness of the intact stratum corneum.[4] According to the findings of a study by Feldmann and Maibach,[5] the highest total absorption of hydrocortisone is that from the scrotum, followed (in decreasing order) by absorption from the forehead, scalp, back, forearms, palms, and plantar surfaces. This large variation has also been shown for certain pesticides.[4] Variations in absorption with anatomical site have also been reported for other species, other than man, for example, monkey skin[6] and rat skin.[7]

18.2.6 Age

The greatest toxicological response to topical administration has been seen in the young. The preterm infant does not have an intact barrier function and hence is more susceptible to systemic toxicity from topically applied drugs.[8,9] A normal full-term infant probably has a fully developed stratum corneum with complete barrier function.[10] Yet, topical application of the same amount of a compound to both adult and newborn results in greater systemic availability in the newborn.[11] This is because the ratio of surface area to body weight in the newborn is three times that in the adult. Therefore, given an equal area of application of a drug on to skin of the newborn and adults, the proportion absorbed per kilogram of body weight is much more in the infant. Barrett and Rutter[12] and Maibach and Boisits[13] provide extensive documentation on this issue. Although counterintuitive, absorption of some compounds decreases in the aged.[14] Later Roskos and Maibach[15] reported that absorption was decreased in older subjects for steroids, but unchanged for other more hydrophilic compounds. They suggested that this was due to the decreased concentration of surface lipids in older subjects. Additionally, the dermal–epidermal junction changes with age, so that the blood circulation of the skin decreases.

18.2.7 Species Variation

Mammalian skin from different species is well known to exhibit great variation in percutaneous absorption. Factors such as stratum corneum thickness, hair follicle and sweat gland number, and the condition of the skin will play role. The distribution of blood supply and sweating ability differs between lab animals and man, therefore affecting absorption through the skin.[16,17]

18.2.8 Temperature

Generally, increased skin temperature enhances penetration rate.[18] This may be due to the increase blood flow associated with increased skin temperature or an increase in skin hydration.[19,20]

18.2.9 Metabolism

It has been well documented that the skin is capable of metabolizing a wide range of xenobiotics and has a full complement of phase I and phase II enzymes. The specific activities found in the skin are relatively low when compared to their equivalent hepatic forms. However, when the total volume of the skin is taken into account, then it is apparent that the skin is an efficient drug-metabolizing organ. This may have implications for the risk assessment of topically applied compounds, as metabolism will determine what form of the compound the systemic circulation will be exposed to. Cutaneous metabolism may also aid/impede percutaneous absorption of certain compounds. Detailed information on skin metabolism can be found in the review by Hotchkiss.[21]

18.2.10 Miscellaneous

Skin hydration, application time, concentration of the compound, particle size, skin injuries/condition, race, sex, and circulatory conditions have all been reported to affect the percutaneous absorption of dermally exposed compounds.

18.3 SYSTEMIC SIDE EFFECTS CAUSED BY TOPICALLY APPLIED COMPOUNDS

Topically applied drugs, cosmetics, and chemicals can cause allergic or irritant contact dermatitis. However, this type of side effect, usually limited to the skin, is outside the scope of this chapter. The reader is referred to the textbooks of Fisher[22] and Rycroft[23] for references to contact dermatitis as well as other chapter within this book. Systemic side effects from topically applied chemicals can sometimes result from either a toxic (irritant) reaction or a hypersensitivity reaction. The latter can be an anaphylactic type of reaction which is the extreme manifestation of the contact urticaria syndrome.[24] Many topical drugs and cosmetics have reportedly caused anaphylactic reactions. While anaphylactic reactions to topical medicaments are uncommon, their potentially serious nature warrants attention. However, reports of toxic (as distinct from allergic) reactions to applied drugs, cosmetics, or chemicals are more numerous and include many medicaments that have been safely used for many years, but which can be toxic under special circumstances.

The following is a short summary of the chemicals that have been reported to cause systemic side effects after topical application or accidental exposure.

18.3.1 Agrochemicals

It has been proposed that the most serious occupational skin exposure hazard is in agricultural workers involved in pesticide application. Contaminated clothing, lack of adequate protection, and unsafe spraying procedures have caused numerous toxic responses, mainly due to skin absorption.[25] Systemic toxicity after topical exposure to agrochemicals has been widely reported. A prime example is the insecticide Lindane, which

when absorbed into the body accumulates in the CNS and the brain and has been linked with cancer.[26] Therefore, the use of Lindane has been restricted in the United States and has been replaced by the far safer insecticide permethrin.[27] Although, more recently one case of permethrin poisoning was reported after application to damaged skin.[28] Other pesticides have been found to be genotoxic after topical exposure, including aminocarb, chlordane, DDT, and Dichlorous.[29] Chlorophenoxy herbicides cause a variety of systemic toxicities, including transient GI irritation and progressive mixed sensor motor peripheral neuropathy.[30] More recently, new guidelines have been proposed for the safety assessment of systemic toxicity caused by agrochemicals, to take into account the significant exposure after skin contact.[31] Agrochemicals such as parathion, malathion, and chlordane have been reported to persist in the skin up to 2 years after exposure.[32]

18.3.2 Antibiotics

18.3.2.1 Chloramphenicol

Oral administration of chloramphenicol may lead to aplastic anemia.[33] Marrow aplasia with a fatal outcome after topical application of chloramphenicol in eye ointment was described by Abrams et al.[34] This claim has been more recently disputed, and Walker and co-workers[35] concluded that topical chloramphenicol should not be considered to be a health hazard.

18.3.2.2 Clindamycin

Topical clindamycin is widely used in the treatment of acne vulgaris. Approximately 5% clindamycin hydrochloride is absorbed systemically.[36] The degree of absorption largely depends on the vehicle, ranging from 0.1 (acetone) to 14% (DMSO).[37] Several cases of topical clindamycin-associated diarrhea have been reported.[38] Pseudomembranous colitis is a side effect of systemic administration of clindamycin. A case of pseudomembranous colitis has been reported after topical administration by Milstone et al.[39] An updated overview is reported by Akhaven and Bershad.[40]

18.3.2.3 Gentamycin

Ototoxicity is a well-known toxic effect of systemic gentamycin administration. However, topical application to large thermal injuries of the skin has similarly caused ototoxic effects, ranging from mild to severe hearing loss, with an associated decrease of vestibular function.[41,42] Drake[43] described a woman who developed tinnitus each time she treated her paronychia with gentamycin sulfate cream 0.1%. Use of gentamycin eardrops may also be associated with ototoxic reactions.[44]

18.3.2.4 Neomycin

Just as ototoxicity is a well-known hazard of parenteral neomycin administration, so has deafness been reported after local treatment, including skin infections and burns,[45] application as an aerosol for inhalation, instillation into cavities,[46] irrigation of large wounds,[47] and use of neomycin containing eardrops.[48] Kellerhals[49] reported 13 cases of inner ear damage in which the use of eardrops containing neomycin and polymycin were incriminated. All cases had perforated tympanic membranes.

18.3.3 Antihistamines

18.3.3.1 Diphenylpyraline Hydrochloride

Diphenylpyraline hydrochloride is a histone H1 receptor agonist and has been used topically in Germany for the treatment of eczematous and other itching dermatoses. Symptomatic psychosis has been observed in 12 patients, 9 of which were children. The amounts of the active drug applied ranged from 225 to 1350 mg. The first symptoms of toxicity were psychomotor restlessness in all cases, usually within 24 h. Other symptoms included disorientation, and optic and acoustic hallucinations. All symptoms disappeared 4 days after discontinuation of the topical medication.[50] Recent studies have shown that diphenylpyraline hydrochloride acts as a dopamine transporter inhibitor similar to cocaine.[51]

18.3.3.2 Doxepin

Five percent topical doxepin has been introduced as an antipruritic. Percutaneous absorption frequently leads to clinical sedation.[52,53]

18.3.3.3 Promethazine

Block and Beysovec[54] reported a 16-month-old male treated with 2% promethazine cream for generalized eczema. The child showed abnormal behavior, loss of balance, inability to focus, irritability, drowsiness, and failure to recognize his mother. A diagnosis of promethazine toxicity through percutaneous absorption was made.

18.3.4 Antimicrobials

18.3.4.1 Boric Acid

The toxicity of this mildly bacteriostatic substance is reviewed in detail by Stewart et al.[55] The misuse of borates has been abandoned because of their limited therapeutic value and high toxicity, resulting in few new cases of borate intoxication.

18.3.4.2 Castellani's Solution

Castellani's solution (or paint) is an old medicament mainly used for the local treatment of fungal skin infections. It contains boric acid, fuchsin, resorcinol, water, phenol (90%), acetone, and spirit. Lundell and Nordman[56] reported a case in which two applications of Castellani's solution severely poisoned a 6-week-old boy who became cyanotic with 41% methemoglobin. Another case report states that hours after the application of Castellani's paint to the entire body surface (except the face) of a 6-week-old infant for severe seborrheic

dermatitis, the child became drowsy and had shallow breathing.[57] Castellani's solution can no longer be used for medication due to the critical status of its ingredients.[58]

18.3.4.3 Hexachlorophene

Since 1961, hexachorophene has been extensively used[59] mainly for reducing the incidence of staphylococcal infections among the newborn. In addition, it has been an ingredient of many medical preparations, cosmetics, and other consumer goods. Hexachlorophene readily penetrates damaged skin, and its absorption through intact skin has also been demonstrated.[60,61] In 1972, as a result of the accidental addition of 6.3% of hexachlorophene to baby talcum powder, 204 babies fell ill (convulsions, behavioral changes, and CNS depression) and 36 died from respiratory arrest.[62] This report was followed by animal experiments with hexachlorophene confirming that the drug is neurotoxic.[63] It has effects on motor, sensory, or cognitive function that are detectable using functional measures such as behavior. Furthermore, there is evidence that if exposure occurs during critical periods of development, many of the chlorinated hydrocarbons are developmental neurotoxicants.[63] Developmental neurotoxicity is frequently expressed as alterations in motor function or cognitive abilities or changes in the ontogeny of sensorimotor reflexes. Marzulli and Maibach[64] have placed in perspective lessons to be learned from its toxicity.

18.3.4.4 4-Homosulfanilamide

4-Homosulfanilamide (sulfamylon) is a topical sulfonamide used for the treatment of large burns. Sulfamylon is a carbonic anhydrase inhibitor and has caused hyperchloremic metabolic acidosis in patients with extensive burns treated topically, caused by percutaneous absorptions of the drug.[65] Reversible pulmonary complications and methemoglobinuria have also been reported.[66]

18.3.4.5 Povidone-Iodine

Povidone-iodine (Betadine) is a water-soluble iodine complex that retains the broad-range microbiocidal activity of iodine, without the undesirable effects of iodine tincture. However, toxicity still occurs from povidone-iodine percutaneously absorbed, mainly when it is used on large areas of burnt skin or on neonates. Further information can be found in the review by Postellon and Aronow.[67]

18.3.4.6 Phenol

In dilutions of 0.5–2%, phenol is sometimes prescribed as an antipruritic in topical medicaments and is used for phenol face peels. It is readily absorbed through the skin and has been shown to have a prolonged elimination due to extensive tissue distribution.[68,69] Phenol-induced ochronisis has been reported in patients, who for many years treated leg ulcers with wet dressings containing phenol.[70] Several case reports document fatal reactions to percutaneously absorbed phenol: by accidental spillage of phenol,[71] due to treatment of burns with a phenol-containing preparation,[72] and to the application of phenol to wounds.[73] A 1-day-old child died after application of 2% phenol to the umbilicus.[74] Several cases of sudden death and intra- or postoperative complications have been reported after phenol face peels.[75] Major cardiac arrhythmias were noted in 10 out of 43 patients during phenol face peels.[76] However, this is rather controversial and some authors feel that when the procedure is performed correctly phenol face peels are not potentially hazardous.[77]

18.3.4.7 Resorcinol

Resorcinol is used for its keratolytic properties in the treatment of acne vulgaris. It is also a constituent of the antifungal Castellani's solution. Formerly, leg ulcers were treated with external applications of resorcinol. It has an antithyroid activity similar to that of methyl thiouracil. Consequently, several cases of myxoedema caused by percutaneous absorption of resorcinol, especially from ulcerated surfaces, have been described.[78] Resorcinol, administered at high doses, can disrupt thyroid hormone synthesis and can produce goitrogenic effects.[79] However, risk-assessment analysis of these effects from "real-world" conditions suggests that human exposure to resorcinol is not expected to cause adverse effects on thyroid function after topical application.

Methemoglobinemia in children, caused by absorption of resorcinol applied to wounds, has also been reported.[80] Cunningham[81] reported many cases of infant toxicity, including, cyanosis, hemolytic anemia, and hemoglobinemia. In the literature, the author found seven cases of acute poisoning in babies as a consequence of topical resorcinol application and five fatalities were recorded. Although the use of resorcinol in young children and for leg ulcers should be avoided, topical resorcinol, when used for acne vulgaris, has been reported to be safe.[82]

18.3.4.8 Silver Sulfadiazine

Silver sulfadiazine is intended primarily for the control of pseudomonas infections in burns patients. Its relative freedom from side effects has contributed to its popularity. There have been reports of nephrotic syndrome, leucopenia, and granulocytosis following topical therapy.[83–85] Current evidence suggests a causal relationship of silver sulfadiazine with leukopenia, although the mechanism of this reaction is unknown. The drug presumably affects the white blood cells peripherally, but not the erythrocyte count. The sulfadiazine-induced leukopenia is at its nadir within 2–4 days of starting therapy, with the leucocyte count returning to normal within 2–3 days, and recovery is not affected by contination of therapy. Maitre et al.[86] have reported several cases of systemic silver accumulation in patients undergoing prolonged silver sulfadiazine treatment. It provokes hepatic, renal, and neurological tissue toxicity.[86]

18.3.5 Aromatic Amines

Aromatic amines are known to cause a wide range of systemic toxicities, from acute hepatotoxicity to carcinogenic effects.

4,4′-Methylenedianiline and 4,4′-methylene-bis-chloroaniline are two widely used aromatic amines employed in the manufacture of polyurethane foams, epoxy resins, and as curing agents in rubber manufacture. These two chemicals have been shown to be carcinogenic and mutagenic in a number of animal species, and induce liver damage in humans and rats.[87–89] Both chemicals have been detected in the urine of factory workers[90] and several authors have reported extensive absorption through human and rat skin *in vitro*.[91,92]

18.3.6 Arsenic

von Roemeling et al.[93] reported multifocal malignancies of the bowel and bladder in a psoriatic patient treated 20 years with topical Fowler's solution, indicating percutaneous absorption can also be carcinogenic. Dermal exposure to arsenic can cause cardiovascular diseases, developmental abnormalities, neurological disorders, hearing loss, various types of cancer, and diabetes.[94] However, the severity of the reaction is directly related to the chemical form of arsenic to which the individual is exposed.

18.3.7 Camphor

Camphor is a cyclic ketone of the hydroaromatic terpene group. It is an ingredient of a large number of over-the-counter topical remedies (with a camphor content of 1–20%), taken especially for symptomatic relief of "chest congestion" and "muscle aches." Camphor is readily absorbed from all sites of administration, including topical application. The compound is classified as a class IV chemical, i.e., a very toxic substance. Hundreds of cases of intoxications have been reported, usually after accidental ingestion by children[95] and usually from exposure to relatively small amounts.[96]

18.3.8 Cosmetic Agents

Cosmetic ingredients and fragrance materials are derived from a class of chemicals generally characterized by low toxicity. In a study by Di Giovanni et al.,[97] 3500 cosmetics consumers were questioned and of all the adverse effects caused by cosmetic use, only 4% of reactions were systemic (including headaches and nausea). Henna dye is used on nails, skin, and hair by married women in the Islamic community and consists of the dried leaves of *Lawsonia alba* (the coloring matter, lawsone, is a hydroxynaphthoquinone) and when mixed with *p*-phenylenediamine (to accelerate the fixing) over 20 cases of toxicity, some fatal, have been noted in Khartoum alone over a 2-year period. Initial symptoms are those of angioneurotic edema with massive edema of the face, lips, glottis, pharynx, neck, and bronchi and occur within hours of skin exposure. The symptoms may then progress on the second day to anuria, renal tubular necrosis, and acute renal failure with death occurring on the third day.[98] Whether this toxicity is due to *p*-phenylenediamine *per se* (probably grossly impure) or its toxicity is potentiated in its combination with henna is unknown. Systemic administration of the *p*-phenylenediamine leads to similar symptoms.[99]

Spencer and Bischoff[100] reported that after skin penetration musk ambrette (mainly used as a fragrance) causes the breakdown of cellular elements within the brain, spinal cord, and peripheral nerves. These types of effects were also reported for the fragrance acetyl ethyl tetrametyl tetralin.

Recently, it has been suggested in the literature that certain UV filters, a common cosmetic ingredient, represent a new class of endocrine active chemicals, for example, 3-benzylidene camphor.[101,102]

18.3.9 Crude Oil

Feuston et al.[103] have reported major systemic toxic effects after the dermal application of crude oils to rats. The major effects included: reduction in body weight gain, increases in absolute and relative liver and thymus weight. Red blood count, hemoglobin, hematocrit, and platelet count were all affected. These effects were related to concentrations of polycyclic aromatic compounds found in the crude oil.

18.3.10 Dimethyl Sulfoxide

The toxicology of topical dimethyl sulfoxide (DMSO) has been investigated by Kligman.[104] In this study, except for the appearance of cutaneous signs as erythema, scaling, contact urticaria, stinging, and burning sensations, DMSO was tolerated well by all but two individuals, who developed systemic symptoms. In one, a toxic reaction developed that was characterized by a diffuse erythematous and scaling rash accompanied by severe abdominal cramps; the other had a similar rash, nausea, chills, and chest pains. These signs, however, abated in spite of continued administration of the drug. One fatality due to a hypersensitivity reaction has been alleged.[105]

18.3.11 Dinitrochlorobenzene

Dinitrochlorobenzene (DNCB), a potent contact allergen, has been used for the treatment of recalcitrant alopecia areata. Today, however, its use has been discouraged because of suspicion that DNCB may be mutagenic and the fact that it is absorbed in substantial amounts through the skin, with about 50% of an applied dose recoverable in the urine.[106] Possible systemic reactions to DNCB have been reported.[107] For example, a 25-year-old man treated with 0.1% DNCB (daily for 2 months) after prior sensitization experienced generalized urticaria, pruritus, and dyspepsia.

18.3.12 Ethanol

Twenty-eight children with ethanol toxicity from percutaneous absorption were described by Gimenez et al.[108] following a popular procedure where ethanol-soaked cloths are applied to the abdomen of babies as a "home-remedy" for the treatment of disturbances of the GI tract, or because of crying, excitability, and irritability. Ethanol-soaked cloths had been applied under rubber panties, and the number of applications varied from one to three (40 mL/application). All 28 children showed some degree of CNS depression, 24 showed miosis,

15 hypoglycemia, 5 convulsions, 5 respiratory depression, and 2 died. Of the two who died, one was autopsied and the findings were consistent with ethanol toxicity. Topically applied ethanol in tar gel and beer-containing shampoo has caused Antabuse effects in patients on disulfiram for alcoholism, through percutaneous absorption.[109,110]

18.3.13 Fumaric Acid Monoethyl Ester

The effect of systemically or topically administered fumaric acid monoethyl ester (ethyl fumarate) on psoriasis was studied by Dubiel and Happle[111] in six patients. Two patients who had been treated dermally developed symptoms of renal toxicity.

18.3.14 Pesticides

18.3.14.1 Lindane

Lindane, the γ-isomer of benzene hexachloride, is widely used in the treatment of scabies and pediculosis. The percutaneous absorption of the drug has been widely documented,[112,113] as has toxicity from excessive topical therapeutic application of Lindane.[114] The issue of possible toxic reactions to a single therapeutic application of Lindane, notably CNS toxicity, has not been completely settled. Lindane absorption through human skin is more rapid than through animal skin. It is relatively slowly metabolized, meaning a possible accumulation and slow removal from the blood and brain.[115] Therefore, over the past few years the safer alternative, permethrin, has evolved as the standard care for scabies.

18.3.14.2 Diethyltoluamide

N,*N*-diethyl-*m*-toluamide (DEET) has been used as an effective insect repellent for nearly 50 years. It is commercially available in various topical forms containing between 10 and 95% DEET. Although DEET has an overall low incidence of toxicity, prolonged use in children has been discouraged because of reports of toxic encephalopathy and death.[116] Although most reports of CNS toxicity have been in children, adults and fetuses may also be at risk. Long-term occupational exposure has led to episodes of confusion, depression, insomnia, and muscle cramps.[117] Schaefer and Peters[118] reported a 4-year-old boy with mental retardation, impaired sensorimotor coordination, and craniofacial dysmorphology, whose mother applied a lotion containing 25% DEET daily to her arms and legs throughout her pregnancy. Other systemic toxicities reported include seizures, cardiovascular toxicity, with a few cases of death due to extensive skin absorption.[119]

18.3.14.3 Malathion

The detailed toxicology of malathion is dealt with by Haddad.[59] Malathion is used in the treatment of lice (0.5% solution being customary). Used in this way, it is generally safe. Ramu et al.[120] reported four children with toxicity following hair washing with 50% malathion in xylene for the purpose of louse control. Tos-Luty et al.[121] conducted dermal toxicity studies in rats and concluded that higher doses of malathion applied dermally exerted a damaging effect on the intracellular structure of the liver, kidney, heart, and lungs.

18.3.14.4 Paraquat

The herbicide paraquat has been shown to cause genotoxicity in the bone marrow of rats after dermal application.[122] It has also been shown to be genotoxic and cytotoxic to germ cells in the male rat.[123]

18.3.14.5 Combination Effects

Some of these common pesticides have been studied in combination.[124] These authors concluded that real-life doses of DEET, permethrin, and malathion, alone or in combination, produce no overt signs of neurotoxicity, but do induce significant neurobehavioral deficits and neuronal degeneration in the brain of rats.

18.3.15 Local Anesthetics

18.3.15.1 Benzocaine

Methemoglobinemia has been reported following the topical application of benzocaine (ethyl aminobenzoate) to both skin and mucous membranes, with most cases occurring in infants.[125–127] However, toxicity is uncommon.

18.3.15.2 Lidocaine

Lidocaine hydrochloride is widely used for topical and local injection anesthesia. Serum lidocaine concentrations, higher than 6 μg/mL, are associated with toxicity,[128] whose signs include CNS stimulation followed by depression and later inhibition of cardiovascular function. Systemic toxicity from lidocaine applied to the oral cavity in two children has been described.[129,130]

18.3.16 Mercurials

Mercury is a toxic and hazardous metal and its mechanisms of toxicity are comprehensively dealt with by Aronow.[131] With few exceptions, the use of mercury in medicine is considered to be outdated. However, mercury may still be present in many drugs, even in over-the-counter formulations. Metallic mercury is readily absorbed through intact skin, as is ammoniated mercury chloride in psoriatic patients.[132] Young[133] examined 70 psoriatic patients treated with an ointment containing ammoniated mercury. Symptoms and signs of mercurial poisoning could be detected in 33 patients. Nephrotic syndrome has been reported after ammoniated mercury-containing ointment application.[134,135] There have been two case reports of children who died following the treatment of an omphalocele with merbromin (an organic mercurial antiseptic).[136]

18.3.17 Monobenzone

Monobenzone (monobenzyl ether of hydroquinone) is used topically by patients with extensive vitiligo to depigment

their remaining normally pigmented skin. In 11 patients with vitiligo, on monobenzone therapy, conjunctival melanosis and pingueculae was acquired.[137]

18.3.18 Monochloroacetic Acid

Monochloroacetic acid has caused many fatal occupational accidents via skin exposure.[138] These authors concluded that the severe toxicity was probably a consequence of rapid absorption causing hepatocellular injuries, renal dysfunction, dysglyconeogenesis, and perturbation of ammonia metabolism. Monochloroacetic acid is thought to enter the tricarboxylic acid (TCA) cycle and inhibit aconitase.

18.3.19 2-Naphthol

2-Naphthol (β-naphthol) is used in peeling pastes for the treatment of acne, and between 5 and 10% of a cutaneous dose has been recovered from the urine of subjects.[139] Extensive applications of 2-naphthol ointments have been responsible for systemic side effects, including vomiting and death.[140] Hemels[139] concludes that 2-naphthol-containing pastes should be applied only for short periods of time and to a limited area not exceeding 150 cm^2.

18.3.20 Podophyllum

The toxicity of podophyllum was reviewed by Cassidy et al.[141] Although there have been a significant number of case reports describing serious neurological illness or death following the application of podophyllum, these are generally related to its use in widespread dermal lesions.[142,143] Systemic symptoms after dermal exposure include, thrombocytopenia, leucopenia, abnormal liver function, sensory ataxia, and neurological effects. A cause of suspected teratogenicity (simian crease on left hand and preauricular skin tag) has also been reported after topical podophyllum resin treatment.[144]

18.3.21 Retinoic Acid

Antiacne creams have been shown to cause systemic toxic effects. For example, retinoic acid is a known teratogen and is found in certain formulations.[145]

18.3.22 Salicylic Acid

The general toxicology and percutaneous absorption of salicylates is reviewed by Proudfoot.[146] Salicylic acid (SA) is widely used in dermatology as a topical application for its keratolytic properties, and salicylate poisoning after topical use has been reported. An unpublished review by the U.S. Department of Health, Education and Welfare, quoted by Rasmussen,[10] revealed 13 deaths associated with the widespread use of SA preparations, 10 in children. von Weiss and Lever[147] reported 13 deaths resulting from intoxication with SA following application to the skin, reported in literature up to 1964, and several nonfatal intoxications. The most dramatic account is that of two plantation workers in the Solomon Islands, who were painted twice daily with an alcoholic solution of 20% SA involving about 50% of the body. The victims were comatose after 6 h and dead within 28 h.[148] A case of SA toxicity leading to coma in an adult patient with psoriasis, who had been treated with 20% SA in petrolatum, was also described by Treguer et al.[149] Metabolic acidosis has also been reported after percutaenous absorption of SA.[150,151] Chronic SA exposure can also cause systemic inflammatory response syndrome.[152]

18.3.23 Selenium Sulfide

Ransone et al.[153] reported a case of systemic selenium toxicity in a woman who had been shampooing her hair two or three times weekly for 8 months with a selenium sulfide suspension.

18.3.24 Silver Nitrate

Ternberg and Luce[154] observed fatal methemoglobinemia in a 3-year-old girl suffering from extensive burns, who was treated with silver nitrate solution. Owing to the hypotonicity of the silver nitrate dressings, hyponatremia, hypokalemia, and hyperchloremia may develop, especially in children.[155] Excessive use of silver-containing drugs has led to local and systemic argyria and to renal damage involving the glomeruli with proteinuria.[156,157]

18.3.25 Steroids

18.3.25.1 Corticosteroids

Topically applied glucocorticosteroids are absorbed through the skin,[158] resulting in sufficient quantities in the systemic to replace endogenous production. Systemic side effects of topical corticosteroids occur more frequently in children than adults and in patients with liver disease due to reduced metabolism of the drug.[159,160] The two main causes of systemic side effects are hypercorticism leading to an iatrogenic Cushing's syndrome and suppression of the hypothalamic-pituitary-adrenal axis.[161] In rat's topical application of several corticosteroids caused body weight gain suppression, total cholesterol and triglycerides were increased and the lymphatic tissue was atopic. In addition, several corticosteroids caused adrenal and renal lesions.[162]

18.3.25.2 Sex Hormones

Topical application of estrogen-containing preparations leads to resorption of these hormones and therefore systemic estrogenic effects. Beas et al.[163] reported on seven children with pseudoprecocious puberty due to an ointment containing estrogens. The most important clinical signs were intense pigmentation of mammillary areola, linea alba of the abdomen and the genitals, mammary enlargement, and the presence of pubic hair. Three female patients also had vaginal discharge and bleeding. After discontinuation of the drug, all symptoms progressively disappeared in every

patient. Pseudoprecocious puberty has also been observed in young girls after contact with hair lotions and other substances containing estrogens.[164] Gynecomastia has been reported in young boys and men.[165–167]

18.3.26 Miscellaneous

There are many other examples of systemic toxicity caused by absorption through the skin. For example, exposure to acrylamide dust in polymer factories, causing a chronic disease of the nervous system.[168] Skin exposure to ethylene glycol dinitrate during dynamite production results in toxic effects after only a few minutes.[169] Carbon tetrachloride and 2-chloroethanol cause hepatotoxicity and hepatocarcinogenicity.[170] Glycol ethers, in particular ethylene glycol monoethylene ether are teratogenic and cause menstral disorders in women.[171] Mint[172] showed that repeated dermal exposure of rats *in vivo* to dibutyl phthalate caused significant hepatic peroxisome proliferation within 14 days.

Transdermal systems contain an excess amount of drug to maintain the needed concentration gradient for drug delivery. Upon removal, patches still retain a substantial amount of active drug,[173] increasing the risk of toxicity if applied to the skin of an infant or young child, and emphasizing the need for proper use and disposal of transdermal drug-delivery systems.

Monoethanolamine, diethanolamine, triethanolamine (TEA) are industrial chemicals, and the principle route of exposure is through the skin. Systemic effects after 2-year TEA administration included hyperplasia of the renal tunular epithelium and small microscopic adenomas and nonneoplastic changes in the liver.[174]

18.4 COMMENT

This chapter summarizes literature citations and the basic aspects of percutaneous penetration to alert the reader to the potential for systemic toxicity from topical exposure. From the information provided in this chapter, the reader can clearly see that systemic toxicities are important considerations for a diverse group of compounds after skin exposure. The severity of these systemic reactions is often worse in young children/infants or in patients with impaired barrier function (i.e., due to increased absorption).

Demonstrating causality (rather than association) requires careful documentation. Combining knowledge of the inherent molecular and animal toxicology, cutaneous penetration, and metabolism with the adverse human reaction literature permits a more precise determination of causality. The above data focus the need for controlled studies on the toxicity of chemicals, which come into contact with the skin, either accidentally or deliberately. There are many other texts emphasizing current approaches and technology.[1–3,175]

19.1 INTRODUCTION

The skin is a major interface between the environment and the body. Many investigations of its barrier functions by means of pharmacokinetic methods have been performed and have demonstrated that the skin is a very effective barrier against most potential environmental hazards. However, the awareness of multiple functional activities of this organ such as its capability (1) to mediate enzyme-dependent xenobiotica metabolism, (2) to express specific transporter proteins for influx as well as for efflux into or out of its cells, (3) of multiple activities as an immunocompetent organ including the antigen-presenting Langerhans cells, and (4) of interactions of these cells for the protection of the body against the hazards of ultraviolet (UV) radiation has resulted in new and additional concepts about how the skin works as a barrier organ [1,2]. In addition, new technologies such as quantitative real-time PCR or the gene-array technique, which can be used for human *in vivo* studies, have offered superb possibilities to analyze the multiple capabilities of this complex organ system. These developments have also led to new avenues of research in dermatotoxicology and may provide powerful instruments for dermatotoxicological risk assessments.

To illustrate this exciting development, the molecular mechanisms of UV as well as infrared radiation-induced biological effects will be discussed, followed by the presentation of the cutaneous armentarium of xenobiotica metabolizing enzymes and recent findings about cutaneous transporter proteins. Finally, three examples of toxic events by small molecular weight compounds—cutaneous chemocarcinogenesis, drug allergy and allergic contact dermatitis (ACD)—and the role of xenobiotica metabolism will be outlined.

19.2 MOLECULAR MECHANISMS OF UV AND INFRARED RADIATION-INDUCED BIOLOGICAL EFFECTS

As a result of increased leisure time, the growing popularity of staying outdoors, holidaying in the sun as well as the use of sunbeds, human skin is increasingly exposed to shortwave (290–320 nm; UVB) and longwave (320–400 nm; UVA) UV radiation. UV radiation is well known to exert a variety of

Merk, H.F., Baron, J.M., Heise, R., Fritsche, E., Schroeder, P., Abel, J., and Krutmann, J., Concepts in molecular dermatotoxicology. *Exp. Dermatol*., 15, 692–704, 2006. © The Authors 2006. Journal compilation © 2006 Blackwell Munksgaard.

deleterious effects on human skin [3]. Chronic and possibly also acute exposure to UV radiation increases the risk of developing skin cancer including basal cell carcinoma as well as malignant melanoma. UV radiation causes premature skin ageing, which is characterized by generalized wrinkling, dry and thin appearance, and seborrhoeic keratoses [4]. There are also several specific diseases, which are triggered or exacerbated by UV radiation exposure, such as phototoxic or photoallergic reactions, autoimmune diseases including lupus erythematosus and idiopathic photodermatoses, for example, polymorphous light eruption or solar urticaria. In addition to UV radiation, exposure to near infrared radiation from sunlight or artificial irradiation devices has recently been found to cause skin damage in a manner similar to that observed after UV irradiation [5].

19.3 MOLECULAR BASIS OF THE UVB RESPONSE: NUCLEAR DNA DAMAGE, MEMBRANE EFFECTS, CYTOPLASMIC SENSORS AND MORE

For UVB radiation-induced signal transduction, the generation of photoproducts within the DNA of epidermal keratinocytes is thought to be of critical importance. Among the DNA lesions induced by UVB radiation, cyclobutane pyrimidine dimers predominate. Dimer formation is crucial for the initiation of skin cancer, because it is closely linked to the generation of mutations in tumor suppressor genes, expressed in UV-induced skin tumors [6]. There is, however, also a growing evidence that dimers contribute to photocarcinogenesis by the suppression of the skin's immune system, allowing the transformed cells to grow unimpeded [7]. This information has prompted the development of liposomes, which contain functionally active, dimer-specific DNA repair enzymes and which can be topically applied to human skin to achieve dimer repair and prevent UVB radiation-induced immunosuppressive effects. The effectiveness of this approach has first been demonstrated in animal models, and more recently in human skin [8]. In this study, topical application of photolyase-containing liposomes to UVB-irradiated human skin and subsequent exposure to photoreactivating light has been found to partially remove the UVB radiation-induced dimers in epidermal keratinocytes and to completely prevent the UVB radiation-induced immunosuppressive effects. Also, in a consecutive placebo-controlled multicenter trial, it has been demonstrated that daily application of a DNA repair enzyme containing liposome lotion is effective in preventing the generation of precancerous and cancerous lesions in patients with the DNA repair deficiency syndrome xeroderma pigmentosum [9].

In addition to DNA damage, membrane effects have been shown to play a crucial role in UVB radiation-induced signal transduction [10]. UVB radiation-induced biological effects in keratinocytes such as gene expression or apoptosis (which occurs at higher UVB doses) can be prevented by removal of UVB radiation-induced dimer formation. This inhibition, however, is only partial. Similarly, partial inhibition can be achieved, if the UVB radiation-induced clustering of growth factor receptors on the surface of the plasma membrane of keratinocytes, rather than nuclear DNA damage, is inhibited. However, complete inhibition of UVB-induced effects was found to require prevention of both DNA damage and receptor clustering [11]. The precise biochemical nature of UVB radiation-induced membrane effects is not yet clear and the relevant chromophore(s) unknown. It has been established, however, that receptor clustering is followed by a well-defined cascade of signalling steps that eventually lead to MAP kinase (MAPK) activation, transcription factor activation, and increased gene expression [10]. In this regard, it is of interest that a similar, if not identical, signalling pathway may be triggered in unirradiated cells that are exposed to hyperosmotic stress, indicating the possibility that alterations in cell volume homeostasis may be of relevance to UVB radiation-induced signalling. Accordingly, recent studies have demonstrated that the presence of osmolyte transport systems in human epidermal keratinocytes and osmolyte loading of keratinocytes prevents UVB radiation-induced biological effects such as apoptosis or gene expression (Krutmann J., Grether-Beck S., Schade N., Esser C., unpublished observations). The exact level at which osmolytes interfere with UVB radiation-induced signalling is currently not known.

It should be noted that UVB radiation, in addition to DNA, can be absorbed by several other molecules, some of which are present in the cytoplasm of cells as well. In this regard we have recently shown that part of the UVB response involves cytoplasmic tryptophan as a chromophore, and through the photochemical concepts in molecular dermatotoxicology, generation of the arylhydrocarbon receptor (AhR) ligand 6-formyindolo[3,2]-b-carbazole initiates signalling events, which are transferred to the nucleus and the cell membrane via activation of the cytoplasmic AhR [89].

19.4 THE UVA RESPONSE: FROM CELL MEMBRANE LIPIDS TO MITOCHONDRIA

There is an increasing evidence that similar to UVB radiation, UVA radiation plays a pivotal role in the pathogenesis of skin cancer, in photodermatosis such as polymorphous light eruption and extrinsic (1/4 photo) ageing of human skin. In recent years, substantial progress has been made in understanding the mechanisms through which UVA radiation induces gene expression in human skin cells [12]. In keratinocytes, UVA radiation-induced gene expression was found to involve the formation of second-messenger ceramide from cell membrane sphingomyelin through a photobiological mechanism that is mediated by the generation of singlet oxygen and is capable of hydrolyzing the cell membrane sphingomyelin through a nonenzymatic mechanism [13]. Second-messenger ceramide, without the induction of apoptosis, subsequently acts on mitochondria and causes the release of mitochondria-derived cytochrome C into the cytoplasm [14]. Within the cytoplasm, a redox interaction between cytochrome C and a transcription factor, termed AP-2, occurs, which leads to the oxidation

of AP-2 and reduction of cytochrome C. Oxidized AP-2 has a greatly increased capacity to bind to AP-2 consensus binding sites within the promoter region of UVA-responsive genes and has been shown to be responsible for increased transcriptional expression of UVA radiation-inducible genes in human keratinocytes such as ICAM-1 [15]. UVA radiation-induced signalling thus involves the generation of reactive oxygen species at a very early stage, that is, during the generation of second-messenger ceramide, and at a later stage, that is, during the oxidation of AP-2. This knowledge has been used in further studies to modulate the UVA radiation-induced gene expression by means of various antioxidants.

Further analysis of the very early, that is, the initial signalling events responsible for UVA radiation-induced gene expression, identified signal-transducing microdomains (rafts) within the keratinocyte membrane as critical targets for UVA radiation. Accordingly, enrichment of cell membranes with cholesterol rendered keratinocytes completely unresponsive to UVA radiation (Krutmann J., Grether-Beck S., unpublished observations). These observations indicate that cholesterol and cholesterol-like molecules may serve a previously unrecognized role in photoprotection of human skin.

Similar to UVB, UVA radiation-induced signalling in keratinocytes can be effectively prevented by treatment of cells with osmolytes such as taurine. In addition, preliminary evidence suggests that osmolytes interfere with UVA radiation-induced signalling at a very early stage, for example, by preventing the UVA radiation-induced ceramide formation (Krutmann J., Grether-Beck S., unpublished observation). The exact mechanisms by which osmolytes stabilize cell membrane lipids or rafts are currently under investigation.

19.5 INFRARED RADIATION-INDUCED SIGNALLING IN HUMAN SKIN CELLS

Human skin is exposed to infrared radiation (760 nm to 1 mm) from natural as well as artificial sources that are increasingly used for cosmetic or medical purposes [5]. Epidemiological data and clinical observations indicate that infrared radiation can damage the human skin. In particular, infrared radiation, similar to UV radiation, seems to be involved in photoageing and possibly also in photocarcinogenesis. Recent studies indicate that the basic molecular processes such as signal transduction and gene expression, triggered by exposure to infrared radiation, differ to some extent from those induced by UV radiation. Accordingly, infrared radiation, but not UV radiation-induced upregulation of the mRNA and protein expression of matrix metalloproteinase-1 in human skin fibroblasts, required extracellular signal-regulated kinase 1/2 (ERK1/2) activation [16]. In addition to ERK1/2, infrared radiation has also been shown to activate the p38-MAPK (mitogen-activated protein kinase) signalling pathway. Because MAPKs are involved in transcriptional regulation of a multitude of genes, it is very likely that infrared radiation is able to influence the expression of several genes via activation of MAPK signalling pathways. Taken together, these observations indicate that infrared radiation is capable of eliciting a molecular response in human skin cells similar to, but not identical, the response induced by UV radiation. We have, therefore, recently proposed the term "infrared response" to emphasize the ability of infrared radiation to influence cellular functions such as signal transduction and gene expression specifically [5].

The photophysical and photochemical mechanisms that mediate the before-mentioned molecular effects and biological consequences of infrared radiation are largely unknown. Recent studies from our laboratory suggest that oxidative processes, which are initiated in the mitochondrial electron transport chain of infrared-irradiated human cells, are critically involved in infrared radiation-induced gene expression. These studies may also allow the development of photoprotective strategies against unwanted infrared radiation effects [90].

Although the majority of skin cancers are linked to exposures to UV irradiation, several chemicals were found to be able to induce skin carcinogenesis, and chimney sweep-induced skin cancer was the first reported chemically induced squamous skin tumor. In addition, cutaneous chemocarcinogenesis has become a classical model to study the processes of carcinogenesis on a molecular level. Most of the chemicals are small molecular weight compounds, which must be metabolized in most cases to highly reactive species to be the ultimate carcinogen [17]. The xenobiotica metabolizing enzymes, which are involved in this process, have been found to be present in the skin as well as transporter proteins for the influx and efflux of those compounds [18–20]. In particular, techniques of molecular dermatotoxicology have increased our knowledge about these proteins and their genes and allowed new possibilities to study this metabolism in extrahepatic organs such as the skin [21].

19.6 METABOLISM AND TRANSPORT IN HUMAN SKIN

For many years, the skin was thought to be a passive structural barrier between the body and the environment. We now know that the skin is indeed an active site of diverse types of metabolic activities involving an array of metabolizing enzymes. Recent research results demonstrate that (1) keratinocytes in human skin express various transport-associated and detoxifying metabolic enzymes, and (2) they are, therefore, capable of providing active uptake, biotransformation, and antitransport of different xenobiotics such as drugs, solvents, and carcinogens.

Besides the role of the stratum corneum as the most critical structure for epidermal barrier function, there is increasing evidence indicating that xenobiotic metabolizing enzymes and transport proteins function as the second biochemical barrier of the skin [22]. The metabolic interaction between small molecular weight compounds and molecular targets in the cell can at least be in these phases. After penetration, the xenobiotics are first chemically activated or inactivated by oxidative reactions [23]. The most important family of enzymes involved in these reactions is the family of

cytochrome P450 enzymes (CYP). Normal human epidermal keratinocytes and dermal fibroblasts reveal the constitutive expression of CYP1A1, 1B1, 2B6, 2E1, and 3A5 in the cytoplasm of epidermal keratinocytes and show the expression of CYP3A4 after incubation with drugs like dexamethasone [18,19]. Expression of the retinoic acid metabolizing CYP26AI is restricted to keratinocytes of the basal layer [24]. The expression of multiple CYP enzymes has also been shown in murine skin [25,26]. In addition to their detoxifying functions, these CYP enzymes may be involved in allergic reactions to substances of low molecular weight, for example, drug allergy or ACD as well as chemocarcinogenesis.

Efflux-transport associated proteins, such as P-glycoprotein (MDR1) and multidrug resistance-associated proteins (MRPs), are overexpressed in drug-resistant cell lines and human tumors from various histological origins, including malignant melanoma [27,28]. Several studies have been performed to investigate the expression, regulation, and specific substrates of these transport proteins in human skin cells [19,29].

Real-time polymerase chain reaction (RT-PCR) analysis of normal human epidermal keratinocytes (NHEK) revealed constitutive expression of MRP1 as well as MRP3–6 but was negative for MDR1 and MRP2. Expression of MDR1 was seen on the mRNA level after induction with dexamethasone. RT-PCR results were confirmed by immunoblots, which demonstrated the constitutive expression of MRP1, 3, and 5 as well as expression of MDR1 after induction with dexamethasone. Immunohistological analysis of healthy human skin showed positive staining for MRP1 in the cell membrane of epidermal keratinocytes [19]. Functional activity of MRPs in skin cells such as NEHK and dermal fibroblasts could be demonstrated *in vitro* using the calcein acetoxymethyl (AM) ester assay [30]. Other studies showed that mutations in the MRP6 gene cause pseudoxanthoma elasticum (PXE), a connective tissue disorder affecting the elastic structures in the body including the skin, although the exact pathomechanisms of PXE are not completely understood [31].

As regulatory mechanisms for these transporters in skin cells were unknown, influence of inflammatory cytokines on the expression of MRPs in these cells was analyzed [32]. Stimulation of NHEK and human dermal fibroblasts with interleukin-6 (IL-6), in combination with its soluble α-receptor (sIL-6R), or oncostatin M (OSM), for 24–72 h resulted in an upregulation of MRP expression and activity, which could be shown on the RNA level and by the use of efflux transport assays. Both cytokines induced a strong activation of signal transducer and activator of transcription STAT1 and STAT3 as well as the MAPK Erk1/2. OSM additionally activated protein kinase B strongly. Using the MAPK/extracellular signal-regulated kinase, kinase 1-specific inhibitor U0126, a stimulatory effect of MAPK on MRP gene expression could be excluded. Inhibition of the phosphatidylinositol 3-kinase, however, indicated that this pathway might be involved in OSM-mediated upregulation of MRP4 in dermal fibroblasts [32]. Several inflammatory skin diseases show an enhanced expression of IL-6-type cytokines. Corresponding to *in vitro* data, upregulation of MRP expression was found in lesional skin taken from patients with psoriasis and lichen planus [32].

Current studies focus on the specific substrates of the MRP-transporter expressed in the skin cells. Active transport of retinoids, which are known to have not only a pharmacological but also a physiological role in human skin and skin tumors, could be demonstrated. Treatment of cells with IL-6 and sIL-6R has increased the active efflux transport of all-trans [20-methyl-3H] retinoic acid in NHEK in comparison with transport measured in the absence of this cytokine [32]. Specific MRP-inhibitors like indometacin are able to inhibit this transport (Heise R., Rodriguez F., Neis M., Marquardt Y., Joussen S., Wosnitza M., Merk H. F., Baron J. M., 2006).

Influx-transport proteins, such as the organic anion transporting polypeptide (oatp1), were first identified on the molecular level in rats as a multispecific and sodium ion-independent transporter for various organic anions, including bile acids, conjugated metabolites, and xenobiotics. Subsequently, rat oatp2 and 3 were isolated as homologues of oatp1 and were shown to be present in various tissues and to transport anionic and neutral compounds. As they are structurally very closely related, they are considered to form a single protein family—the OATP family. In humans, OATP-A was first cloned from human liver as a homologue of rat oatp1. Tamai et al. [33] identified three novel human transporters (OATP-B, -D, and -E), structurally belonging to the organic anion transporting polypeptide (OATP) family. These OATPs exhibit a broad, and to a certain degree, overlapping substrate specificity and transport a wide range of more bulky organic compounds including steroid conjugates, cardiac glycosides, endothelin-antagonists, and certain toxins [33]. Studies by Schiffer et al. [20] were able to show a constitutive expression of OATP-B, -D, and -E in normal epidermal keratinocytes using RT-PCR and Northern blot analysis, as well as in human skin tissue shown by tissue blot hybridization and immunostaining. Expression of OATP-A and -C were not detected in any of the keratinocyte samples. Even though the substrate specificity of the OATP isoforms were only partially known until now, these findings gave a strong evidence that the uptake of large organic cations like drugs in keratinocytes is an active transport process mediated by members of the OATP family.

Interaction and synergism between CYP-mediated metabolism and active transmembrane transport occurs, if metabolites produced by the CYP enzymes are better substrates for transport proteins than the parent drug, or if the efflux transporter prolongs the duration of absorption by necessitating the repeated entry of the drug into the skin cell. This process increases the exposure of the substrate to the CYP enzyme and could, therefore, prevent kinetic saturation of this protein [18,34]. Resulting drug metabolites often have specific functions on gene expression in skin cells, which could be demonstrated for the 4-oxo metabolites of retinoic acid [35]. Interaction of the influx proteins of the OATP family and the efflux proteins of the MRP family has recently been

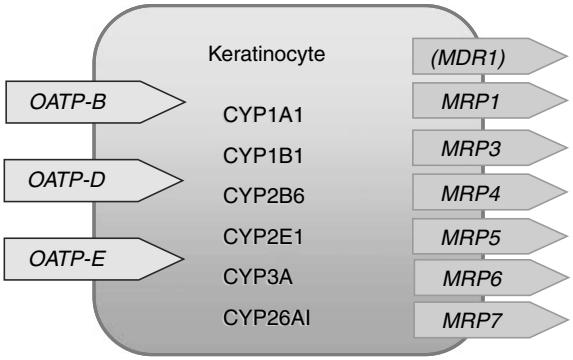

FIGURE 19.1 Transport and metabolism of xenobiotics in human skin cells [19,20]. Reprint of Merk, H.F., Baron, J.M, Heise, R., Fritsche, E., Schroeder, P., Abel, J., Krutmann, J., *Exp. Dermatol*., 15, 692–794, 2006. With permission.

described as a physiological mechanism for the transport of xenobiotics and has been named vectorial transport [36].

In conclusion, these studies showed that skin cells express various metabolizing and transport-associated proteins. Currently, it is presumed that in skin cells MRP transport proteins (phase III)—which play a major role in efflux of endogenous and exogenous compounds including leucotrienes and prostaglandins [37,38]—directly interact with the influx transport proteins such as OATPs (phase 0) and metabolizing enzymes such as CYPs (phase I and II) (Figure 19.1).

19.7 MECHANISM OF CHEMICAL CARCINOGENESIS

Occupational exposures to various chemical and topical applications of dermal medicinal preparations like coal tar have been considered as sources for skin cancer in humans. There is a broad group of environmental chemical agents known to produce skin cancer in animals; however, the contribution of such agents to human skin cancer is still unclear [39].

For skin carcinogenesis, it is generally believed that originating from a single mutated cell, the cancer develops over a series of preneoplastic and premalignant states. On the basis of animal studies, the multistage model of carcinogenesis has been developed. This operational model involves stepwise accumulation of several genetic changes leading to outgrowth of the malignant tumors. There is evidence that the stages of initiation, promotion, and progression involve qualitatively different kinds of molecular events. Initiation is an irreversible event, which occurs after a single treatment of mouse skin with a carcinogen. Tumor promoters do not act mutagenic by themselves, but promote the selection of initiated cells and induce the outgrowth of premalignant papillomas. Tumor progression is characterized by conversion of premalignant papillomas into carcinomas, and it has been suggested that additional mutational events are involved in the processes of conversion and progression. As the multistage model is intensely reviewed [40–42], we will summarize here the new findings in the field of chemically induced skin carcinogenesis.

An important step in skin carcinogenesis is tumor initiation that occurs by the interaction of a reactive chemical with DNA in the target cells. This interaction results in an irreversible alteration of genes involved in the regulation of terminal differentiation. Most of the chemicals with initiating activity have to be activated before inducing the DNA damage, and human and animal skins express the respective activating system, which catalyzes xenobiotic metabolism (see previous paragraphs in this review).

In experimental skin carcinogenesis, classical initiators are polycyclic hydrocarbons, such as benzo(a)pyrene (BaP) and 7,12-dimethylbenzo(a)anthracene (DMBA), which can be activated by the constitutively expressed cytochrome P4501A1 (CYP1A1) and cytochrome P450 1B1 (CYP1B1) [43]. An important function during the metabolic activation of polycyclic aromatic hydrocarbons has the aryl hydrocarbon receptor (AhR). This ligand-activated transcription factor is involved in the regulation of several phase 1 and phase 2 enzymes. Among the many AhR ligands, TCDD has been found to bind to the AhR with high affinity, and all the effects caused by this compound are mediated by the AhR. After ligand binding, the cytosolic AhR translocates to the nucleus and forms a heterodimer with ARNT. The AhR/ARNT dimer then binds to specific DNA sequences termed xenobiotic responsive element (XRE) and interacts with the transcriptional machinery. DNA microarray analyses have revealed that more than 300 genes are up- or down-regulated by this pathway including genes coding for phase 1 and phase 2 enzymes like CYP1A1, CYP1A2 CYP1B1, UGT 1A5 GSTYA and MNOR, respectively [44]. Recently, a AhR-related gene has been cloned and termed AhR repressor (AhRR). The AhRR is a heterodimer with ARNT and recognizes XRE, but functions as a transcriptional repressor [45]. AhR, AhRR, and their common partner ARNT are expressed in dermal and epidermal cells. The importance of the AhR in skin carcinogenesis could be demonstrated in AhR-deficient animals. Mice lacking in AhR are resistant toward BaP-induced skin tumorigenesis [46]. Besides its function in regulating the xenobiotic metabolism, the AhR seems to be functional in regulation of normal skin homeostasis. Skin of AhR-deficient mice exhibits interfollicular and follicular epidermal hyperplasia with hyperkeratosis and acanthosis associated with marked dermal fibrosis [47]. The involvement of AhR in regulation of skin homeostasis is supported by a recent study, in which transgenic mice with constitutive active AhR in keratinocytes were generated [48]. At birth, the transgenic animals were normal, but they developed severe skin lesions with itching, postnatally. The skin lesions were accompanied by inflammation and immunological imbalances and resembled typical atopic dermatitis. The inflammation-related genes, keratins 1, 6, and 16, the chemokine CCl 20, and IL-18 were strongly upregulated, reflecting the proinflammatory state of the skin of the transgenic animals. Based on these findings, the possibility has emerged for the authors that blocking the AhR signal may help to relieve the allergic symptoms, as many xenobiotics like P(a)H can exacerbate allergic reactions via the AhR pathway.

Metabolic activation and DNA binding of carcinogens in skin can produce successive accumulation of mutations, which can activate oncogenes or inactivate tumor suppressor genes. The p53 tumor suppressor gene is the most frequently mutated gene in humans [49] and in experimental models [50]. The mutations resulted in loss of function and are thought to play a causative role in tumorigenesis [49]; hence, p53-deficient animals develop a variety of spontaneous tumors such as lymphomas, osteosarcomas, and soft tissue sarcomas [51]. Although p53 mutations occur in skin cancer especially after UV radiation [41], it is not clear whether the loss of p53 function is critical in chemically induced skin carcinogenesis. After subjecting p53-deficient mice to a multistage chemical protocol, the animals were resistant to papillomatogenesis [52]. In addition, mating experiments between p53-deficient and transgene mice expressing epidermally targeted v-ras, v-fos, and transforming growth factor α showed an inhibition of spontaneous and TPA-promoted papilloma formation [53–55]. However, transgenic animals expressing a dominant-negative p53 mutation in the epidermis showed an increased sensitivity to two-stage chemical carcinogenesis [56]. While the majority of papillomas in control mice regressed after termination of TPA treatment, the p53-mutated papillomas progressed to carcinomas and metastases. The effect of accelerated tumorigenesis was explained with an increase in genomic instability that resulted from an inhibition of G1 arrest. Taken together, there is little evidence that p53 mutations can act as an initiating event in chemical skin carcinogenesis, as p53 null mice were not prone to spontaneous tumor formation unless they were initiated by treatment with a chemical mutagen. Therefore, loss of p53 function may induce tumor progression rather than initiation.

In contrast to p53, there is strong evidence that activation of the Ha-ras oncogene occurs early in mouse skin carcinogenesis and in fact represents the critical initiation event [57]. Activated Ha-ras has been found in papillomas and carcinomas induced by DMBA, and the activation correlated with a high frequency A–T transversions in codon 61 [58]. Lines of transgenic mice carrying a v-Ha-ras oncogene fused to the regulatory region of the human keratin K1 gene have the properties of genetically initiated skin and develop tumors after promoter application without initiation with a chemical mutagen [53,54]. There is a large body of evidence showing a strong correlation between ras activation and alterations of expression of cell cycle regulating genes, and skin tumor promotion is characterized by selective and sustained hyperplasia leading to specific expansion of initiated cells in papillomas [41].

The observation that tumor-promoting agents like TPA induce inflammation in mouse skin prompted a number of investigations to study the mechanisms of inflammatory mediators in skin tumor development. The eicosanoid pathway, composed of cyclooxygenases and lipoxygenases metabolites, has been identified to be important during tumor promotion. This has been demonstrated in studies using COX and LOX inhibitors [59] and evidenced by several gene-targeting experiments.

The LOX family catalyzes the regio- and stereo-specific insertion of molecular oxygen into polyunsaturated fatty acids by generating 5S-, 8S-, 12S- 12R-, and 15S-hydroperoxyeicosotetrataeconoic acids. Several isoenzymes such as 8S-Lox and 12S-Lox have been found to be preferentially expressed in the epidermis of humans and mice [60,61], and tumor induction studies in mice showed that both the enzymes were overexpressed in papillomas and squamous cell carcinomas [62,63]. The expression correlated with an increased accumulation of the corresponding HETE products. Interestingly, the amount of HETE correlated with the formation of etheno adducts of DNA [64], suggesting that HETE generates an endogenous mutagene that might induce chromosomal damage in neoplastic cells. However, in contrast to 12S-LOX, the epidermis-type (e) 12S-LOX seems to be downregulated during epidermal tumor development indicating an antitumorigenic activity. This could be demonstrated by generating e12S-Lox transgenic animals [65]. Low transgene expression of e12-LOX was correlated with decreased skin tumor response paralleled by an accumulation of the linoleic acid derivate of 13S-HODE, whereas high transgene expression led to an increased skin tumor formation paralleled by the accumulation of the arachidonic acid derivate of 12-S-HETE. These results indicate opposite functions for production of arachidonic acid and linoleic acids in modulation of chemically induced skin carcinogenesis.

In addition, dysregulation of prostaglandin synthesis, which is catalyzed by the cyclooxygenases Cox 1 and Cox 2, is known for a long time to have a critical role in tumor development [66,67]. Using arachidonic acid as substrate, both enzymes catalyze the formation of prostaglandin H, which is converted by prostanoid synthases into biologically active products like PGE2, PGF2, PGI2, and thromboxane A. While Cox 1 is constitutively expressed in all cells, Cox 2 can be induced by various endogenous and exogenous stimuli like growth factors, cytokines, and the tumor-promoting agent (TPA). An overexpression of Cox 2 has been found in various tumor tissues including breast cancer, stomach cancer, colon cancer, and squamous cell carcinoma of skin [68]. Conclusions for the importance of Cox in tumor promotion have been obtained from studies with Cox-deficient animals. The animals exhibited a reduced sensitivity for multistage carcinogenesis. The effect was more prominent in Cox-2-deficient animals than in Cox-1-deficient mice [69]. Moreover, specific Cox 2 inhibitors have been found to suppress both TPA-induced prostaglandin synthesis and tumor promotion [67], and the prostanoid PGF2a has been identified as a tumor promoter in the mouse skin model of multistage carcinogenesis [70].

In conclusion, chemical skin carcinogenesis is the result of a complex interaction of genetic and epigenetic events, and the development of mouse skin models by gene targeting has been and is helpful to identify the critical genes during tumorigenesis. As mentioned in this review, the AhR and its related proteins are important in chemically induced

carcinogenesis. Recently, we have observed that UV radiation can activate the AhR pathway. Therefore, the analysis of AhR function during UV-induced skin carcinogenesis could contribute to a better understanding of the physiological function of the AhR family, in general, and in skin, in particular.

19.8 DRUG ALLERGY

Similar to chemocarcinogenesis, in which small molecular compounds must be bound to the high molecular compound DNA, sensitization requires the presentation of a high molecular weight compound such as a peptide to T lymphocytes, indicating that small molecular weight compounds must be bound to those peptides before they can become antigenic. Drug-induced skin rashes occur in 2–3% of hospitalized patients. The skin is a preferred target organ for B-type reactions. Dangerous reactions are in particular the anaphylactic shock and angioedema as well as bullous drug reactions including toxic epidermal necrolysis (TEN). Most often, the involved drugs are antibiotics—in particular β-lactamantibiotics and sulfonamides—anticonvulsiva, radio contrast media, and cytotoxic agents such as cis-platin derivates. Investigations about the function of T cells in delayed type reactions have improved our understanding of the pathophysiology and led to new diagnostic options and therapeutic concepts. Recently established animal models as well as investigations on the level of antigen-presenting cells may improve the chances of predicting the immunogenicity of small molecular weight compounds.

Drug allergy and ACD are examples of hapten-induced allergic reactions. Because haptens are small molecular weight compounds, this makes it necessary at least in most cases that they be transformed into highly reactive chemical species, which can be bound to peptides. Therefore, it is not surprising that it has become overt that xenobiotica metabolizing enzymes also play a role in the formation of nominative antigens in the hapten-derived allergic reactions. There are several evidences that CYP-mediated metabolites are involved in drug allergic reactions:

- In our own studies, we were able to show that drug-modified microsomes, which contain the main CYP activity, enhance the reactivity of antigen-specific T lymphocytes [71–73]. In addition, Wolkenstein et al. [74] showed that carbamazepine which induced allergic drug reactions quite often—compared with other drugs—is covalently bound with its reactive metabolites to CYP isoforms present in the skin.
- In several cases of drug allergic reactions including cases of toxic epidermal necrolysis to sulfonamides and phenytoin, microsomal antibodies were detected in the serum of the patients, which bind to CYP isoenzymes, which are involved in the metabolism of the drug or microsomal proteins with a position in the microsomal membrane close to the CYP isoenzymes.
- Sensitization to sulfamethoxazole in mice is dependent on the CYP-dependent metabolism of sulfamethoxazole to nitroso-sulfamethoxazole derivatives [75]. This supports the necessity of the processing of the hapten to be bound to peptides and finally to be presented by MHCII receptors to sensitize CD4+ T lymphocytes. In addition, Schnyder et al. [76] proposed an additional model by studying the sensitized T lymphocytes. They found that sulfamethoxazole could directly bind to the HLA–peptide complex stimulating T lymphocytes through an HLA-restricted processing- and metabolism independent pathway. However, under the condition of challenges, MHCI presentations to CD8+ T lymphocytes are also possible and probably circumvent the processes, which lead to a binding with MHCII receptors, which, however, is a prerequisite for sensitization.

19.9 ALLERGIC CONTACT DERMATITIS

Similar to allergic drug reactions, ACD is mediated by small molecular weight compounds. This is a frequently occurring disease and about 6% of the patients who are seen by a dermatologist suffer from it. In addition, this disease has a major socio-medical impact, because it is quite often the reason for an occupational skin disease, which costs, for example, the German health system about 3 billion per year (Diepgen T. L., personal communication).

Allergic contact dermatitis is a form of delayed-type hypersensitivity reaction mediated by T lymphocytes. Up to now, much efforts have been taken in the elucidation of cellular reactions to contact allergens such as nickel and uroshiol to understand the immunological process to define populations at risk and to facilitate hazard evaluations. The ACD as well as other immunological reactions such as drug allergy has two main phases: sensitization and elicitation. During the sensitization phase, the individual acquires a specific immunological memory at the T-cell level to the contact sensitizer after its presentation to them by Langerhans cells in the local lymph node. Upon renewed contact with the sensitizing substance, those sensitized T lymphocytes will be reactivated and this will amount to an inflammatory response, which finally leads to ACD. Multiple cytokines, chemokines, as well as transmembrane signalling proteins are involved in this process and the use of different interactions of potential haptens with these compounds has been tried for hazard evaluations in predicting whether a specific hapten is more or less sensitizing. However, these assays work in some cases but not in others, which makes the predictivity unsafe. One reason may be that these compounds are metabolized and that it is necessary to understand the sensitization process on a more precise molecular level including the enzyme-dependent metabolism of most of these compounds.

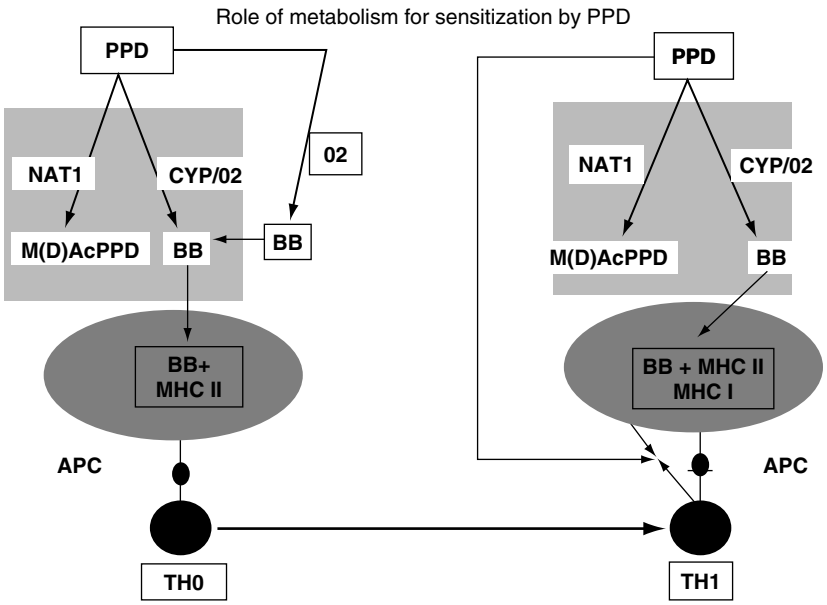

FIGURE 19.2 Metabolic pathways of PPD to BB and its acetylated (Ac) derivatives and its relation to sensitization and challenge by PPD. Reprint of Merk, H.F., Baron, J.M, Heise, R., Fritsche, E., Schroeder, P., Abel, J., Krutmann, J., *Exp. Dermatol*., 15, 692–794, 2006. With permission.

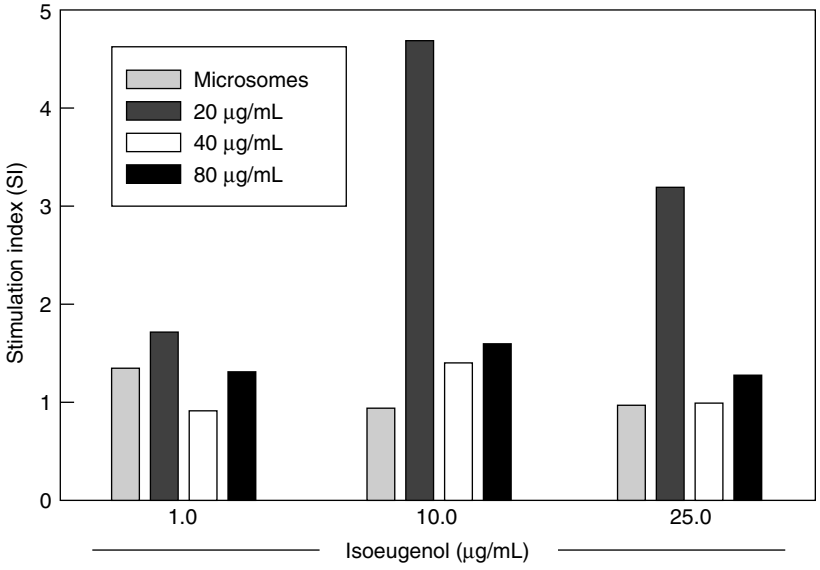

FIGURE 19.3 Effects of fragrance-modified human liver microsomes. To study the involvement of metabolizing enzymes in the presentation of fragrances, antigen-modified human liver microsomes (at indicated final concentrations) were tested for their ability to obtain a polyclonal stimulation of T lymphocytes of a sensitized patient. Proliferation was determined by 3H-thymidine incorporation and is given as the stimulation index (SI). Reprint of Merk, H.F., Baron, J.M., Heise, R., Fritsche, E., Schroeder, P., Abel, J., Krutmann, J., *Exp. Dermatol*., 15, 692–794, 2006. With permission.

19.10 *p*-PHENYLENEDIAMINE

p-Phenylenediamine (PPD) is one of the most frequently encountered contact allergens and up to 50–60% of subjects in certain professions are sensitized. This compound is acetylated in human skin and keratinocytes and alternatively oxidized to Bandrowski's base (BB), which is involved in the allergic reactions to PPD [77,78]. Our own studies demonstrated that PPD itself could be recognized by sensitized T lymphocytes through a processing-independent pathway, whereas its autoxidation product BB required processing and possible metabolism to stimulate T lymphocytes. In addition, the polyclonal response to BB was enhanced by metabolically active enzymes such CYP isozymes [78]. There was no reactivity to acetylated derivatives of PPD, suggesting that this pathway is a detoxifying pathway (Figure 19.2). This acetylation is mediated by the enzyme N-acetyltransferase 1 (NAT1) which is known to be polymorphically expressed in the population leading to high and low capacity to acetylate PPD. Preliminary investigations of the relation of this polymorphism and the likelihood of becoming sensitized to PPD demonstrated at least a trend that slow-acetylators possess an increased risk to develop this contact dermatitis; however, these data are not statistically significant till now.

19.11 FRAGRANCES

Sensitization rates to fragrances are the highest beside nickel sulfate in most countries with western lifestyle [79]. Their ubiquitous distribution leads to unavoidable exposure and

they are present not only in cosmetic products but also in household products, medicaments, food, paper, and paints. There are several examples that fragrances must be oxidized to become the nominative antigen. This may occur by spontaneous oxidation as in the case of D-limonene, abietic acid [80,81], or by enzymatic metabolism, for example, cinnamic alcohol or eugenol [82–85]. In our own studies, we observed that the T-cell stimulation of eugenol- or isoeugenol-sensitized patients was increased in the presence of antigen-modified human liver microsomes (CYP) or recombinant CYP 1A1 in five of seven cases [84] (Figure 19.3). This suggests that metabolically active enzymes such as CYPs may be involved in the activation of fragrances and that the study of those enzymatic pathways may be important to recognize the potential strong antigens by appropriate *in vitro* cell systems or expert systems such as DEREK.

19.12 CONCLUDING REMARKS

In conclusion, the improvement in our knowledge of dermatotoxicologic processes in the skin on a molecular level as well as the possibility to apply new techniques such as the cloning of lesional T lymphocytes [86], transgenic mice [87], and *in vivo* analysis of gene expression in human skin by means of chip technology and quantitative real-time PCR—just to mention some examples—has led to an improved understanding of the toxicological processes. This development allows not only the replacement of older experimental settings but also the use of the easily obtainable skin cells to investigate the principal toxicological processes, which may be valid for other organs as well. An example for this may be the recent suggestion to use real-time (Taqman) PCR to quantify the levels of CYP mRNA in the skin to study phenotypes within the population with differential drug-metabolizing abilities [88]. In this regard, the skin might represent an ideal model organ to assess the interaction of the human body with environmental noxae.

20.1 INTRODUCTION

Among the pathological conditions in which chemistry plays an especially important role is contact allergy (Lepoittevin, 1998), and chemical reactions/interactions are involved throughout the biological process that will result in the patient developing delayed hypersensitivity. Thus, the crossing of the cutaneous barrier is mainly controlled by the physicochemical properties of the allergen (molecular volume and lipophilicity). The formation of the hapten–protein complex, which involves the formation of new chemical bonds, is driven by molecular orbital properties. Finally, the recognition between the antigen and the receptors on T lymphocytes can be explained by a discipline undergoing rapid development, that of supramolecular chemistry.

Recently, there has been a major step forward in our understanding of the molecular basis of hapten recognition by T cells. Nevertheless, this does not eliminate the need to understand the characteristics of the preceding processes, as it is true that the properties of a chemical are implicit in its molecular structure.

To cause sensitization, a compound has to penetrate the skin (Roberts and Walter, 1998), where it may be metabolized (Hotchkiss, 1998), and react with Langerhans cell surface proteins to form new chemical structures that are recognized as foreign. We discuss in this chapter the way low molecular weight chemicals can react with skin proteins to form complete antigens, and how these structures could be recognized by T-cell receptors.

20.2 SOME CHEMICAL REMINDERS

Haptens (small molecules with a molecular weight less than 1000 Da) can interact with biological macromolecules by mechanisms leading to the formation of bonds of various strengths (Figure 20.1). These bonds, known as chemical bonds, are the result of electronic interactions between atoms and are characterized by the energy involved. This reflects the bond stability, as this amount of energy must be provided to break the link between the two atoms. In general, a distinction is made between so-called weak interactions, involving energy levels from a few Joule to around 50 kJ/mol, and strong interactions, covalent or coordination bonds, with energies ranging from 200 to 450 kJ/mol.

20.2.1 Weak Interactions

Weak interactions are normally grouped into three main categories: hydrophobic bonds, dipolar bonds, and certain ionic bonds. Although these weak interactions involve modest energy levels and produce structures of low stability, they are nonetheless of great biological importance, as they control virtually all the phenomena of interaction between receptors and substrates.

Hydrophobic bonds represent the ability of organic molecules to organize themselves in water so as to minimize the contact area that they expose to the aqueous solvent. It is, for example, by such means that hydrophobic molecules insert themselves into the phospholipid bilayers of cell membranes

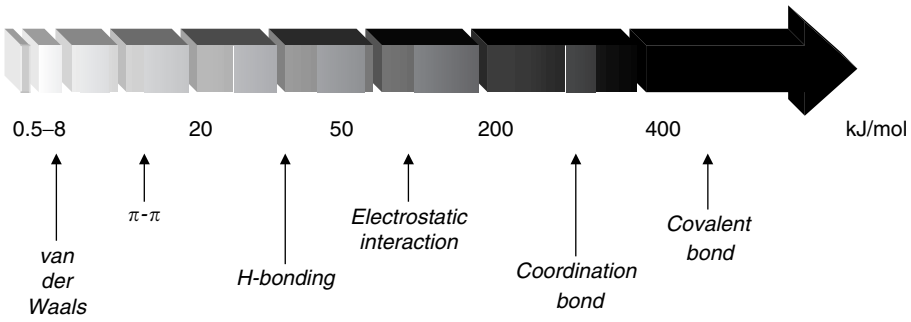

FIGURE 20.1 Energy level of chemical bonds.

and into the hydrophobic regions of proteins or membrane receptors. These hydrophobic bonds, which involve energies in the order of 40–80 J/Å^2/mol, seem, nevertheless, to play an important role in allergies to very lipophilic products (Darley et al., 1977), such as the allergens from poison ivy (*Rhus radicans* L.) or poison oak (*Rhus diversiloba* T.). This could also be of importance for the interactions of haptens with the lipophilic domains of antigen-presenting cells.

Dipolar bonds are electrostatic interactions between permanent or induced dipoles. The electron clouds do not always have a uniform charge density (these variations result from the structure of the molecule), and the zones of high electron density can interact electrostatically with zones of low electron density (permanent dipoles). Electron clouds can also be deformed and polarized as they approach one another, thus creating induced dipoles. These interactions between dipoles, also known as van der Waals bonding, involve energies in the order of 0.5–8 kJ/mol. Hydrogen bond is a special case of dipolar interaction and they occur between a hydrogen atom, bound to an electron-withdrawing atom, and an electron-rich atom. The energy of such bonds can be as high as 25 kJ/mol.

Ionic bonds are based on electrostatic interactions between preexisting and generally localized charges on organic molecules or minerals. Such interactions occur, for example, between the charged amino acids in proteins and are, therefore, important in recognition phenomena.

20.2.2 Strong Interactions

Covalent bonds result when two atoms share a pair of electrons and are classically represented in chemical formulas by dashes. They involve energies in the order of 200–450 kJ/mol and are, therefore, very stable compared with the weak interactions. The two electrons required for bond formation can be contributed by both partners, which is called a radical reaction, or can be provided by one of the atoms, which is especially electron rich, and shared with an electron-poor atom; this case is referred to as a reaction between a *nucleophile* (electron rich) and an *electrophile* (electron poor) center. These two terms, nucleophile and electrophile, represent the capacity of a molecule, or rather an atom of this molecule, to donate or accept electrons to form a covalent bond. Nucleophilic centers are rich in electrons and, therefore, partially negatively charged, while electrophilic centers, deficient in electrons, are partially positively charged.

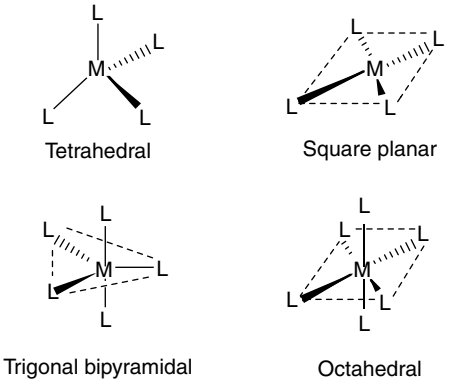

FIGURE 20.2 Examples of geometry for coordinate bonds.

Coordination bonds are another type of relatively strong bond, comparable to covalent bonds; this occurs between metals or metal salts and electron-rich atoms (mainly heteroatoms, such as nitrogen or oxygen). These interactions permit the electron-rich groups or ligands to transfer part of their electron density to the metal and increase its stability. Coordinate bonds are characterized by the number of ligands and by a geometry characteristic both of the metal and of its oxidation degree (Figure 20.2). For example, cobalt (II) (Co^{2+}) is characterized by a tetrahedral arrangement, nickel (II) (Ni^{2+}) by a square planar tetra coordinated arrangement, and chromium (III) (Cr^{3+}) by a six-ligand octahedral arrangement. The number of ligands and the geometry of these coordination complexes determine whether the metals are allergenic and control cross-reactions.

20.2.3 Mechanisms of Bond Formation

The main mechanisms for the formation of covalent bonds involved in contact allergy can be grouped into three main categories: nucleophilic substitutions, on either a saturated or unsaturated center, and nucleophilic additions (Figure 20.3).

Nucleophilic substitution on a saturated center involves the attack by an electron-rich nucleophile on an electron-poor electrophilic center. As the electrophilic carbon already has four single bonds, a new bond can only be formed if one of the existing bonds is broken. The overall effect will, therefore,

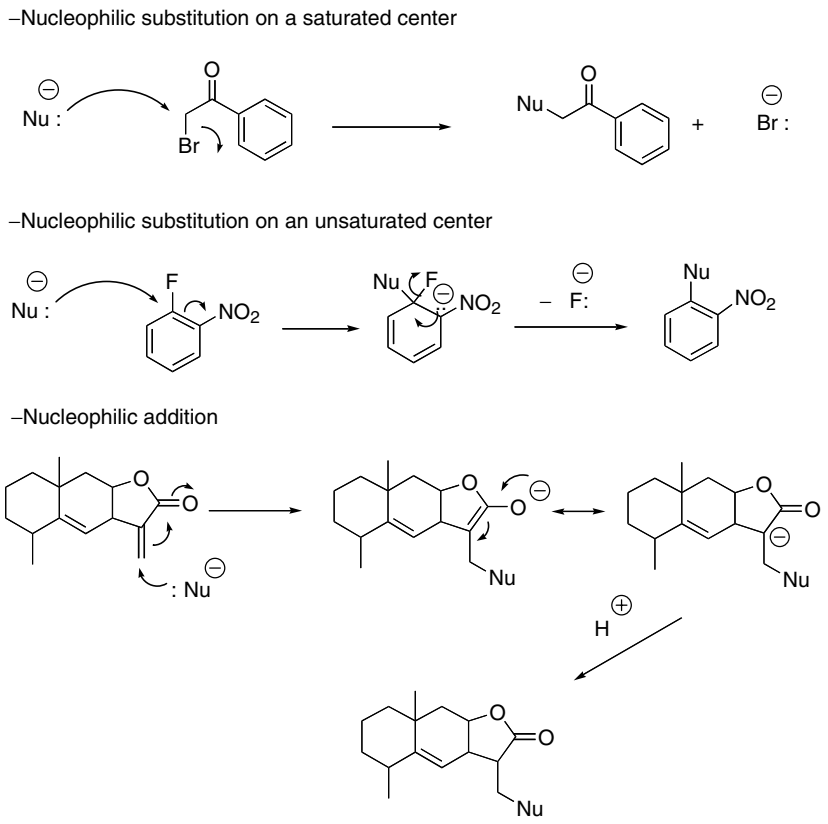

FIGURE 20.3 Principal mechanisms of covalent bond formation in contact allergy.

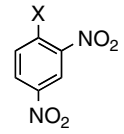
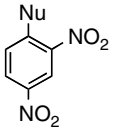
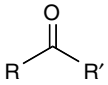
be a substitution of one of the groups (the leaving group) by the nucleophile.

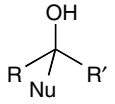
A *nucleophilic substitution* reaction can also take place at an *unsaturated center* (a carbon with one or more multiple bonds). In this case, although the overall result is again a substitution, the mechanism is slightly different. The presence of a multiple bond allows the formation of a saturated intermediate and the subsequent reformation of the multiple bond permitted by the departure of a leaving group, resulting in the substitution product. This mechanism is illustrated in the aromatic series in which it is all the more favored by attracting groups (e.g., nitro), which stabilize the intermediate.

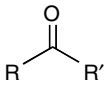
Nucleophilic addition is simply the addition (with no leaving group) of a nucleophilic atom to an unsaturated electrophilic center (containing one or more multiple bonds). This mechanism is very similar to the first stage of nucleophilic substitution on an unsaturated center, but the absence of a leaving group rules out the reformation of the multiple bond. A saturated compound is thus produced.

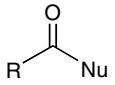


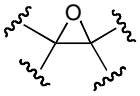


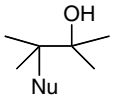


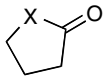


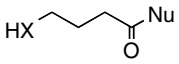


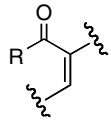


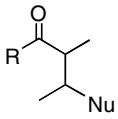


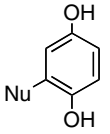


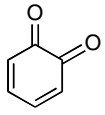


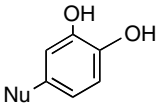


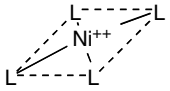












20.3 PRINCIPAL ELECTROPHILIC CHEMICAL GROUPS PRESENT IN CONTACT ALLERGENS

Many chemical groups have electrophilic properties and are thus able to react with various nucleophiles to form covalent bonds. Table 20.1 shows those chemical groups most frequently found in contact allergens and the mechanism by which they react with nucleophilic groups. The previously defined three main types of mechanism, nucleophilic substitution on a saturated center (e.g., alkyl halides and epoxides), nucleophilic substitution on an unsaturated center (aromatic halides or esters), and nucleophilic addition (carbonyl derivatives and α,β-unsaturated systems), can be seen.

20.3.1 Back to Contact Allergy

If we consider biological systems from a chemical viewpoint, it becomes apparent that a very large proportion of structures, especially nucleic acids and proteins, contain many electron-rich groups (those containing nitrogen, phosphorus, oxygen, or sulfur). We can thus consider biological systems as being overall nucleophilic. It is, therefore, not surprising that many biological mechanisms are disturbed on contact with electrophilic chemical substances. Depending on the site of action of these electrophilic molecules, the effect can be mutagenic (Frierson et al., 1985), toxic (Guengerich and Liebler, 1985), or allergenic if the target is the epidermis. In proteins, the side chains of many amino acids contain electron-rich groups capable of reacting with allergens (Figure 20.4). Lysine and cysteine are those most often cited, but other amino acids containing nucleophilic heteroatoms, such as histidine, methionine, and tyrosine, can react with electrophiles (Means and Feeney, 1971). Thus, it has been shown by nuclear magnetic resonance (NMR) studies that nickel sulfate, for example, was interacting with histidine residues of peptides (Romagnoli

TABLE 20.1
Principal Electrophilic Groups Seen in Contact Allergy with Mechanisms of Reaction and the Products

Group	Name	Reaction Mechanism	Product
$R\text{-}CH_2\text{-}X$ X = Cl, Br, I	Alkyl halide	Nucleophilic substitution on a saturated center	$Nu\text{-}CH_2\text{-}R$

et al., 1991) and that methyl alkanesulfonates, allergenic methylating agents, were mainly reacting with histidine and to a less extent with lysine, methionine, cysteine, and tyrosine (Lepoittevin and Benezra, 1992). If we consider the chemical structure of some allergens (Figure 20.5) in the light of the chemical principles already outlined, it is easy to understand that all of these molecules will be able to react with biological nucleophiles. The so formed extremely stable covalent bonds could then lead to the triggering of delayed hypersensitivity. Again, the previously described three main

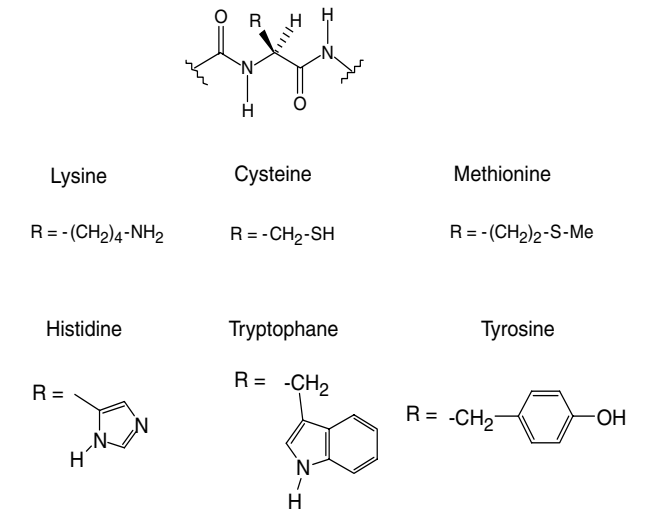

FIGURE 20.4 Principal nucleophilic residues in proteins.

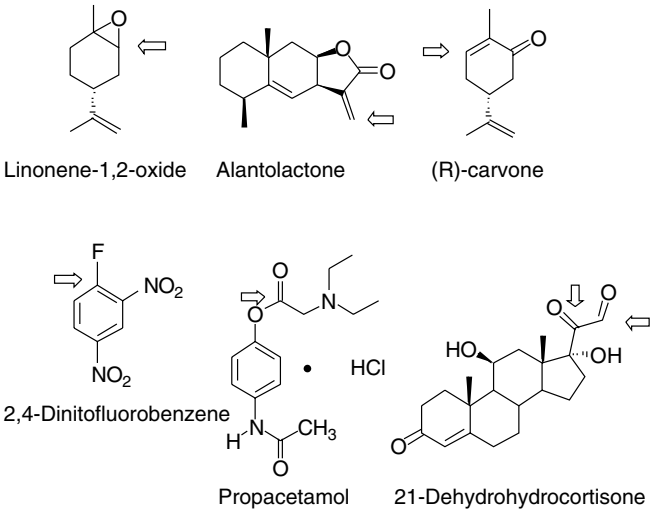

FIGURE 20.5 Examples of sensitizing molecules. The electrophilic center is indicated by an arrow.

types of mechanism for the formation of covalent bonds are seen; the arrows indicate the reactive center of each molecule.

20.3.2 Chemical Selectivity of Haptens for Amino Acids

A direct consequence of the diversity of hapten–protein interactions is the existence of selectivity for amino acid modifications. For example, we have shown that the α-methylene-γ-butyrolactones, the major allergens of plants of the Asteraceae family, principally modify lysine residues (Franot et al., 1993). It has also been shown that not all modifications were antigenic and that the sensitization potential of a molecule is probably more related to its ability to modify some specific residues rather than to modify a large number of amino acids. Thus, the difference in sensitizing potential of two sultone derivatives, an alkenylsultone (a strong sensitizer) and an alkylsultone (a weak sensitizer), which differ only by the presence of a double bond, could be rather explained by the selective modification of lysine residues by the strong sensitizer than by the many tyrosine residues modified by both derivatives (Meschkat, 2001a,b). The same observation can apply to 5-chloro-2-methylisothiazol-3-one (MCI) and 2-methylisothiazol-3-one (MI), the main components of Kathon CG. While both molecules were very reactive toward cysteine residues (Alvarez-Sanchez et al., 2003), the strong sensitizer MCI was also shown to react with lysine and histidine residues in proteins (Alvarez-Sanchez et al., 2004a,b).

These differences, initially purely chemical, seem increasingly to have a major impact on the response of the immune system. The selectivity of the sites of haptenization is directly involved in the selection of the peptide fragments that are presented by the APC to the T cells and thus in the selection of T cell receptors. This selectivity also indirectly controls the level of haptenization of the protein, or proteins. It appears that the epitope density on the surface of the APC directly or indirectly directs the immune response towards Th1 or Th2, high epitope densities directing the response toward Th1 and low densities toward Th2 (Hosken et al., 1995). It is reasonable to ask if this selection of response profile, related to epitope density and thus to hapten reactivity, might not explain, for example, the observed differences between respiratory and skin allergens.

In recent years, the radical mechanism has gained increased interest in the discussion of the mechanism of hapten–protein binding. This mechanism, which has never been firmly established, has been postulated to explain, for example, the allergenic potential of eugenol versus iso-eugenol (Barratt, 1992). More recently, studies indicating that radical reactions are important for haptens containing allylic hydroperoxide groups have been published (Giménez-Arnau, 2002, Bézard et al., 2005).

20.4 METABOLISM, PROHAPTENS, AND PREHAPTENS

Far from being an inert tissue, the skin is the site of many metabolic processes, which can result in structural modification of xenobiotics that penetrate into it. These metabolic processes, primarily intended for the elimination of foreign molecules during detoxification, can, in certain cases, convert harmless molecules into derivatives with electrophilic, and, therefore, allergenic properties. The metabolic processes are mainly based on oxidation reactions via extremely powerful enzymatic hydroxylation systems, such as the cytochrome P-450 enzymes (Mansuy, 1985), but monoamine oxidases, which convert amines to aldehydes, and peroxidases seem to play an important role in the metabolism of haptens. When activated by the production of hydrogen peroxide during the oxidative stress following the introduction of a xenobiotic into the skin, peroxidases convert the electron-rich aromatic derivatives (aminated or hydroxylated) into quinones, which are powerful electrophiles. In this way, it has been proposed that the long-chain catechols, responsible for the severe allergies to poison

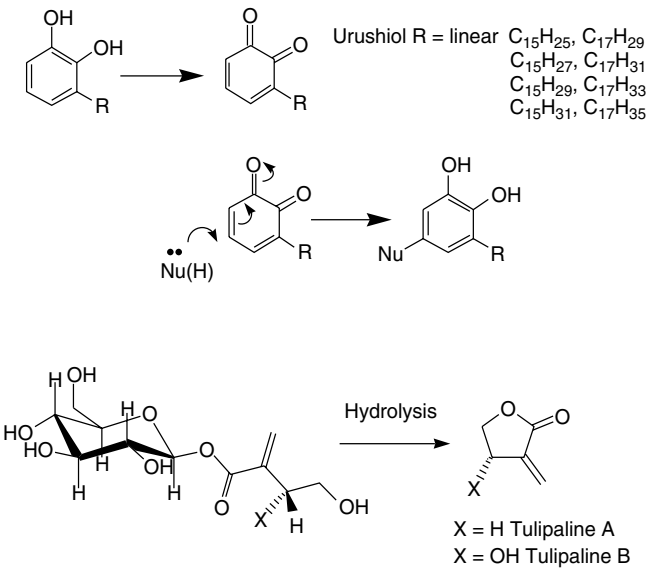

FIGURE 20.6 Examples of prohapten metabolism.

ivy *(Rhus radicans* L.) and poison oak (*Rhus diversiloba* T.), could be oxidized *in vivo* to the highly reactive orthoquinones (Dupuis, 1979) (Figure 20.6). The same applies to paraphenylenediamine or hydroquinone derivatives, such as the allergens from *Phacelia crenulata* Torr. (Reynolds, 1981), which are converted into electrophilic paraquinones. If the formation of such reactive intermediate in the epidermis could explain the sensitizing potential, it is not clearly established if these transformation are linked to specific enzymatic systems or could occur by chemical oxidation with molecular oxygen present in tissues. Metabolic reactions involving enzymatic hydrolyses can also occur in the skin. It is thus that the tuliposides A and B, found in the bulb of the tulip (*Tulipa gesneriana* L.), are hydrolyzed, releasing the actual allergens, tulipalines A and B (Bergmann et al., 1967).

All these molecules, which have themselves no electrophilic properties and cannot, therefore, be haptens but which can be metabolized to haptens, have been referred to as prohaptens (Landsteiner and Jacobs, 1936; Dupuis and Benezra, 1982) and play an important role in contact allergy because of their number and their highly reactive nature. The fact that the structure of the metabolized molecule can be far removed from the structure of the initial molecule can make allergologic investigations even more difficult.

Nonenzymatic processes, such as reaction with atmospheric oxygen, ultraviolet irradiation, or oxygen present in tissues can also induce changes in the chemical structure of molecules. Many terpenes spontaneously autooxidize in air, producing allergizing derivatives. In 1950s it was found that allergenic activity of turpentine was mainly due to hydroperoxides of one of the monoterpene Δ^3-carene (Hellerstrom et al., 1955). This is also the case for abietic acid, the main constituent of colophony, which is converted into the highly reactive substance hydroperoxide (Karlberg, 1988) by contact with air (Figure 20.7). Such an autooxidation mechanism has also been demonstrated for another monoterpene, *d*-limonene,

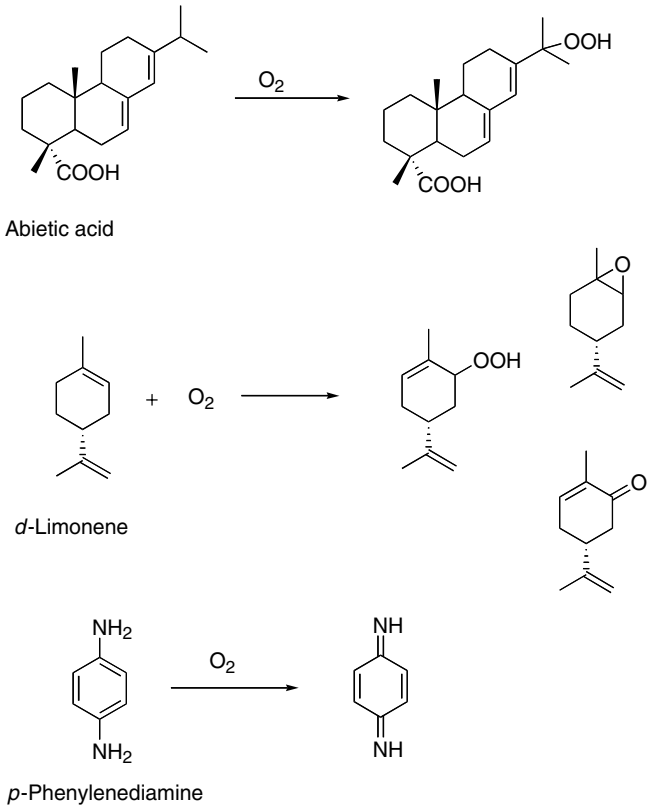

FIGURE 20.7 Examples of prehapten chemical modifications by reaction with air.

found in citrus fruits. *d*-Limonene itself is not allergenic, but at air exposure hydroperoxides, epoxides, and ketones are formed, which are strong allergens (Karlberg et al., 1994).

Since this original classification of sensitizing molecules into "haptens" and "prohaptens," no significant revision has been proposed to take into account more recent developments of the chemical understanding of the sensitization mechanism.

So far these nonreactive molecules have been referred to as prohaptens, even if no specific metabolic enzyme is needed to activate them into haptens. Recent efforts made to develop alternative methods to animal experimentation in the perspective of the European Union ban on *in vivo* testing of cosmetic and toiletry ingredients have shown that this prohapten classification was in fact a break to their development and acceptance.

To make it more clear and stimulate further research on how nonreactive molecules are reacting with proteins to form antigens, a third category named "prehapten" for nonreactive sensitizing molecules transformed into haptens by simple chemical transformation and without requirement of a specific enzymatic system has been proposed (Lepoittevin, 2006). This would also make the development and validation of alternative methods for the identification of sensitizers easier.

20.5 HAPTENS AND CROSS-ALLERGY

The factors that control molecular recognition during the elicitation stage are primarily the nature of the chemical group

and the compatibility of the spatial geometry. Although the first factor (the identity of the chemical group) is very important and serves to define what are commonly called the group allergies, it cannot account for all structure–activity relationships. Receptor molecules are highly sensitive to volume and shape, and molecules must have a similar size and spatial geometry to be recognized by the same receptor. Thus, even though the molecules tulipaline A or B and alantolactone (the allergen of *Inula helenium* L.) bear the same chemical group, α-methylene-γ-butyrolactone, they cannot give rise to cross-allergenic reactions, as their spatial volumes are too different. In contrast, isoalantolactone and alantolactone produce a cross-allergic reaction (Stampf et al., 1982), since they share a homologous chemical group and spatial volume. The term cross-allergy is often misused and should be restricted to the well-defined cases that can be called the true cross-allergies (Baer, 1954; Benezra and Maibach, 1984).

True cross-allergy between a sensitizer A and a triggering agent B can be interpreted in various ways:

- A and B are chemically and structurally similar.
- A is metabolized to a compound that is similar to B.
- B is metabolized to a compound that is similar to A.
- A and B are metabolized to similar compounds.

The identification of cross-allergenic responses can be especially difficult, particularly in humans, in whom the possibility of co or polysensitization should never be ruled out. In addition, the metabolism of molecules can be very complex, and two molecules with a priori little in common can be converted to derivatives that have a similar structure. Thus, derivatives of hydroquinones and *p*-phenylenediamines can be converted into benzoquinone derivatives. It is, therefore, dangerous to draw conclusions from tests without knowing how the substances used are liable to be metabolized. Many reactions described as demonstrating cross-allergy are, without doubt, due to cosensitization (Benezra and Maibach, 1984). Experimental studies in animals are often the only means of being really certain of what happens during recognition. The concept of the prohapten is very important in the interpretation of results in allergy. As the structure of the metabolized molecule can sometimes be very different from that of the initial molecule, it can be difficult to establish similarities of chemical groups and structure.

20.6 APPLICATION TO THE *IN VITRO* PREDICTION OF SKIN SENSITIZERS

In view of the forthcoming European Union ban on *in vivo* testing of cosmetic and toiletry ingredients following the publication of the 7th amendment of the Cosmetic Directive, there is an urgent need to develop *in vitro*/in silico alternative methods. To that respect, our knowledge of the chemistry of skin sensitizers and the way they interact with skin proteins, as the first step of the biological mechanism leading to skin sensitization, could be used as a toxicological end-point. Human serum albumin (HSA) has often been used as a model of choice for protein-binding assay. However, its large molecular weight makes it difficult to use as a screening tool. Therefore, the potential of model peptides to assess the covalent binding of chemicals has been explored. Thus, a GSH binding assay using MALDI-MS to detect the formation of adducts was found to identify 13 of 14 sensitizing chemicals while all nonsensitizers were found unreactive toward GSH (Kato et al., 2003). However, this binding assay based on the detection by mass spectrometry of formed adducts on GSH was not able to detect paraphenylenediamine probably due to the complex chemistry of this molecule. More recently, an approach based on the measure of the depletion of three peptides when reacted with chemicals was proposed (Gerberick, 2004). The proposed peptides were GSH and AcRFAAXAA where X = K or C to cover the cystein and lysine reactivity. Thirty-eight chemicals embracing a wide chemical diversity and classified as extreme, strong, moderate, weak, and nonsensitizers according to the LLNA were tested. The results demonstrate that a significant correlation (Spearman correlation) exists between allergen potency and the depletion of GSH ($p = 0.001$), lysine-peptide ($p = 0.025$), and cystein-peptide (0.020). Thus, by performing a peptide reactivity assay one can reduce the number of compounds that would require testing on an animal model.

20.7 CONCLUSION

The principles that we have just discussed permit a rational approach to the phenomena of contact allergy, but, in actual fact, we often have only indirect evidence suggestive of one mechanism or another available. Although the chemical bases for hapten–protein interactions can be checked in the laboratory by the use of nucleophilic amino acids, small peptides, and model proteins, and although a certain number of steps can be checked, at the present time, no method is available to follow a hapten step by step during the entire immunological process leading to contact allergy. Many points await investigation, but in many cases a "chemical" analysis of the problem does allow us to understand and to foresee cross-allergies and thus to warn the patient about structurally related products.

21.1 INTRODUCTION

Drug-induced skin photosensitivity is a well-documented phenomenon. Exogenous chemicals and drugs may cause photosensitivity by two main mechanisms: phototoxicity and photoallergy. Both processes occur as a result of an offending exogenous agent combined with light exposure. Multiple chemicals, such as psoralens, fluorescein dye, some thiazide diuretics, and some fluoroquinolones are able to produce both types of cutaneous reactions. It may be difficult to distinguish between these entities, however, they are pathophysiologically distinct processes.

Phototoxicity is much more frequently encountered. It is typically an acute (within minutes to hours), chemically induced nonimmunologic skin irritation requiring light (photoirritation), which is prominent in areas of sun exposure, and clinically resembles an exaggerated sunburn. Edema, pruritis, erythema, increased skin temperature, vesiculation, and desquamation may be present. These signs may followed by long-lasting hyperpigmentation. In the classic form, a large amount of chemical or drug exposure is necessary to induce a phototoxic reaction. Histamine, kinins, and arachidonic acid derivatives such as prostaglandins are released during the inflammatory processes. Histologic changes resemble those that would be seen in sunburned skin with epidermal dyskeratosis and vacuolation, as well as dermal edema and vascular changes. Mononuclear infiltrate may be evident.

Photoallergic reactions are much more rare. In contrast to phototoxic reactions, photoallergies usually appear between 24 and 72 hours after exposure to a small amount of the exogenous chemical. Cutaneous manifestations resemble acute, subacute, or chronic dermatitis with significant pruritis, and affected areas may spread beyond areas of sun exposure. Photoallergy requires previous sensitization to the agent and is believed to be immune mediated. Reactions may result from cross-reaction between related chemicals. After drug cessation, re-exposure to sunlight may cause a reoccurence of the reaction. This phenomenon does not occur with phototoxic agents. Histologic changes include epidermal spongiosis, perivascular lymphoidosis, and mononuclear exocytosis, which may resemble allergic contact dermatitis.

Clinical identification of photosensitivity reactions requires knowledge about skin effects of photosensitizing chemicals and clinical insight gained from practical experience. However, classic morphologic aspects of photosensitivity are not always apparent; prompt and accurate identification of phototoxic and photoallergic dermatoses induced by oral agents may be a challenge to the clinician.

21.2 PHOTOSENSITIZING AGENTS

Naturally occurring plant-derived furocoumarins, including psoralen, 5-methoxypsoralen (bergapten), 8-methoxypsoralen (xanthotoxin), angelicin, and others, constitute an important class of phototoxic chemicals. Bergapten, psoralen, and xanthotoxin are among the more commonly encountered phototoxic agents.

Psoralens are naturally occurring and are synthesized by plants of the Rutaceae (common rue, gas plant, Persian limes, bergamot) and Umbelliferae (fennel, dill, wild carrot, cow parsnip) (Juntilla, 1976). They also occur in a wide variety of other plants, such as parsley, celery, and citrus fruits (Pathak, 1974; Juntilla, 1976). Phototoxicity reactions have been reported to psoralen-containing sweet oranges (Volden et al., 1983) and to common rue (*Ruta graviolens*) (Heskel et al., 1983).

Bergapten is the active component of bergamot oil and is a well-known perfume ingredient whose toxic skin effects have been accorded the name berlock dermatitis. Based on results of

their studies of perfume phototoxicity, Marzulli and Maibach (1970) suggested that perfume should contain no more than 0.3% bergamot, which is equivalent to about 0.001% bergapten, to avoid phototoxicity. Their work also established that bergapten was the only one of five components isolated from oil of bergamot that was responsible for phototoxic effects of the parent material. Limettin (5,7-dimethoxycoumarin), although more intensely fluorescent than bergapten, did not prove phototoxic to human skin. Bergapten phototoxicity continues to occur in some countries where bergapten-free bergamot is not used (Zaynoun et al., 1981), in Norway, from contact with *Heracleum lacinatum* (Kavli et al., 1983), and in Denmark from skin contact with *Heracleum mantegazzianum*, the giant hogweed (Knudsen, 1983).

Xanthotoxin (8-MOP) is effective in treating vitiligo and psoriasis by oral administration or topical application followed by exposure to UVA psoralen plus UVA light (PUVA phototherapy). The *Ammi majus* plant, containing xanthotoxin (8-MOP) in crude form, has been used therapeutically in Egypt since ancient times (El Mofty, 1948). However, at present, PUVA therapy is considered to have carcinogenic potential and warrants caution. Chronic use of this therapeutic regimen enhances prospects of inducing squamous-cell skin cancer, especially in young patients and in those who are genetically predisposed (Stern et al., 1979). This potential has resulted in a reduced use of PUVA phototherapy in the United States (Parrish et al., 1974).

There are a number of agents outside of the furocoumarin family that are phototoxic. Coal-tar derivatives produce occupational contact photodermatitis and phototoxicity in industrial workers and road workers. Anthraquinone-based disperse blue 35 dye caused such effects in dye process workers. Radiation in the visible spectrum activates the dye (Gardiner et al., 1974). Pyrene, anthracene, and fluoranthrene are strongly phototoxic to guinea pigs (Kochevar et al., 1982).

Phenothiazines, such as chlorpromazine, cause phototoxic effects, which have also been ween with oral therapeutic use of amiodarone, a cardiac antiarrhythmic drug (Chalmers et al., 1982). Incidence, time course, and recovery from phototoxic effects of amiodarone in humans were studied by Rappersberger et al. (1989). Antimalarials quinine and quinidine appear to be phototoxic, and some of these have been studied *in vitro* and *in vivo* (Moore and Hemmens, 1982; Epling and Sibley, 1987; Ljunggren and Wirestrand, 1988). Cadmium sulfide, used in tattoos for its yellow color, may be phototoxic (Bjornberg, 1963). Thiazide diuretics were shown to have a phototoxic potential in one study (Diffey and Langtry, 1989), but thiazide-induced phototoxicity is actually rare in clinical practise. There have been recent reports of phototoxicity induced by perforatum hypericum, contained in herbal antidepressant St. John's wort (Schultz et al., 2001). This agent may function through mechanisms including inhibition of proteasome function (Pajonk et al., 2005).

Tetracyclines, particularly demethylchlortetracycline, and also doxycycline, chlortetracycline, and tetracycline, are phototoxic when orally ingested (Verbov, 1973; Frost et al., 1972; Maibach et al., 1967). Doxycycline was reported more potent than demethylchlortetractracycline or limecycline in one human study (Bjellerup and Ljunggren, 1985).

Some fibric acid derivatives, such as fenofibrate, have been reported to exhibit photosensitizing effects *in vivo*. Bezafibrate and gemfibrozil are mildly phototoxic, and clofibrate has shown not to be phototoxic at all (Diemer et al, 1996). Diltiazem has also shown to cause photoxicity in some case reports (Rao et al., 2006).

Fluoroquinolone antibiotics have recently proven to be phototoxic (Ferguson et al., 1993). There have been a number of controlled trials supporting this phenomenon. Fluoroquinolones differ significantly in their extent of phototoxicity. Recently, in a randomized, placebo-controlled study comparing phototoxicity, Dawe et al. (2003) found sitafloxacin to be mildly phototoxic; enoxacin and sparfloxacin proved to be much more photoactive in white subjects. Levofloxacin and placebo failed to show a phototoxic effect. In contrast, among Asian subjects, sitafloxacin failed to demonstrate significant phototoxicity. A randomized-controlled trial supported the fact that lemofloxacin, but not moxifloxacin had phototoxic effects (Man et al., 1999).

It is generally accepted that clinafloxacin $\gg$ lomefloxacin, sparfloxacin $\gg$ trovafloxacin, nalidixic acid, ofloxacin, ciprofloxacin $>$ enoxacin, norfloxacin (Snyder and Cooper, 1999). Perfloxacin and sparfloxacin also appear to result in higher amounts of phototoxicity than ciprofloxacin (Ioulios et al., 2003). It is generally believed that levofloxacin and moxifloxacin are among the least phototoxic drugs in this class.

Antimicrobials, such as sulfonamides, and some fluoroquinolones (enoxacin and lomefloxacin) cause a cutaneous photoallergic reaction, as can sunscreen ingredients, most notably para-aminobenzoic acid (PABA) and its derivatives, and fragrances such as musk ambrette. As previously mentioned, thazides, fluorescein dye, and psoralens are phototoxic, as well as photoallergic.

Multiple case reports suggest that pyridoxine hydrochloride (vitamin B6), may have some photoallergenic activity and have been photopatch tested as positive for this agent (Kawada et al., 2000; Morimoto et al., 1996).

Several psychiatric medications including tricyclics, carbamazepine, and benzodiazepines have shown to be cutaneous photoallergens.

Other miscellanous drugs implicated as photoallergens include amantidine, dapsone, nifedipine, and isotretinoin. However, for a number of these agents, formal data proving their photoallergenic potential are lacking.

21.3 NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAID) were the subject of extensive investigations for phototoxic potential following reports that benoxaprofen, a suspended British antirheumatic NSAID, has this capacity (Webster et al., 1983; Allen, 1983; Stern, 1983; Anderson et al., 1987). *In vitro* studies with sheep erythrocytes or human leukocytes suggested a phototoxic potential (Anderson et al., 1987; Pryzbilla et al., 1987).

NSAID that are structurally related to propionic acid have been shown to possess phototoxic potential, whereas certain other types of NSAID, such as tenoxicam and piroxicam were not experimentally phototoxic by *in vivo* or *in vitro* test methods (Anderson et al., 1987; Kaidbey and Mitchell, 1989; Western et al., 1987). The propionic acid-derived NSAID produce unique immediate wheal and are, in contrast, with a much delayed exaggerated sunburn response that typifies psoralen phototoxicity.

Although piroxicam is not phototoxic under experimental conditions involving human test conditions (Kaidbey and Mitchell, 1989), it has been implicated as a possible clinical photoallergic or phototoxic photosensitizer. One explanation for the unexpected photoactivity of piroxicam in skin is that a metabolite of piroxicam is indeed phototoxic when isolated and tested on human mononuclear cells *in vitro* (Western et al., 1987). These positive findings and likely explanation are related to the production of singlet oxygen, as indicated by emission at 1270 nm when the suspect metabolite was irradiated with ultraviolet (UV) *in vitro* (Western et al., 1987; Kochevar, 1989).

Other propionic acid–derived NSAID associated with an immediate phototoxic response are nabumetone, naproxen, and tiaprofenic acid (Kaidbey and Mitchell, 1989; Diffey et al., 1983).

Carprofen (Merot et al., 1983), ketoprofen (Alomar, 1985), benzydamine hydrochloride, topical tiaprofenic acid, suprofen, and possibly piroxicam appear to be photoallergenic. However, further work may be needed to separate, clarify, and identify three possible outcomes—allergy, photoallergy, and phototoxicity—in studies involving NSAID.

The general area of cutaneous reactions to NSAID has been extensively reviewed by Ophaswongse and Maibach (1993).

21.4 MECHANISMS OF PHOTOTOXICITY

Phototoxic and photoallergic chemicals typically exhibit biologic response with the UV area of the electromagnetic spectrum, which is subdivided arbitrarily into UVA (320–400 nm), UVB (290–320 nm), and UVC (200–290 nm). UVA represents the less energetic portion of the spectrum and UVC the more energetic (cytotoxic) area. UVA in the range 320–340 nm (UVA2) is more energetic and more skin damaging than UVA in the range 340–400 nm (UVA 1). *In vivo*, both phototoxicity and photosensitivity are primarily due to UVA range light. However, *in vitro*, phototoxic agents absorb and are activated by both UVA and UVB wavelengths. The cause of this discrepancy is unknown. Some phototoxic chemicals, such as porphyrins and fluorescein dye, absorb visible light (400–800 nm).

Exogenous phototoxic reactions are initiated when a photoactive chemical (one capable of absorbing UV radiation) or one of its metabolites enter viable skin cells. The photoactive chemical may enter into the skin by topical administration or it may reach the skin indirectly by the circulatory system following ingestion or parenteral administration. Some systemically administered and possibly topical chemicals may require metabolic conversion to become photoactive. When the photoactive chemical is in the skin, appropriate wavelengths of light penetrate the skin and subsequently photons are absorbed by, and thereby excite electrons in the phototoxic chemical. This process may lead to formation of unstable singlet or triplet states. As these molecules transfer energy to achieve a more stable state, the transferred energy induces cellular damage and generates inflammatory mediators.

The questions of site and mechanism of action of phototoxic chemicals and the importance of oxygen have been much studied. Some phototoxic agents are oxygen dependant, or photodynamic, whereas others are not. Photodynamic chemicals may transfer their energy to oxygen, exciting it to the singlet or doublet state, thereby exerting phototoxic effects. In its excited state, the photodynamic chemical may react with oxygen and form free radicals. Though mechanisms causing reactions of photoactive drugs are mainly free radical in nature, reactive oxygen species are also involved. Photochemical activity of drugs, such as hydrochlorthiazide, furosemide, chlorpromazine, and some NSAIDS is caused by free radical formation. In other systems, the reactive excited singlet form of oxygen is directly toxic toward lipids and proteins (Moore, 2000).

Studies by Gendimenico and Kochevar (1990) have shown that acridine requires oxygen to produce a lethal (phototoxic) effect on mast cells. (Dermal mast cells are known to participate in cutaneous phototoxic responses initiated by UV and visible radiation.) Chlorpromazine is also thought to be activated by a photodynamic process involving molecular oxygen.

Reactive oxygen intermediates may be a main cause of photosensitivity reactions, which can be stopped by agents that block the production of these intermediate products. Antioxidant supplementation may be beneficial in suppressing phototoxic reactions. Vasoactive amines such antihistamine and serotonin may also play a role in cutaneous phototoxic reactions. Eucosanoids, such as prostaglandins and leukotreines, have also been implicated in the process.

Mathews (1963) showed that toluidine blue requires oxygen to produce its lethal (phototoxic) effect on *Sarcina lutea*; however, oxygen is not needed for the phototoxic effect of 8-MOP on *S. lutea*. In addition, it was found that 8-MOP phototoxicity results in damage to cellular DNA, whereas toluidine kills by action on the cell membrane. Psoralens also do not require molecular oxygen to produce phototoxic effects.

Some photoactive chemicals act on cellular DNA (psoralens, may be tricyclics), whereas others act on cellular membranes (tricyclics). Fluoroquinolones may induce DNA breaks and lead to cell death. Keratinocytes may be the most sensitive cells and melanocytes most resistant (Marrot et al., 2003). The differences in phototoxicity potential may be based on differences in substituent placement on the various chemicals (Hayashi, 2005).

Photoallergic reactions are believed to be cell mediated, with radiation-dependant antigen production, therefore stimulating the immune response. UV energy may cause the drug hapten to find a native protein on epidermal cells, therby forming a complete photoantigen. When the antigen is

formed, the photoallergic process is similar to allergic contact dermatitis, with sensitization of the immune system, and a subsequent cutaneous eruption.

A more complete discussion of mechanisms of photosensitized reactions is given in Spikes (1983).

21.5 ELEMENTS OF THE TEST FOR PHOTOTOXICITY

Tests for phototoxic potential of topically applied chemicals are usually conducted with radiation within the UVA range. Some phototoxic chemicals are activated by wavelengths in the visible spectrum (bikini dermatitis) (Hjorth and Moller, 1976), some by UVB (Jeanmougin et al., 1983), and some (doxycycline) are augmented by UVB (Bjellerup, 1986).

Accurate measurements of radiation intensity and frequency are important prerequisites for work in phototoxicity.

Phototesting procedures include photopatch testing and determination of minimal erythema dose (MED) for UVA and UVB. Photopatch testing may be more useful in detecting photoallergy, and MED may be more useful for testing phototoxic agents. In practice, however, it is recommended to perform both types of testing to ensure comprehensive evaluation.

Among animal models for which photopatch testing has proven useful in predicting human phototoxicity are the mouse, rabbit, swine, guinea pig, squirrel monkey, and hamster, in that approximate order of effectiveness (Marzulli and Mailbach, 1970).

The test material is applied to the skin of a human subject or an animal model (clipped skin of mouse, guinea pig, rabbit, or swine). After a suitable waiting period for skin absorption to take place (several minutes, depending on the rate of skin penetration), the chemical test site is irradiated with UV of appropriate wavelengths. The test site is then examined at 1, 24, 48, and 72 h for evidence of phototoxicity, such as erythema, vesiculation, bullae, and finally hyperpigmentation. A comparison is made between the skin of the test site and control sites (one without chemical and one without light).

Results are modified by factors that affect skin penetration, such as test concentration and vehicle, as well as by duration of exposure and by distance from the irradiation source to the test area.

Some photoirritants (e.g., bergapten) produce clinical phototoxicity when the photoirritant site is irradiated within minutes to 1 h after skin application; with others, irradiation is effective when administered at 24 h.

Phototoxic effects are expected when UV is directed at and absorbed by a phototoxic chemical residing in the skin. This results in a skin reaction with cellular components such as DNA.

One of the earliest indicators of phototoxic potential was based on a paralyzing effect on the cilia of *Paramecium* from acridine plus light, reported by Oscar Raab at the close of the nineteenth century. This test method was later followed by a simpler test involving a lytic effect on red blood cells, as an endpoint for phototoxicity.

The subject of *in vitro* assay for phototoxic effects has recently been reviewed (Rougier et al., 1994).

Recently, reconstructed human epidermis models, such as EpiSkin, ShinEthinc, and EpiDerm, have demonstrated ability to serve as *in vitro* models for phototoxicity testing. Certain models have proven effective in discriminating between phototoxic and nonphototoxic compounds, as compared to *in vivo* data. Several protocols for use are currently available. In the future, data obtained from these models will likely contribute a wealth of information, thereby increasing our knowledge and understanding of photosensitivity.

21.6 HIGHLIGHTS

Investigative studies in photosensitivity require a rudimentary understanding of what constitutes appropriate radiation sources for experimental work, as a first step. Knowledge about safety in the use of radiation equipment is equally important.

Well-calibrated equipment for measuring radiation is another prerequisite, including a recognition that with time and use, equipment changes and requires proper upkeep to ensure its quality in performance.

Filters are sometimes needed to provide an appropriate cutoff of unwanted radiation. Window glass is useful in eliminating wavelengths below 320 nm.

Natural sunlight is filtered by atmospheric oxygen, ozone, clouds, particulates, and other environmental factors including altitude, so that wavelengths below 290 nm are effectively shielded from reaching the earth's surface. Consequently, radiation sources that deliver highly energetic shorter wavelengths in the UVC range are unlikely to be useful in experimental photosensitivity studies involving humans.

The radiation ranges that are of greatest biologic focus in photosensitivity studies are UVA (320–400 nm), UVB (280–320 nm), and UVC (<280 nm). As the Commision de l'Eclairage recommends 315 nm as the cutoff for UVB rather than 320 nm, it is important that the investigative photobiologist identify the system of use. However, a rationale for using 320 nm rather than 315 nm as the cutoff for UVA is given in Peak and van der Leun (1992).

The first rule of photochemistry is that cells are injured or killed when photons of radiant energy are absorbed and energy is transferred to target molecules (Spikes, 1983). Phototoxic effects are therefore produced when absorption wavelengths of the sensitizer are the same as those of the radiant energy source (Grotthus–Draper law).

DNA, RNA, deoxy- or ribodeoxynucleotides, enzymes containing such cofactors, and aromatic and cysteine residues of proteins are typical targets of UV phototoxic damage.

Oxygen may or may not participate in the production of a phototoxic event; however, when oxygen is indeed involved, it is often referred to as a photodynamic action.

Psoralens are among the most frequently encountered phototoxic chemicals, as they are present in many plants. Petroleum products, coal tar, cadmium sulfide, acridines,

TABLE 21.1
Clemicals, Plants, and Drugs with Phototoxic Potential

Topical dyes—anthraquinone, fluorescein dye, disperse blue 35, cosin, methylene blue, rose Bengal, toluidine blue, cadmium sulfide in tattoos
Fragrances—oil of bergamot
Furocoumarins—angelicin, bergapten, psoralen, 8-methoxypsoralen. 4,5, 8-trimethylpsoralen
Plant products—celery, figs, limes, hogweed, parsnips, fennel, dill
Coal-tar components—acridine, anthracene, benzopyrene, creosote, phenanthrene, pitch, pyridine
Systemic antibiotics—griseofulvin, ketoconazole, nalidixic acid, sulfonamides, ceftazidime, tetracyclines, fluoroquinolones
Chemotherapeutics—dacarbazine, 5-fluorouracil, vinblastine, methotrexate
Drugs—amiodarone, chlorpromazine, quinine, quinidine, tolbutamide, diltiazem, fibric acid derivatives, hyerpicum perforatum (St. John's wort)
Diuretics—hydrochlorothizide, bendroflumethiazide, furosemide
Nonsteroidal anti-inflammatories—benoxaprofen, naproxen, piroxicam, tiaprofenic acid, nabumetone
Porphyrins—hematoporphyrin

porphyrins, and other chemicals may also be implicated as causative agents for phototoxic effects. Table 21.1 provides a list of phototoxic chemicals.

Finally, it is suggested that investigators be complete in identifying equipment and methodology that they employ to reduce some of the confusion that may enter and has already entered the literature on this subject.

21.7 CONCLUSIONS

Years of investigative efforts, along with improved methods of measuring and administering radiation, have brought considerable progress in our understanding of various aspects of photosensitivity. We appear to have identified and continue to identify major chemical structures that are currently involved in producing phototoxic and photoallergic effects in humans. We have also gained some insight into some of the mechanisms that are involved. Nevertheless, it is always important to be flexible and aware that time may change some of our present and apparently well-conceived perceptions, as it often does.

22.1 INTRODUCTION

Exposure to metals and their derivatives in industrial processing, to their emissions from power plants and from waste deposits constitute a human health risk, both in an occupational setting and in normal everyday activities among the general population. According to EPA's Toxic Release Inventory for the year 2000, metal mining accounted for 47% of their releases into air, water, and land (7.10 billion lb), and of the bioaccumulative releases, mercury and mercury compounds accounted for 36% of the total 12.1 million lb. Besides respiratory and gastrointestinal exposure, traditionally a prime concern in toxicology, also skin contact more recently has gained recognition as an important port of entry for xenobiotics into the living organism. Cases of morbidity and mortality due to exposure of the skin to toxic agents has contributed to such a shift in attention (Plueckhahn et al., 1978; Toribara et al., 1997).

The skin is permeable to a wide range of chemicals; it can function as a barrier, a filter, or as a potential reservoir for their accumulation and source for their slow release. Over the past years, skin diffusivity of organic chemical structures has proven amenable to mathematical modeling, and their bioavailability has become predictable with increasing accuracy using mathematical models to describe quantitative structure–permeability relationships (Flynn, 1990; Potts and Guy, 1995). Metal compounds, however, defy such modeling and predictability; this is especially true for strongly electropositive metals as they avidly react with electronegative constituents they encounter along the path of diffusion through the skin. A number of confounding factors come into play expressing their idiosyncrasy, which impact both rate and route of skin penetration, the importance of which is not estimable with our present knowledge. What complicates the picture further is the interdependence among these multiple factors. Those which have an obvious bearing on the process of metal diffusion and which have to be taken into account if one were to anticipate degree of their penetration through biological membranes for purposes of dermal exposure assessment are briefly discussed in Section 22.3. Those perceived as critical for skin diffusion are discussed under two headings: those proper to the metals themselves, the exogenous factors, and those inherent in the barrier tissue as part of the target organism itself, the endogenous factors. These factors are illustrated with observations for the metals nickel and copper in particular. In the following, the term metal applies equally to the elemental state, as well as the ionized form.

22.2 DESCRIPTORS OF SKIN PERMEABILITY

22.2.1 The Permeation Coefficient Kp and Fick's First Law of Membrane Diffusion

The most commonly used descriptor to characterize the diffusion of chemical compounds is the permeation coefficient Kp. It is determined experimentally by measuring the rate of diffusion through excised skin in a one-chamber diffusion cell (Franz, 1975) or the flow-through two-chamber cell (Bronaugh et al., 1986); the latter allowing automatic sampling of the receptor phase. The *in vitro* technique is used for determining quantitative percutaneous absorption data of potentially toxic metal compounds through human skin in particular. The solute passes from the fixed higher concentration medium in the donor chamber by passive diffusion into the less concentrated solution in the receptor chamber. The advantage of such diffusion experiments lies in the standardized expression of the quantitative results when Fick's first law of diffusion is applicable (Fick, 1855). Formulated to characterize passive diffusion of compounds across membranes, in general, Fick's law has been shown to also apply to passive diffusion of xenobiotics through the SC of the skin, and with restrictions also applicable to the skin's permeability for metal compounds. That law states that, if the permeation process from an "infinite" reservoir reaches the point of steady state equilibrium, that is, the concentrations in the donor and receptor phases remain constant over time, the measured steady-state flux Jss describes the amount of permeant per unit time and area, usually expressed as $mg/h/cm^2$. The permeability coefficient or permeation constant Kp, typically in cm/h, is then calculated from the Jss value divided by ΔC, the concentration gradient between donor and acceptor phase. In a diffusion experiment conducted under dynamic conditions, that is, where the permeant reaching the receptor fluid is constantly removed, C in the receptor compartment is zero, and the resulting calculation then becomes $Kp = Jss/C$.

The technique is easily standardized and allows the determination of Kp through skin or other membranes as long as the barrier properties are not affected by either permeant or carrier solvent. This implies that the permeant, in this case the metallic ion, may not react with barrier material, thereby changing barrier permeability. Because heavy metals are electrophilic and avidly bind to electron-rich moieties present in epidermal tissue, such as oxygen, nitrogen, or sulfur, this prejudices the general validity of Kp values (discussed later). Nevertheless, flux values for metal compounds *in vitro*, if obtained under conditions of steady state from an infinite reservoir and normalized for concentration, are the most reliable descriptor available for the skin penetration of such metals also, and the calculated Kp serves as a convenient parameter for putting their diffusion in context with that of other more conforming permeants.

22.2.2 Percentage of Dose Absorbed

The optimal *in vivo* method for the determination of skin absorption is the one developed by Feldmann and Maibach (1969). It yields large part of the data so far available on skin penetration by drugs and pesticides, using human volunteers or monkeys.

In human studies, following topical application of the permeant, the plasma levels of test compounds are low and the use of radiolabelled compounds becomes necessary.

The compound labeled with carbon-14 or tritium, or a metal isotope, is applied to the skin in a minimal volume of a volatile solvent that is left to evaporate, and the total amount of radioactivity excreted is then determined. The amount retained in the body is corrected for by determining the amount of radioactivity excreted following parenteral administration of the compound. The resulting radioactivity value is then expressed as the percent of the applied dose absorbed. Fick's postulates for membrane diffusion are not met there. A concentration of the permeant cannot be defined and neither is a steady state equilibrium observable with this method; the permeability coefficient thus cannot be calculated. Nevertheless, for purposes of risk assessment the indication of potential (whole-body) absorption is an important factor as it gives a measure for human (worst case) exposure.

22.2.3 Predicting Absorption through Stratum Corneum Analysis

The predictive method through which the systemic uptake of a permeant can be derived from the amount that diffuses into the stratum corneum (SC) after a limited time of exposure *in vivo*, developed by Rougier (Rougier and Lotte, 1987a), is only applicable for compounds with Fickian behavior. It cannot be used for electrophilic metals, which react with barrier tissue that, by altering its barrier properties, renders in-depth diffusion unpredictable. In addition, certain metals such as copper or zinc are essential trace metals subject to homeostatic controls, which appear to determine deposition or mobilization in function of fluctuating body burdens.

SC stripping and analysis is used for other purposes, however, and can be applied in the investigation of metal diffusion into the SC and beyond (Hostynek et al., 2001a,b). Tracing the concentration profiles of permeants in SC has been rendered facile by using that semiinvasive method and by state-of-the-art analysis with inductively coupled plasma atomic emission spectroscopy (ICP-AES) and inductively coupled plasma mass spectroscopy (ICP-MS). With this method it is now possible to analyze for the presence of elements in trace amounts in skin tissues and other biological materials to a level of 0.5 ppb (0.5 µg/kg), making the use of radioisotopes unnecessary. The method makes it possible to estimate actual metal concentration profiles to the level of living epidermal tissue.

22.3 PRINCIPAL FACTORS DETERMINING SKIN PERMEATION BY METAL COMPOUNDS

22.3.1 Exogenous Factors

22.3.1.1 Dose

Review on the diffusivity of transition metals shows that their diffusion is not necessarily dose-related; this appears to be one of the several effects attributable to the electrophilic properties, which causes them to form stable bonds with proteins of the skin. In some cases, absorption at first increases with increasing dose, then reaches a plateau value and decreases again with a further increase in concentration, as was recorded for the diffusion of sodium chromate through guinea pig skin *in vivo* (Wahlberg, 1965). For others, such as potassium chromate and human epidermis *in vitro*, absorption steadily decreased with increasing dose (Fitzgerald and Brooks, 1979).

22.3.1.2 Vehicle

A factor for consideration when choosing a vehicle for percutaneous penetration studies is the effect the solvent will have on the skin membrane and thus its barrier properties. The choices may be restricted for the sake of adequate solubility of the permeant. Petrolatum, for instance, is a poor solvent for metal salts, where the permeant remains suspended in fine particles affording less than ideal uniformity in skin contact; however, petrolatum has an occlusive effect, which increases skin hydration and thus promotes diffusion of hydrophilic compounds. Another solvent that enhances penetration is dimethylsulfoxide. It appears to modify intercellular solute diffusion to include the transcellular path (Sharata and Burnette, 1988).

22.3.1.3 Counter Ion

Intuitively, size of permeant is critical for its rate of diffusion through biological membranes, aside from other factors that may play a part in the process. A measure of the effect of the counter ion is the degree of irritancy (and thereby diffusivity) certain metals salts have on contact with the skin, investigated with nickel and chromium with the purpose of optimizing skin patch-test materials for immunological diagnostic testing (Shabalina and Spiridonova, 1988; Wahlberg, 1990, 1996; Lansdown, 1991).

Depth–concentration profiles of a number of different nickel salts in the SC demonstrated the difference in their diffusivity in function of the counter ion. The profile was made visible by the standard protocol of sequential tape stripping of the SC following application of the chloride, sulfate, nitrate, and acetate on the skin of human volunteers (Hostynek et al., 2001b). Following single open application at 1% nickel concentration, the skin was tape stripped 20 times and the strips analyzed for metal content by ICP-MS. The concentration gradient between the superficial and deeper layers of the SC varied distinctly from one salt to the other: acetate $>$ nitrate $>$ sulfate $>$ chloride. The concentration-versus-depth profiles obtained using this method confirmed that the counter ion in nickel salts plays a role in its passive diffusion through the SC, suggestive of ion pairing. The steep initial concentration gradient observed for all four nickel salts also demonstrated the differential formation of a reservoir in the outermost layers of the SC.

22.3.1.4 Molecular Volume

Size of a permeant plays a decisive role in its rate of diffusion through a biological membrane, regardless of other factors

that may be part of the process. Diffusion of a cation is necessarily tied to the diffusion of its counter ion, that is, diffusion of a metal will also proceed as an ion pair, otherwise an electrical potential builds up, which will inhibit further diffusion. In a number of experiments with four nickel salts, the nitrate as the more lipophilic one was the only salt that penetrated the SC at a slow but steady level, leading to the hypothesis that more lipophilic compounds choose the intercellular lipid bilayer as diffusion pathway. For confirmation, diffusion of nickel chloride was compared with that of the di-octanoate as a limit case of lipophilicity. Results, however, showed that rather than polarity, molecular volume is the decisive factor for membrane diffusion. A statistically significant difference appeared between the permeation of the chloride compared to the octanoate ($P = 0.044$). The slower diffusion of the octanoate is likely due to the molecular volume increment of the two octanoate groups, an effect which in this case overrides the effect of polarity (Hostynek, 2003).

22.3.1.5 Nature of Chemical Bond and Polarity

To the degree to which metals form compounds ranging from inorganic (ionic) to organic ligands, bonds increasingly assume covalent character, and their penetration characteristics become similar to those of common organic nonelectrolytes. The lipophilic category, mainly alkyl and aryl derivatives of the more toxic metals, thus represents a major risk in chemicals manufacture due to their ease of skin penetration. The polarity of nickel salts, as measured by their solubility in the nonpolar solvent *n*-octanol at 22°C, increases in highly significant intervals ($p < 0.0005$) in the sequence: nitrate < chloride < acetate < sulfate, ranging over four orders of magnitude (Hostynek et al., 2001b). The effect of counter ion and polarity on the diffusivity of those nickel salts became evident from the slope of the depth–concentration profile obtained through SC stripping and from the area-under-the-curve (AUC) values for the four salts, a measure for the amount retained in the SC: for the nitrate, the AUC was significantly higher (AUC = 26.1 ± 1.2; $p < 0.0005$) than were the totals for the other salts applied at comparable Ni (II) concentrations (AUC = 3.3 ± 0.6 to 18.5 ± 4.1). A reasonable explanation would be the choice of an alternate diffusion pathway and deposition by the more lipophilic nitrate, that is, via the intercellular lipid domains. The salt with the most covalency may thus achieve greatest diffusivity through the SC barrier over time.

22.3.1.6 Valence

The outer electron shell of elements expresses their valence, determines their size and electropositivity. As a consequence, these two associated factors effectively determine diffusivity: degree of steric hindrance retarding penetration, and bond formation with electronegative molecular functions in proteins, which result in deposits.

In transition metals such as copper, the five d electron orbitals, each able of accepting a pair of electrons, are being filled with electrons while an outer s electron shell of slightly lower energy is most often complete with two electrons.

Copper has a single s electron outside the filled 3d shell. Removal of this electron gives rise to the Cu(I) oxidation state with d^{10} electron configuration, while removal of another electron yields the more common Cu(II) oxidation state with the $3d^9$ electron configuration. Although these oxidation states can interchange easily as the equilibrium 2Cu(I) g Cu(0) + Cu(II) can be readily displaced in either direction; further oxidation to Cu(III) is difficult.

22.3.1.7 Depot Formation

Nickel and copper ions present examples of highly electrophilic ions, which readily complex with SC proteins, leading to depot formation. *In vitro* diffusion experiments with several copper complexes showed that a substantial portion of the permeant is retained in the SC, epidermis and dermatomed skin, membranes tested for that purpose (Hostynek, unpublished data). Such retention in the SC is a fair indication of the exogenous agent (copper), which under homeostatic control will eventually become systemically available. For that reason also, measuring diffusion rates only presents part of the overall picture, as the chemical absorbed into the SC will continue to diffuse into the viable tissue, even after exposure has stopped. In that sense, the SC is more than an accumulation of dead keratin, as it fulfills the multiple functions of barrier, reservoir, and filter, depending on the physicochemical nature of the permeant. The amount of material accumulated which, in most cases, can become available for absorption, is appropriately referred to as the SC reservoir (Schaefer and Redelmeier, 1996).

22.3.2 Endogenous Factors

22.3.2.1 Age of Skin

The permeability of the skin for xenobiotics appears to change with advancing age, according to most observations in a decreasing mode. This is attributed to a diminishing blood supply and also to decreasing lipid content of aging skin (Roskos et al., 1989). Investigation of skin permeability to a nickel salt versus a nickel soap using dermatomed skin under identical experimental conditions, including anatomical site, confirmed the decreasing trend in skin diffusivity with age, specifically between skin from a young (age 16) and an older source (age 64). The rate of nickel diffusion for both types of compounds was over two orders of magnitude slower in the older skin: $Kp = 9.8 \pm 4.9 \times 10^{-3}$ versus $6.2 \pm 4.3 \times 10^{-5}$ for $NiCl_2$, and $1.4 \pm 0.57 \times 10^{-3}$ versus $0.9 \times 10^{-5} \pm 0.07$ for the nickel dioctanoate. Remarkably, the ratio between the "young" and "old" values remained constant at a value of 7 for both compounds (Hostynek, 2003).

22.3.2.2 Anatomical Site

Since penetration of electrolytes appears to occur mainly through the skin's appendages, diffusion in hairy areas may be at an advantage, although absorption was also observed through the palm of the hands devoid of hair follicles; route of diffusion there were probably the sweat ducts (Feldmann, 1967).

The effect of anatomical site on the *in vivo* absorption into the SC was studied using tape stripping. Following single open application of nickel chloride on the arm and back over 24 h application sites were stripped 20 times and the strips analyzed for metal content by ICP-MS. At the identical concentration of 314 μg/cm^2, the two sites showed steep, although differing depth–concentration gradients, declining toward deeper SC layers with significantly different areas under the curve : 30.8 for skin on the back versus 62.4 on the arm ($p < 0.0005$), an indication of heightened diffusivity (Hostynek et al., 2001b).

Anatomical differences in penetration of xenobiotics have been observed by several authors. A ranking could be established for different sites, in decreasing order: scrotum-forehead-postauricular-abdomen-forearm-leg-back (Wester and Maibach, 1980; Rougier et al., 1986; Wahlberg, 1996). Such differences were attributed to regional SC thickness and shunt density, but also to intercellular lipid abundance and composition, which play a pivotal role in diffusion (Loth et al., 2000; Elias, 1983; Lampe et al., 1983; Rougier et al., 1987; Guy and Maibach, 1984). Site dependence becomes apparent in effects that depend on diffusivity, such as inflammatory reactions (Wahlberg, 1996), or elicitation of contact allergy, the latter particularly leading to false-negative reactions when hypersensitive subjects are patch tested on the less penetrable skin on the back rather than on the antecubital fossa on the arm (Basketter and Allenby, 1990; van Strien and Korstanje, 1994; Seidenari et al., 1996a,b; Simonetti et al., 1998).

22.3.2.3 Homeostatic Controls

Essential elements such as copper present in the SC, epidermis, and dermis are kept in equilibrium by homeostatic control mechanisms, which play a part of overall physiological dynamics of micronutrients and also appear to regulate the body burden of xenobiotics. These mechanisms ascertain maintenance of equilibria necessary for optimal functioning of the organism, for example, by preventing undue loss due to perspiration through reabsorption as occurs with sodium in particular (Cage and Dobson, 1965). They can also act as surveillance capable of sequestering toxic levels of certain metals, for example, complexing copper with metal-binding proteins such as metallothioneins and coeruloplasmin. Particularly *in vivo* dermal absorption experiments thus should account for such natural processes, which may counteract passive diffusion, attaching a degree of uncertainty on the permeability constants measured.

22.3.2.4 Skin Tissue Section

Comparison of Kps determined through different skin strata *in vitro* by different authors shows that penetration by nickel chloride is slowest through the SC (Samitz and Katz, 1976; Bennett, 1984; Fullerton et al., 1988a; Emilson et al., 1993); from the Kp of 10^{-7} cm/h in the SC (Tanojo et al., 2001), it progressively increases toward full thickness skin, with a maximum seen in dermatomed skin, Kp = 10^{-4} cm/h (Hostynek, 2003), a rate which is three orders of magnitude higher than that in the SC.

22.3.2.5 Role of Skin Shunts

A number of direct or indirect observations speak to the role of shunts in electrolyte diffusion through skin. Penetration through sweat ducts can occur within 1–5 min following exposure, with no comparable transport occurring via the transcellular path in that time span (Abramson and Gorin, 1940; MacKee et al., 1945; Shelley and Melton, 1949). Poral transit by nickel salts in particular can become manifest in clinically follicular inflammation or punctate erythema on patch testing (Menné and Calvin, 1993; Kanerva and Estlander, 1995).

An argument that also speaks for a relatively rapid penetration of nickel via shunts is the finding by Fullerton that when all strata of full-thickness skin had been analyzed by stripping following an *in vitro* diffusion experiment, only 64% of the dose were accounted for (Fullerton, 1988b). The unaccounted-for portion may be explained by shunt diffusion, which eludes strip analysis. At higher doses of nickel nitrate applied on the ventral forearm *in vivo*, strip analysis of the SC also accounted for only 75% of the dose (Hostynek et al., 2001b).

22.3.2.6 Metabolism in the Skin

Metabolic activity, including redox reactions by metals in the organism's tissues, such as the skin, can change the valence *in situ* and significantly alter the diffusivity of ions. Both Cr(III) and Cr(VI) penetrate the skin, with hexavalent chromium (as CrO_4^{2-}) usually the better penetrant; Cr(VI), present as chromate $(CrO_4)^{2-}$ and dichromate $(Cr_2O7)^{2-}$, the most injurious to human health and a carcinogen, applied to the skin is converted into the more electrophilic Cr(III) during transit (Gammelgaard et al., 1992). While chromate and dichromate ions (CrVI) do not complex with organic substances, Cr(III) is inhibited in its diffusivity due to formation of stable complexes with epithelial and dermal tissues (Samitz et al., 1969). The skin diffusion constant Kp, through human skin *in vitro*, for Cr(VI) falls into the 10^{-3} cm/h range, while that for Cr(III) is of the order of 10^{-5} cm/h (Fitzgerald and Brooks, 1979).

22.4 METHODOLOGY

22.4.1 Analytical Techniques

22.4.1.1 Inductively Coupled Plasma–Atomic Emission Spectroscopy

ICP-AES permits detection of metals at the trace amount level, which obviates the use of radioisotopes (Di Pietro, 1988). For the detection of nickel or copper, the current quantitation limit falls in the 5–10 ppb (μg/L) range, a factor of 5 above the true instrumental detection limit as defined by the United States Environmental Protection Agency (US EPA). In practice, ICP-AES is used for analysis of elemental levels at and above the 1 ppm levels, concentrations where an ICP-MS instrument would be swamped, leading to experimental problems.

Quantitative detection of metals with this method is accomplished by ionization of elements in an atmosphere of inductively coupled argon plasma, maintained by the interaction of a radio frequency field and ionized argon gas. In a sample aerosol (e.g., a vaporized metal salt solution), atoms and ions are activated at 6000°C to an unstable energy state, and as they revert to their ground state again, they emit light of characteristic wavelength and intensity, which can be measured.

22.4.1.2 Inductively Coupled Plasma–Mass Spectrometry

Complementary to ICP-AES, ICP-MS is a technique applicable to μg/L (ppb) concentrations of many elements in aqueous medium upon appropriate sample preparation of biological materials. Reliability of the method for elemental analysis is based upon multilaboratory performance tests when compared to results obtained with either furnace atomic absorption spectroscopy or ICP-AES.

ICP-MS measures characteristic emission spectra of ions produced by a radio frequency inductively coupled plasma using optical spectrometry. Compound to be analyzed, present in liquid form, is nebulized and the resulting aerosol transported by argon gas into the plasma torch, also at 6000ºC. The ions produced are entrained in the plasma gas and introduced, by means of a water-cooled interface, into a quadrupole mass spectrometer. The ions produced in the plasma are sorted according to their mass-to-charge ratios and quantified with a channel electron multiplier.

Determining the permeation constants of nickel and copper compounds in solution is possible by this method at the sub-ppb level, obtained upon exposure of human skin *in vitro* in the collected receptor fluid (Tanojo et al., 2001), or from *in vivo* experiments upon digestion of the SC tape strips (Hostynek et al., 2001b).

In *in vivo* experiments, sequential adhesive tape stripping has been used to characterize the penetration of nickel and copper in the SC of human volunteers, applied as the salts or as the metal itself. Exposure areas are stripped to the level of the glistening layer at given intervals postdosing, and the strips analyzed for metal content by ICP-AES or ICP-MS. The metal concentration/depth profiles obtained give clear indication of diffusion depending on time of exposure, and on counter ion of the salt when appropriate, anatomical site, and on the concentration applied (Hostynek et al., 2001a,b).

22.4.2 Diffusion Experimental

22.4.2.1 *In Vitro* Diffusion of Salts

Glass low-volume flow cells exposing a skin application area of 0.8 cm^2 are used (Reifenrath et al., 1984). Cells are mounted in the wells of aluminum cell holders (Stratacor, Richmond, California), whose internal channels are perfused with water at 37°C from a circulating water bath. The cell holders are mounted on a fraction collector (Retriever IV, Isco, Lincoln, Nebraska). The collector's movement is controlled by an external programmable timer (Stratacor), so that receptor fluid exiting the flow cells is fractioned into 12.4 h collection intervals. Distilled water containing 1 mL/L of gentamycin sulfate solution (l00 mg/mL, Sigma, St. Louis, Missouri) is pumped through the cells at approximately 2 mL/h with a 12-channel peristaltic pump (Van Kel Industries, Edision, New Jersey).

Frozen split-thickness human skin is thawed, cut into circles with a #15 cork borer, mounted on the diffusion cells and the donor chambers clamped in place. Eight cells were typically set up at one time, with four cells used for each of the two treatments.

Test solutions (l.0 mL) are placed in the donor chambers, which are then closed with ground glass stoppers and sealed with Parafilm to prevent evaporation of donor solution.

Receptor fluid samples are collected in 20 mL polyethylene screw-cap scintillation (LSC) vials (Maxi-vial, Packard Instruments, Downers Grove, Illinois). Samples are stored at 4°C until analysis. At completion of an experiment, the donor cell contents are pipetted into LSC vials. The donor chamber and skin surface are rinsed (3 × 2 mL) with distilled water and the rinses saved LSC vials. Skin samples are removed from the cells and placed in 20 mL glass LSC vials. Nitric acid (0.75 g) is added to each skin sample and the vials heated (50–60ºC) to effect dissolution. After cooling, samples are diluted with 15 mL distilled water to give a final nitric acid concentration of 3.5% required for ICP analysis. Samples are filtered prior to analysis (Tanojo, 2001).

22.4.2.2 *In Vivo* Diffusion of Salts

Nonatopic in good health and no history of allergies or significant skin disease are selected for the study. As a rule, replicate experiments for statistical purpose are conducted on the same volunteer to minimize experimental variability. Also for each of the parameters investigated, the stripping experiment is conducted on the same volunteer. Salts are dissolved in methanol, targeting a metal content of 0.001–1%. The actual metal concentration in the test solutions is determined by ICP-AES analysis, prior to application, to allow accurate interpretation of results. Methanol is chosen as a model vehicle with the intent to minimize disruption of SC membrane integrity, to optimize volatility and thus expedite open application, and for adequate solubility of nickel salts.

Prior to application of test solution, the targeted area of the skin is cleansed by threefold wiping using cotton swabs moistened with deionized water, then dried with a stream of compressed air for 30 s. 100 mL of the solutions were applied on a 2.83 cm^2 area of the skin using a shallow glass cylinder (1.9 cm inner diameter) for containment, to the base of which a film of silicone grease has been applied to prevent leakage. Following application of the test solution, a gentle air stream (compressed air) was directed at the application site through a plastic tube to enhance solvent evaporation, usually complete within 60 s. During the experiment, care is taken not to touch the area of application; or exposure times of 3 h and longer the application sites were covered with a rigid, perforated plastic shield open at both ends to ensure free air circulation but at the same time preventing mechanical abrasion. The shield is

held in place by taping it to the skin, the tape strips being applied transversally across the shield in such a way as to not cover the air vents. At the end of the dosing period, in several experiments, the application sites are wiped clean with cotton swabs to remove residual test material remaining on the surface prior to tape stripping. Repeated wiping with a water-moistened cotton swab is followed by a dry swab, and finally an air stream is passed over the skin surface for 30 s. The combined swabs are placed in a glass vial for separate extraction and nickel analysis.

Adhesive tape of 2.54 cm width is cut in 5 cm strips, and the SC is stripped according to the following protocol. The area of application on the volar forearm between cubital fossa and wrist or on the intrascapular area on the back is marked using a felt-tipped marker pen, then stripped sequentially 20 times. This is accomplished by covering the 2.83 cm^2 treated with the precut tape, thus removing SC from a 6.45 cm^2 area, abundantly exceeding the area originally exposed in dosing. Constant and uniform pressure (100 g/cm^2) is applied on the tape for 5 s by resting an appropriate weight on the area, and the tape is then gradually removed from the skin in one draw. Each tape strip is stored individually in a 20 mL glass vial.

5 mL of concentrated nitric acid is added to the vials containing tape strips and decontamination swabs. After 3 h of vigorous agitation in a rotary shaker, the acid solution is diluted to 10 mL with deionized water prior to analysis by ICP-AES (Hostynek et al., 2001b).

22.4.2.3 *In Vivo* Diffusion of Metals Applied in the Elemental State

Micronized metal powder used (e.g., nickel or copper, 99.7% 3 μm particle size) is commercially available grade. The occlusive and semiocclusive application systems consist of a plastic chamber and Micropore semiocclusive (breathable) tape, respectively.

Polypropylene tape with a backing of pressure-sensitive acrylate adhesive tape is used for sequential SC removal by stripping. A 5% aqueous solution of Ethylene diamine tetraacidic acid (EDTA) (metal complexing agent) is used for skin decontamination prior to stripping. Scintillation vials containing tape strips in concentrated nitric acid are agitated over 4 h for extraction.

Prior to application of the metal powder, skin sites are cleansed with deionized water and dried using cotton swabs. The powder is applied on the volar forearm of volunteers between wrist and antecubital fossa. 25 mg of powder is placed on a 12 mm plastic chamber (1.15 cm^2), the chamber is then placed on the premarked area of the flexor surface of the arm, covered with transparent dressing, and is left undisturbed for the predetermined length of time. Treated areas are covered with a rigid, perforated plastic shield open at both ends to ensure free air circulation but at the same time preventing mechanical abrasion. The shield is held in place by taping it to the skin. At the end of the exposure period, the occlusive materials are removed, the site washed with a metal-complexing detergent containing EDTA using cotton swabs to remove all traces of metal left on the skin surface, then rinsed with De-ionized (DI) water. The skin is dried by tapping with cotton balls and finally by passing an air stream over the surface. The area of application is stripped sequentially 20 times after covering the 1.15 cm^2 treated area with a 1 $in.^2$ (6.45 cm^2) of the pre-cut adhesive tape strips, thus abundantly exceeding the perimeter of treated skin. Constant and uniform pressure (100 g/cm^2) is applied on the tape for 5 s, which was then gradually removed in one draw. The tapes with adhering SC are placed individually in scintillation vials, 5 mL of concentrated nitric acid (70%) is added and the vials agitated vigorously for 3 h on the rotary shaker. The acid solution is then diluted 20-fold with deionized water for ICP analysis (Hostynek et al., 2001a).

22.5 DIFFUSION DATA

22.5.1 Nickel

In industrialized parts of the world, nickel allergy is the leading cause of delayed as well as immediate type allergy following iatrogenic, respiratory, and gastrointestinal, as well as dermal exposure, with a constantly increasing prevalence (Hostynek et al., 2001a and references therein). The effects due to contact with the skin in particular are an indication of the formation of a skin-diffusible form of the metal apt to penetrate beyond the SC. This phenomenon was difficult to reconcile with earlier observations made when nickel diffusivity was investigated for its behavior in contact with the skin.

In *in vitro* tests with human skin, permeability coefficients for water-soluble inorganic nickel salts were measured in the range of 10^{-6}–10^{-4} cm/h, with lag times of up to 90 h preceding the appearance of the permeant in the acceptor phase (Table 22.1). This is difficult to reconcile with the phenomenon that even contact of intact skin with nickel-releasing metallic objects may elicit dermatitis in those allergic to the metal (Hostynek et al., 2001a and references therein). Evidence for a process that would explain the facile elicitation of contact allergy to nickel in particular was obtained through exposure of the skin of volunteers to the metal under occlusion. Using the technique of ICP-MS for skin strip analysis, it could be shown that at contact times as brief as 5 min with the metal under occlusion, nickel could be detected in the superficial strata of the SC, and that on longer exposure it had reached the live tissue of the epidermis (Hostynek et al., 2001a). Immunogenic nickel ion is likely to be formed *in situ* in reactions with skin exudates, to form small, hydrophilic complexes or salts, such as the chloride, pyruvate, or lactate of facile diffusion through the aqueous environment of sweat ducts. Lipophilic salts or soaps, in contrast, are likely to penetrate via the intercellular lipid bilayer (Hostynek, 2003).

22.5.1.1 Diffusion of Nickel Applied as Metal *In Vivo*

When exposure sites on the arm of volunteers were stripped 20 times for up to 96 h postdosing and the strips analyzed for metal content, the gradients of nickel distribution profiles increased proportionally with occlusion time. Although nickel values decreased from the superficial to the deeper levels of

the SC, from the 10th strip to the 20th strip continued at constant levels.

Total nickel removed with 20 SC strips to the level of the glistening layer after maximum occlusion of 96 h was 41.6 mg/cm^2 (Hostynek et al., 2001a). The observations serve to confirm the function of the intercellular lipid matrix of the SC as alternate pathway for the diffusion of lipophilic nickel salts generated with skin exudates *in situ*. The role of skin as a toxicologically important route of exposure to xenobiotics in general and metal compounds in particular is thereby underscored, as altogether three routes of entry present themselves to potentially toxic agents.

22.5.1.2 Diffusion of Nickel Salts *In Vivo*

The characteristics of nickel penetration through the human skin *in vivo* were investigated by sequential stripping of the SC with adhesive tape following application of a number of soluble nickel salts. $NiC1_2{\cdot}6H_2O$, $NiSO_4{\cdot}6H_2O$, $Ni(NO_3)_2{\cdot}6H_2O$, and $(CH_3CO_2)_2Ni{\cdot}4H_2O$ were dissolved in methanol, the solvent chosen to minimize disruption of SC membrane integrity, optimize volatility, and thus expedite open application, as well as to attain adequate solubility of nickel salts. The depth–penetration profiles obtained by stripping of the previously occluded application sites on the arm and back of volunteers, at intervals of 30 min to 24 h postdosing, showed that up to 24 h most of the nickel remained on the surface or was absorbed in the uppermost levels of the SC; the concentration gradients varied with counter ion and anatomical site, dose, and exposure time. While the depth profiles converged toward nondetectable levels by the 20th strip for three of the salts, the levels for nitrate continued at low but constant levels toward the viable strata of the epidermis. Determined experimentally to be the least polar of the salts, the diffusion of the nitrate appears to be facilitated through the intercellular lipid domain of the SC (Hostynek et al., 2001b).

22.5.1.3 Diffusion of Nickel Salts *In Vitro*

Diffusion constants of nickel salts were measured through human SC. Aqueous solutions of $Ni(NO_3)_2$, $NiSO_4$, $NiCl_2$, and $Ni(\text{-}OOCCH_3)_2$ at 1% Ni^{2+} concentration were used as the donor solution, at 400 mL/cell. The receptor fluid, pure water, was collected up to 96 h after the application of the donor solutions. The nickel concentrations in the donor and receptor fluid, as well as in the SC were analyzed using ICP-MS (Tanojo et al., 2001).

Based on the total recovery of nickel from the experiments, about 98% of the dose remained in the donor solution, whereas 1% or less was retained in SC, and less than 1% was found in the receptor fluid. From the flux data, the steady-state permeability coefficients for nickel were calculated at 8.5 cm/h $\times 10^{-7}$ for the sulfate, 6.8 cm/h $\times 10^{-7}$ for the chloride, and 5.2 cm/h $\times 10^{-7}$ for both the nitrate and acetate.

22.5.1.4 Diffusion of a Nickel Salt versus a Nickel Soap *In Vitro*

In vitro results seemed to indicate increased diffusion of a relatively lipophilic nickel salt compared to more polar ones

(Hostynek et al., 2001b). The flux of nickel chloride, as prototype of a hydrophilic salt, was compared to that of nickel dioctanoate, a lipophilic, poorly water-soluble nickel soap, at comparable nickel concentrations in water using dermatomed skin. Based on the median steady-state nickel flux over 16 h, the permeability coefficients were

$$\mathrm{Kp} = 9.8 \times 10^{-3}\ \mathrm{cm/h} \pm 4.8 \times 10^{-3}$$

for nickel chloride, and

$$\mathrm{Kp} = 1.4 \times 10^{-3}\ \mathrm{cm/h} \pm 5.7 \times 10^{-4}$$

for nickel dioctanoate.

With a statistically significant difference, the unexpected slower diffusion of the dioctanoate as compared to the chloride can be ascribed to the molecular volume increment of the two octanoate groups, an effect that overrides the effect of polarity (Hostynek, 2003).

22.5.2 Copper

Since antiquity copper in several of its forms: pulverized or as sheet metal, as basic copper acetate (verdigris), or as copper sulfate (vitriol), has been used in the therapy of arthritic conditions. Modern science has recognized copper to be essential for most living organisms; playing a role in biochemical pathways and electron transport reactions in most living organisms.

Recognition that copper is an essential, homeostatically controlled trace element, whose concentration increases in serum and plasma of animals and humans as consequence of inflammation, as well as of its accumulation in inflamed joint exudates, led to the investigation of its therapeutic potential also as supplementary, exogenous agent in the treatment of numerous pathologies, and for the control of chronic inflammatory diseases. This resulted from investigations in animals showing that, while inflammation induces an increase in the amount of endogenous copper, exogenous sources can potentiate its anti-inflammatory (AI) effect in both acute and chronic models of inflammation (Milanino et al., 1993).

Ongoing investigations into the diffusivity of various copper compounds, peptides in particular, through human skin by quantitative *in vitro* experiments identified diffusion values (Kps), which may be adequate for application of those cupriphores as skin patches for AI therapy (Table 22.2).

22.5.2.1 Diffusion of Copper Applied as Metal *In Vivo*

The process of copper diffusion following application of the finely distributed (micronized) metal on the skin was demonstrated by applying the metal under occlusion and semiocclusion followed by SC stripping. Copper concentration profiles were recorded to the level of the living epidermal tissue. It thus became possible to document in depth penetration and presumed subsequent uptake by dermal microcirculation. Untreated skin of the volunteers was stripped in the same fashion for analysis, to determine baseline levels of this essential trace element prior to exposure.

[e] Kps from separate sets of cells in the same diffusion experiment.

Under occlusion thus excluding access of air, up to 72 h copper values decreased from the superficial to the deeper layers of the SC with gradients increasing commensurately with occlusion time, characteristic of passive diffusion processes. From the 10th strip on, however, levels reverted to background values.

Under semiocclusion, allowing access of oxygen by covering the applications with "breathable" tape, initial copper values lay significantly above baseline values and concentration gradients increased proportionally with occlusion time. At 72 h exposure, from the 10th to the 20th strip reaching the glistening epidermal layer, copper values continued at constant levels, significantly above baseline values. At 72 h, an average of about 0.6 mg/cm^2 of copper was measured in each of the layers going from 15 to 20 (Hostynek, unpublished data).

The results indicate that, in contact with skin, copper will oxidize and may penetrate the SC after forming an ion pair with skin exudates. The rate of reaction seems to depend on contact time and availability of oxygen. Also a marked interindividual difference was observed in baseline values, and subsequently in the amounts of copper absorbed.

It is also worth noting that, in contrast to organic compounds (e.g., drugs) for which accelerated absorption under occlusive conditions is predictable due to increased SC hydration, increased blood flow and temperature (Zhai and Maibach, 2001), this does not necessarily apply to all metals, for which exclusion of oxygen can have the opposite effect. In the case of nickel, described earlier, corrosivity permits oxidation of the metal even under limited access of oxygen, this in contrast to copper, which has a higher ionization potential or resistance to oxidation.

22.5.2.2 Diffusion of Copper Compounds *In Vitro*

Work linking copper and inflammation has been done by Sorenson, who demonstrated that copper(II) acetate alone has an AI activity in experimental models of inflammation, with the suggestion that the active metabolites for AI activity are copper chelates (Sorenson, 1982a,b; Sorenson and Berthon, 1995). Sorenson and Hangarter (1977) then reported on the AI effectiveness of injectable low molecular weight copper complexes in the treatment of rheumatoid arthritis (RA) and other acute and chronic degenerative diseases in some 1500 patients over 30 years. It appears important to maintain a needed minimum level of copper in tissues for the control of inflammation (Milanino et al., 1978, 1985).

These observations were pivotal in motivating the search for skin-diffusible forms of copper toward administration of exogenous copper, as topical cupriphores represent a potential alternative to AI therapy.

The current investigations into the diffusivity of certain copper compounds, peptides in particular, through human skin by quantitative *in vitro* experiments identified diffusion values (Kps), which may be adequate for application of those cupriphores as skin patches for AI therapy (Table 22.2).

22.6 DISCUSSION AND CONCLUSIONS

The process of barrier diffusion by metal ions is multifactorial, and the rate of their diffusion imponderable, both *in vitro* and *in vivo* due to a number of potentially promoting and retarding processes simultaneously involved.

Although there is a considerable volume of literature addressing skin absorption of metal compounds, the data vary considerably from experiment to experiment. Results are difficult to reconcile due to the diversity of conditions used: diffusion cell design, vehicle, metal speciation, skin tissue compartment, anatomical site, human versus animal tissue, data acquired *in vivo* versus *in vitro* etc., some of which have been briefly discussed earlier. Results in the research of skin diffusion by metal compounds are too fragmented to make possible the derivation of a unifying algorithm with which to assess dermal absorption of metal compounds *a priori*, or to bring results from different researchers in relation to each other. In determining skin diffusivity of metals *in vitro* for toxicological risk assessment, for instance, it would appear important not to limit the focus solely on permeant reaching the receptor phase. Analysis should also include permeant retained in the strata of the skin for topical bioavailability purposes. In the case of some metals, the more electrophilic ions in particular, that value may be the preponderant quantity, potentially a significant factor for consideration in exposure risk analysis. As an example serves the apparent paradox of nickel diffusion—measured *in vitro*—it appears extremely slow, and yet *in vivo*, it elicits allergic skin reactions on mere contact; nickel retained in the epidermis appears to be a determinant for immune response. Also, metals of slow diffusivity such as transition metals encounter a countercurrent effect in the strata of the skin. As the barrier is characterized by continuous desquamation with a total turnover over 2–3 weeks (corresponding to an approximate "inverse" Kp of 10^{-6}), bioavailability of the metal may be less than what is indicated by absorption in skin tissue, since epidermal turnover can significantly reduce further diffusion into the systemic circulation of highly electrophilic compounds. Sweat can also be such a contributing countercurrent factor to the loss of water-soluble metal salts diffusing into sweat ducts. Some metals form a reservoir that can be mobilized on homeostatic demand, such as copper, zinc, or calcium; others again penetrate into the strata by passive diffusion and, albeit slowly, reach the systemic compartment. At times the same metal can follow several patterns. Data, which deduct Kps from values reaching the receptor compartment only may underestimate the true level of absorption. Seen from the perspective of the presently available database, derivation of a unifying algorithm predictive of dermal absorption of metal compounds does not appear feasible.

23.1 INTRODUCTION

Exposure to environmental, occupational, and iatrogenic chemicals may sometimes be followed by scleroderma-like clinical findings whose cause and effect relationship is not easily established. This chapter reviews some chemicals that appear to suggest an association between chemical exposure and subsequent symptomatology suggestive of scleroderma.

23.2 ENVIRONMENTAL AGENTS

23.2.1 Toxic Oil Syndrome

In 1981, an epidermal multisystem disorder with chronic scleroderma-like cutaneous changes was linked with the ingestion of rapeseed oil that was sold as olive oil in Spain. Called the toxic oil syndrome, more than 300 deaths resulted (Phelps and Fleishmajer, 1988). The patients first presented with an acute phase of fever, pneumonitis, adenopathy, nausea, arthralgias, and pruritic exanthems (Martinez-Tello et al., 1982). Eosinophilia was always present. The initial symptoms soon resolved, and an intermediate phase of intense myalgias, edema, and paresthesias of the extremities occurred. Months later, many patients, especially women, had progressive neuromuscular atrophy and paralysis, pulmonary hypertension, sicca syndrome, Raynaud's phenomenon, and alopecia. The pruritic exanthems became sclerotic, leading to a diffuse scleroderma-like picture (Martinez-Tello et al., 1982). The pruritic exanthem resembled those caused by viruses and involved the abdomen, trunk, and limbs. Sometimes there was also an associated erythema multiforme or palpable purpura. Another skin eruption occurred in 10% of patients that consisted of yellowish or brownish papules, which spared the palms and soles (Iglesias and De Morgas, 1983).

The histopathologic features have been well characterized and are caused by a multiorgan systemic vasculopathy. The chronic dermal lesions showed thickening of the collagen bundles, hyalinization, perivascular inflammation, endothelial swelling, and slight luminal obliteration (Martinez-Tello et al., 1982; Fonsecaea and Soils, 1985). Toxic substances in the oil (e.g., anilides) may stimulate the proliferation of mast cells that thereby interact with fibroblasts and mediate sclerosis (Prestana and Munoz, 1982).

Others have suggested that the progressive vasculopathy primarily stimulates fibrosis, including the sclerotic changes observed clinically (Martinez-Tello et al., 1982). Soon after the initial cases of toxic oil syndrome were reported, more than 3 million liters of oil were seized; however, the causative agent may be persistent in stored oils because it appears to be stable (Phelps and Fleishmajer, 1988). The contaminant found in the toxic oil has been identified as 3-phenylamino-1, 2 propanediol (D'Cruz, 2000).

23.2.2 Hexachlorobenzene

During the outbreaks of porphyria turcica due to accidentally ingested hexachlorobenzene-treated seed grain, patients were also noted to have sclerodermoid changes (Peters et al., 1982; Schmid, 1960; Cripps et al., 1980). It is believed that these sclerodermoid changes may have been due to the production of hyalin stimulated by the deposition of porphyrins in the skin (Cripps et al., 1980). The pathogenesis of the sclerodermoid changes in porphyria turcica may be related to the dermal perivascular hyalinization as a residual alteration of the abnormal accumulation of porphyrins (Torinuki et al., 1989). Hexachlorobenzene is no longer produced for use as a fungicide. It is now present only as an unwelcomed byproduct in the manufacturing of pesticides and hydrocarbons (Burns et al., 1974; Peters et al., 1982). Hexachlorobenzene has a strong tendency to persist in soil and to accumulate in aquatic environments (Isensee et al., 1976).

23.2.3 Urea Formaldehyde Foam Insulation

Urea formaldehyde foam insulation may lead to a scleroderma-like syndrome that has been reported in one case. The patient, shortly after cleaning out the ceiling of his garage, developed Raynaud's phenomenon, arthritis, pulmonary fibrosis, and sclerodermatous skin changes. Dermal fibrosis was noted histologically. It is thought that urea formaldehyde foam insulation may elicit an immunologic response, which, in conjunction with genetic susceptibility, may lead to this syndrome (Rush and Chaiton, 1986). However, as only one case has been reported, chance association remains a very likely explanation for its appearance.

23.3 OCCUPATIONAL AGENTS

23.3.1 Vinyl Chloride Disease

Some workers in the plastics industry, especially those exposed for long periods to the unreacted vinyl chloride monomer while cleaning polymerization reactors, have had a scleroderma-like illness (Meyerson and Meier, 1972). This is characterized by fatigue, Raynaud's phenomenon, shortened fingers with sclerodactyly, distinctive distal phalangeal bone resorption sparing the tufts (acro-osteolysis), facial telangiectasias, and pulmonary and hepatic fibrosis. Angiosarcoma can develop in areas of severe hepatic involvement with the added association of ethanol ingestion. The findings in the skin include plaque-like fibrotic lesions that show thickened dermal collagen histologically with perivascular lymphocytic infiltrates. Endothelial cell swelling has also been seen in the microvasculature (Meyerson and Meier, 1972; Maricq et al., 1976; Steen 1999).

Because less than 10% of those exposed are susceptible, immunogenetic factors appear to be additionally important in providing for the capillary pathologic condition that may mediate vinyl chloride disease (Ward et al., 1976). Cellular immune reactivity was decreased, while circulating immune complexes and human leukocyte antigen (HLA) B8, and DR3 frequency were increased in workers who experienced vinyl chloride disease (Meyerson and Meier, 1972; Veltman, 1980; Black et al., 1983).

A genetic susceptibility to developing scleroderma when exposed to vinyl chloride may be a possible reason for the great difference in the reported incidences of the disease in vinyl chloride workers from various countries. For example, Czirjak has pointed out that British vinyl chloride workers have a much higher frequency of developing scleroderma compared to Hungarian workers (Czirjak et al., 1995).

The vascular occlusion, in particular, may stimulate new collagen synthesis through ischemia, thus producing fibrosis (Black et al., 1983). However, if the level of exposure to vinyl chloride monomer is reduced in the workplace, additional cases of vinyl chloride disease are less likely to occur (Maricq et al., 1976).

23.3.2 Trichloroethylene and Perchloroethylene

Chemically similar to vinyl chloride, trichloroethylene and perchloroethylene exposure may also lead to scleroderma-like conditions. Trichloroethylene is used as a degreasing agent, which is used in clothes dry-cleaning. Upon exposure to trichloroethylene, a severe irritant contact dermatitis may occur. Characteristic features of the scleroderma-like condition produced by trichloroethylene include myalgia, weakness, hepatitis, Raynaud's phenomenon, and sclerodermoid skin tightening (Sparrow, 1977). Other symptoms that have been reported associated with prolonged trichloroethylene exposure include malabsorption syndrome, pigmentation, gynecomastia, impotency, lymphadenopathy, peripheral neuropathy, and sleepiness (Saihan et al., 1978).

Although one series of workers who developed scleroderma usually involved prolonged exposure to trichloroethylene in the range of 2–14 years, one woman reportedly developed acute swelling of her hands and scleroderma after only 2.5 h of intense exposure to the chemical (Bottomlay et al., 1993). A study by Nietert and associates demonstrated

a statistically significant association between organic solvents including trichloroethylene with men who had scleroderma and positivity for antitopoisomerase antibody. This association may have implications concerning the pathogenesis of scleroderma in some patients (Nitert et al., 1998). Trichloroethylene has also been implicated as a cause of localized morphea of the forearm and ankles in a female worker who was exposed to it by inhalation (Czirják et al., 1994).

Skin biopsy in trichloroethylene exposure reveals extensive dermal fibrosis extending into subcutaneous tissue consistent with scleroderma. Although sclerodermoid changes are not pathologically demonstrated in perchloroethylene exposure, endothelial swelling and a perivascular infiltrate have been noted (Sparrow, 1977).

The pathogenesis of trichloroethylene and perchloroethylene disease may involve the altering of proteins by these chemicals, providing for an immune response to be manifested in genetically susceptible individuals (Sparrow, 1977; Lockey et al., 1987; Khan et al., 1995).

23.3.3 Aromatic Hydrocarbon Solvents

Aromatic hydrocarbon solvents such as benzene and toluene, which are used for cleaning clothes, painting, and removing oil and grease in industry, have been associated with scleroderma-like features (Walder, 1983). These chemicals predominantly enter the body through vapor inhalation and later produce systemic manifestations. Scleroderma skin changes are limited only to areas of direct contact (Haustein and Ziegler, 1982). Aliphatic hydrocarbons may also produce scleroderma changes through either vapor exposure or direct contact (Yamakage and Ishikawa, 1982). Histologic features are consistent with scleroderma.

23.3.4 Organic Solvents

A study of 21 women with systemic scleroderma revealed that eight of them were exposed to organic solvents on an occupational level (Czirják et al., 1987). Other abnormalities reported in these eight patients included hypofunction of the thyroid gland, delayed-type hypersensitivity to D-penicillamine, antimicrotubullis antibody, and lupus anticoagulant. This study also reported that there was a slight decrease in OKT4 positive cells in the peripheral blood of the eight affected patients.

A case reference study of 21 cases of scleroderma in the province of Trento, Italy, concluded that there was a statistically significant association between organic solvent exposure and the development of scleroderma. The range of exposure time to the solvents was 9–38 years (Bovenzi et al., 1995).

The toxicity of aliphatic hydrocarbons was further demonstrated by the induction of skin changes through intraperitoneal injection in mice (Haustein and Ziegler, 1982). Solvents are constituents of paints, varnishes, lacquers, polishes, inks, adhesives, pharmaceutical products, and preservatives. If protective clothing is worn and ventilation is improved, thereby decreasing contact, disease production should be limited (Haustein and Ziegler, 1982).

Another report suggests that prolonged exposure to toluenes, toluidines, xylenes, xylidines, aniline compounds, and ethanolamine and its derivatives produced a syndrome of cold receptivity, restrictive lung defect, peripheral neuropathy, esophageal dysfunction, hypertension, monoclonal paraproteinemia, and diffuse thickening of the skin and subcutaneous tissue, which spared the hands and feet (Bottomlay et al., 1993).

23.3.5 Epoxy Resins

In the early 1980s, 6 of the 233 Japanese workers exposed to the vapor of epoxy resins used in television set transformer production were reported to have experienced fatigue, myalgia, arthralgia, erythema, and skin sclerosis (Yamakage et al., 1980). The cause was ascertained to be the amine known as *bis*(4-amino-3-methyl-cyclohexyl)methane. Histologically, dense collagen bundles were noted in the lower dermis with superimposed glycosaminoglycan deposits and a perivascular lymphocytic infiltrate. Investigators found the full histologic picture to be more consistent with that of generalized morphea than systemic scleroderma (Yamakage et al., 1980).

Heparan sulfate extracted from the glucosaminoglycans in the skin of these patients induced sclerotic changes in mice, indicating that, perhaps through faulty metabolism, the biogenic amine in eposy resins indirectly elicits the clinical syndrome observed (Ishikawa et al., 1980). Further outbreaks of epoxy resin induced scleroderma have not been reported, indicating that the toxic exposure to this amine may be an incidental finding (Yamakage et al., 1980).

23.3.6 *meta*-Phenylenediamine

Workers exposed to *meta*-phenylenediamine have been reported to develop a systemic sclerosis-like disorder. These workers developed Raynaud's phenomenon, hyperpigmentation, pulmonary fibrosis, and sclerodermatous skin changes (Owens and Medsger, 1988). *meta*-Phenylenediamine, as a biogenic amine, most likely induces sclerodermatous changes similarly to the epoxy resins. Chemical workers exposed to large quantities appear to be at most risk.

23.3.7 Detergents

One report from Japan suggests that a patient exposed to a commercial detergent containing polyoxyethylene alkyl ether and fatty acid alkanol amide developed Raynaud's phenomenon, joint pain and decreased ability to close his hands within 3 months after exposure (Tanaka et al., 1993). By 13 months after exposure, he had hardening of the skin of his trunk as well. A skin biopsy done 10 months after exposure was consistent with scleroderma.

23.3.8 Silica

Exposure to silica dust, primarily in mining in South Africa, Pennsylvania, and Germany, has not been linked with pseudoscleroderma, but with true progressive systemic sclerosis (Rodnan et al., 1967; Reiser and Last, 1979). Symptoms

include Raynaud's phenomenon, arthritis, sclerodactyly, and other classic features of scleroderma. Silicotic lung changes frequently precede the scleroderma in those patients who are affected (Rodnan et al., 1967; Reiser and Last, 1979). The pulmonary pathologic condition is consistent with progressive systemic sclerosis showing diffuse alveolar, interstitial, perivascular, and vascular fibrosis (Reiser and Last, 1979).

The role of silica in the pathogenesis of scleroderma is thought to involve the enhancement of fibroblast collagenosis, perhaps by immune adjuvantcy (Rodnan et al., 1967; Reiser and Last, 1979). Whether this stems from macrophage fibroblast interaction remains debatable.

It has been proposed that the mechanism of action of silica exposure producing progressive systemic sclerosis involves the macrophages engulfing the silica, then as the macrophages die the silica is released again. IL-1 is then released which stimulates fibroblasts to increase their production of collagen. This increased collagen production leads to skin sclerosis, vascular occlusion, and fibrosis of the lungs (Yañez et al., 1992). On a basic research level, Haustein and Anderegy have been able to demonstrate that silica when injected into mice can produce changes in fibroblasts and mononuclear cells, which are similar to changes seen in the cells in patients with idiopathic scleroderma (Haustein and Anderegy, 1998). Studies have shown that exposure to silica can lead to the production of antinuclear antibodies, immune complexes, and damage to endothelial cells (Rustin et al., 1990). The pathogenicity of silica *in vitro* and *in vivo* is related to its structure, particle size, and concentration, and its association with scleroderma is less well established than its relationship with lung disease (Rodnan et al., 1967; Reiser and Last, 1979). According to investigators, the incidence of progressive systemic sclerosis in Germany is 25 times higher in workplaces where there is exposure to silica and 110 times higher for those patients with silicosis. This indicates that some immunomodulating mechanism may be operating in an adjuvant manner (Rodnan et al., 1967; Reiser and Last, 1979).

A study by McHugh et al. demonstrated increased frequency of antitopoisomerase antibody levels in patients with scleroderma who were exposed to silica (McHugh et al., 1994). Similarly, another study (Conrad et al., 1995) showed an increased frequency of positive anticentromere antibody levels in men who developed scleroderma who were exposed to silica. This study also surprisingly demonstrated that there were increased anticentromere antibodies even in men who were exposed to silica at high levels while working in uranium mines and did not develop scleroderma (Conrad et al., 1995).

23.3.9 Pesticides

Sclerodermatous changes have occurred in workers handling pesticides such as chlordane, heptachlor, malathion, parathion DDT, sodium dinitro-*ortho*-cresolate, and 7-chlorocylohexane. Reported patients developed Raynaud's phenomenon and sclerodermatous skin changes, but no internal involvement. Histological features are compatible with scleroderma (Jablonska, 1975).

There is a report of a 58-year-old West Indian man who had a 3-month intense exposure to a herbicide, which contained bromacil, diuron, and aminotriazole and then developed generalized sclerosis of his skin along with sclerodermatous symptoms of his esophagus and muscles (Dunnill and Black, 1994). The patient suffered particularly from prominent acrosclerosis of his hands, which extended up his forearms. It should be noted that aminotriazole has also been reported to produce an allergic contact dermatitis in workers exposed to it (English et al., 1986).

23.4 IATROGENIC AGENTS

There have been several reports of scleroderma developing between 2 and 21 years after silicone breast implantation (Sahn et al., 1990). Silicone fluids in breast implants are chemically known as dimethylpolysiloxane. These substances can "bleed" through the silicone envelope into surrounding tissue.

Clinical symptoms include Raynaud's phenomenon, sicca syndrome, pulmonary and gastrointestinal abnormalities, and diffuse skin sclerosis that usually begins in the upper extremities (Lilla and Vistner, 1976; Kumagai et al., 1984; McCoy et al., 1984; Brozenza et al., 1988; Silverstein et al., 1988; Spiera, 1988). With injection, breast masses, local erythema, and adenopathy may develop locally (McCoy et al., 1984). Histopathologic examination shows thickening of collagen bundles through the dermis, sclerosis of subcutaneous fat, blood vessel dilatation, and a perivascular lymphocytic infiltrate (Lilla and Vistner, 1976; Kumagai et al., 1984; McCoy et al., 1984; Brozenza et al., 1988; Silverstein et al., 1988; Spiera, 1988; Varga et al., 1989).

It has been proposed that macrophages ingest the silicone and produce silica. The presence of silica would then stimulate a more intense immunologic reaction. This would further stimulate macrophages to release transforming growth factor-β and platelet-derived growth factor, which would then stimulate fibroblasts to produce collagen (Sahn et al., 1990). Upon removal of the breast implants, some, but not all, patients show gradual improvement in the edema and firmness of their skin.

23.4.1 Bleomycin and Cisplatin

Scleroderma-like changes have been reported in patients with cancers of primary gonadal origin after treatment with bleomycin and cisplatin (Nixon et al., 1981; Finch et al., 1980). Histopathologically, in bleomycin-induced scleroderma, the dermis shows dense collagen with areas of homogenization, particularly associated with endothelial thickening (Cohen et al., 1973).

Many factors may contribute in the development of this iatrogenic syndrome. Bleomycin produces endothelial cell injury by peroxidation of the plasma membrane, which may then initiate fibrosis (Adamson and Bowden, 1974; Burkhardt and Holtje, 1976; Tom and Montgomery, 1980; Mountz et al., 1983). Bleomycin has stimulated collagen synthesis by

cultured normal skin fibroblasts, and may induce a lymphoproliferative response *in vitro* (Mountz et al., 1983).

There is a case report describing three patients having been exposed to less than a total of 100 U total of bleomycin, developing Raynaud's phenomenon along with thickening of fingers, periungual erythema, and sclerodactyly all within 6 months of exposure, some as early as 3 months after exposure (Kerr and Spiera, 1992).

23.4.2 Pentazocine

Pentazocine, when used as an analgesic, has been linked to the development of diffuse pigmentation changes and sclerotic fibrosis around injection sites, with the formation of large, irregular ulcers (Parks et al., 1971; Swanson et al., 1973; Palestine et al., 1980). On examination of a skin biopsy specimen, there is dermal thickening and fibrosis with an inflammatory cell infiltrate that is granulomatous in areas. Histologic examination also shows both venous and arterial small vessel thrombosis, endarteritis with endothelial hyperplasia, and lymphohistiocytic perivascular inflammation.

Pentazocine-induced fibrosis has been related to vascular ischemia, and the resultant tissue changes to pentazocine-induced vasoconstriction. Because their vasculature is already compromised, patients with diabetes may be more prone to developing these skin changes with the additive effect of pentazocine-induced vasoconstriction (Parks et al., 1971; Swanson et al., 1973; Palestine et al., 1980).

23.4.3 Ethosuximide

Ethosuximide, an anticonvulsant, has been associated with a lupus-scleroderma syndrome in one patient (Teoh and Chan, 1975). Clinical features included fevers, arthritis, malar flush, maculopapular eruption, and widespread skin sclerosis. Histological examination revealed dermal collagen bundles to be homogeneous and hyalinized with a perivascular lymphocytic infiltrate (Teoh and Chan, 1975).

An immunopathogenetic mechanism appears evident in ethosuximide-induced scleroderma with the coincident development of lupus. Connective tissue changes may also be considered when evaluating epileptic patients with rheumatological symptoms, as well as primary connective tissue diseases (Alarcon-Segovia, 1969; Teoh and Chan, 1975).

23.4.4 Penicillamine

A teenager with Wilson's disease who was treated with penicillamine developed systemic sclerosis-like lesions. Hyperpigmentation, pulmonary restriction, and proximal scleroderma were also evident (Miyagawa et al., 1987).

Penicillamine has been noted to have connective tissue and autoimmune effects that may involve its relation to the development of a scleroderma-like picture (Fulghum and Katz, 1968; Hasimoto et al., 1981; Walsh, 1981). As penicillamine is utilized as a treatment for progressive systemic sclerosis, its "sclerodermatous" effect is questionable in consideration of this one case.

There has also been a case of morphea-like plaques developing in a patient with rheumatoid-type arthritis who had been treated with D-penicillamine at 250 mg/day for 1 year (Bernstein et al., 1981).

23.4.5 Ergot Methysergide

Patients with migraine headaches treated with ergot and methysergide have been linked with the development of scleroderma. Clinical manifestations noted included Raynaud's phenomenon, as well as additional features associated with progressive systemic sclerosis. Histological features were also consistent with scleroderma (Robb, 1975).

As similar vasoactive phases are involved in the pathogenesis of migraines and Raynaud's phenomenon, it would seem as though they could be linked. Perhaps ergot and methysergide perpetuate this linkage by mediating vascular hyperreactivity leading to a scleroderma-like condition (Barret and McSharry, 1975; Robb, 1975). Ergot, in particular, has been shown to exacerbate Raynaud's phenomenon, and caution may be needed in treating patients with migraine headaches with these medications (Barret and McSharry, 1975; Robb, 1975; Goldberg et al., 1978).

23.5 NONPRESCRIPTION DRUGS

23.5.1 Eosinophilia-Myalgia Syndrome

First reported in October 1989 by the Centers for Disease Control and now including more than 1500 cases, an association has been made between the ingestion of L-tryptophan and the occurrence of the eosinophilia-myalgia syndrome, which often involves sclerodermoid features (Hertzman et al., 1990; Silver et al., 1990). L-tryptophan is an essential amino acid that is available in dietary supplement form. It is used to treat insomnia, depression, tinnitus, and premenstrual-related symptoms. The eosinophilia-myalgia syndrome is primarily defined by severe, incapacitating myalgias and peripheral eosinophilia (Sternberg et al., 1980; Centers for Disease Control, 1990a,b; Hertzman et al., 1990; Silver et al., 1990; Stutsker et al., 1990; Varga et al., 1990).

Characteristic clinical features also include arthralgias, fevers, dyspnea, edema, and macular exanthems, followed by acrally sparing sclerodermatous induration with a puckered or a peau d'orange appearance (Fishman and Russo, 1991). Eosinophilic fasciitis and papular mucinosis may also be observed (Lin et al., 1992). Raynaud's phenomenon, however, is absent in this condition (Sternberg et al., 1980; Centers for Disease Control, 1990a,b; Hertzman et al., 1990; Silver et al., 1990; Stutsker et al., 1990; Varga et al., 1990). On deep incisional biopsy, dermal thickening and homogenization of collagen bundles with mucin accumulation are seen replacing fat and adnexa. Blood vessel walls show thickening and endothelial swelling, and mast cells and plasma cells may be seen perivascularly and in the dermal infiltrate (Lin et al., 1992). Two additional observations are minimal tissue eosinophilia, despite the extent of peripheral eosinophilia, and minimal myofiber atrophy, regeneration, or

necrosis, despite the clinically significant myalgias (Kaufman et al., 1990; Silver et al., 1990; Lin et al., 1992).

The fibrotic effects of L-tryptophan have most often been associated with its role as a precursor in two metabolic pathways, one involves the production of serotonin and the other involves the production of nicotinic acid (Hertzman et al., 1990; Silver et al., 1990). This is supported by the development of cutaneous sclerosis in the carcinoid syndrome in which serotonin is produced in excess (Zarafonetis et al., 1959). The kynurenine pathway leads to the production of nicotinic acid. A patient with progressive systemic sclerosis has been described who had an elevated urinary kynurenine level along with a partial deficiency of kynurenine hydroxylase (Zarafonetis et al., 1959; Conolly et al., 1990). Additionally, in a patient who received L-5-hydroxytryptophan and carbidopa, both pathways may have been involved in the production of scleroderma because carbidopa can bind pyridoxal phosphate, which is a necessary cofactor in each pathway (Zarafonetis et al., 1959; Conolly et al., 1990). Isoniazid has been reported to have produced an apparent pyridoxal phosphate deficiency with elevated levels of urinary kynurenine and pellagra, as well as subsequent sclerodermatous changes (McConell and Cheltham, 1952). Some investigators report a possible genetic mechanism for L-tryptophan-induced fibrosis. *In situ* hybridizations have shown L-tryptophan to enhance expression of the collagen gene resulting in dermal and fascial fibrosis (Price et al., 1967). Mast cells may mediate this interaction (Lin et al., 1992; Conolly et al., 1990). Finally, endothelial changes with associated vascular alterations as observed histologically may induce sclerosis (Lin etal., 1992). Tryptophan is no longer widely available because it was taken off the market in November 1989 by the Food and Drug Administration. Factors such as individual susceptibility and particular preparation contaminants may explain the relatively low incidence of eosinophilia-myalgia syndrome (Centers for Disease Control, 1989). However, recent data appear to implicate a Japanese company that also produces the presumed toxin di-L-tryptophan as the source of the L-tryptophan-producing eosinophilia-myalgia syndrome (Stutsker et al., 1990).

The contaminant responsible for eosinophilia-myalgia syndrome appears to have been 3-(phenylamino) alanine (D'Cruz, 2000). Philen and Hill (1993) have pointed out that the contaminants in toxic oil syndrome and eosinophilia-myalgia syndrome are chemically similar and this may explain why the two syndromes produce similar clinical features.

23.5.2 Appetite Suppressants

A report out of England has proposed that the appetite suppressants diethylpropion and mazindol may induce sclerosis. Patients had taken appetite suppressants and subsequently developed Raynaud's phenomenon, arthritis, pulmonary and gastrointestinal symptoms, and sclerodermatous skin changes (Tomlinson and Jayson, 1984). Histological examination was not performed.

The sympathomimetic properties of diethylpropion may lead to vasomotor stress, which leads to Raynaud's phenomenon and other features of skin ischemia. Diethylpropion and mazindol also have serotonergic properties that may play a role in the kynurenine and serotonin metabolism reported in other scleroderma-like conditions (Bourgeois and Aeschlimann, 1991).

23.5.3 Cocaine

The association between cocaine abuse and scleroderma was suggested in two male patients (Trozak and Gould, 1984; Kerr, 1989). Common features included Raynaud's phenomenon, acral scarring, and diffuse sclerosis (Trozak and Gould, 1984). A skin biopsy specimen of one of the patients showed dermal thickening and collagen sclerosis.

An association between cocaine use and sclerodermatous changes has also been reported in four other young males (Kilaru and Kim Sequeira, 1991). All cases showed Raynaud's phenomena, sclerodactyly, skin thickening proximal to metacarpal phalangeal joints, and digital scars. It was hypothesized that the vasoconstrictive properties of cocaine may either promote or unmask an underlying propensity for scleroderma. Skin biopsy of one of the four patients demonstrated dermal thickening and collagen sclerosis (Kilaru and Kim Sequeira, 1991).

24.1 INTRODUCTION

Many disorders result in disturbances of pigment formation by the melanocytes (Mosher et al., 1987). Hypomelanosis or a decrease in the formation of the pigment melanin may be caused by many disorders. Leukoderma, derived from the Greek terms, λευκο white + δερμα skin, due to chemical exposure has been associated with several different classes of compounds, most being phenols or thiols. These chemicals are useful as antioxidants and find utility in rubbers and plastics, in foods, and as polymerization inhibitors in monomers. Because of the widespread use of these chemicals, it is important to examine the effects of exposure and the mechanism of depigmentation.

24.2 HISTORY

Occupational leukoderma due to exposure to chemicals was first reported more than 65 years ago (Oliver et al., 1939). The depigmentation, which may resemble vitiligo, was produced by the monobenzyl ether of hydroquinone (MBEH), which translocated from rubber gloves worn by workers. Once it was documented that chemical agents could depigment the skin, it became important to test them for this property, and several laboratory procedures have been developed for this purpose. The methods used for testing depigmenting chemicals have been reviewed previously (Gellin and Maibach, 1987).

24.3 CHEMICAL STRUCTURES CAUSING DEPIGMENTATION

Chemical depigmentation has been associated with a variety of compounds. Most are phenols or sulthydryl compounds, but divalent metals that bind to melanin have also been implicated. These materials are useful as antioxidants and inhibitors of polymerization. Because of these properties, they are employed in a wide variety of products and can potentially contact many people during manufacture and use. In addition, some of these agents have been applied intentionally for the purpose of lightening hyperpigmented skin. The structures and acronyms of these materials are shown in Figure 24.1, but catechol (CAT) and phenol have not been included. MBEH has been used to intentionally depigment hyperpigmented skin in humans (Lerner and Fitzpatrick, 1953; Becker and Spencer, 1962). The results were not very satisfactory because the response had wide individual variation. Furthermore, depigmentation occurred at sites remote from the site of application. There was no depigmentation without some evidence of inflammation. In another study, MBEH was used at 10–33% concentration in lotions and ointments, and was deemed to give satisfactory results when used to treat hyperpigmentation in patients (Denton et al., 1952). Bleaching creams containing hydroquinone (HY) have also been reported to cause leukoderma (Fisher, 1982).

Some clinical data have been gathered from exposures to products containing depigmenting chemicals. Some ceramic lacquers contain phenolic compounds (exact structure unidentified), and one case of leukoderma has been reported from exposure to these materials (Tosti et al., 1991). One case of leukoderma from contact with neoprene swim goggles has been reported (Goette, 1984), but the agent responsible was not identified. A case of hypopigmentation due to contact with phototypesetting paper containing *tert*-butyl catechol (TBC) has been described (Fardal and Gurphey, 1983). TBC is also used as an antioxidant in industrial lubricants and workers who come in contact with these experience depigmentation (Gellin et al., 1970). Antioxidants are added to polyethylene film, and these materials can translocate if the film is in contact with skin. Polyethylene film, used as an occlusive dressing during steroid treatment, produced two cases of leukoderma (Vollum, 1971). A case of depigmentation due to adhesive

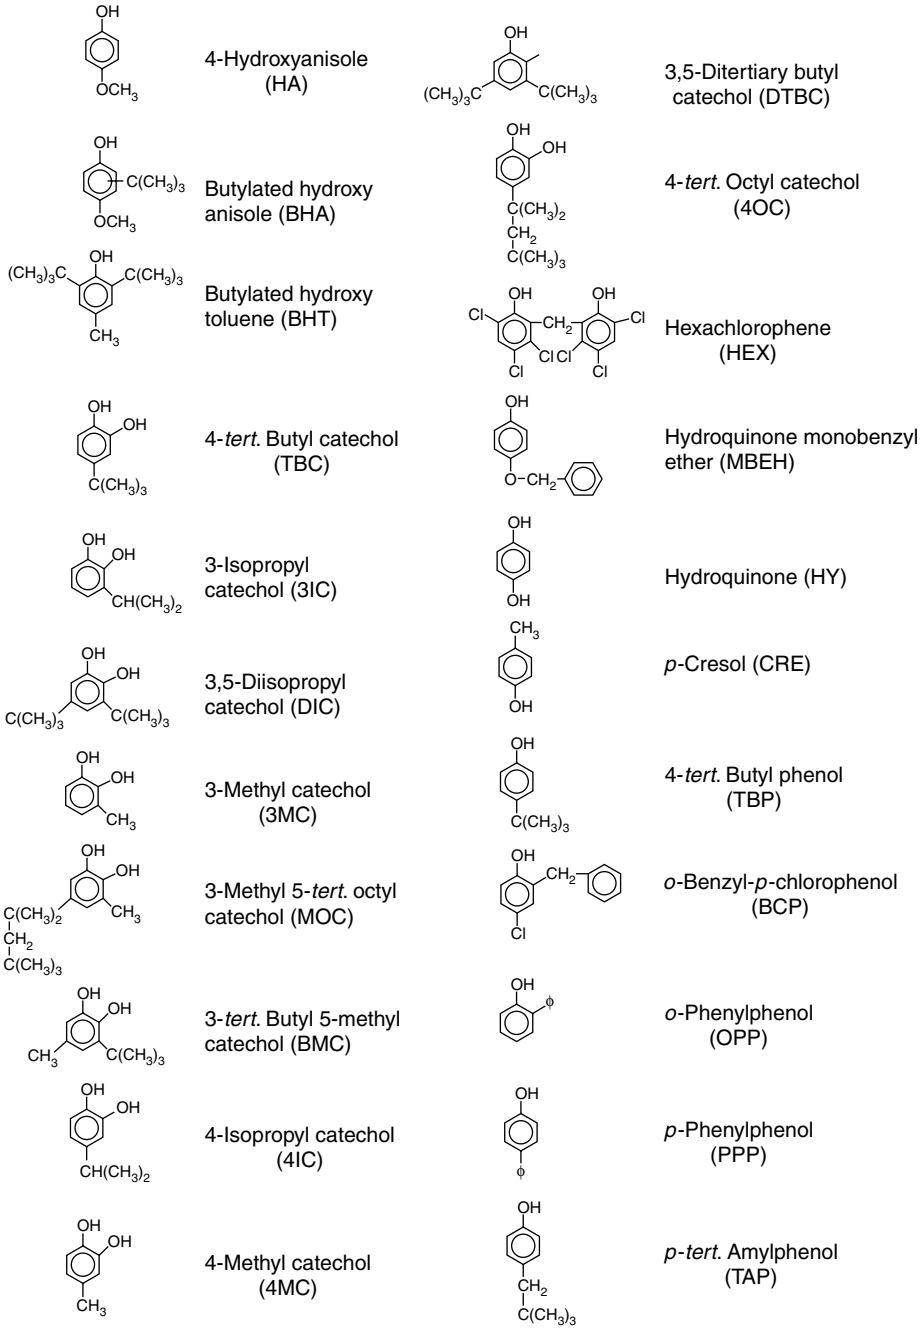

FIGURE 24.1 Compounds that have caused depigmentation.

tape was described (Frenk and Kocsis, 1974), but the component in the tape was not identified because the subject refused to be tested with the individual components.

Phenols are a common ingredient in germicidal disinfectants. A study describing five cases of depigmentation in one hospital and seven in another was reported (Kahn, 1970). The antiseptic used for cleaning surfaces in the hospital contained 4.1% of *o*-benzyl-*p*-chlorophenol (BCP) and 3% 4-*tert*-butylphenol (TBP). In addition, experimental studies were carried out on five volunteers who were tested with 6% TBP in 70% ethyl alcohol applied to the upper arm under occlusion. Maximal pigment loss occurred at approximately 1 month, and pigment returned in all subjects about 1 month later. Another group of subjects was tested with 6% hexachlorophene (HEX), *o*-phenyl phenol (OPP), BCP, and MBEH, and 1% solutions of *tert*-amyl phenol (TAP) and BCP. Depigmentation was produced in some of the subjects by all materials with the exception of MBEH. MBEH is capable of producing depigmentation as shown by other studies where a 20% solution was used (Lerner and Fitzpatrick, 1953; Becker and Spencer, 1962).

Exposure to depigmenting agents can and does occur if proper handling procedures are not practiced during the manufacture. Thirteen cases of leukoderma have been described among workers in a plant producing OPP and *p*-phenyl phenol (PPP) (Ito et al., 1968). Two cases of leukoderma in a

plant producing the monomethyl ether of hydroquinone or 4-hydroxyanisole (HA) were described, although 169 other men in the same plant were examined and showed no sign of depigmentation (O'Sullivan and Stevenson, 1981). HA is used as a stabilizer of vinylidene chloride, and two cases of leukoderma have been described in a plant where the material was being made (Chivers, 1972). A plant making TBP had 54 of 198 men with leukoderma; the intensity of the disorder was related to the degree of exposure (James et al., 1977). A total of nine cases of leukoderma was seen in two plants engaged in the production of TBP, butylated hydroxytolutene (BHT), and TBG (Romaguera and Grimalt, 1981).

In addition to the clinical observations, experimental studies have identified many compounds that cause hypomelanosis. Laundry ink containing *p*-cresol (CRE) produced depigmentation in CBA/J mice (Shelly, 1974). Thirty-three compounds were tested in black guinea pigs (Bleehen et al., 1968). Of these, 12 compounds produced depigmentation to some degree. Those that were very strong depigmenters were TBC, 4-isopropyl catechol (4IC), 4-methyl catechol (4MC), and catechol (CAT). Some produced definite but moderate hypopigmentation, among them, 3-isopropyl catechol (3IC), 3,5,-diisopropyl catechol (DIC), HY, 3-methyl catechol (3MC), and 3-methyl-5-*tert*-octyl catechol (MOC). Others produced definite but weak depigmentation: 3-*tert*-butyl 5-methyl catechol (BMC), 3,5-ditertiary butyl catechol (DTBC), and 4-*tert*-octyl catechol (4OC). Twenty-two additional compounds are listed in Table 24.1; some produced depigmentation and others did not. It is stated that substitution in the 4 position confers greater activity than the same substituent in the 3 position; for example, 4-methyl catechol is more potent than 3-methyl catechol. Some, but not all, compounds containing a sulfydryl group are capable of producing depigmentation. β-Mercaptoethylamine hydrochloride (MEA) and *N*-(2-mercaptoethyl)-dimethylamine hydrochloride (MEDA) were strong depigmenting agents. 3-Mercaptopropylamine hydrochloride and cystamine hydrochloride are weak to moderate depigmenters. Sulfanilic acid, cystamine, *bis*(2-amino-1-propyl)disulfide, 2-(*N,N*-dimethylamine)ethanethiol *S*-acetate, 2-mercaptopropylamine hydrochloride, and α-mercaptoacetamide were weak depigmenters. Another study compared HQ, MEA, and MEDA in black guinea pigs (Pathak et al., 1966). There is not as clear a pattern of structure–activity relationship among the thiols as there is with the phenols.

Another study on 23 compounds was carried out in black guinea pigs and black mice (Gellin et al., 1979). Strong depigmentation was found with HA, TBG, TAP, and MEBH. Moderate depigmentation was noted with HQ, TBP, phenol, and catechol. They failed to find depigmenting properties when testing butylated hydroxyanisole (BHA), BHT, octyl and propyl gallate, ethoxyquin gum guaiac, diethyl amine, hydrochloride, dilauryl thiodiproprionate, nonyl phenol, *o*-phenyl phenol, *p*-phenyl phenol, octyl phenol, nordihydroguaiarctic acid, and tocopherol. All the compounds mentioned last are used in a wide variety of products with which a large population comes in contact.

TABLE 24.1
Compounds Tested in Black Guinea Pigs

Compound	Depigmenting Potency
1,2,4-Trihydroxybenzene	0 to ±
2-Hydroxy-1,4-napthoquinone	0
2,3-Dihydroxybenzoic acid	0
Sulfanilic acid, pH 3.9	0
bis(2-Amino-1-propyl) disulfide	±
β-Mercaptoethylamine hydrochloride (MEA)	± to + +
2-Aminoethanethiol *S*-acetate	0
2-Mercaptoisopropyl amine	0 to ±
Hydrochloride x-Mercaptoacetic acid	0
2-Ethyl-*n*-hexyl-diphenylmethylene cyanoacetate	0
2,3,5,6-Tetrahydroxyquinone	0
2,3,5,6-Tetrahydroxyquinone	0
3,4-Dihydroxyphenylacetic acid	0
Sulfanilic acid, pH 7	0
bis(2-Aminoethyl) disulfide or cystamine	0 to ±
2-Hydroxypyridine	0
N-(2-mercaptoethyl) dimethylamine hydrochloride (MEDA)	± to + +
2-(*N,N*-dimethylamine) ethanethio-*S*-acetate	±
Cystamine hydrochloride	± to +
α-Mercaptoacetamide	0 to ±
1,3-Propane sultone	0
3-Hydroxypropane sodium sulfonate	0

Note: Criteria for assessing activity are as follows:

1. No visible depigmentation; skin color similar	0
2. Small spots or speckles of depigmentation	±
3. Uniform hypopigmentation	+
4. Complete depigmentation	+ +

24.4 REPIGMENTATION

Repigmentation after exposure to depigmenting agents is highly variable. Aside from individual variation, it is related to the degree and length of exposure to the agent. After application of MBEH for 30 days, repigmentation occurred 1 month after cessation of application (Denton et al., 1952). After workers ceased wearing rubber gloves containing MBEH, repigmentation commenced, but the degree of repigmentation is not stated (Oliver et al., 1939). Black subjects tested with 20 or 5% MBEH (Lerner and Fitzpatrick, 1953) had one subject who depigmented in 1 month and repigmentation was complete 2 months later. A case of depigmentation resulting from rubber swim goggles containing a depigmenting agent gradually repigmented over a 8 weeks period after use of the goggles was discontinued (Goette, 1984). MBEH was used to depigment black subjects, and in some, white patches remained after 2 years and the investigators speculated it might be permanent (Becker and Spencer, 1962). Some subjects tested with TBP repigmented within 6 months but others remained depigmented after 1 year (Kahn, 1970). Those areas that depigmented least, repigmented first.

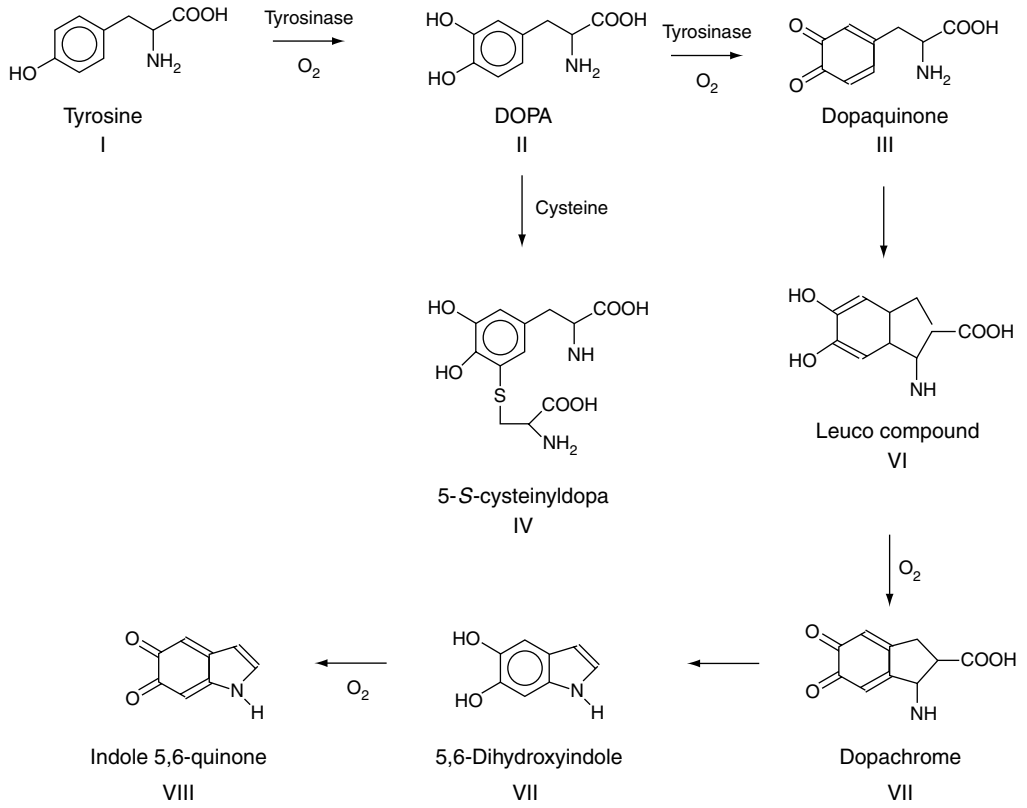

FIGURE 24.2 Steps in the synthesis of melanin (Lerner and Case, 1959). Indole 5,6-quinone undergoes condensation with proteins to form eumelanins, which are black or brown. The cysteine conjugate, 5-*S*-cysteinyldopa is further oxidized to a quinoid structure and then is conjugated with proteins to form pheomelanins, which are red or yellow in color. Tyrosinase activity can be diminished by substrate inhibition and, since several depigmenting agents with a phenolic structure can act as substrates, this may be one mechanism (Menter, 1988; McGuire and Hendee, 1971).

24.5 MECHANISM OF ACTION

The biosynthesis of melanin is a complex process that involves several steps, several of which are still not known. For example, several different protein structures can condense with indole quinone or 5-*S*-cysteinyldopa to give different colored pigments. Some of this is under genetic control and thus is different in individuals, as well as species. Some of this process is shown in Figure 24.2. Pigment formation can be disrupted by interference at any of these steps.

Seven mechanisms have been suggested by which the chemical agents could be producing depigmentation (Bleehen et al., 1968):

1. The agent may act selectively on a specific cell. The phenols do structurally resemble some of the intermediates involved in the synthesis of melanin, such as tyrosine or DOPA. Menter (1988) tested eight compounds as substrates for tyrosinase and found all of them to be suitable. Among them were the depigmenting agents TBC, 4MC, HA, and BHT. The presence of dopa-melanin enhances the action of tyrosinase on these substrates. It has been suggested that some of these products may act as antimetabolites and lead to degeneration or death of the cell (Lerner, 1971).
2. Chemical agents such as 4IC may react and tie up the active sites of tyrosinase. The molecule does not have the necessary side chain for conversion to the indole quinone and the reaction may bog down at step III in Figure 24.2.
3. The agent can inhibit the melanin formation by blocking the enzymatic oxidation of tyrosine to DOPA and the subsequent conversion to melanin.
4. The agent can interfere with the biosynthesis of the organelles—premelanosomes and melanosomes. Melanin is a free radical and produces a signal when analyzed by electron spin resonance. The addition of HA to the system changes and increases the signal (Riley, 1970). Free radicals are capable of generating peroxides and disrupting cell and organelle membranes by lipid peroxidation. Investigations by electron microscopy have shown disruption of melanosomes and destruction of membranous organelles in melanocytes (Jimbow et al., 1974).
5. The agent can interfere with the biosynthesis of the protein (e.g., by combining with the melanocytic ribosomes, which appear to be the sites for tyrosinase synthesis) (Jimbow et al., 1974). This may be another facet of lipid peroxidation.
6. The agent can interfere with the transfer of melanosomes to keratinocytes, either by inhibiting the

arborization of melanocytic dendrites or by causing intercellular edema. Irritation plays a role in pigment loss (Gellin et al., 1979; Becker and Spencer, 1962). Irritation is accompanied by edema, thus this may be a factor in depigmentation.

7. The agent can chemically alter the melanin present in the melanosomes. Because of the reducing action of some of the thiols, it appears that the dark-colored, oxidized form of melanin could be altered to the lighter-colored, reduced form. Since cysteine can condense with DOPA to yield pheomelanins, it may be possible for other thiols to be involved in a similar reaction.

It has also been suggested that depigmenting agents may act as an antigen after increased cellular permeability due to inflammation. An antibody is formed and this stops the formation of melanin granules. If antigen is produced in sufficient quantities, the reticuloendothelial system could respond (Becker and Spencer, 1962). This hypothesis has not been tested, but it may explain depigmentation at remote sites (Gellin et al., 1970).

Another mechanism that alters the level of glutathione reductase, which in turn affects the level of the reduced form of glutathione, may involve a change in the type of pigment produced (Yonemoto et al., 1983). Hairless mice treated with TBC showed an increase of the enzyme glutathione reductase. It was suggested that this change increases the level of reduced glutathione and in turn increases the number of pheomelanins, which are lighter in color than eumelanins.

Some important findings have been made using cultures of human melanoma cells (Del Marmol et al., 1993). In this study, intracellular glutathione was depleted by treating the cells with buthionine-*S*-sulfoximine (BSO). Tyrosine hydroxylase activity increased in parallel with glutathione depletion. The effect of thiols on melanogenesis can occur by at least two different mechanisms. First, low molecular weight thiol compounds can inhibit melanogenesis by direct interaction of the thiol groups with the tyrosinase active site, thus inhibiting tyrosine hydroxylation. Second, thiol groups are able to react with L-dopaquinone to form dopa-thiol conjugates that are pheomelanogenic precursors.

24.6 CONCLUSIONS

Many chemicals have been identified as depigmenting agents from clinical observations and experimental studies. These agents fall into primarily two categories: phenols and thiols. The most potent phenols are those containing an alkyl substitution in the 4 position. Those that are most irritating to the skin have the greatest potential for depigmentation. The mechanism by which depigmentation occurs is probably related to interference with one or more of the many steps of melanin biosynthesis. It is accompanied by destruction of melanocytes and their organelles. The structure–activity relationship of the thiols is much less defined. The mechanism of action of the thiols may be related to the depletion of glutathione or the involvement of the thiol in the place of glutathione in the formation of melanin. Fortunately, experimental methods have been developed to test compounds for depigmenting properties. Once the potential is recognized, proper protective measures can usually be instituted to minimize human exposure. The human is more sensitive than other species, and there is a large variation in sensitivity among individuals.

Recent literature reviews (PubMed and Embass) fail to reveal new depigmenting agents and mechanisms. We question whether this represents lack of interest, few reportable cases, or that the depigmenters have been identified and removed from the environment. The authors welcome new information that may have escaped our notice.

25.1 INTRODUCTION

Skin cancer is the most prevalent malignancy in fair-skinned people (Diepgen and Mahler, 2002; Ley, 2002). The incidence of both the more common nonmelanoma skin cancer (NMSC) and the more lethal cutaneous melanomas continue to increase, reaching epidemic numbers. NMSC accounts for up to one-third of all cancers in the United States and Australia. According to recent population-based studies from Australia, the incidence rate is over 2% for basal cell carcinomas in males and 1% for squamous cell carcinomas. Mortality for NMSC is low. Surgical therapy is highly effective, but recurrence is frequent. Therefore, the associated morbidity is significant to the patient as is the burden on health care system. For melanoma, the American Cancer Society predicted there would be approximately 53,600 new cases in the United States during 2002, and 7400 deaths from melanoma during the same period. In Australia, there are over 50 new cases of melanoma per 100,000. The good news is that among cancers, skin cancer is believed to be one of the most preventable malignancies. Life style risks include ultraviolet radiation (UVR) exposure and diet. These factors can be modulated to decrease risk.

25.2 SUSCEPTIBILITY TO SKIN CANCER

Epidemiology studies and molecular data implicate exposure to UVR as the most important etiological factor for risk of skin cancer. While UVR plays a central role, other agents are clearly involved. These include the immune response, certain viral infections, genetic predisposition, and diet. As shown later, these risk factors are not exclusive.

25.2.1 Ultraviolet Light Radiation

UVR is the carcinogenic factor in sunlight. UVR has been mainly associated as a factor for NMSC, but some role for UVR has been suggested in malignant melanoma (Grossman and Leffell, 1997). Over time, accumulation of mutations induced by UVR contributes to cancer. Most mutations are repaired or damaged cells are removed by apoptosis. However, the additive effects of mutations involved in genes, involved in DNA repair, apoptosis, and control of the cell cycle can lead to tumor formation. UVR, like other agents that cause DNA damage, induces expression of the tumor suppressor gene p53, important for DNA repair, and apoptosis in response to DNA damage (Soehnge et al., 1997). It is, therefore, not surprising that many skin cancer cells have mutant p53. Mutations in p53 are present in about 56% of basal cell carcinomas (Lacour, 2002). Not only does UVR cause mutations in cellular DNA, but UVR also has profound effects on the cutaneous immune system. In an animal model of ultraviolet (UV) light-induced skin carcinogenesis, cyclooxygenase-2 was upregulated by UVR (Fischer, 2002), which would clearly stimulate inflammatory processes (An et al., 2002). Psoralen and ultraviolet A photochemotherapy (PUVA) is associated with a dose-dependent increase in the risk of nonmelanoma skin cancer (Studniberg and Weller, 1993). Like UVB radiation, PUVA is both mutagenic (Nataraj et al., 1997) and immunosuppressive (Ullrich, 1991) and therefore, can be considered a complete carcinogen.

25.2.2 Viruses

More and more evidence suggests that the human papillomaviruses (HPV) may have a role in promoting NMSC. These

viruses can affect tumor suppressors such as p53 and retinoblastoma (zur Hausen, 2000). Epidermodysplasia verruciformis, with a papillomavirus etiology, has long been regarded as a model for nonmelonotic skin cancer (Majewski and Jablonska, 2002). Flat warts occur in individuals with this disease, and cancers develop from lesions on sun-exposed areas. The presence (viral DNA) of a number of lesser-studied types of HPVs occur at a very high frequency in immunocompromised patients, for example, persons with renal transplants (de Villiers et al., 1997). These HPVs are also being found in lesions from immunocompetent patients as well (Biliris et al., 2000). Present data indicate that a primary infection occurs in the majority of individuals early in life. The virus remains latent, and prolonged UVR is needed to activate the virus or inactivate cellular genes responsible for controlled cell growth (de Villiers, 1998). Not only has UV light been shown to activate latent papillomaviruses (Amella et al., 1994), but also one of the viral proteins (E6) from diverse cutaneous HPV types inhibits apoptosis in response to UVR damage (Jackson and Storey, 2000). Studying HPV in skin cancer has been limited by detection methods. Currently, degenerate PCR methods are identifying many more HPV types and identifying HPV DNA in premalignant and malignant skin lesions (Biliris et al., 2000; Harwood et al., 1999). Consistent with the observations that HPV may be a cofactor for the development of skin cancers, several mouse strains exist with HPV transgenes and serve as models for progressive skin cancer (Arbeit et al., 1994; Kang et al., 2000). Other conditions add to the circumstantial evidence that HPVs are cofactors for skin cancer. The gradual loss of immunity in AIDS increases the cutaneous lesions associated with HPVs in these patients (Milburn et al., 1988), and increases in skin cancers are likely with long-term survivors of AIDS. An analysis of PUVA-related benign and malignant lesions found a prevalence of HPV DNA (Weinstock et al., 1995).

25.2.3 Genetic Disposition

The fair-skinned Caucasian population poses the greatest risk for skin cancer. Other genetic factors such as defects in DNA repair, the immune system, or detoxifying enzymes increase risk. For example, the transmission of Epidermo-dysplasia verruciformis (described earlier) is autosomal recessive, and the disease has the characteristic of decreased cell-mediated immunity (Cooper et al., 1990). Susceptibility loci have been identified (Ramoz et al., 2000). Individuals with functional polymorphisms in the detoxifying enzymes, glutathione-*S*-transferases (GSTM1 and GSTT1) show enhanced sensitivity to sunlight (Kerb et al., 2002), and such polymorphisms occur at high frequency among Caucasians. Moreover, these GST genotypes modulated Hypericum extract (St. John's wort)–induced photosensitization.

25.2.4 Immunity

Renal transplant patients have a well-documented risk of increased skin cancer. This increase is 50–100-fold (Birkeland et al., 1995). The cumulative incidence of skin cancer is 27–44% after 10–25 years of immunosuppression (London et al., 1995). This increase is concomitant with an increase in cutaneous lesions associated with HPVs; the virus is very often detected in both benign and malignant cutaneous lesions (Blessing et al., 1990; Benton et al., 1992).

25.2.5 Diet

A number of studies, which include animal and human studies, indicate that diet can affect skin cancer risk. A number of studies suggest that a high-fat diet may directly or indirectly affect skin cancer. For example, more skin cancers occurred at an accelerated rate in mice with transgenes for HPVs when the mice were given a diet with 20% corn oil (Qi et al., 2002). Grape skin and some other food products contain resveratrol, a phytoalexin. In a skin cancer model, it inhibited the development of preneoplastic lesions in a skin cancer model (Jang et al., 1997). This phytochemical is known to act as an antioxidant, induce phase II drug-metabolizing enzymes and inhibit cylooxygenase. Low selenium (a mineral found in garlic and related foods) levels in plasma have been linked to increasing risk of nonmelanoma skin cancer in humans. In a study of selenium deficiency using UVR-induced skin tumors in SKh:HR-hairless mice. Pence et al. (1994) showed the correlation between decreased risk with selenium deficiency, and that the deficiency resulted in decreases-glutathione peroxidase and increases in superoxide dismutase and catalase. In another study, men with basal cell and squamous cell cancers had lower levels of beta-carotine than controls. However, high intake of cruciferous vegetables, foods with beta-carotene and vitamin C, and fish were associated with a reduced risk (Lamberg, 1998). Support for antioxidants came from a cohort study in Great Britain showing a substantial protective effect for NMSC with vitamin E (Davies et al., 2002).

25.3 PREVENTION

Chemoprevention of photodamage and thus for photocarcinogenesis has been collectively referred to as photochemoprotection. Sunscreens and educational efforts may be an effective method to reduce UVR-induced photodamage. Additionally, many naturally occurring compounds such as antioxidants present in the diet have potential for human benefit. Fruits, vegetables, and certain beverages boost levels of antioxidants in the body and can serve as scavengers of sunlight-induced free radicals. For example, green tea, which is rich in polyphenolic antioxidants, has been suggested as an adjunct to sunscreen to prevent photodamage and subsequent skin cancer (Almad and Mukhtar, 2001).

A diet low in fat may reduce actinic keratosis and nonmelanoma skin cancers. Expanding intervention studies support that a diet with less than 20% of total calories is efficacious. Patients in low-fat groups had a significant lower rate of new cancers detected at 2 years (Jaax et al., 1997).

Consistent with animal studies, selenium appears to be beneficial. When a group of patients with a history of basal cell or squamous cell carcinomas were randomized into a

group of persons taking 200 mg selenium per day or placebo and followed for 6 years, the treatment showed a trend but not significance for reducing the incidence of skin cancers. However, the study was stopped because there was a significant reduction of total cancer mortality and total cancer incidence in the selenium group (Clark et al., 1996).

At a meeting of the American Academy of Dermatology (1998), Arbesman reported on the findings from more than 50 animal and human studies and suggested that the studies would support a diet of less than 20% calories from fat, five servings of fruit and vegetables, carotine from food equivalent to one and one-half medium carrots, vitamin E supplements, and selenium and vitamin C from food (Lamberg, 1998).

Together, studies (from basic science to intervention) support that life style change could dramatically reduce the incidence of skin cancers, particularly the NMSCs.

26.1 INTRODUCTION

Retinoids comprise a large class of small lipophilic molecules related to vitamin A, retinol (ROL), in their chemical structure, biological activities, or receptor binding. The naturally occurring retinoids include ROL; retinyl esters (retinyl palmitate); 11-*cis*-retinal, 11cRAL; 9-*cis*-retinoic acid, 9cRA; all trans retinoic acid, tRA (tretinoin, Retin A); 13-*cis*-retinoic acid, 13cRA, (isotretinoin, Accutane); and as many as a few dozen active and inactive metabolites of these molecules. The provitamin beta-carotene may be included by extension as it can furnish retinyl esters when cleaved in the intestine. The synthetic retinoids now number well over 2000, only a few of which have been successfully commercialized as etretinate (Tigason, Tegison), acitretin (Soriatane, Neotigason), tazarotene (Tazorac), adapalene (Differin), and bexarotene (Targretin). This massive synthetic effort by a number of large pharmaceutical companies has been largely an attempt to obviate the toxicity of retinoids when administered in pharmacologic doses for treatment of various skin diseases and carcinomas but has had thus far limited success in divorcing desirable and undesirable biological actions.

Recognition of night blindness in ancient Egypt in the fifteenth century BC followed by recommendations in ancient Greece for its treatment by topically applied or ingested liver were proven to be prescient observations in the early twentieth century after discovery of the active principle vitamin A followed by its synthesis and animal and human experience involving dietary vitamin A for supplementation and pharmacologic therapy. The class is named after the retina, the site of the important interaction of 11-*cis*-retinal with opsin to form rhodopsin, the light sensitive pigment of the rods that is involved in night vision.

Both insufficient and excessive ingestion of vitamin A result in well-established clinical syndromes. Hypovitaminosis A manifesting as night blindness, keratomalacia, skin thickening and roughness, and embryologic defects is by far the most common presentation especially in developing countries where inadequate dietary vitamin A is a prevalent problem.[1] Hypervitaminosis A of the chronic type is more common than acute hypervitaminosis A and presents with dry, pruritic, erythematous, desquamating skin and lips, hair growth abnormalities, pain and tenderness of bones, anorexia, fatigue, irritability, headache, papilledema, and embryopathic manifestations in exposed fetuses as a result of overzealous dietary ingestion, which is more frequent, or intentional pharmacologic administration of vitamin A, which is now rather uncommon. Reports of acute

TABLE 26.1
Possible Factors in Retinoid Toxicity, General Aspects

Chemical structure, stereochemistry, chain isomerization, polarity, charge, lipophilicity
Absorption and first-pass metabolism
Plasma protein binding
Tissue distribution and localization within tissue
Pharmacokinetic parameters Cmax, Tmax, AUC, T1/2
Peak, trough and mean plasma levels of drug and its metabolites
Hepatic metabolism and activity and pharmacokinetics of metabolites
P450RAI (CYP26) induction, expression, and activity
Catabolism, glucuronidation, excretion, reabsorption
Possible competitive inhibition of enzymes
Specifics of placental transfer
Genetic polymorphisms and snps

Signal transduction pathways utilized or opposed
Transcription factors utilized or opposed
Hox-RARE interactions in embryogenesis
Other gene interactions
Regulatory feedback loops

hypervitaminosis A are rare as the retinoids generally have low toxicity in single doses even at substantial dose levels.[2] Few individuals have the opportunity to ingest large amounts of polar bear liver, which contains 12 mg retinol/gram and which in the past produced dramatic manifestations of acute hypervitaminosis A including headache, convulsions, coma, hallucinations, even death in early arctic explorers.

These observations and the long clinical experience of utilizing high-dose vitamin A for treatment of acne and disorders of keratinization that demonstrated substantial efficacy but also a side effect profile deemed undesirable, provided there was an stimulus for the synthetic retinoid programs. Thus the extremely enthusiastic reception of the marketing of Etretinate, Tigason in Europe for treatment of psoriasis and disorders of keratinization and isotretinoin, 13-*cis*-retinoic acid, Accutane in the United States in 1982 for treatment of the formerly nearly untreatable severe nodulo-cystic acne. In the United States, a storm of adverse events soon reported to the manufacturer, followed in 1983 by the first reports of human birth defects, tempered enthusiasm, and let loose an avalanche of governmental, regulatory agency, legal and congressional scrutiny. Presently these events have result in a highly restricted availability of isotretinoin and a marked dampening in the enthusiastic synthesis of retinoids, which once seemed such promising future therapy.

There has never been a time when it was more important to have a complete understanding of retinoid toxicity with a view to its abrogation or minimization. This chapter will address the issue of retinoid toxicity first in its broadest perspective (Table 26.1) and then in the specific details of its organ, cellular, and molecular origins (Table 26.2). The therapeutic effects of retinoids as well as the syndromes of hypo and hypervitaminosis A reveal several clues in many of their specific signs and symptoms of the critical and central role of vitamin A in development and maintenance of many, perhaps all organ and cellular systems. In the past three decades, a rapid accumulation of understanding of the basic mechanisms of biological actions of retinoids has resulted from the intense and now highly sophisticated research in chemistry, molecular and developmental biology, and genetics. This chapter will attempt to provide a sufficient and coherent background of present knowledge of retinoid action to allow a more complete understanding as the science continues to unfold. As much of the literature addresses the role of tRA and involves *in vitro*, animal *in vivo*, and transfection and transgenic experimentation, the observations cannot always be immediately extrapolated to effects in the human with therapeutic doses of tRA or other retinoids; but this molecule and the enormous literature documenting retinoid experimentation can serve as parts of a useful paradigm of action for the other retinoids. A working knowledge of the chemistry, pharmacokinetics, metabolism, and receptor binding of these natural and synthetic ligands is critical for an understanding of the complex mechanisms of their biological activities.

26.2 CHEMISTRY

Naturally occurring retinoids are small lipophilic molecules composed of a six-membered ionone ring that is essential to biological function, an unsaturated polyene side chain, which is unstable at its double bonds and subject to isomerization in several locations, and a terminal end group usually an alcohol, ester, aldehyde, or acid in structure (Figure 26.1). Synthetic retinoids have been classified as first-, second-, or third-generation compounds, based on the structural changes in the ring, side chain, and terminal group. The first generation is represented by the naturally occurring retinoids including 13cRA. In the second-generation retinoids, the ring is aromatized as with etretinate and acitretin and in the third generation, the so-called arotinoinds such as Ro 13-7410 and tazarotene, the side chain has been folded on itself to create one or more additional ring formations. Further modifications can produce molecules with retinoid activity but which ligand only RXR receptors. This is in contrast to most of the active first-, second-, and third-generation retinoids most of which are ligands of retinoic acid receptor (RAR) receptors, the

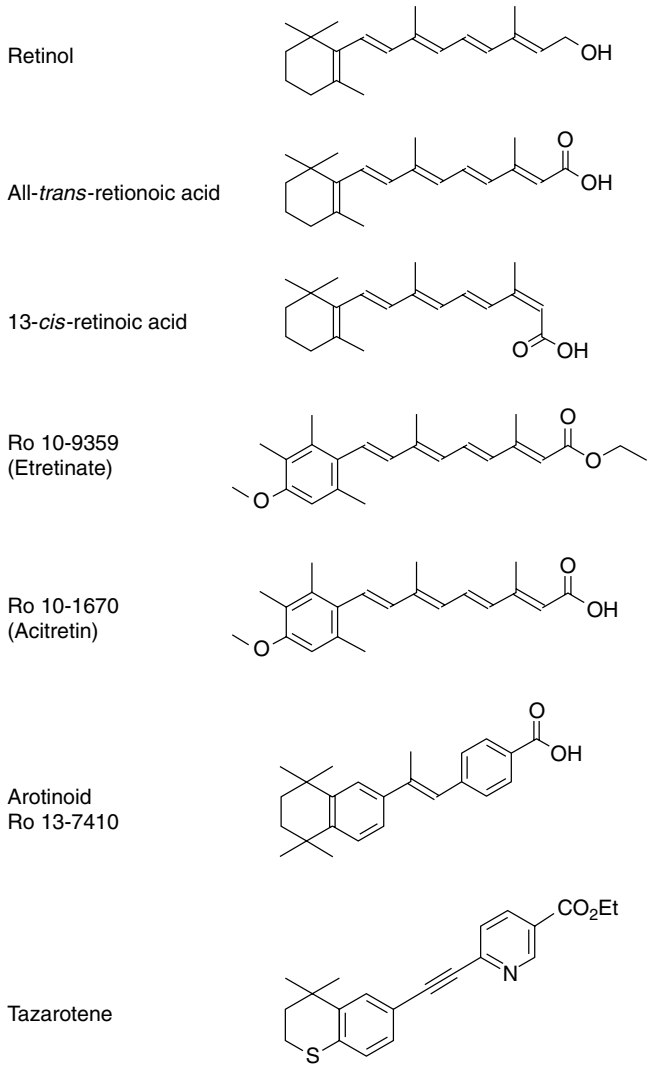

FIGURE 26.1 Structures of representative retinoids.

exception being 9cRA, which is also a ligand of RXR. These structural aspects are of considerable importance *in vivo* as they influence many of the critical aspects of absorption from the gut or skin, plasma protein binding and transport, pharmacokinetics, membrane transport—and as will be discussed later in some detail—enzyme interactions, and receptor binding.

Synthesis of several of the biologically natural retinoids can be accomplished *in vivo* via several enzyme systems provided that there is sufficient substrate of vitamin A equivalents available from dietary sources. Retinol and retinyl esters such as retinyl palmitate comprise the majority of dietary vitamin A equivalents with a smaller proportion obtained from carotenoids such as beta-carotene. Synthesis is generally in the direction of alcohol (retinol) to aldehyde (retinal) to acid (retinoic acid) through the action of a series of alcohol and aldehyde dehydrogenases. Thus the organism's requirement for both 11-*cis*-retinal for the visual cycle and tRA for most other functions is readily achieved with adequate retinol or retinyl ester ingestion.

26.3 ABSORPTION, TRANSPORT, AND TISSUE DISTRIBUTION

Most lipophilic drugs are absorbed only in the small intestine, and in their passage through the gut epithelium, they utilize membrane-bound protein receptors to facilitate their transport.[3] Dietary retinyl esters such as retinyl palmitate are cleaved to retinol in the small intestine by pancreatic enzymes and retinol is then absorbed into intestinal cells by a carrier-mediated process specifically utilizing cellular retinol binding protein 2, CRBPII. Retinol is re-esterified in the intestinal cell, incorporated into chylomicrons and reaches plasma via the lymphatics. Hepatocyte uptake by receptor-mediated internalization of chylomicrons allows hepatic storage or transfer of retinol to plasma bound to retinol-binding protein (RBP), a specific carrier protein synthesized and controlled by hepatic mechanisms. The importance of RBP is considerable in limiting the availability of free retinol to cells and RBP is one part of the complex and highly regulated system by which cellular retinol and thus retinoic acid are controlled. This system is lacking in administration of other retinoids and has potentially important consequences.

Most other retinoids such as tretinoin, isotretinoin, etretinate, and acitretin are poorly absorbed from the gut (e.g., approximately 60% for acitretin even with food) except in the presence of food, particularly high fat containing food where absorption can exceed 90%. Retinoids are transported nonspecifically mostly bound to plasma proteins, principally albumin, and thus their potential tissue availability is limited only by their plasma levels. Once in plasma, tissue distribution of retinoids is widespread but their specific local utilization and eventual biological activities and toxic consequences are highly complex processes, regulated by a number of factors, which will be subsequently elaborated.

26.4 PHARMACOKINETICS

A wide range in several pharmacokinetic parameters is encountered with therapeutic dosing of retinoids due to their inherently poor and variable bioavailability manifested by intrasubject variability and probable genetic differences manifesting as intersubject variability.

Mean plasma levels of endogenous retinoids are generally in the low single-digit or subnanogram range but can be elevated after high dietary intake of vitamin A equivalents or vitamin A containing food especially liver.[4] All therapeutic regimens with most retinoids produce plasma levels 10 to several hundred-fold than the endogenous levels.

All-trans retinoic acid is variably absorbed and its bioavailability is enhanced with concomitant food intake. Time to maximal plasma concentrations of tRA is 1–2 h and elimination is also rapid with a $T_{1/2}$ of 40–60 min. In several

studies of doses of 45–80 mg/m^2/day, AUC ranged from 387 μg/L/h to 682 μg/L/h.[5]

Isotretinoin is absorbed best when administered with food. A single 80 mg oral dose results in mean maximum blood concentrations of 256 ng/mL with a range of 167–459 ng/mL demonstrating high intersubject variability at a mean of 3.2 h with a similar variable range of 1–6 h.[6] These levels are 100–500-fold higher than mean endogenous levels of 13cRA. The major metabolite of 13cRA is 4-oxo-isotretinoin, where concentrations are 87–399 ng/mL at 6–20 h. Isomerization to the trans isomer also occurs resulting in significant levels of tRA. The parent compound (mean steady state 160 ng/mL) and metabolites are primarily bound to albumin in the circulation. The terminal elimination half-life of isotretinoin is 10–20 h and that of the 4-oxo metabolite is 17–50 h. Thus in spite of roughly equivalent plasma concentrations, there is a pronounced (up to 20-fold) difference in elimination of tRA or 13cRA. This results in a large pool of nonspecifically bound and potentially toxic 13cRA, tRA, and several of their active metabolites and isomers in plasma even at trough levels between daily doses.

Acitretin is also best absorbed in the presence of food, and after oral administration of a 50 mg dose it obtains maximal plasma concentrations in 2–5 h (mean 2.7 h) of 196–728 ng/mL (mean 416 ng/mL).[7] Metabolism and interconversion by isomerization of acitretin mainly to 13-*cis*-acitretin is followed by chain shortening and conjugations to water-soluble compounds eliminated via hepatic and renal excretion. The half-life of acitretin has been determined to be 33–96 h but for 13-*cis*-acitretin 35–148 hours. Furthermore, acitretin metabolism and elimination are significantly altered in the presence of alcohol that results in back conversion of acitretin to its parent acid form etretinate, a compound which has a very prolonged half-life of 84–168 days.

At least two conclusions can be drawn from these data: one, that the half-lives of these compounds demonstrate great disparity from a few hours to days to weeks and months; and second, that in the therapeutic dosing regimens usually employed, extremely high drug levels are maintained, which are up to several hundred-fold higher than usual endogenous and tightly controlled plasma levels. Thus these aspects may be considered to contribute to the overall toxicological profiles.

26.5 RETINOID METABOLISM

Metabolism generally, but not always, is a path to less therapeutically active and more water-soluble compounds that may be excreted in urine or bile. In the case of retinoids with side chains, changes in conformation due to isomerization may also occur spontaneously or as a result of enzymatic action, producing at times a somewhat confusing picture of still active metabolites and active stereoisomers. Studies of tRA, 13cRA, 9cRA, and their 4-oxo and other metabolites demonstrated that not only did many parent compounds and metabolites have substantial but relative binding affinities, but also that they were active in various cell culture assays with similar efficacy.[8] This has also recently been well demonstrated for

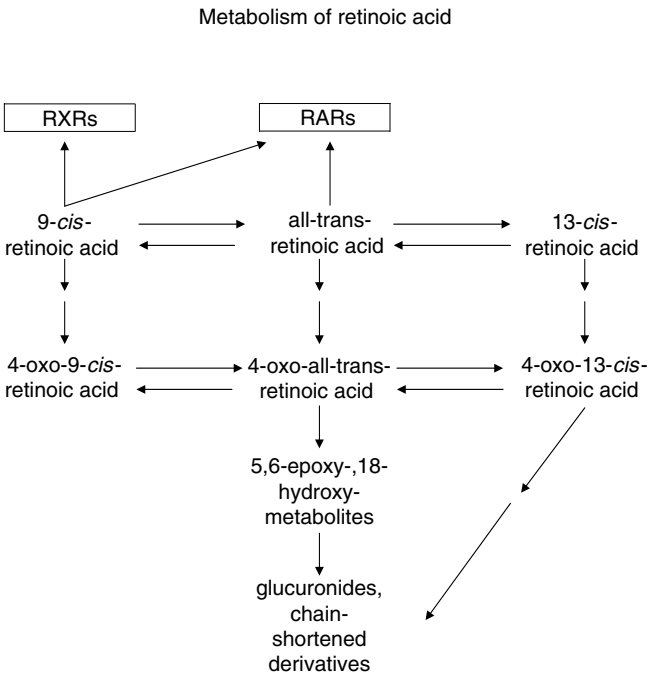

FIGURE 26.2 Metabolism of retinoic acid.

tRA, 13cRA, 9cRA, and their 4-oxo metabolites utilizing microarray and proteomic analyses that demonstrated substantial biological effect for the 4-oxo metabolites.[9]

Metabolism of the naturally occurring retinoids involves the successive hydroxylation, then oxidation of various parts of the molecule, followed by its glucuronidation to more water-soluble compounds that can be excreted in bile and urine (Figure 26.2). The principal enzymes of RA metabolism are cytochrome P450 enzymes *Cyp26A1*, *Cyp26B1*, and *Cyp26C1* that oxidize RA to more polar metabolites such as 4-oxo-RA, 4-OH-RA, and 18-OH-RA.[10] The gene for Cyp26A1 contains two functional retinoic acid receptor elements (RAREs) believed to contribute to its RA inducibilty, a factor particularly important in the developing embryo where RA synthesis and catabolism are tightly and reciprocally regulated. During midgestation *Cyp26A1* is expressed in the tailbud neuroepithelium and cervical mesenchyme; *Cyp26B1* is present in the hindbrain, branchial arches, and limb bud; and *Cyp26C1* is transiently expressed in the hindbrain.[11] There is a complimentary expression of these enzymes with retinaldehyde dehydroxigenase (RALDH) that is responsible for the locally restricted RA levels in the embryo.

26.6 BIOLOGICAL ACTIONS OF RETINOIDS

Naturally occurring retinoids are substrates for a number of enzymes, including those involved in their local synthesis for specific tissue needs and their local and systemic metabolic degradation. Enzyme interaction is particularly relevant in the eye's utilization of 11cRAL as a ligand of opsin to form rhodopsin, and where this synthesis of 11cRAL by

retinol dehydrogenase is a crucial step yet a possible site for interaction with other retinoids will be discussed later. The most interesting, relevant, and elucidated aspects of retinoid biology, however, involve retinoic acid's several interactions in the complex, redundant, highly regulated cellular control systems, particularly encompassing the signal transduction and nuclear transcription pathways of the cell.

Cellular homeostasis, function, and replication are regulated by integration of a combination of multiple influences including the cell's surrounding extracellular milieu, external signals such as growth factors, hormones, and cytokines, many mediated through signal transduction pathways, and of internal genetic pathways mediated by nuclear transcription. These pathways are complex, frequently highly redundant, tightly regulated, highly integrated, and reciprocally related and interactive with each other.

26.6.1 Retinoid Receptors and Gene Interactions

Retinoids act principally as ligands for two families of nuclear receptors, the (RAR), and its isotypes α, β, and γ and multiple isoforms and the retinoid X receptor, RXR, and its three isotypes α, β, and γ and their isoforms.[12] Retinoid receptors are members of the superfamily of nuclear receptors, which includes the receptors thyroid (TR), glucocorticoid (GR), androgen (AR), vitamin D (VDR), and peroxisome-proliferator-activated (PPAR) with which the RXR receptors can heterodimerize.

Nuclear receptors with their attached ligands function as transcription regulators of genes and bind to specific parts of the gene, a so-called response element usually of the promoter region (RARE). Transactivation of retinoid responsive genes is accomplished through an interaction of a heterodimer of RAR/RXR and its binding to the RARE, accompanied by ligand binding of tRA to the RAR ligand-binding domain (LBD), and an interaction of this complex bound to the RARE of the promoter with additional other so-called transcription factors, which include small proteins, phosphorylating kinases, and other molecules generated in the signal transduction pathway. Recent evidence has indicated that nuclear receptors may also bind in other ways to regions of genes and act with other transcription factors to transrepress, instances of which involve retinoids and will be discussed later.

Retinoid receptors demonstrate the same conserved modular structure as other nuclear receptors of the superfamily and similarly their amino acid sequences have been divided into regions A–F, each region being related to a different aspect of their functionality.[10] The central C region is the DNA binding domain (DBD) containing sequences of amino acids, which can bind to a RARE. The E region contains the LBD, as well as a transcriptional activation function, AF-2, and a dimerization surface for complexing with other nuclear receptors. The D region or hinge allows conformational change, a particularly important aspect of receptor function because of the exceedingly complex and conformationally restricted interactions of these various elements with the appropriate areas of the gene. The amino terminal end A/B regions contain a second transcriptional activation function termed AF-1.

RAREs are polymorphic, composed of hexameric motifs of the various combinations of nucleotides, and usually located in the regulatory area of the gene. The motifs are spaced most frequently by a 5 base pair (BP) or a 1 or 2 BP spacer. This polymorphism combined with the number of possible combinations of RAR and RXR isotopes and isoforms allows a large number of possible gene interactions and thus transactivation outcomes. The presence of a RARE does not always indicate RA responsiveness under physiologic conditions; however, a caveat, which is also very important, may apply to the many *in vitro* and gene transfection experiments where these genes may be vastly overexpressed.

The RARE is the primary site of interaction of the RAR/RXR heterodimer, which appears to be the preferred configuration of the two receptors and is the functional unit that transduces the retinoid signal *in vitro*. RAR or RXR can also form homodimers but these do not appear to be as important in most systems. RXR, however, can form heterodimers with large other nuclear receptors including GR, TR, VDR, PPAR, etc.; and these interactions may be important *in vivo*.

The most important natural ligand of RAR is tRA and this is overall the most important interaction physiologically. Although 9cRA also can bind RAR, a physiological importance has yet to be demonstrated for this ligand. Only 9cRA is a natural ligand of RXR but again, this binding has not been proven to be of significance *in vivo*. A very large number of other naturally occurring and synthetic retinoids can bind RAR with widely varying affinities, but the affinity of binding is not always related to the degree of its agonist or antagonist activities, the findings of which may be relevant to discussions of 13cRA. Interestingly, ligand binding of the RAR of the heterodimer RAR/RXR is determining for transactivation, but RXR need not always be liganded under physiological conditions and thus has been termed a transcriptionally active and silent partner in these circumstances. RXR heterodimerization with the TR, GR, etc. also follow this pattern of RXR being sometimes liganded and sometimes unliganded. In any case, the very presence of RXR confers specifics of conformation to all of these heterodimers and these allosteric effects may impact not only RARE binding but also binding of other transcription factors, which require their own space and positioning on the entire transcription complex.

In addition to the importance of the overall conformation of the RAR/RXR heterodimer in its binding to the RARE by its DBD and the possible conformational and other changes induced by liganding the LBD, the two activating function domains of the RAR or RXR also play an important role in the transcription machinery. AF-1 of the amino terminal A/B region is ligand-independent in its contribution but AF-2 is a receptor type-specific area of the LBD and thus is ligand specific. These two domains have varying amino acid sequences depending on the isotype of the receptor and act synergistically with each other and with other nuclear proteins called

transcriptional intermediary factors (TIFS), also called mediators or coactivators as part of the overall transcriptional machinery. There is evidence that autonomous transactivation that occurs in the absence of ligand could be related to an activating domain (AF-2 AD) in region E, the LBD.[10] Finally, the discovery of many putative coactivators that may react differently with various LBDs of the many isotopes and isoforms of the retinoid receptors further increases the possible combinations and permutations of diversity of transcriptional response to signals from retinoid liganding of receptors.

Transactivation does not appear to be the sole manifestation of retinoid signaling, however, as much evidence has been generated in the past decades indicating that retinoid signaling can also result in transrepression of genes. The mechanisms of transrepression have not been completely elucidated but it has been demonstrated that in transfected cells, RAR in the absence of its ligand can transrepress the basal level of promoter activity of target genes and that this is associated with an interaction of part of the LBD of RAR with a number of nuclear proteins that function as corepressors. Transrepression of the gene for AP-1, activating protein, by RAR was demonstrated in cultures of HeLa cells and to involve glycogen synthase kinase activation, negative regulation of junD hyperphosphorylation, and decreased RNA polymerase II recruitment. The investigators conclude that transrepressive effects of retinoids involve the RAR-dependent control of transcription factors and cofactor assembly on AP-1 regulated promoters.

As activation of the AP-1 complex is regulated through several of the mitogen-activated protein kinase (MAPK) signal transduction pathways described later, it is a clear demonstration of the cross talk or modulation now known to occur between signal transduction and nuclear signaling pathways. The complex structure of retinoid receptors and the marked allosteric changes induced in them by ligand binding help to explain the many possible interactions with the promoter of the gene and the many coactivators and corepressors of its transcription that are known to be functionally important.

Regulation of retinoid signaling is a complete feedback loop under precise systemic and local tissue control. RA induces its own receptor RAR and its own synthesizing RALDH and metabolizing CYP 450 enzymes. Finally, the ultimate regulation of retinoid signaling takes place after transcription when the ligand is released and the RAR is degraded via the ubiquitin/proteosome pathways. Agonistic ligands convert RARγ into a strong transcriptional activator. Concomitantly, RARγ is degraded by the ubiquitin-proteosome pathway.[13–17]

In 2002, over 532 genes had been proposed to have some degree of regulatory control by retinoids.[18] In this review of 1191 reports in the literature, 27 genes were classified as direct targets of retinoid control and another 105 genes were candidates pending additional confirmatory investigation. In a recent study of acne lesions, 211 genes were found to be upregulated, including those known to be associated with inflammation and scarring and several known to be retinoid sensitive.[19] These studies indicate the likelihood of an overall importance of these ligands in gene regulation of biological processes. In the sections that follow, the specific and critical nature of a few of these genes involved in embryologic development and epidermal differentiation will be presented. It is intuitive that perturbation of these pathways by administration of excessive natural or synthetic ligands may have significant consequences and manifest as toxicity.

26.6.2 Cell Signaling–Signal Transduction

The integration of internal and external cellular events is mediated primarily through a large number of transmembrane proteins serving in some cases as regulated conduits as in calcium and sodium channels, as facilitators of drug or molecule transport through the plasma membrane as the g-protein coupled receptors (GPCR), and as signaling moieties as in membrane receptors of signal transduction that are widely utilized by the immune and other cellular control systems.

Signal transduction is essentially a system of pathways by which an external stimulus to a cell is received, interpreted, or translated into a message by a membrane protein, then transduced through multiple second messengers in cytoplasmic pathways involving phosphorylations and dephosphorylations by protein kinases and phosphatases, and ultimately, by generation of a number of different transcriptional mediators that interact with nuclear receptors to transactivate appropriate genes. The stimuli are as diverse as exposure to light, (as in the g-protein coupled receptor, GPCR, signaling of rhodopsin), exposure to growth factors, hormones and drugs, or events of immune system functioning. The mechanisms by which the translation and transduction occur are frequently interactive (cross talk), redundant, utilized by diverse stimuli, and reciprocal with nuclear signaling pathways.

The signal transduction pathway is too complex to describe here in detail but a conceptual overview applicable in general to cell signaling will be helpful in understanding the complexities of retinoid action. Membrane receptors are generally complex proteins composed of an extracellular domain that is an LBD, a transmembrane domain sometimes of considerable complexity, and a cytoplasmic domain that activates protein tyrosine kinases that are either an intrinsic part of its cytoplasmic domain and that can self-phosphorylate or that bind with and are phosphorylated by cytoplasmic receptor–associated tyrosine kinases. Phosphorylation has several important aspects: it results in activation of the molecule, particularly important for enzymes; it results in conformational change that allows recruitment and attachment of other signaling proteins; it is quickly accomplished enzymatically through high-energy adenosine triphosphate (ATP) or guanosine triphosphate (GTP); and it is rapidly reversible. The initial signaling protein is frequently the enzyme phospholipase C-gamma (PLC-gamma), which after phosphorylation in this membrane process is activated and cleaves the membrane phospholipid phosphatidylinositol biphosphate (PIP_2) into two parts, inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 acts with its receptor in the endoplasmic reticulum to cause the release of Ca^{2+} into the cytosol elevating intracellular free Ca^{2+} several fold, and

triggering the opening of Ca channels allowing more Ca into the cell and sustaining the signal. DAG also participates in the activation of members of the PKC family. Finally, as part of this initial signal generation, adaptor proteins that mediate protein–protein interactions through their SH2 and SH3 domains facilitate binding of phosphotyrosine residues and proline-rich regions in this initial signaling complex of multiple proteins and other molecules.

Propagation of the signal thus generated from the tyrosine kinase–associated receptor next activates a class of small GTP-binding proteins (small G proteins), the best-known example of which is the *Ras* oncogene protein product Ras. The small G proteins exist as inactive GDP-bound forms and active GTP-bound forms the activation being mediated by guanine-nucleotide exchange factors (GEFs) that exchange GDP for GTP. The active G-proteins, as a source of high-energy phosphate through their GTP, participate in the activation of the subsequent cascade of successive phosphorylations of the MAPK cascade that result in phosphorylation and activation of transcription factors such as AP1 in the nucleus. MAPK consists of at least 10 different families, 2 of which, extracellular signal-related kinases 1 and 2 (ERK1 and -2), are activated through growth factor receptors and by phorbol esters such as TPA, the overall pathway being designated as $MAPK^{ERK}$. A related module is termed $MAPK^{JNK}$ where the kinase is a jun *N*-terminal kinase. This pathway is activated by many stress stimuli including UV (ultraviolet) light, osmotic stress, and proinflammatory cytokines such as TNF and IL-1. Stressful stimuli and proinflammatory cytokines can also active the $MAPK^{p38}$ pathway.

A classic example of transcription factors, the AP-1 family is composed of various combinations of jun (c-jun, junB, and junD) and fos (c-fos, fosB, fra1, and fra2) proteins that are themselves products of the proto-oncogenes *jun* and *fos*. These transcription factors are important participants in the nuclear events that result in gene transactivation and transrepression. Retinoid signaling may be involved in both of these processes.

Many details of this generic signal transduction pathway have been omitted in this brief overview and many important variants of signal transduction pathways have not been discussed but most pathways follow this general paradigm. As some of these additional components are relevant to retinoid activity they will be discussed specifically in that context.

Some signal transduction pathways are enhanced by retinoids, an example being induction of IL-8 production accompanied by enhanced IL-8 mRNA expression in cultured human keratinocytes treated with 10^{-7} M tRA.[20] Increased expression of NFkB was accompanied by increased expression levels of its constituents p65, RelB, p52, and p50, increased DNA-binding of p65, and phosphoylation of IkB, the inhibitor of NFkB activation. As the IL-8 gene does not contain a classical RARE, it was concluded that the action of this retinoid is mediated through these secondary events described rather than through transactivation. IL-8 is an inflammatory cytokine that could play a role in the skin irritation observed during topical retinoid treatment.

A number of signaling pathways are operative in keratinocytes including different receptors and signaling pathways of signal transduction utilized by IL-1, TNF-α, or TGF-α, which while varying in their specifics of receptor type; specific kinases employed; and signaling proteins involved; all achieve in the end, one or more transcription factors such as AP-1 and NFkB.[21]

In some circumstances, retinoids oppose the direction of signal transduction, a good example being the frequently reported inhibition of AP-1 activation. This opposition to the direction of signal transduction may also be important to keep in mind when interpreting *in vitro* results where signal transduction is lacking and retinoid signaling is therefore unopposed.[22] These aspects will be further discussed in relation to effects of retinoids on skin.

Inhibition of the metaloproteinases (MMPs), collagenase, gelatinase, and stromelysin has been demonstrated after pretreatment of skin with topical tRA prior to UV irradiation and is mediated by repression of AP-1 activity through inhibition of its c-jun component.[23,24]

26.6.3 Apoptosis

Apoptosis is a pathway of cell death that is induced by a tightly regulated intracellular program in which cells destined to die activate enzymes (including caspases) that degrade the cell's own nuclear DNA and cytoplasmic proteins.[25] Although its structure is sufficiently altered to make it a target of phagocytosis, the cell's plasma membrane remains intact without sufficient leakage of cellular contents to provoke inflammation. The process occurs in skin, the "sunburn cell" of the epidermis being well described as an apoptotic cell resulting from irreparable UV damage, but it occurs in many other circumstances and organs. Retinoids can induce apoptosis in many *in vivo* and *in vitro* circumstances including keratinocyte cultures and skin equivalents.[26,27] In keratinocyte cultures and skin equivalents exposed to UV, tRA strongly increased the mRNA and protein expression of p53 and caspase-3, -6, -7, and -9, which are important regulators of apoptosis.[28] In cell cultures of CTCL lines MJ, Hut78, and HH, bexarotene induced apoptosis in a dose-dependant manner as demonstrated by activation of caspase-3, decreased levels of survivin, and cleavage of poly(ADP-ribose) polymerase without effect on expression of Fas/Fas ligand.[29]

26.7 RETINOIDS IN SKIN

There has been extensive research in the past few decades investigating the specific outcomes and mechanisms of retinoid effects. Skin biology has progressed in that same time frame and revealed a complexity that has been exhilarating yet at times frustrating when specific mechanisms of action such as that of retinoids were sought. One of the most confusing aspects of retinoid biology was the frequent and very differing results of *in vitro* and *in vivo* investigation, particularly when tumor cell lines or immortalized lines were studied or even normal human keratinocytes were cultured under

different conditions or exposed to high or low concentrations of retinoids.

Retinoids are normally involved in several regulatory pathways that involve the homeostasis, growth, and differentiation of keratinocytes and some functions of fibroblasts. As in other systems, most if not all of the actions of retinoids in the skin can be traced to their functions as ligands for their retinoid receptors. The principal retinoid receptors in the skin are RARγ and RXRα, which, as elsewhere, form heterodimers in their binding to RARE. The recent study of acne cited earlier revealed 211 genes that were upregulated in acne lesions, many of which are known to be regulated or influenced by retinoids. This gives one an idea of the potential scope of retinoid action in the skin and in many of these instances, RARE have been identified and the gene sequenced, manipulated by transfection, or mutated and knocked out in mice, providing an enormous database to be digested and understood.

In vivo, retinoids primarily produce epithelial hyperproliferation that can be demonstrated histologically by a thickened epidermis, acanthosis, more space surrounding keratinocytes and fewer desmosomes, hypergranulosis, and a thinner and more compact stratum corneum.[30] These aspects are mirrored ultrastructurally by fewer desmosomes, decreased tonofilaments, enhanced keratinocyte autolysis, and intercellular deposition of glycoconjugates that one group has demonstrated to be hyaluronate.[31–33] Clinically the skin manifests erythema; scaling; a loosened stratum corneum; a tendency for dysadhesion; and by instrumental techniques, increased transepidermal water loss.[34]

Numerous investigations utilizing human epidermal cells or neoplastic epidermal cells in culture have demonstrated that multiple markers of epidermal differentiation such as keratin, involucrin, and loricrin, expression are altered and have concluded that retinoids primarily effect differentiation. In human skin *in vivo*, however, it has been repeatedly demonstrated that the primary effect of retinoid treatment is hyperproliferation. Chronic application of topical tRA to photodamaged human skin demonstrated epidermal thickening (25 of 25 samples), stratum granulosum thickening (15 of 25), parakeratosis (13 of 25), a marked increase in the number of cell layers expressing transglutaminase (13 of 25), and focal expression of keratin 6 (12 of 25), and keratin 13 (8 of 25). Three major differentiation products keratins K1, K10, and K14 were not altered.[35] Essential confirmation of these results in biopsies of buttock skin of normal volunteers treated with topical tRA again demonstrated that hyperproliferation is the primary effect of topical retinoid treatment and that markers of differentiation such as keratin, involucrin, and filaggrin do not substantiate primary differentiation effects.[36]

Proliferation of skin can be caused by many external stimuli but while the specific mechanisms may vary, it appears that signal transduction pathways are involved in most instances. Epidermal proliferation as a result of injury or stress may involve cytokine stimuli such as IL-1 or TNF-α, each acting via differing yet cross-modulating signal transduction pathways. One of the most important and common initiators of epidermal proliferation is epidermal growth factor (EGF), an autocrine and paracrine ligand for the family of keratinocyte receptors EGFR. This important mitogenic pathway can be initiated by a number of related growth factors including the ligands EGF; TGF-α; amphiregulin (AR); and heparin-binding EGF (HB-EGF). This is a typical signal transduction pathway involving ras as an intermediate protein and ERKs as kinases.

Very convincing evidence has recently been put forth demonstrating that the proliferation of skin observed with retinoid treatment is related to the induction of ligands HB-EGF and AR and their subsequent effects on keratinocyte proliferation via this signal transduction pathway.[34,37] Demonstration that mRNA levels for HB-EGF and AR were several-fold increased in skin treated with topical tRA was confirmed by increased protein levels of AR in human skin and increased processed forms of AR and HB-EGF proteins in skin organ cultures (the investigators were unable to reliably extract HB-EGF from skin samples). Confirmation that signal transduction is involved was demonstrated by a 2.5-fold increase in ERK1/2 phosphorylation compared to vehicle. Blocking EGFR kinase activity by the inhibitor genistein reduced epidermal cell growth. These results are very convincing of a retinoid-EGFR signal transduction pathway link but do not further elucidate the mechanism of action of the retinoid. As no putative RA response elements have yet been demonstrated for the gene for HB-EGF, alternate mechanisms than gene transactivation may be operative.[38] Some of the observations of putative retinoid action in signal transduction pathways discussed earlier may be relevant.

Profound suppression of sebum has been presumed to be one of the principle actions by which 13cRA exerts its therapeutic effect on acne but the mechanism of sebum suppression remained undetermined. Utilizing immortalized SEB-1 sebocytes, recent work has demonstrated that 13cRA but not 9cRA or tRA inhibits growth and induces apoptosis, and these effects are accompanied by decreased DNA synthesis, an increase by 2.64-fold in the expression of the cell cycle inhibitor p21, and a 3.58-fold increase in cleaved caspase3 in sebocyctes.[39]

The mechanism of hair loss during retinoid therapy had likewise remained unclear but a recent report may provide some clarity. Human scalp hair follicles (HF) grown in culture and treated with 10^{-8} or 10^{-10} M tRA demonstrated that at day six, 80% had prematurely entered catagen compared to the control group.[40] An upregulation of apoptotic and a downregulation of Ki67 positive cells were noted in tRA-treated HF. Significant upregulation of TGF-β2 was observed in anagen HF in the dermal papilla and the dermal sheath. As TGF-β2 has demonstrated capacity to stimulate keratinocyte apoptosis, it may contribute to the mechanism of hair loss.[41]

26.8 RETINOIDS IN THE VISUAL SYSTEM

Normal vision is highly dependant on the availability and conversion of retinol to 11-cis-retinal, 11cRAL and the interaction of 11cRAL with opsin to form the light-sensitive GPCP,

g protein coupled receptor rhodopsin utilized particularly by the rods of the retina in low light conditions.[42] Only retinol and not retinoic acid can be converted to 11cRAL in this system and a deficiency of retinol results in impairment of night vision of varying severity depending on degree and duration of deficiency. Dietary tROL is isomerized in the eye to 11cROL that in turn is converted to 11cRAL by dehydrogenase enzymes.

Exposure of rhodopsin to light results in isomerization of the chromophore 11cRAL to 11tRAL and generation of an action potential-like signal (phototransduction) that is amplified and propagated in the retina, conveyed via the optic nerve and interpreted by the brain as vision. After the dissociation of 11tRAL it is isomerized back to 11cRAL, which is then again available as a ligand for opsin to again generate rhodopsin. As these reactions occur very rapidly in microseconds to seconds, a sufficient source of 11cRAL must always be available to enable rhodopsin formation and thus normal rod vision in low light conditions.

A number of retinoids including 13cRA have been reported to be associated with decrease in night vision. Night vision decrease in three of 50 patients receiving 13cRA at a dose of 1 mg/kg/day was accompanied by abnormal dark adaptation curves in two patients, abnormal ERKs in two patients and a mildly abnormal electrooculogram in one patient.[43]

It has been demonstrated that tRA and 13cRA inhibit ocular retinol dehydrogenases *in vitro* in an amphibian system hindering formation of 11cRAL from its 11cROL precursor.[44] Inhibition of the isomerases involved in the isomerization of all-trans retinal to 11-*cis*-retinal was not, however, observed in this system. No impairment of rod function was demonstrable by electroretinography, ERK in rats treated with 13cRA but regeneration of rhodopsin was slowed 50-fold. The experimental findings were consistent with 13cRA inhibition of the retinoid isomerase and of the 11-*cis*-retinol dehydrogenase.[45] The experimental conditions did not allow a determination of whether competitive enzyme inhibition or other mechanisms were operative however.

Photoreceptor-specific retinol dehydrogenase (prRDH) catalyses reduction of all-trans-retinal to all-trans-retinol and prRDH knock-out mice ($prRDH^{-/-}$) demonstrated delayed recovery of rod function on ERK demonstrating the importance of this enzyme system for rod recovery.[46] Demonstration *in vitro* and *in vivo* of the capacity of positively charged retinoids to inhibit isomerization in the retinoid cycle of retinal pigmented epithelium was further refined in additional work by the same group that indicated competitive inhibition of lecithin:retinol acyltransferase (LRAT), an enzyme that catalyzes the transfer of an acyl group from phosphatidylcholine to all-trans-retinol, thus interfering with an additional step in the retinoid cycle that must quickly regenerate 11cRAL, the ligand for opsin.[47,48]

Taken together, the evidence suggests retinoid interference in rod recovery, by their possible inhibition of a number of enzymatic steps in the generation of 11cRAL. Further evidence of this type of inhibition in other systems is that tRA and a number of synthetic retinoids have been demonstrated to be classical competitive enzyme inhibitors for the enzyme ribonuclease P (RNase P) in keratinocytes.[49]

26.9 RETINOIDS IN LIPID METABOLISM

Dyslipidemias are frequently observed during retinoid therapy. Although the true toxicity of dyslipidemias is not the elevation or decrease of specific lipids *per se*, but rather the long-term consequences of the perturbation measured primarily by cardiovascular pathology, in no other of the retinoid toxicities is the undesirable effect as easily quantitated in frequency and magnitude as in that of abnormalities of lipid metabolism. Furthermore, there is in these a single end point easily measured by a simple blood test, a large clinical population already studied for the perturbation and to some extent the long-term effect, and importantly a significant degree of understanding of the cellular and subcellular initiating activities. This may be the optimal paradigm for retinoid toxicity with potential application to the understanding of other retinoid toxic manifestations.

Dietary lipids and those synthesized in the liver (carrier proteins, enzymes, and apoproteins) interact in a highly complex system, which is substantially perturbed by therapeutic levels of retinoids. Dyslipidemia involving serum triglyceride elevations of over 800 mg/dL (as chylomicrons and very low density lipoprotein, (VLDL)), cholesterol elevations (as low density lipoprotein, (LDL)), and high density lipoprotein (HDL) decreases occurred in approximately 25, 7, and 15%, respectively, among young individuals treated for severe nodular acne with isotretinoin in standard therapeutic doses of 1 mg/kg/day.[50] Very similar incidences and severities are observed with etretinate or acitretin therapy in spite of the pronounced differences in structure, absorption, distribution, metabolism, and excretion (ADME), disease indication, and age and health of the treated populations.

Dietary lipids and endogenous lipids synthesized by the liver are carried in the blood and delivered to sites of utilization packaged in spherical structures (chylomicrons, VLDL, LDL, HDL) containing various combinations of triglycerides (TG), cholesterol, cholesterol esters, and phospholipids.[51] These structures also incorporate, as an essential component, one or more hepatic-synthesized apolipoproteins that function in various ways as structural components, ligands, cofactors for enzymatic reactions, or activators or inactivators of lipoprotein lipase (LPL).

26.9.1 TRIGLYCERIDES

Several enzymes are involved in lipid metabolism notably LPL, the major plasma lipolytic enzyme, which hydrolyses TG from chylomicrons and VLDL. Apolipoprotein C-III, apo C-III has several functions including the inhibition of LPL and possibly also inhibition of hepatic uptake of chylomicron and VLDL remnants. Most studies in humans do not demonstrate retinoid effects on LPL but substantial evidence indicates that retinoids may induce apo C-III gene expression. Increase in apo C-III also appears to inhibit the binding of TG-rich particles to endothelial surfaces. Thus direct effects

on the major catabolic enzyme of TG as well as inhibition of their uptake and thus utilization by target cells or metabolism by liver would contribute to the cause of elevations of TG.

Induction of apo C-III gene expression has been demonstrated in human hepatocytes and other cell systems and specificity for RXR agonists is demonstrated. Gene transcription of apo C-III is by a DR-1-like response element. It is further noted that several other nuclear receptors, such as TR and PPAR, may also have a role in regulation of the apo C-III gene at the same site, perhaps mediated by heterodimerization with RXR.

26.9.2 HDL

HDL attracts and carries cholesterol from cell membranes and delivers it for hepatic metabolism and excretion into the bile. HDL incorporate many apolipoproteins but apo A-1 is particularly important in its role in "reverse cholesterol transport," particularly, for example, in cholesterol removal from atherosclerotic lesion macrophages.

Although studies in many cell lines demonstrate a retinoid effect via receptor binding to the gene for apo A-I and apo A-II, in humans the levels of these apolipoproteins are not affected. Retinoids have demonstrated binding and activation at the specific response element for cholesteryl ester transfer protein (CETP) transcription. This plasma protein is involved in the exchange of cholesteryl esters for TG from HDL to VLDL and LDL. The explanation for decreases in HDL with retinoid therapy requires additional information but likely involves retinoid effects on specific gene response elements affecting the lipids, enzymes, or apolipoproteins involved with HDL.

26.10 RETINOIDS IN EMBRYOLOGIC DEVELOPMENT

Normal embryologic development is an extremely complicated and exquisitely regulated process in which retinoids, specifically tRA, play a critical role. Perturbation of this process by deficiency or excess tRA or excess agonistic retinoid or the wrong timing or placement of tRA's presence locally can lead to significant embryotoxicity ranging from minor developmental defects through major malformations, to embryolethality depending on the degree and timing of the perturbation. The active ligand in normal embryologic development is tRA whose local synthesis, metabolism, nuclear receptor, and gene transactivation are tightly regulated and which factors in turn determine the dose, timing, and the specific localization of ligand available for receptor binding and transactivation of appropriate genes.

Nearly all that is detailed in the preceding text regarding synthesis, metabolism, pharmacokinetics, receptor-binding aspects, and signal transduction apply in some way to embryotoxicity and must be borne in mind in the background of the very specific events that take place during embryogenesis and that have been elaborated in some detail in the past two decades utilizing a highly sophisticated array of biochemical and genetic techniques.

Embryogenesis, by the very nature of its dynamic events from mitosis to organ development and anterior–posterior (AP), cephalo–caudal, and side-to-side orientation and patterning, must be strictly regulated by transactivation and transrepression of multiple interactive genes and by strict regulation of signal transduction and enzymatic pathways. Retinoic acid (RA), sonic hedgehog (Shh), and fibroblast growth factor (fbg) pathways appear to play important signaling roles in conjunction with the *Hox* genes of the Homeobox family, and with *Raldh* and *Cdx* genes. At least 39 murine hox genes in four clusters *Hoxa* to *Hoxd* have been described and four *Raldh* 1–4, and four *Cdx* 1–4. Other genes are undoubtedly involved but have not been as well characterized.

A number of experiments utilizing dietary manipulation and gene knock-out mutants such as *Raldh2*$^{-/-}$ have elucidated the role of tRA in early development. Maternally supplied retinol is converted to tRA in the developing embryo. tRA is synthesized in the embryonic paraxial mesoderm by retinal dehydrogenase 2 (Raldh2/Aldh1a2) and induces *Hox* expression in the adjacent neural tube. RA concentration is spatiotemporally regulated by this local synthesis, and by local inactivation by cytochrome P450 enzymes. Disruption of the murine *Raldh2* gene precludes tRA synthesis and results in midgestational lethality accompanied by impairment of morphological segmentation throughout the hindbrain of *Raldh2*$^{-/-}$ embryos.[52] Additional RA-generating activities in the differentiating forebrain, hindbrain, and spinal cord are attributable to RALDH1 and RALDH3 enzymes, which may be operative in experiments of embryonic rescue from lethality by maternal administration of RA.[53]

RA-supplemented *Raldh2*$^{-/-}$ embryos exhibit impaired development of their posterior (third–sixth) branchial arch region and this affects the development of its derivatives including aortic arches, pouch-derived organs (thymus, parathyroid glands), and postotic neural crest cells that adversely affects the posterior (9th–12th) cranial nerves.[54] The embryonic heart tube of these animals forms properly but fails to undergo rightward looping and instead forms a medial distended cavity.[55] Embryonic RA synthesis is thus required for realization of heart looping, development of posterior chambers, and proper differentiation of ventricular cardiomyocytes. In mice, *Raldh3* knockout suppresses RA synthesis and causes malformations restricted to ocular and nasal regions.[56] The accumulated evidence thus suggests that there is some specificity as well as some overlap of functions of the various RALDH enzymes.

At, or shortly following, gastrulation, the unsegmented paraxial mesoderm begins to regionalize into segments that will eventually result in anterior–posterior patterning of neural, head and neck, vertebral, and cardiac structures. In the mouse, *Hox* expression is initiated at embryonic day

7.5 (E7.5) in the primitive streak and this expression is aligned in an AP direction in spatially restricted expression domains, sometimes termed a Hox code.[57] This spatiotemporal code is important in determining and enabling AP structural development as seen in the hindbrain, cranial nerves, vertebrae, heart, etc. An example relevant to development of all these structures is the observation that at least 11 Hox genes from paralogue groups 1–4 must be properly aligned at specific interfaces between rhombomeres to correctly pattern the normal repertoire of cell fates along the AP axis of the developing hindbrain.[58] *Rarb* is a direct transcriptional target of *Hoxb4*, thus this study identifies a new molecular link completing a feedback circuit between *Rarb*, *Hoxb4,* and *Hoxd4*. The timing of *Raldh2* expression and thus tRA synthesis correlates with Hox-inducing activity, and the segmental expression of this gene family is part of the process by which AP positional identity and final cell fate is determined. Although initiation of Hox gene expression is highly dependent on the signal from tRA, other transcription factors are likely to be involved in transactivation and all of these components must be present at the appropriate location, level, and timing for the correct outcome. RAREs have been characterized for *Hoxa1*, *Hoxb1*, *Hoxb4*, and *Hoxd4* that bind RAR/RXR heterodimers. Through a combination of biochemical, genetic, and transgenic techniques, it has been determined first, that *Rarb* uses a two-step transcriptional mechanism: induction by a mesodermal RA signal and maintenance by *Hoxb4* and *Hoxd4*; and second, that *Rarb* is a direct transcriptional target of *Hoxb4*. Transcriptional regulation between the Hox and RAR gene families is thus bidirectional. Furthermore, it was demonstrated that RA produced by the mesoderm is required to induce the early neural expression of *Rarb*. A complex genetic circuit has thus been described that involves direct and indirect interactions among *Rarb*, *Hoxb4*, and *Hoxd4* and that forms a transcriptional feedback circuit to maintain gene expression and to align the expression borders of multiple Hox and RAR genes at a segment boundary.

The Cdx family of genes has also been implicated in embryologic development and as regulators of Hox gene expression due to the evidence that murine *Cdx1*, *Cdx2*, and *Cdx4* are expressed in overlapping domains with Hox genes in the posterior embryo through E12.5 and that consensus Cdx response elements are found in the promoter regions of several Hox loci. Furthermore, RA was demonstrated to induce *Cdx1 in vivo*, and a RARE was determined thus demonstrating *Cdx1* to be a direct RA target.[59] As some Hox genes contain Cdx-binding motifs, these data also support a role for Cdx members in some Hox genes expression. Subsequent work by this group confirmed an autoregulatory loop for *Cdx1* expression and further demonstrated that in addition to response to retinoid signaling, there is an interaction with the Wnt signaling pathway. Wnt nuclear effectors lymphoid enhancer factor 1 (LEF1) and T-cell factor 1 (TCF1) were demonstrated to interact with the *Cdx1* promotor in association with Cdx to form a Cdx1-LEF1 transcription complex to mediate *Cdx* expression in presomitic mesoderm. Taken together, these data indicate that LEF1 and TCF1 are the principal mediators of *Cdx1* expression in the caudal embryo.

In recent experimentation, the three RARs display distinct expression patterns at day E8.5 with RARα strongly expressed in neuroectoderm and mesenchyme of the head region; RARγ strongly expressed in the tail region; and RARβ transcripts found in the trunk tissues and mesonephric duct. These investigators conclude that the primary target of RA-induced cranio-facial teratogenicity is the branchial arch endoderm and that it is mediated by RARβ/RXR heterodimers in which the activity of RXR is subordinated to that of RARβ.[60]

26.11 SUMMARY AND CONCLUSIONS

Retinoids are small ligands that have been demonstrated to produce biological, pharmacological, and toxicological effects via numerous mechanisms. They clearly and most importantly act as ligands for their nuclear receptors RAR and RXR and by this mechanism are involved in transactivation of a large number of genes, many of which are of documented importance in functioning and malfunctioning of skin, eye, and developing embryo. Through interactions with their receptors and signal transduction pathways they may also be involved in gene transrepression.

Retinoid action in vision is also ligand dependent, producing the signal interpreted by the brain as vision through 11cRAL liganded to opsin in the complex rhodopsin and acting as a GPCR in initiating the signal that is propagated by its unique signal transduction pathway to the optic nerve. The visual cycle also provides an additional putative mechanism of action for retinoids as competitive enzyme inhibitors in their inhibition of the isomerases and dehydrogenases involved in local generation of the ligand 11cRAL.

The role of retinoids in inducing apoptosis is likely of importance in therapeutic interventions for tumor treatment or prevention and perhaps in the developing embryo, and may be a further mechanism of action although fewer specifics for this role *in vivo* are available.

These diverse and somewhat disparate observations do not yet allow definition of a single or unified mechanism of biological action and toxicological effects for retinoids. One very simple fact, however, must always be kept in mind irrespective of the precise mechanism operative in any particular circumstances: retinoids administered in therapeutic doses will always result in sustained, high (up to several hundred-fold higher than any endogenous retinoid) plasma and probably tissue levels of potentially agonistic or antagonsitic ligands. It is probably not possible to adequately regulate these high sustained levels by systemic and local metabolism or normal feed back control mechanisms. In these circumstances, some degree of undesirable effects is with currently available retinoids, nearly a certain corollary of potent therapeutic effect.

27.1 INTRODUCTION

Adverse drug reactions involving the skin are a common problem but their real incidence is not known. Among inpatients 2–5% experience a cutaneous adverse drug reaction (CADR),[1,2] but although it is a frequent cause of consultation or urgent observation at a Dermatology department,[3] no precise data exist concerning its incidence in outpatients. Only 2% are severe reactions,[1] therefore most are not reported to the pharmacovigilance systems. Also, in some cases, the diagnosis of CADR is one of presumption, with no definitive test to prove it, or of exclusion for which the dermatologist has to be alert. Some CADR are mild and resolve spontaneously, others represent an exaggeration of the drug pharmacological effect, some are similar to viral exanthems or idiopatic urticaria, and others mimic skin diseases which are not usually drug-induced, namely pemphigus, bullous pemphigoid, lupus erythematosus, psoriasis, and lichen plannus.[1,3,4]

27.2 PATHOMECHANISMS IN CUTANEOUS ADVERSE DRUG REACTIONS

27.2.1 Immune and Nonimmune Mechanisms Involved in CADR

Most CADR are certainly not immune mediated, representing a pharmacological drug effect often exaggerated due to drug interactions, concomitant diseases that modify drug bioavailability, or predisposing genetic polymorphisms of drug detoxifying enzymes. As an example, skin and oral mucosa erosions can occur during metothrexate treatment in patients with low serum albumin, low renal clearance, or on concomitant use of nonsteroidal antiinflammatory drugs (NSAID). These predictable reactions, called type A, may represent up to 80% of CADR[4] and are not the object of this chapter.

Unpredictable, idiosyncratic CADR, called type B, namely drug "rashes" or "drug eruptions," are those mostly dependent on immune hypersensitivity reactions. CADR upon systemic drug exposure include a wide variety of skin reaction patterns occurring either immediately upon exposure or with a delay of hours, days, sometimes after weeks, or months of drug administration, depending on the hypersensitivity mechanisms involved and whether the individual is already sensitized or not. The pathogenic mechanisms involved are not usually simple and include a complex interplay of different effectors of the immune system, which orchestrate the immuno-inflammatory skin reaction in a still not yet fully understood way.[1,4]

The four classical mechanisms of immune hypersensitivity defined by Gell and Coombs participate in CADR. Immediate type I hypersensitivity from drug-specific IgE is involved in acute urticaria and anaphylaxis, type II antibody-mediated cytotoxicity is reported in drug-induced hemolytic anemia and drug-induced immune complexes can be deposited in small cutaneous vessels inducing leukocytoclastic

vasculitis, representing a type III reaction.[4] Delayed type IV hypersensitivity involving T cells that specifically recognize the drug (or a drug metabolite) has been well documented namely in generalized maculopapular exanthema (MPE), in the drug-induced hypersensitivity syndrome (DIHS) also known as DRESS (drug-induced rash with eosinophilia and systemic symptoms), in acute generalized exanthematic pustulosis (AGEP), in fixed drug eruption (FDE), and in the more widespread and severe Stevens–Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN).[4–6] For each of these different clinical and histological patterns, delayed hypersensitivity is involved through different subsets of T cells and soluble effectors that recruit a wide range of other cells and orchestrate the inflammatory response, inducing lesions that affect only the skin or, eventually, also other organs.[5]

Topical drugs cause allergic contact dermatitis, a typical T-cell mediated reaction, which can become widespread simulating a drug eruption due to percutaneous drug absorption.[6,7] Also, systemic exposure to drugs to which patients were previously sensitized through the skin can induce systemic contact dermatitis,[8] presenting as a "baboon syndrome" also known as SDRIFE (symmetrical drug-related intertriginous and flexural exanthema)[9] or an acrovesicular dermatitis.[6,8]

Photo-active drugs, either upon topical or systemic exposure, can induce a photosensitive eruption on sun-exposed areas, due to a phototoxic or a photoallergic mechanism, in this case dependent on a type IV hypersensitivity reaction to the drug or a photoproduct. One such example is piroxicam, an NSAID which upon UVA exposure gives rise to a photoproduct chemically and antigenically similar to the thiosalicylate moiety of thiomersal, and, therefore, induces photoallergy in individuals previously sensitized to thiomersal.[10,11]

In some cases, the drug modifies the immune response promoting autoimmunity or induces the production of pathogenic antibodies directed against skin structures, as in vancomycin-induced linear IgA dermatitis,[12] in drug-induced pemphigus, and in terbinafine-induced subacute lupus erythematosus. Sometimes autoantibodies are found during the eruption but their pathogenic significance is not known, as in a case of DRESS with antibodies against the 190 kDa antigen targeted usually in pemphigus foliaceus or paraneoplastic pemphigus.[13]

27.2.2 Drug Recognition by the Immune System and Skin Reaction Patterns

Apart from the wide list of drugs capable of inducing immune-mediated CADR, each drug can induce several skin reaction patterns and depending on the reaction pattern (and sometimes within the same reaction pattern), the antigenic moiety recognized by the immune system is different: the drug itself, an intermediate metabolite, both the drug and a metabolite, or proteins/peptides modified by reactive drugs or metabolites. Drugs can be specifically recognized by IgE in immediate hypersensitivity, by antibodies fixed on red blood cells inducing hemolytic anemia, by soluble antibodies inducing immune complex vasculitis, or by the TCR of T cells, both in the context of human leukocyte antigen (HLA) class-I or class-II molecules and either covalently or non-covalently bound.[14,15] The problem is more complex as, for instance, in the case of MPE from cotrimoxazol. Some T-cell clones recognize sulfamethoxazole and other antiinfectious sulfonamides with a similar conformational structure, giving rise to cross-reactions,[16] whereas other T-cell clones recognize intermediate metabolites (hidroxilamine sulfamethoxazole or nitroso sulfamethoxazole,[15]) either presented directly in the HLA groove[14,15] or after antigen processing[14,16] with a more restricted cross-reactive pattern. In the case of immediate hypersensitivity to penicillin, IgE can recognize either the benzylpenicilloyl moiety or the side chain; therefore, recognizing by cross-reaction other penicillins or, eventually, also cephalosporins.[17,18] For piroxicam, the moiety recognized by the immune system depends on the reaction pattern. The thiosalicylate moiety, which is formed after UVA radiation, is responsible for the photoallergic reaction. As this photoproduct is exclusive for piroxicam, other oxicams like tenoxicam can be safely used in photoallergy. In FDE the immune system recognizes another oxicam moiety which is common to tenoxicam and, therefore, all patients with FDE to piroxicam cross react with tenoxicam.[10,11,19]

27.2.3 Concomitant and Predisposing Factors in Drug Eruptions

Even though we do not understand all the steps of sensitization to drugs and how some individuals become sensitized and develop CADR while others do not, there are few known predisposing factors.

One important aspect deals with the drug detoxification process where polymorphisms within drug metabolizing enzyme genes, namely in the cytochrome P_{450}, can give rise to different intermediate reactive (or nonreactive) drug metabolites or to distinct amounts of the culprit metabolite.[20,21] Some HLA haplotypes, which may be related to the capacity of the drug to combine or insert into the HLA groove of antigen presenting or target cells, have been associated with increased or reduced capacity to develop a drug eruption to a certain drug,[5] as shown for HLA-B*1502 predominance in patients from Twaian who develop SJS to carbamazepine.[22] Also, polymorphisms in immuno-inflammatory response pathways may increase the risk of some particular drug reactions: predisposition to produce higher levels of soluble FAS ligand and polymorphisms in the TNF-promoter region may correlate with an increased severity of drug reactions,[5,22] disturbances in complement and cinin metabolism, namely in carboxypeptidase that degrades bradykinin, may favor angioedema induced by angiotensin conversing enzyme inhibitors (ACEI), and polymorphisms in the gene for LTC4 synthase may justify familial aggregation of aspirin-induced urticaria.[23]

Also, the immune status of the patient during drug exposure may be important for the outcome of the CADR. Concomitant aggressions (exposure to other reactive chemicals or other drugs), infectious diseases (bacterial or viral infections),

chronic immuno-inflammatory diseases (Still's disease, systemic lupus erythematosus), or nonspecific immune activation by reactive drug metabolites may act as "danger" signals that alert the innate immune system and activate monocyte/macrophages or dendritic cells that become increasingly capable of presenting the drug to T cells.[20,24] Therefore, these concurrent factors may be of extreme importance, especially during active drug sensitization, but also during the development of the CADR in a sensitized individual. As an example, patients with systemic lupus erythematosus or HIV+ patients are more susceptible to CADR, namely from sulfonamides.[15,24] During Epstein-Barr virus (EBV) or Cytomegalovirus (CMV) infection, antibiotics induce MPE in a high proportion of patients,[25,26] but even though aminopenicillins induce an MPE in almost every patient, only a few of these really become sensitized to the drug and develop a skin rash on re-exposure without the concomitant infection.[25–27] Also, during the last decades attention has been drawn to the association of the DIHS/DRESS with human herpes virus type 6 (HHV-6) primo-infection or reactivation.[26,28,29] Concomitant use of aminopenicillins and allopurinol also seem to represent a risk factor for developing CADR.[25,30]

Nevertheless, and apart from these difficulties and variables that complicate the study of pathomechanisms involved in CADR, immediate and delayed skin testing, drug rechallenge, and *in vitro* studies using drug-specific antibodies or drug-specific T cell clones isolated from the blood and skin of patients with CADR or from positive skin tests, have brought new light into the immune mechanisms involved in CADR, which we will review for the main reaction patterns.

27.3 IMMEDIATE ADVERSE DRUG REACTIONS

These reactions occur within minutes to a few hours after drug exposure and present clinically as pruritus, urticaria, or angioedema regressing with no residual lesions within minutes to hours. In severe cases, urticaria and angioedema are associated with systemic symptoms like nausea, abdominal cramps, sneezing, bronchospasm, and dispnea that can progress to hypotension and shock in its most severe expression—anaphylaxis. The most severe acute immediate reactions are induced by beta-lactam antibiotics (pencillin G and aminopenicillins), iodinated radiocontrast media, and muscle relaxants used in anesthesia, whereas the more frequent but less severe immediate reactions are due to aspirin and NSAID, codein, vancomycin, ACEI, heparins, and insulin, but any drug can induce an immediate adverse reaction.[4,17,31] (Figure 27.1 shows an immediate reaction with urticaria and angioedema from an NSAID.)

Immediate reactions are dependent on drug-specific IgE fixed on tissue mast cells and circulating basophils, but clinically similar reactions, although usually less severe, occur without the identification of a drug-specific immune reaction, and are, therefore, called pseudoallergic or anaphylactoid.[1,4,31] In all cases, the tissue mast cells, blood basophils, and, eventually, platelets[32] liberate the content of their granules (histamine, tryptase, heparin, cytokines, and chemokines) and produce secondary vasoactive mediators (prostaglandins, leukotrienes, PAF/platelet activation factor, and cinins), which together are responsible for the vasodilatation, increased vascular permeability, and pruritus observed in urticaria.[4,33]

FIGURE 27.1 Angioedema and urticarial lesions after ingestion of an NSAID (diclofenac).

In immediate hypersensitivity, cell degranulation occurs upon specific mast cell or basophil IgE bridging by the drug.[4] Nevertheless, degranulation can occur by non-IgE-dependent mechanisms like the activation of cell receptors for complement anaphylotoxins (C3a and C5a), direct drug effect on the cellular membrane or in intracellular pathways that regulate degranulation, or imbalance between prostagladins and leukotrienes due to cyclooxygenase inhibition by NSAID. Still, a similar reaction can occur from the increase of bradikinin and other vasoactive mediators due to drugs that inhibit their degradation, like ACEI.[1,4,34–36]

In immediate hypersensitivity reactions, a drug specific IgE is found in *in vitro* tests, there is *in vitro* drug specific basophil activation (measured either by the expression of CD63 by flow cytometry or by mediator release),[33,37] and immediate skin testing (prick or intradermal) and drug rechallenge (which is not advised in severe cases) are positive in a high proportion of patients (>80%).[31] Nevertheless, with several drugs that induce IgE-mediated reactions, like muscle relaxants, iodinated radiocontrast media, and heparins, there is also a direct capacity for nonspecific basophil or mast cell activation, which can be responsible for nonspecific positive skin and basophil activation tests (CD63 expression

or mediator release).[34,35,38] Also, occasionally, drug-specific IgE has been documented in aspirin-induced urticaria and asthma, classically considered pseudoallergic,[39] and even for penicillin a nonspecific capacity for mast cell activation (albeit low) has been documented *in vitro*. Therefore, this makes the distinction between what are called allergic and pseudoallergic reactions difficult, both on clinical and laboratory grounds.

Drug-specific IgG or IgM antibodies can also be responsible for immediate symptoms,[36] because these antibodies give rise to circulating immune complexes and complement activation and induce urticaria with systemic symptoms within the context of serum disease (fever, arthralgia or arthritis, abdominal pain and urticaria, urticaria vascultis, or leukocytoclastic vasculitis), which occurs either immediately or within a few days of drug administration.[4,40]

27.4 DELAYED CUTANEOUS ADVERSE DRUG REACTIONS

There are several clinical and experimental arguments that confirm the involvement of delayed type hypersensitivity with the participation of drug-specific T cells in the following CADR: MPE, DIHS/ DRESS, AGEP, SJS, TEN, and FDE.[4,24,41] (1) These eruptions begin within 7–21 days in the 1st episode and 1–2 days after drug reintroduction; (2) drug-specific positive oral rechallenge with lower doses is usually observed;[42] (3) on histopathology there is mainly a dermo-epidemal infiltration of activated T cells; (4) in a high percentage of cases, the culprit drug induces specific positive patch, prick, or intradermal skin testing with delayed readings;[6,43–46] (5) *in vitro* tests show drug-specific T lymphocyte proliferation/activation;[47,48] and (6) drug-specific T-cells lines and T-cell clones have been isolated from the blood and skin during the acute episode or, later, from positive patch tests.[41,49]

Nevertheless, as there are distinct subsets of T cells with distinct cytokines/chemokines and aggressive machinery, they orchestrate the inflammatory skin reaction giving rise to different patterns of drug reactions. Therefore, a subdivision of delayed hypersensitivity T-cell reactions has been made in agreement into type IVa, IVb, IVc, and, more recently, type IVd.[5] They represent, respectively, the reactions mediated predominantly by T-helper 1 [interferon (IFN)-γ], T-helper 2 [interleukin (IL)-4 and IL-5], cytotoxic reactions (CTL, CD8+ rich in perforin, granzyme B, and FasL), and CXCL8 (IL-8) secreting T cells that promote neutrophilic inflammation.[24,50]

The participation of these subsets is very particular in the different patterns of delayed drug eruptions, as detailed in Table 27.1.

27.4.1 Maculopapular Exanthems

MPE, the most frequent pattern of CADR, appear as generalized symmetric eruptions of isolated and confluent erythematous macules or papules, often starting in the trunk and then spreading to the extremities. Mucosa are not involved, there are no evident systemic symptoms apart from a low-grade fever which can also contribute to mimic a viral or bacterial exanthem. The reaction develops within

TABLE 27.1
General Aspects of the Hypersensitivity (HS) Mechanisms Involved in the Main CADR

Type of Reaction	Immediate	Delayed				
Reaction pattern	Urticaria/ anaphylaxis	MPE	DRESS	AGEP	SJS/TEN	FDE
Main drugs	Penicillins, Contrast media, NSAID	Antibiotics Anticonvulsivants Allopurinol	Anticonvulsivants Allopurinol Minocycline	Antibiotics Aminopenicillins	Allopurinol Anticonvulsivants Sulfonamides	NSAID
Drug recognition	IgE	TCR/HLA I-II	TCR/HLA-II	TCR /HLA I	TCR	TCR
Effector cells	Mast cells Basophils	CD4/CD8	CD4/CD8 eosinophils	CD4+ neutrophils	CD8+CD56+	CD8+CD69
Soluble mediators	Histamine Tryptase PGs, LTs, PAF	Perforin IFN-γ IL-5	IL-5 IFN-γ	CXCL8 GM-CSF IFN-γ	Fas/FasL TNF-α Perforin	Fas/FasL IFN-γ
Target cells	Endothelial cells	Keratinocytes Other skin cells	Keratinocytes Other skin cells	Epidermis	Keratinocytes	Keratinocytes
In vivo tests	Prick/idr	Patch testing Oral challenge	Patch testing	Patch testing	…	Lesional testing Oral challenge
In vitro tests	Specific IgE Basophil activation	LTT	LTT	LTT	LTT	N/A
Other aspects	Similar to pseudoallergic reactions	Mimic viral and bacterial exanthems	Concomitant HHV-6	Neutrophilic Inflammation	High mortality rate	"preactivated" T cells in residual lesions
Type of HS	Type I	Types IVa, IVb, and IVc	Types IVa, IVb, and IVc	Type IVd	Type IVc	Type IVc

FIGURE 27.2 Maculopapular exanthem from carbamazepine.

7–14 days after drug intake (or within 1 or 2 days in sensitized patients) mainly due to antibiotics (aminopenicillins, cefalosporins, and sulfonamides), allopurinol, and anticonvulsivants. The reaction may be mild and regress within a few days, but most often it progresses for a few days even after drug suspension and then fades progressively within 10–15 days, often with desquamation.[5,51] (Figure 27.2 shows an MPE from carbamazepine.)

On histopathology, early lesions show an interface dermatitis with hydropic degeneration of basal keratinocytes, mild spongiosis, scattered dyskeratotic and necrotic keratinocytes, and lymphocytes mainly at the dermal epidermal junction and papillary dermis with eosinophils along dermal vessels.[24,51,52] Lymphocytes are skin homing highly activated T cells (CLA+, CD3+, DR+, CD25+) expressing adhesion molecules such as CD11a-CD18 (LFA-1) and CD62L (L-selectin). They are attracted from the blood through the expression of the corresponding adhesion molecules in endothelial cells and keratinocytes (ICAM-1, HLA-II) and by the production of. keratinocyte chemokines, like CCRL27 (also known as CTACK-cutaneous T-cell attracting chemokine) that selectively recruits skin homing memory T cells expressing the CCR10 receptor.[15,52,53] Most lymphocytes infiltrating the skin are CD4+ T cells expressing high levels of perforin and granzyme B but CD8+ T cells are also found, mainly in the epidermis.[5,51,52] T cells secrete a heterogenous profile of cytokines and chemokines: type 1 cytokines (IFN-γ) activate dendritic cells and keratinocytes increasing their expression of HLA-II that binds the drug and presents it to T cells; IL-5, a type 2 cytokine, along with the eotaxin/CCL-11 is responsible for the recruitment and activation of eosinophils, a local and systemic hallmark of cutaneous maculopapular drug eruptions.[51] During the acute phase, CLA+CD4+ T cells expressing perforin are also increased in the blood and after isolation exhibit *in vitro* cytotoxic activity against keratinocytes, therefore reinforcing their capacity to cause keratinocyte damage in the skin.[51] Similar cells have been isolated from positive epicutaneous patch tests with the culprit drug and it has been shown that T-cell clones isolated from the blood, skin, and positive patch tests in patients with MPE are specifically stimulated by the culprit drug and exhibit similar profiles of activity, namely perforin expression and production of cytokines and chemokines (INF-γ, IL-5).[41,49]

Therefore, after a process of T-cell sensitization, a further exposure to the drug that reaches the skin and combines with skin proteins or HLA molecules of keratinocytes and dendritic cells activates resident skin and circulating CD4+ and CD8+ T cells, which are attracted to the skin and selectively damage the cells where the drug is fixed, mainly by perforin and granzyme B. Cytokines and chemokines produced by T cells and resident skin cells recruit other inflammatory cells that orchestrate the dermal and epidermal inflammatory reaction in MPE. Therefore, various subtypes of delayed hypersensitivity, mainly types IVa, Ivb, and IVc, seem to be involved in this pattern of CADR.[5]

27.4.2 Drug-Induced Hypersensitivity Syndrome/Drug Reaction with Eosinophilia and Systemic Symptoms

DRESS is a severe life-threatening CADR that develops 2–8 weeks after drug intake, usually an anticonvulsivant, allopurinol, a sulfonamide, dapsone, or minocycline. It involves the skin, presenting with a nonspecific maculopapular rash or a more generalized exfoliative dermatitis, often with severe facial edema (Figure 27.3 shows a case of DRESS induced by allopurinol with an exfoliative dermatitis and facial edema). Systemic symptoms are always present and consist of fever, malaise, arthralgia, enlarged lymph nodes, hepatic, renal, or pulmonary failure. Leukocytosis with circulating atypical (activated) lymphocytes occurs with eosinophilia that may appear a few days later. It begins after a longer interval than for other drug rashes and also regresses slowly often with exacerbations, either related with steroid withdrawal, viral reactivation, or administration of a cross-reactive drug.[1,28,29] Also, delayed reactivation apparently with no drug exposure or with exposure to a nonrelated drug has been reported.[54]

In DRESS, circulating activated T cells expressing CLA+ and CCR10 increase in the blood in proportion with the skin severity, and these CD4+ and CD8+ T cells infiltrate the dermis and epidermis.[15] In carbamazepine and lamotrigine sensitive patients, T-cell clones generated from these infiltrating skin and circulating cells react specifically to these drugs on HLA-II matched antigen-presenting cells

FIGURE 27.3 Exfoliative dermatitis with facial edema in a case of DRESS induced by allopurinol.

apparently independent of drug metabolism and antigen processing.[15] Most of these T cells share the TCR Vβ 5.1 chain, suggesting that the drug might also act as a superantigen.[55] These T-cell clones are rich in perforin and secrete a type 1 cytokine pattern with IFN-γ and chemokines that control the duration and severity of the inflammatory response.[15] They also show a very significant IL-5 secretion which is responsible for the characteristic eosinophilia observed in this syndrome.[56]

Nevertheless, and even though these drug-specific T-cells clones have been isolated in DRESS[15] and, in our experience, patch tests with the drug, namely with carbamazepine, are often positive,[57] the pathomechanisms involved seem to be complex and not exclusively dependent on the drug. Most authors refer the need for a concomitant HHV-6 reactivation, which would be responsible for the systemic symptoms as well as for exanthem reactivation without drug.[29,28,54] Recent studies presented by Yoko Kano and Testsuo Shiohara suggest that HHV-6 reactivation, evaluated by detection of viral deoxyribonucleic acid (DNA) by polymerase chain reaction (PCR) and by the increase in anti-HHV-6 IgG titer in blood, occurs after a certain degree of immunossupression, particularly hypogammaglobulinemia, induced by the drug.[29] They also suggest that, just after drug suspension, the recovery of CD4+ and CD8+ cells will be responsible for an immune reconstitution inflammatory syndrome (IRIS) with damage of the tissues where the virus/drug is localized, as observed in acquired immune deficiency syndrome (AIDS) after highly active antiretroviral therapy (HAART) treatment.[58] This might explain why, in their experience, lymphocyte transformation tests (LTT) are positive only after a certain time of evolution of the DRESS when there is a full immune reconstitution.[58]

Although drug-specific T cells with a high production of IL-5 and eotaxin, responsible for the systemic and skin eosinophilia,[55,56] have been observed in DRESS, suggesting the involvement of a type IVb and IVc hypersensitivity reaction, further studies are needed to fully understand the mechanisms underlying this severe ADR.

27.4.3 Acute Exanthematic Generalized Pustulosis

AGEP is a very peculiar reaction pattern induced by drugs in more than 90% of cases, mainly by aminopenicillins and other antibiotics. It is characterized by the acute onset of symmetrical widespread edematous erythema covered by small nonfollicular sterile pustules, predominating in the face and body folds, high fever (>38°C), leukocytosis, neutrophilia, and, occasionally, eosinophilia. (Figures 27.4a and 27.4b show a patient with AGEP from amoxicillin with the predominance of small pustules on body folds.) The reaction develops around 1 week after drug intake and regresses in 5–10 days after drug withdrawal. Lymphocyte transformation tests and, typically, patch tests are positive[9,59] and, after 72 hours, show a pustulous pattern similar to the acute reaction.[60,61]

The histology and immunohistochemistry of early biopsies from AGEP show a dermo-epidermal infiltration of T cells, mainly CD4+DR+CD25+, with discrete vacuolar keratinocyte degeneration and a perivascular infiltrate, sometimes with vasculitis.[62,63] Lesions progress to spongiotic vesicles that soon transform into subcorneal pustules due to neutrophil accumulation.[63] This same pattern occurs at positive patch tests, which make them a very useful tool to study the pathomechanisms involved in AGEP. From the blood and skin biopsies of patch tests, several drug-specific T-cell lines and T-cell clones have been isolated and characterized. They are mainly CD4+ memory effector T cells, which exhibit cytotoxicity against drug laden target cells, both through perforin/granzyme B and Fas ligand.[64] They secrete mainly a type 1 cytokine pattern (IFN-γ and Granulocyte-macrophage colony-stimulating factor (GM-CSF)), in some cases with IL-5, responsible for eosinophilia observed in about one-third of AGEP patients.[61] Nevertheless, the main particular characteristic of these T cells is the high production of CXCL8 (IL-8) and GM-CSF, that recruit and prolong survival of neutrophils in the skin. Actually, *in vitro* tests have shown that apart from CXCL8 that recruits neutrophils bearing the CXCR1, other mediators of these T cells, like GM-CSF and INF-γ, acting mainly through the CXCR2, prevent neutrophil apoptosis and prolong their skin survival.[60]

But, preceding neutrophil skin infiltration, drug-specific CD4+ T cells (with less than 30% CD8+), expressing CCR6 as the skin homing receptor, are present in the skin and exert some cytotoxicity in the epidermis[5] before they secrete

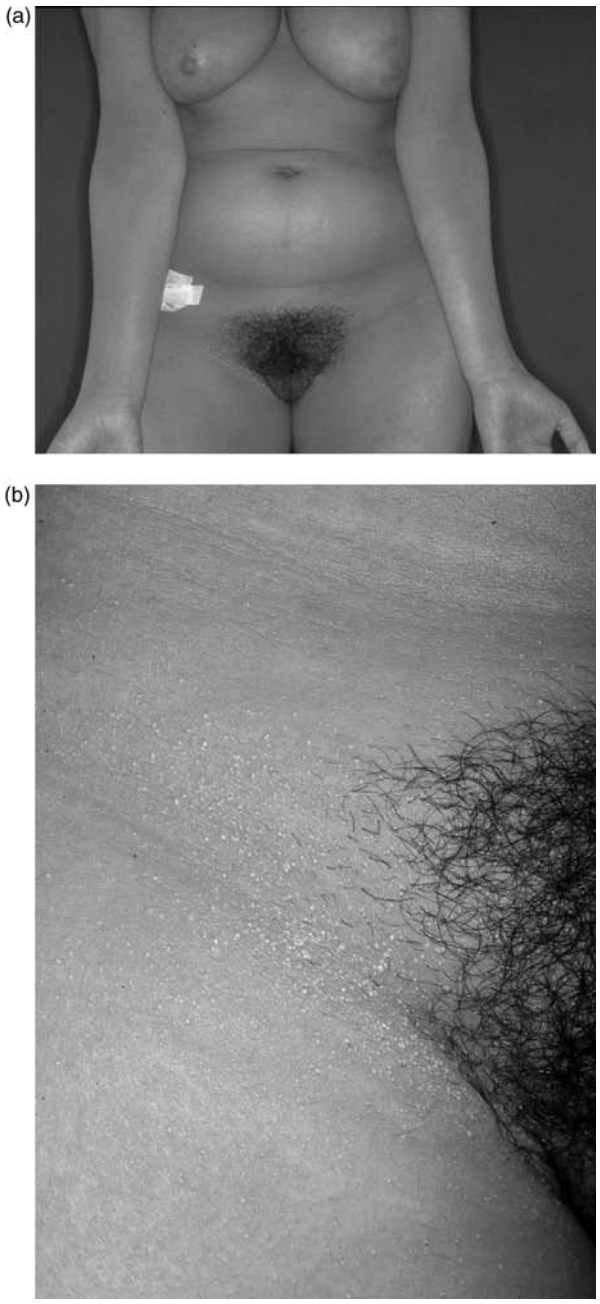

FIGURE 27.4 (a) Acute generalized exanthematic pusutulosis induced by amoxycillin. (b) Detail of Figure 27.4a. Small pustules mainly on body folds in AGEP.

CXCL8 that recruits neutrophils. As both T cells and keratinocytes secret CXCL8 and T cells also express the CXCR1, there is further T-cell activation by CXCL8 produced by keratinocytes.[61] Opposing MPE, there is a much lower expression of HLA-II by keratinocytes and no exotaxin was observed in the epidermis, but only along endothelial cells.[61]

This very peculiar pattern of drug-specific T-cell reaction, now considered a type IVd hypersensitivity reaction,[5] develops with drugs that usually induce other type IV reactions. No reason has, thus far, been found to justify why in some patients and in what circumstances a drug can elicit this particularly CXCL8 rich T-cell activity.

27.4.4 Stevens–Johnson Syndrome/ Toxic Epidermal Necrolysis

SJS and its more extensive variant, TEN, represent a life-threatening pattern of CADR characterized by widespread symmetrically distributed macular lesions, showing typical or mainly atypical targets, with central bulla, that coalesce to form large sheets of necrotic epidermis covering more than 30% of the body surface area in TEN (Figure 27.5 represents a case of TEN from allopurinol, with skin detachment involving about 60% of the body surface area). The eruption is often preceded by fever, malaise, mucosal pain/erosions and, as the skin rash progresses from the head to the extremities, fever and systemic symptoms occur in a variable intensity and combination. Conjunctivae, oral, and genital epithelial shedding is usually intense and painful, and can be associated with epithelial necrosis of the oropharynx, gastrointestinal tract, trachea, and bronchia. SJS/TEN are due to drugs in more than 90% of cases, usually an antibiotic (sulfonamide), allopurinol, an anticonvulsivant (lamotrigine, carbamazepine), or an NSAID (oxicam).[1,4] In the skin there is a variable accumulation of inflammatory cells, ranging from an almost absent to a dense dermal T-cell infiltration, which seems to correlate positively with the area of skin detachment and, consequently, with the mortality rate.[65,66] Factor XIIIa+ dermal dendritic cells are increased contrasting with a reduction of CD1a+ Langerhans cells. CD4+ and CD8+ T cells are scattered in the dermis and many cytotoxic activated CD8+CD56+ T cells are found in the blister fluid.[67,68] But the most striking histologic marker of TEN is the keratinocyte cell death extending to all epidermal layers.[65] There is evidence that this is due to apoptosis, dependent on several mechanisms. The Fas/Fas ligand (CD95/CD95L) pathway, in its membrane bound or soluble form, seems to be mainly involved, but there are other pathways leading to keratinocyte apoptosis, namely TNF-α, granzyme B, and perforin- and calcium-dependent calprotectin.[69–71] These soluble mediators are found in high amounts in the serum but very particularly in the blister fluid, where they are detected with other cytokines (IL-18, IFN-γ, and IL-10) liberated by damaged keratinocytes which amplify the inflammatory loop and epidermal apoptosis.

FIGURE 27.5 Extensive skin detachment in a patient with toxic epidermal necrolysis from allopurinol.

The main origin of these death mediators are drug-specific T cells, mainly CD8+, present in the blister fluid of patients with TEN.[67,68] These CD8+CD56+ T cells have an important cytotoxic potential against HLA-I restricted keratinocytes combined with the culprit drug, mainly due to granzyme B perforin,[16,68] and soluble Fas produced in high amounts after drug stimulation.[70] Therefore, after a first aggression by CD8+ cytotoxic T cells that need cell contact or proximity, other soluble mediators secreted by drug-specific T cells (IFN-γ, sFas) can be important for disease spreading. IFN-γ activates keratinocytes that increase HLA-I expression, rendering them more susceptible to CD8+ specific T-cell killing.[16] It upregulates keratinocyte secretion of CCL27/CTACK, that further attracts CCR10+ cutaneous memory T cells,[53] and increases their expression of receptors for TNF and Fas and their production of Fas ligand, making keratinocytes more susceptible to apoptosis and capable of inducing apoptosis of neighboring cells.[16]

The factors that drive the CADR into an SJS or TEN are not known. TEN inducing drugs are not different from those that induce other CADR, and sometimes at the beginning the skin reaction simulates an MPE. Nevertheless, increased serum levels of soluble Fas may indicate the progression to a more severe life-threatening reaction,[70] and some authors suggest that, in individuals who develop SJS or TEN, their lymphocytes have an increased capacity of secreting sFas, even in basal conditions.[22] Therefore, this and other genetic susceptibility markers can be of importance in determining this pattern of CADR.

27.4.5 Fixed Drug Eruption

FDE is due to drug hypersensitivity in more than 95% of the cases. The clinical presentation is very typical, with round erythematous lesions, that may progress to plaques or bulla and regress spontaneously within 10–15 days with a grey-brown hyperpigmentation (Figure 27.6 shows two typical round lesions of FDE induced by piroxicam). Lesions may vary from a few to a widespread involvement making a differential diagnosis with TEN difficult.[19,72]

At the acute phase there is a mononuclear inflammatory infiltrate, mainly at the dermal epidermal junction, with hydropic degeneration of basal keratinocytes and scattered or more extensive apoptosis of keratinocytes, eventually involving the whole epidermal thickness, as in TEN. Upon regression, melanophages are easily visible in the dermis for years and, if special immunohistochemical stains are performed, CD8+ T cells can also be detected in the epidermis in abnormal numbers over prolonged periods after clinical resolution.[74] This is probably due to the expression of the skin homing receptor (CLA+) and the integrin α3β7 (CD103), which binds E-cadherin in keratinocytes.[73,75] These CD3+, CD45RA+, CD11b+, CD8+ effector memory T cells share some surface and activation markers with NK cells, namely the CD69,[73,75] but in the residual phase they do not harm the neighboring cells, which are protected from apoptosis.[74] Within a few hours upon exposure to the culprit drug these resting or "pre-activated" T cells initiate a process of epidermal aggression. They upregulate mRNA for IFN-γ and secrete this cytokine in high amounts;[73,74] they express Fas ligand which binds Fas on keratinocytes, thus inducing apoptosis;[73–75] TNF-α, perforin, and granzyme secreted by these cells and other CD8+ effector T cells recruited from the circulation also participate in the epidermal aggression.[73,74] Along with CD8+, which migrate mainly to the epidermis, CD4+, localize preferentially in the dermis. Among these CD4+CD25+hi regulatory T cells seem to downregulate the reaction either by direct cell contact or by secretion of IL-10 or TGF-β.[76] These cells also seem to be involved in the process of desensitization in FDE.[77]

The presence of the "pre-activated" T cells in the residual lesional epidermis can explain why patch testing is negative in normal skin, whereas a few hours after application of the culprit drug in a residual lesion reactivation occurs with the clinical and histhopathology typical of an FDE.[19,72] Although some authors suggest that these lesions can be reactivated by nonspecific stress/danger signals,[74,78] in our experience lesional reactivation by patch testing is drug specific and allows the confirmation of the culprit drug and study of cross reactions.[19,79]

FIGURE 27.6 Typical round erythemato-violaceous lesions in fixed drug eruption from piroxicam.

27.5 CONCLUDING REMARKS

The knowledge of the pathomechanisms involved in drug hypersensitivity is of extreme importance for the clinician to understand the clinical and evolutive pattern of CADR, to choose the most adequate therapeutic attitude when facing a CADR, to understand and determine which drug is imputed with the highest probability in patients on multiple therapies, to further choose the most adequate complementary tools to confirm the culprit drug (immediate skin tests and IgE/basophil activation tests in immediate reactions, patch testing, or IDR with late readings and LTT in delayed reactions), and to take the most adequate preventive measures to avoid a further CADR.

Nevertheless, several aspects of these mechanisms are not yet fully understood, namely what triggers sensitization to the drug, which drug epitopes (or other related epitopes) are recognized by the immune system so that cross reactions are better previewed and patients are better informed

on drugs to avoid in the future, how lesions fully develop and how we can interfere in their progression, at least in the most severe reactions like SJS and TEN for which no therapy can significantly reduce mortality.

Also, the study of hypersensitivity mechanisms induced by drugs, where oral rechallenge or patch testing has been a complementary tool to understand more pieces of this complex puzzle, contributed to the understanding of pathomechanisms involved in nondrug-related skin diseases. The discovery of CXCL8+ producing T-cell clones in AGEP has stimulated the study of their contribution in other neutrophil rich inflammatory skin diseases, like psoriasis, Sweet's syndrome, and Beçhet's disease, and have given immunologists the suggestion to consider a new type IV hypersensitivity reaction (IVd).[5,60]

Although the human eye is constantly subjected to both artificial and sunlight, damage rarely occurs from this light exposure (Roberts 2005) unless the eye is aged (Roberts 2001; Andley 2001; Balasubramanian 2005) or the light is particularly intense (Sliney 2005). However, many drugs, dietary supplements, cosmetics, and diagnostic dyes have the potential to induce damage to the lens and retina in the presence of ambient light (Fraunfelder and Fraunfelder 2004; Roberts 2004). This danger is enhanced with increased exposure to intense light because of high altitudes (Hu et al. 1989), outdoor employment (Sliney 2001), sun bed use, or phototherapy for seasonal depression (Roberts et al. 1992).

28.1 STRUCTURE OF THE EYE

The structure of the human eye is shown in Figure 28.1. The outermost layer contains the sclera, whose function is to protect the eyeball, and the cornea, which focuses incoming light onto the lens. Beneath this layer is the choroid containing the iris and ciliary body; this layer is known as the uvea. This region contains melanocytes that contain the pigment melanin, whose function is to prevent light scattering. (Hu 2005) The opening in the iris, the pupil, expands and contracts to control the amount of incoming light. Behind the iris is the lens, whose function is to focus light onto the retina. The iris and the lens are bathed in the aqueous humor, a fluid that maintains intraocular pressure; this fluid also contains various antioxidants. Transport to the lens is through the aqueous.

Behind the lens is the vitreous humor, a fluid that supports the lens and the retina and that also contains antioxidants. The retina itself contains the photoreceptor cells (rods and cones) that receive light and the neural portion (ganglion, amacrine, horizontal, and bipolar cells) that transduces light signals through the retina to the optic nerve. Behind the photoreceptor cells are the retinal pigment epithelial cells, Bruchs' membrane, and the posterior choroid. The photoreceptor cells are avascular; their nutrient support

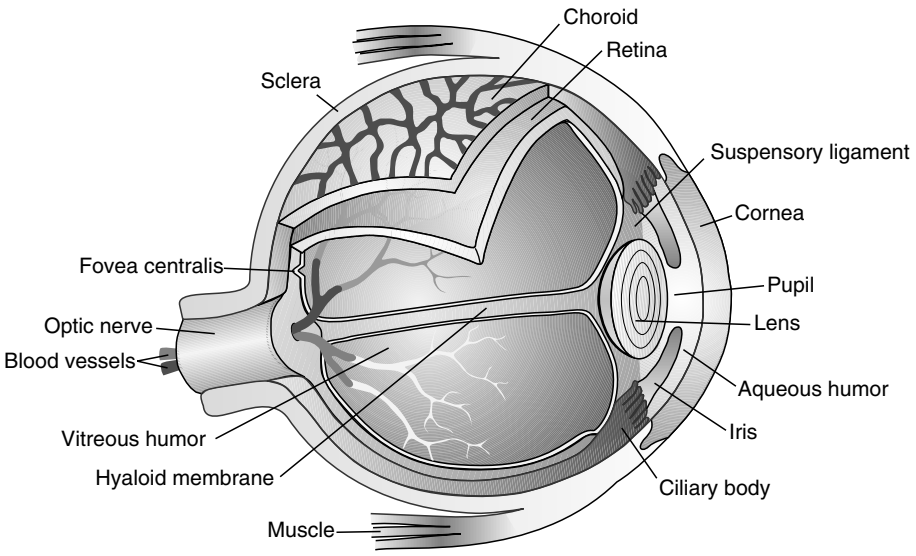

FIGURE 28.1 The structure of the human eye.

(ions, fluid, and metabolites) is provided by the retinal pigment epithelial cells. Transport to the retinal pigment epithelial cells is carried out by the choriocapillaries across the Bruch's membrane.

28.2 TRANSMISSION OF LIGHT THROUGH THE HUMAN EYE

Ambient radiation from the sun or from artificial light sources contains varying amounts of UV-C (220–290 nm), UV-B (290–320 nm), UV-A (320–400 nm), and visible light (400–700 nm). The shorter the wavelength, the greater the energy, and therefore the greater the potential for biological damage. However, although the longer wavelengths are less energetic, they penetrate the eye more deeply (Roberts 2001).

For a photochemical reaction to occur in the eye, the light must be absorbed in a particular ocular tissue. The primate/human eye has unique filtering characteristics that determine in which area of the eye each wavelength of light will be absorbed (Bachem 1956). All light of wavelengths shorter than 295 nm is cut off by the human cornea. This means that the shortest, most energetic wavelengths of light (all UV-C and some UV-B) are filtered out before they reach the human lens (Figure 28.2). Most UV light is absorbed by the lens, but the exact wavelength range depends upon age. The adult human lens absorbs the remaining UV-B and all the UV-A (295–400 nm); therefore only visible light reaches the retina. However, the very young human lens transmits a small window of UV-B light (320 nm) to the retina, while the elderly lens filters out much of the short blue visible light (400–500 nm) (Barker et al. 1991). Transmission also differs with species; the lenses of mammals other than primates transmit ultraviolet light longer than 295 nm to the retina (Barker et al. 1991).

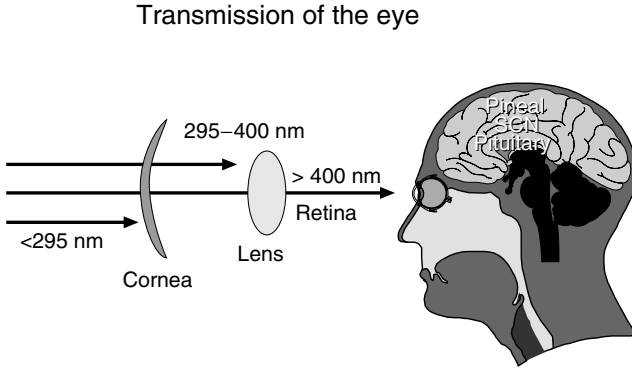

FIGURE 28.2 The eye as an optical system. The cornea filters out light below 295 nm; the adult human lens absorbs light between 295 and 400 nm; and the retina receives light above 400 nm.

28.3 OCULAR PHOTOTOXICITY INDUCED BY XENOBIOTICS

Ultraviolet light (295–400 nm) and very short visible light (400–450 nm) are the source of most of the damage induced in the eye by direct irradiation. However, in the presence of a light activated (photosensitizing) drug, herbal medication (Schey et al. 2000; Taroni et al. 2005; He et al. 2004) or diagnostic dye (Roberts 1981, 1984; Wu et al. 2004) patients are in danger of enhanced ocular injury from both ultraviolet and all wavelengths of visible light (295–700 nm) (Roberts 2004). The extent to which a particular dye or drug is capable of producing phototoxic side effects in the eye depends on several parameters including: (l) the chemical structure; (2) the absorption spectrum of the drug; (3) binding of the drug to ocular tissue; and (4) the ability of the drug to cross blood-ocular barriers.

28.4 SHORT SCREEN FOR PREDICTING POTENTIAL PHOTOTOXICITY

Any compound that has a tricyclic, heterocyclic, or porphyrin ring structure is a potential ocular chromophore. If a drug absorbs ultraviolet light, it may damage the lens, whereas if it absorbs visible light it may also affect the retina. When exogenous sensitizers bind to ocular tissues (i.e., lens proteins; Roberts et al. 1991, 1990), melanin (Borel et al. 2005; Kristensen et al. 1995), and DNA (Martinez and Chignell 1998), their lifetime in the eye is extended and the hazard is enhanced. Substances that are amphiphilic or lipophilic are able to cross most blood-ocular barriers (Roberts et al. 1991).

In summary, there are certain chemical characteristics that allow for the prediction of potential ocular phototoxicity of a substance. These are presented in Table 28.1.

The chemical structure and absorption spectrum of a drug gives the first clear indication of potential phototoxicity. For a chemical compound (prescription drug, herbal medication, diagnostic dye) to induce a phototoxic response in any biological tissue, it must first absorb light. This absorption is limited by the filtering characteristics of the biological tissues involved. The human cornea absorbs all optical radiation below approximately 293 nm (Bachem 1956). In general the lens absorbs most of the radiation between 300 and 400 nm, transmitting light of longer wavelengths to the retina. However, the exact filtering characteristics of the lens vary with age (Figure 28.2) and certain disease states (Barker et al. 1991). Therefore, a drug with an absorbance in the near UV or visible range is a potential photosensitizer of the lens or retina. The most potent photosensitizers usually have structures, which are heterocyclic, tricyclic, or porphyrin-related ring systems (Figure 28.3). They should be amphiphilic or lipophilic to cross blood–brain, blood–retina, and aqueous–lenticular barriers.

Additional information can be obtained by measuring the absorption spectrum of the drug in the presence and absence of lens proteins, DNA, or melanin (Roberts et al. 1991, 1990; Martinez and Chignell 1998; Kristensen et al. 1994). In the presence of any of these biomolecules, binding of the sensitizer to the biomolecule is indicated by a red shift in the absorption spectrum of the drug. For example, the Soret band of a porphyrin is shifted to the red in the presence of cytosol lens proteins (Figure 28.4) compared to the porphyrin alone, indicating binding of the porphyrin to the lens protein. Binding of a drug to an ocular tissue would increase its retention time in the eye and therefore the drug would be more likely to induce phototoxic damage (Roberts et al. 1991).

Finally, any reports of skin phototoxicity for a particular drug should provide a clear warning of potential ocular phototoxicity. Skin phototoxicity is more readily apparent than ocular phototoxicity, although it is induced by compounds with similar chemical features (Barratt 2004).

TABLE 28.1
Short Screen for Predicting Potential

1. Absorption spectrum	$\lambda > 295$ nm lens $\lambda > 400$ nm retina

4. Solubility	Amphiphilic/lipophilic
5. Skin phototoxicity	

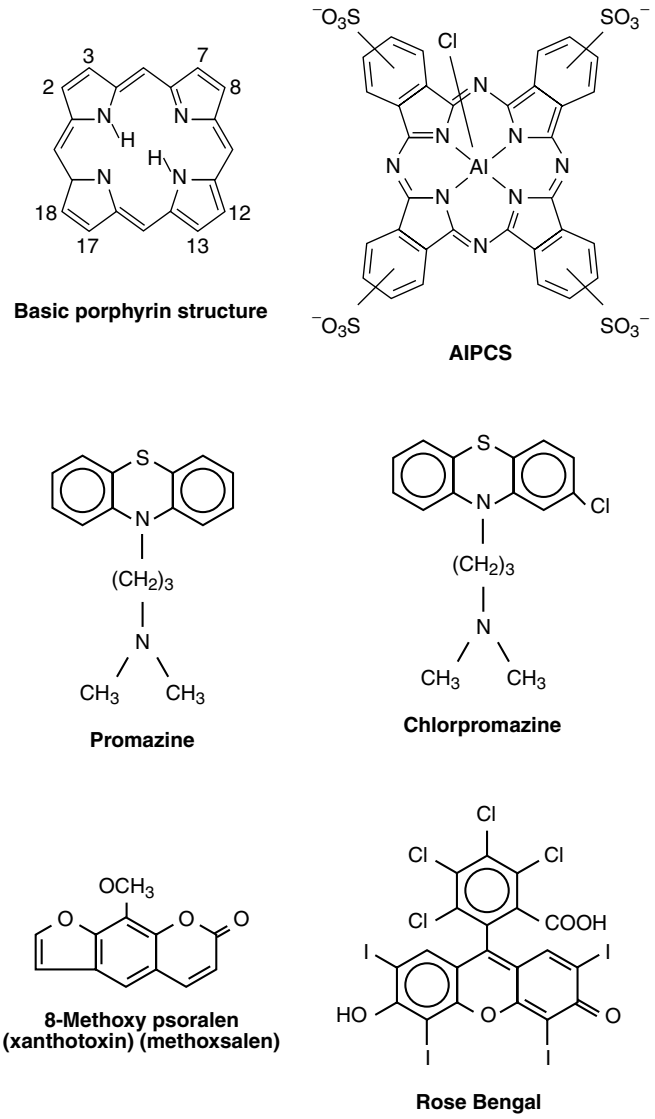

FIGURE 28.3 The chemical structures of photosensitizer—porphyrin, tricyclic, and heterocyclic ring systems.

28.5 ADDITIONAL TECHNIQUES

The simple screen presented earlier gives the first clear indication of whether or not a substance might be potentially

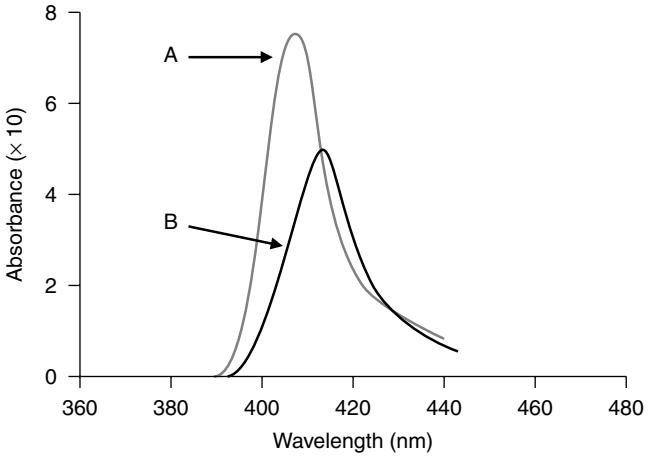

FIGURE 28.4 The Soret band of porphyrin (A); with the addition of lens protein there is a red shift (B) of this band, which is indicative of binding.

phototoxic to ocular tissues. It is a very valuable tool to screen out substances that *will not* be photosensitizers in the eye. Once it has been determined that a substance is a potential photosensitizer, additional *in vitro* and biophysical assays, which take into consideration the photochemical mechanisms of phototoxicity, are useful to get a more accurate assessment of potential phototoxicity.

28.6 PHOTOCHEMICAL MECHANISM OF PHOTOTOXICITY

The molecular mechanism involved in the phototoxic damage induced in the eye is through a photooxidation reaction. This reaction begins with the absorption of light by the sensitizer (drug, dye, herbal medication), which excites the compound to the singlet state (fluorescence) and then, through intersystem crossing, goes to the triplet state. It is generally the excited triplet state of the drug/dye that then proceeds either via a type I (free radical) or type II (singlet oxygen) mechanism to cause the eventual biological damage (Spikes 1998).

Photooxidation reaction

Drug + light →

singlet → triplet →

free radicals/reactive oxygen species →

ocular damage

28.7 BIOPHYSICAL STUDIES

In complex biological systems like the eye, photooxidation can occur by either a type I or a type II mechanism or by both concurrently. Additional information about the precise excited state intermediates produced and the efficiency of production (quantum yield) for a phototoxic reaction in the eye can be obtained by using several photophysical techniques (flash photolysis, luminescence, pulse radiolysis, electron spin resonance) (Broniec et al. 2005; Motten et al. 1999; Roberts et al. 2002, 2000; Roberts 2001; Bilski et al. 1998; Reszka et al. 1992; Gorman and Rodgers 1992). Determining the specific reactive intermediate(s) produced by a particuar sensitizer not only defines the mechanism of toxicity but can also later be used as a tool to prevent the damage. The techniques and the reactive species that are measured are summarized in Table 28.2.

TABLE 28.2
Biophysical Studies

Technique	Reactive Species
Laser flash photolysis	Triplet
Luminescence	Singlet oxygen, excited singlet, and triplet states
Pulse radiolysis	Radicals and oxyradicals
ESR	Radicals and oxyradicals

The extent of photooxidation is also influenced by the oxygen content of ocular tissues. Thus in addition to measuring excited-state intermediates, the measurement of the oxygen content of a particular component of the eye is useful. The cornea is highly oxygenated and its content can be measured by the single-chamber polarographic oxygen permeability measurement method (Weissman et al. 1990). The retina is supplied with oxygen by the blood so that different portions of retinal tissues have varying but high oxygen content. This may be measured, noninvasively and *in vivo*, with a scanning laser ophthalmoscope (Ashman et al. 2001). The aqueous and the lens have low oxygen content but it is sufficient for photooxidation to occur. Measuring the excited-state lifetime of phosphorescent dyes in the anterior chamber provides a useful method for determining oxygen concentration *in vivo*, without penetrating the eye (McLaren et al. 1998).

We have confirmed that photophysical studies correlate well with *in vivo* data (Roberts et al. 1991). For instance, TPPS, which binds to lens proteins, shows a long-lived triplet in the intact calf and human lens, and produces singlet oxygen efficiently; it also causes photooxidative damage *in vivo* in pigmented mice.

28.8 *IN VITRO* STUDIES

28.8.1 Location/Uptake of the Dye/Drug

For a drug, dye, or herbal medication to have a toxic effect, it must first be taken up into some compartment of the eye. The classical method for determining uptake into ocular tissues is *in vivo* radiolabeling. This method is time-consuming and expensive, although it is effective in determining which ocular tissues have accumulated the drug in question.

An alternative method to determine uptake of a drug into ocular tissues is ocular fluorometry (Taroni et al. 2003). After a dye or drug has absorbed light and is excited to the singlet state, it can decay to the ground state, accompanied by the emission of light (fluorescence). Since most

TABLE 28.3

	DNA adducts
	Protein modification

photosensitizers are fluorescent, transmitted or reflective fluorescence provides accurate means of measuring uptake of a sensitizer into ocular tissue, a measurement that is simpler, less expensive, and less arduous than using radiolabeled materials. This technique may also be used noninvasively, *in vivo*, as for instance, in using a slit lamp to detect uptake of sensitizers into the human eye, or in using scanning laser ophthalmoscopes, or reflective fluorometry to determine the presence of endogenous and exogenous fluorescent materials in the lens or retina (Elsner et al. 2002; Cubeddu et al. 1999; Taroni et al. 2005; He et al. 2004; Sgarbossa et al. 2000) (Table 28.3).

28.8.2 Substrates of Photooxidative Damage

The targets of photooxidative reactions may be proteins, lipids, DNA, RNA, or cell membranes (Spikes 1998). *In vitro* tests can be designed to determine the specific site(s) of damage to the various ocular compartments (i.e., lens and retinal epithelial cells and photoreceptor cells) and the products of those reactions.

28.8.3 Complementary DNA Microarray Technology

Complementary DNA (cDNA) microarray technology has been developed to decode the complex genetic networks altered in response to environmental insults and disease (Wilson et al. 2002). This technique has been used by Andley to uncover the UV-A effects on human lens epithelial cells (Andley et al. 1994). This group (Andley et al. 2004) conducted a genome-wide screen of UV-A-induced changes in human lens epithelial gene expression. They found that a single dose of UV-A radiation (365 nm) modified genes linked with signal transduction, nucleic acid binding, and enzymes with a majority of genes repressed. This technique may now be applied to compare the effect of UVA alone to that of UVA with phototoxic agents.

28.8.3.1 Comet Assay

The comet assay is a very sensitive way of measuring low levels of DNA damage in individual cells (Singh et al. 1988). It is basically single-cell gel electrophoresis, which can measure oxidative-induced base damage, DNA–DNA/DNA–protein cross-linking, and both single-stranded and double-stranded breaks in DNA. This technique has been used to measure UV damage to both corneal epithelial cells (Choy et al. 2005) and retinal pigment epithelial cells (Roberts et al. 2002).

28.8.4 Scan Tox System—Focal Length Variability of the Lens

The Scan Tox system, which measures focal length variability, is a method for monitoring lens optical quality in culture conditions that mimic conditions inside the eye (Dovrat and Sivak 2005). The ocular lens is an ideal organ for long-term culture experiments because it has no direct blood supply and no connection to the nervous system; the Scan Tox system makes it possible to keep lenses for long-term studies of up to several weeks. The use of cultured lenses, mainly bovine, replaces the need for testing the effects of potentially damaging agents on live animals.

The optical monitoring apparatus uses a computer-operated scanning laser beam, a video camera system, and a video frame analyzer to record the focal length and transmittance of the cultured lens. The scanner is designed to measure the focal length at points across the diameter of the lens. The lens container permits the lens to be exposed to a vertical laser beam from below. The laser source projects its light onto a plain mirror, which is mounted at 45° on a carriage assembly. The mirror reflects the laser beam directly up through the test lens. The mirror carriage is connected to a positioning motor, which moves the laser beam across the lens. The camera sees the cross section of the beams and by examining the image at each position of the mirror, Scan Tox software is able to measure the quality of the lens by calculating the back vertex distance for each beam position. The cultured lenses continue to maintain their original refractive function.

When foreign substances are introduced to a cultured lens, the Scan Tox system measures the resulting optical response, providing a very sensitive means to follow early damage to the eye lens. It has recently been used to define the ocular toxicity of radiofrequency radiation (Dovrat et al. 2005) and the phototoxicity of hypericin, a phototoxic component of St. John's wort (Wahlman et al. 2003).

28.8.4.1 Gel Electrophoresis, Amino Acid Analysis

Gel electrophoresis has been used to monitor polymerization of ocular proteins (Kristensen et al. 1995; Roberts 1992; Roberts et al. 1985; Roberts 1984; Zigler et al. 1982). Photopolymerization is one of the most apparent changes in ocular protein induced by photosensitizing dyes and drugs.

Quantitative changes can be measured by scanning the gel and determining relative reaction rates. Specific amino acid modifications can be determined using amino acid analysis (Roberts 1984). Zhu and Crouch (1992) have illustrated the wide variety of classical protein analysis techniques (gel electrophoresis, amino acid analysis, sequencing, isoelectric point determination, western blot, ELISA) that can be used to investigate phototoxic damage induced by dyes and drugs.

28.8.4.2 Mass Spectrometry

Recent innovations in the field of mass spectrometry (liquid secondary ion mass spectrometry [LSIMS] and electrospray ionization [ESI]) have allowed for the identification of specific amino acid modifications within large proteins through molecular weight mapping. These techniques have been applied to determine the specific sites of photooxidative damage in corneal, lenticular, and retinal proteins (Schey et al. 2000; Roberts et al. 2001; Ablonczy et al. 2005).

These studies can serve as a model for defining damage from any potential phototoxic agent in the eye.

28.8.4.3 Thin Layer Chromatography

Thin layer chromatography is the method of choice for separating free fatty acids and phospholipids from lens (Fleschner and Cenedella 1997) and retinal (Organisciak et al. 1992) membranes. Thin layer chromatography/gas mass/mass spectrometry (TLC/GC/Mass Spec) may be used to measure lenticular or retinal lipid modifications (Handelman 2001). Specific lipids may be modified in the presence of photosensitizing agents and separated on TLC plates. The plates can then be scanned for quantitative analysis of these specific changes.

28.8.4.4 High Pressure Liquid Chromatography

HPLC is particularly effective at separating and identifying lipid peroxides from the retina (Akasaka et al. 1993). It has also been used to identify adducts formed between DNA nucleotides and phototoxic agents (Oroskar et al. 1994). HPLC has been used to assess the rates of photooxidation of lens proteins in the presence of a sensitizer; with this technique it is possible to determine which amino acid modifications have been induced within the protein, where they are located, and whether sensitizing drugs may have been bound to specific lens crystallines (McDermott et al. 1991).

28.8.4.5 Normalization for Photons Absorbed

Whatever the target tissue or extent of damage, the toxic effects of these dyes and drugs are the result of photochemical reactions. As such, their efficiency depends strongly on the number of photons absorbed by the sensitizer in the biological tissue. Therefore, to get an accurate comparison of the photosensitizing potency of various dyes and drugs with different structures and absorptive characteristics, it is essential to normalize for the number of photons absorbed by each drug in a particular system.

Normalization can be accomplished with a simple computer-generated mathematical formula (Roberts 2004), which takes into account the absorption spectrum of the drug, the output of the lamp source used in the experiments, and the optical properties of the eye. The total relative number of photons absorbed by a drug under particular experimental conditions is the area under the product curve:

$$\text{Photons absorbed} = I \times \text{AB} \times \lambda$$

where I is the intensity of the lamp at various wavelengths, adjusted for the transmission characteristics of the cornea or lens; AB is the absorbance of the dye/drug; and λ is the number of photons per energy unit at those wavelengths. The rate of photooxidative damage is then adjusted accordingly for each sensitizer.

28.8.4.6 Cell Culture/Whole Tissues

The first reported assay for phototoxicity in human cells (Roberts 1981) measured changes in macromolecular synthesis in the presence and absence of a light-activated drug. Other studies have assessed damage to corneal, lenticular, and retinal cells by measuring pump function, DNA cross-links, and enzyme activities both *in vitro* and *in situ* (Andley 2001; Roberts et al. 2002; Organisciak and Winkler 1994; Rao and Zigler 1992).

Photochemical Reactions in Tissues

Excited state	→	Intermediates	→ Target and damage
		singlet oxygen	proteins → polymers
triplet		superoxide	lipid → peroxides
		OH·, ROO·	DNA, RNA → cross-links

In vitro techniques determine the potential damage done to an ocular substrate, which gives information about the photoefficiency of a drug should it be taken up into the various compartments of the eye. Additional information about the site of potential damage can be predicted based on which ocular substrates (proteins, DNA, lipids) are modified.

28.8.4.7 Site of Damage

There are numerous locations subjected to phototoxic damage in the eye. The site of damage is determined by the penetration of the drug and the transmission of the appropriate wavelengths of light to that site.

28.8.4.7.1 Cornea

Corneal epithelial and endothelial cells may be easily damaged, leading to keratitis (Pitts et al. 1976; Hull et al. 1983). However, these cells have a very efficient repair mechanism and the damage is rarely permanent.

28.8.4.7.2 Lens

The epithelial cells of the lens, whose function is to control transport to the lens, have direct contact with the aqueous and are thus most vulnerable to phototoxic damage. Damage to these cells would readily compromise the viability of the lens (Andley 2001; Roberts 2004). The lens fiber membrane

can be photochemically harmed through damage to the lipids or the main intrinsic membrane protein (Roberts et al. 1985). Such damage leads to changes in the refractive index resulting in a loss of transparency (opacification) (Benedek 1971).

Phototoxic reactions can cause a modification of certain amino acids (histadine, tryptophan, cysteine) (Roberts 1984; McDermott et al. 1991) or a covalent attachment of sensitizer to cytosol lens proteins. In either case, the physical properties of the protein are changed, leading to aggregation and finally opacification (cataractogenesis). The covalently bound chromophore may now act as an endogenous sensitizer, producing prolonged sensitivity to light. Since there is little turnover of lens proteins, this damage is cumulative.

28.8.4.7.3 Retina

Phototoxic damage can occur in retinal pigment epithelial tissues, the choroid, and the rod outer segments, which contain the photoreceptors. If the damage is not extensive, there are repair mechanisms to allow for recovery of retinal tissues. However, extensive phototoxic damage to the retina can lead to permanent blindness (Organisciak and Winkler 1994; Ham et al. 1982; Glickman 2002).

28.8.4.8 *In Vivo* Testing

The screens described earlier will not totally eliminate the need for accurate *in vivo* experiments. However, the function of these studies is to limit the need for *in vivo* testing of large numbers of drugs for ocular phototoxicity. Those drugs found to be highly likely to produce phototoxic side effects in the eye should be tested further in animal studies to determine the exact site and extent of damage to be expected in humans.

With simple, inexpensive *in vitro* testing, compounds can be checked for phototoxicity at the developmental stage. It may be that a portion of the molecule can be modified to reduce phototoxicity while leaving the primary drug effect intact. This may reduce the necessity of future, more costly, drug recalls.

28.8.4.9 Protection

Even if a drug has the potential to produce phototoxic side effects in the eye, no damage will be done if the specific wavelengths of optical radiation absorbed by the drug are blocked from transmittance to the eye. This can be easily done with wraparound eyeglasses, which incorporate specific filters (Sliney 2001; Merriam 1996). Furthermore, nontoxic quenchers and scavengers could be given in conjunction with the phototoxic drug to negate its ocular side effects while still allowing for the primary effect of the drug (Roberts and Mathews-Roth 1993; Roberts et al. 1991, 2002; Roberts 1981 Busch et al. 1999; Wuet al. 2004).

ACKNOWLEDGMENT

The author wishes to thank Dr. Ann Motten, NIEHS, North Carolina, for help in preparing this manuscript.

29 Water: Is It an Irritant?

Tsen-Fang Tsai

CONTENTS

References 281

An irritant is defined as any agent, physical or chemical, which is capable of producing cell damage. Everything can be an irritant if applied for sufficient time and in sufficient concentration. Water, being the most abundant element of the skin, is usually regarded as banal and gentle. However, the irritancy of water is beyond doubt. All nature evolves from the water. However, as man evolved from the water and became adapted to the earthy environment, the protection from water became one of the chief functions of the skin, which is the major protective organ of the human beings. Except in the fetus, protected by vernix caseosa, prolonged soaking in water is incompatible with human life.

Irritant contact dermatitis is the hallmark of an irritant reaction. It has been traditionally classified into an acute and chronic type. Strong irritants will induce a clinical reaction in a single application whereas with less potent irritants the response may be delayed and subclinical, requiring repeated or prolonged application (Hassing et al., 1982). However, not all irritant reactions manifest as dermatitis. Water, being an unconventional irritant, may irritate the skin in a way other than dermatitis. Fingertip dermatitis, or wear and tear dermatitis, is the best example of cumulative irritant reaction. In this condition, hands are chronically irritated by a variety of insults, especially water. The involved skin is hardened and fissured, but typical signs of dermatitis or inflammation such as erythema, swelling, or scaling are often lacking in the early stage. People who deal with wet work, such as hair dressers, hospital cleaners, cannery workers, bartenders, and hydrotherapists (Lazarov et al., 2005, p. 327), are especially at risk (Meding and Swanbeck, 1990). In rare conditions, water may also produce pruritus (Potasman et al., 1990), or pain (Shelley and Shelley, 1998) in susceptible patients. Substance P (Lotti et al., 1994, p. 232) and VIP (Misery et al., 2003, p. 195), respectively, have been implicated in their pathogenesis. Another water-induced condition is aquagenic urticaria (Medeiros, 1996), in which impurity and osmolarity of water may be important. Water as solvent for putative epidermal antigen has been proposed for its pathogenesis (Czarnetzku et al., 1986, p. 623).

Occlusive patch test is the gold standard for the study of contact dermatitis and the irritancy of water under occlusion has likewise attracted most clinical attention. Prolonged warm water immersion under occlusive shoes was considered to be the culprit of tropical-immersion-foot (Taplin et al., 1967). This is a condition of painful swollen feet first noticed in soldiers during the Vietnam war. Another condition is juvenile plantar dermatosis in which children, mostly atopic, present with dry, glazed, and fissured forefeet. Repeated wet-to-dry process in conjunction with friction was incriminated as the main cause.

Occlusive dressing has long been used as an effective adjuvant therapy for diverse conditions such as keloid (Sawada and Sone, 1992), periungual verrucae (Litt, 1978), and psoriasis (Broby-Johansen and Kristensen, 1989). Occlusion has been demonstrated to modify reactive events in Langerhans cells, and has profound effect on cytokine production (Wood et al., 1994). Occlusion can be achieved with either plastic dressing, silicone, or by water-soaked patches. Normal skin will show typical signs of inflammation such as vasodilation, perivenular lymphocytic infiltration, edema, mast cells degradation, and proliferation of fibroblasts after occlusion for up to two weeks (Kligman, 1996). Agner and Serup (1993) studied skin reactions after closed patch tests and six of twenty participants had a grade 1 clinical response to water after occlusion for 24 h. The irritation of water under occlusion can result from the water *per se* or from retention of sweat, which is far more irritative than the water *per se* (Hu, 1991). However, a state of anhidrosis will result after prolong occlusion (Papa, 1972; Sulzberger and Harris, 1972).

A normal water gradient is required for a healthy skin. The outermost layer of stratum corneum contains 10–30% water, while the viable epidermis contains roughly 70% water. In the stratum corneum, topically applied water exerts mechanical stress on individual corneocytes resulting in an alteration of barrier function. Treatment with distilled water results in swelling of stratum corneum cells and formation of massive water inclusions between adjacent cell layers. Corneocytes near the live-dead transition zone can swell nearly to double their thickness (Richter et al., 2004, p. 246). In the viable epidermis, the control of water passage is more complex. Water can slowly permeate the lipid bilayer by simple diffusion. In addition, some specialized cell membranes show higher water permeability. Water channel proteins, aquaporins, mediate the efficient movement of water

across the membrane. Skin bears abundant water channel aquaporin 3, important in the maintenance of cell volume (Matsuzaki et al., 2002, p. 85).

Water, as an irritant, exerts its damaging effect on the skin through different mechanisms. Skin occlusion will induce a change in the water gradient, and an adaptation of skin physiology ensures accordingly. The normal desquamation process is highly dependent on the water gradient of the stratum corneum. Increased water content of the stratum corneum will dilute the enzymes and change the pH value important for the corneodesmolysis (Watkinson et al., 2001). As a result, in macerated skin, the stratum corneum shows retentional hyperkeratosis and is shed in large sheets. Water may also inactivate type 1 transglutaminase and result in a special condition called self-healing collodian baby. Increased water content in the stratum corneum will also have a negative feedback response on the formation of natural moisturizing factors (NMFs) through the deactivation of keratohyalin granules degradation. Keratohyalin granules are known to be the main source of NMFs. The skin surface becomes excessive dry after the removal of occlusion. This drying effect of water is best demonstrated in wet packing for management of exudative lesions.

The importance of water as a primary irritant was demonstrated by Willis in 1973. Clinical and histological observations of skin occluded for 72–144 h revealed intense subacute dermatitis (Willis, 1973, p. 166). In 1997, Ramsing et al. have also induced experimental irritation by sodium lauryl sulfate in 21 healthy volunteers; one hand was exposed to water for 15 min twice daily for two weeks, while the other hand served as control. Water did not significantly influence transepidermal water loss, but caused a significant increase in skin blood flow, as evaluated by laser Doppler flowmetry. Clinical evaluation did not show any difference of dryness or scaling in this study (Ramsing and Agner, 1997). Without occlusion, the irritancy of water by itself is questionable in this model. However, it is impossible to clearly separate the effects of occlusion and water. The effect of occlusion must be conduction to the skin through water as a medium under physiologic condition. And even though erythema alone does not equate to irritancy, temperature stimulated erythema has been observed to augment pre-existing irritation (Loffler, 2001). Thus, water may also exert its irritancy through its other nonchemical nature. The temperature dependency of irritation has been well recognized (Berardesca et al., 1995, p. 83; Ohlenschlaeger et al., 1996). Besides, hydration changes the optics of the skin, and increases the penetration and absorption of the ultraviolet light. Photo bleaching of the melanin is also more prominent in dampened hairs and swimmers (Dubief, 1992; Basler et al., 2000, p. 299).

Persistent hydration of the skin surface also changes the ecological environment and supports the overgrowth of pathological organisms on the skin (Roth and James, 1989; Faergemann et al., 1983; Aly et al., 1978; Rajka et al., 1981). Diaper rashes and pitted keratolysis are the best examples. Dermatophytosis complex of the toewebs is likely affected. Occlusion alone may clear the periungual verrucae, and spread the mucosal type HPV, that is, condylomata acuminata, to the extragenital areas. Extraction of water soluble substances, or NMFs, from the skin is another mechanism. NMFs are a goup of water extractable substances, including sodium pyrrolidone carboxylic acid, sodium calcium lactate, amino acids, urea, and a sugar–protein complex. These substances can bind three to four times their own weight of water (Jacobi, 1959; Bank, 1952; Yamamura and Tezuka, 1989). The presence of water in the stratum corneum relies on an intercellular bilayer membrane that encloses the NMFs as in an envelope (Imokawa et al., 1991). Since water is the main plasticizing factor of the horny layer, the water content of the stratum corneum decreases when the NMFs are reduced, and superficial cracks might develop. The amino acid contents in senile skin are decreased (Jacobson et al., 1990). Frequent showering removes these water extractable substances and a delay in the replenishment of NMFs in aging skin may further aggravate this situation. It is for these reasons that frequent or prolonged bathing and showering, even without the use of soaps, is discouraged for the care of dry and senile skin (Hogstel, 1983).

Water may also interfere with electrolyte homeostasis and cause skin wrinkling. Water diffuses into the porous skin of the hands and soles via its many sweat ducts. Altered epidermal electrolyte homeostasis may cause changes in membrane stability of the surrounding dense network of nerve fibers and trigger increased vasomotor firing with subsequent vasoconstriction. Vasoconstriction, through loss of volume, leads to negative digit pulp pressure resulting in a downward pull on the overlying skin, which wrinkles as it is distorted. Impairment in this process may result in transient reactive papulotranslucent acrokeratoderma (English, 1996, p. 686), also called aquagenic keratoderma (Yan, 2001, p. 696) and aquagenic syringeal acrokeratoderma (MacCormack, 2001, p. 124). It is especially common in patients with cystic fibrosis, and has been reported to occur after amikacin (Katz, 2005, p. 621) or tobramycin treatment (Ludgate, 2006). Bedside immersion-wrinkling test is used as a test of autonomic digital nerve function, which is impaired in diabetes mellitus and trauma (Wilder-Smith, 2004, p. 125).

The importance of skin surface acidity was only unveiled recently after a long dispute (Schmid and Korting, 1995). This acidic milieu is vital for both the integrity of barrier function and for the regulation of skin flora (Rippke et al., 2002). The skin surface pH has also been found to be predictor for the development of irritant contact dermatitis (Wilhelm and Maibach, 1990). The irritancy of water can theoretically also result from its neutral pH of 7.0, which is alkaline compared to skin surface pH of between 4.2 and 6.0. The origin of this skin surface pH has remained enigmatic. A recent study implicates urocanic acid as the key factor in the maintenance of this acid mantle (Krien and Kermici, 2000). The neutralization capacity of lesional skin in hand eczema has been shown to be defective (Schieferstein and Krich-Klobil, 1982). The change in skin surface pH has been shown in atopic dermatitis, ichthyosis, diabetes mellitis, and patients on dialysis.

Water is a universal solvent. The trace elements in the thermal water are the corner stone of the alleged beneficial effect of crenotherapy. On the contrary, the hardness of water may sometimes contribute to the irritancy of water (Warren and Ertel, 1997). Hypotonicity of pure water, and change of water pressure gradient across the stratum corneum, which may trigger the release of cytokines, may also play a role in the irritancy of water. Specific osmotic sensitive receptor, such as TRPV4, may also be involved (Liedtke et al., 2000, p. 525). The same receptor may also be activated by heat (Guler et al., 2002, p. 6408), low pH, and citrate (Suzuki et al., 2003, p. 22664). Hydration of the stratum corneum also facilitates the penetration of foreign substances, and contributes to the development of allergic and irritant contact dermatitis. This is best exemplified in occupational contact dermatitis involving wet work (Meding and Swanbeck, 1990). Occlusive dressing therapy and wet wrapping therapy involve the same principle to enhance the therapeutic effects of topical corticosteroids (Sauer, 1977).

Water is the most important element of the human body. The control of water passage is a highly regulated, but poorly studied process. In the skin, it was previously considered to be a passive process controlled by the "dead" stratum corneum. But recent studies have revealed the importance of aquaporin, TRPV4, hyaluronic acid, and its receptor. To maintain this water homeostasis, a relatively dry and impermeable skin is highly desirable. Any change in this water gradient will bring about major changes in skin physiology. Water is a ubiquitous irritant, and exerts its irritancy through different mechanisms. The irritancy of water under occlusion has long been recognized. But even contact with pure water will produce physiologic changes of the skin, and these changes might be involved in some pathological processes. The irritancy of water is controlled by the quality and quantity of water as well as by individual susceptibility, including genetic predisposition and concomitant diseases, especially atopic dermatitis. Everything can be an irritant, including water.

30.1 INTRODUCTION

Sodium lauryl sulfate (SLS) is an anionic surface active agent used as an emulsifier in many pharmaceutical vehicles, cosmetics, foaming dentifrices, and foods, and it is the sodium salt of lauryl sulfate that conforms to the formula: $CH_3(CH_2)10CH_2OSO_3Na$.[1] The action of SLS on surface tension is putatively the cause of its irritancy, and its great capacity for altering the stratum corneum (SC) makes it useful to enhance penetration of other substances in patch tests and in animal assays.

Kligman[2] found no sensitization to SLS was seen in hundred volunteers in which SLS was employed in provocative or prophetic patch-test procedures. There are isolated reports of contact sensitization to SLS.[3–5] Some important characteristics have been proposed for irritants used experimentally: no systemic toxicity, noncarcinogenic, not a sensitizer, chemically well defined, no extreme pH value, and not a cause of cosmetic inconveniences to exposed subjects.[6] SLS fulfills these criteria as a model irritant in the study of experimental irritant contact dermatitis.

30.2 APPLICATION METHODS

Many studies concerned with cutaneous irritation utilize a 24-h patch application. A 7-h patch[7] and 4-h patch[8] with high concentration of SLS have been developed. In real life, surfactant exposure is usually of short duration, open application, and cumulative. A single challenge of the skin with an irritant insult is a momentary reflection of the skin's susceptibility, which does not consider the cumulative effect of irritation or the repair mechanisms of the skin. Repetitive challenges allow for these effects. Assay methods similar to real usage situation such as repeated short duration chamber test,[9,10] repeated open application test,[11–14] plastic occlusion stress test (POST),[15,16] and soak or wash test[17,18] were developed.

A correlation coefficient of 0.63 between a single exposure and a 4-day repetitive exposure to patch testing with SLS was found.[19] With repeated open application of SLS for 5 days as well as a single 24-h patch test with SLS using small (8 mm) patch-test chambers, only the degree of skin damage caused by the repeated open test was found associated

with prior skin complaints.[20] Lammintausta et al.[11] observed the decrease in patch-test reactivity secondary to cumulative open SLS application using small (8 mm) patch-test chambers and suggested that the induced hyporeactivity might be one of the false negative diagnostic patch tests. There are two contrasting responses of cumulative SLS irritation; hyporeactivity may be noted if epidermal responses, including hyperkeratosis and dryness, were major reactions to irritant; whereas, if dermal reactions, such as erythema and edema, were major components, hyperreactivity may develop.[21] Recently, Heinemann et al.[22] observed decreased response during the third week of 0.5% SLS irritation and the increase of ceramide first three weeks after irritation, and they suggested that ceramide one seemed to play a key role as a protective mechanism against repeated irritation.

Tupker et al.[23] divided the studies on SLS into two categories with respect to aims. The first category, provocative testing, concerns studies in which SLS is used to induce a definite skin reaction in all individuals. Aims of the first category are to elucidate the mechanisms of skin irritation, to predict the irritant potency of different detergents, to study the time course after irritation, to compare the sensitivity of different noninvasive methods, to compare the efficacy of different moisturizers, barrier creams, or corticosteroids in preventing or healing skin irritation. The second category, susceptibility evaluation, concerns studies aimed to predict the irritant susceptibility of individuals, and investigate individual and environmental factors determining this susceptibility.

There are some variations in skin responses to identical patch tests and standardization of patch-test procedure is necessary to minimize the variations in patch-test responses. Tupker et al.[23] suggested the guidelines on SLS exposure tests.

30.2.1 Purity and Carbon Length of SLS

There were significant differences in the irritant potential *in vivo* for different qualities of SLS, and there were cases in which some of the C12 chains had been substituted by longer and less-irritating carbon chains.[24] The presence of C12 chains of SLS is known to elicit a maximum irritant reaction[25–28] suggested that only SLS qualities of high purity (>99%) should be used for irritant patch testing and that the quality and the purity of SLS should be stated.

30.2.2 Quantity and Concentration of Test Solution

Quantity of test solution is important and larger quantities of test solution give more intense skin reactions, although the concentration of the irritant is kept constant,[29,30] and Agner[31] suggested that the Duhring chamber, the 12-mm Finn chamber, or even large chambers having bigger test areas are more effective in eliciting a response. Mikulowska and Andersson[32] observed that the effects of 8-mm chambers could result in increased, unchanged, or decreased Langerhans cells (LC) numbers, while 12-mm chambers always produced decrease in LC numbers. Lee et al.[33] also compared the effect of chamber size on SLS irritation on the volar forearm using three different sizes (8, 12, and 18 mm) of Finn chambers. The increase in visual score and transepidermal water loss (TEWL) at the patch-tested sites with large (12 mm) Finn chamber was greater than that with the small (8 mm) Finn chamber. However, there were no significant differences between large and extralarge (18 mm) Finn chambers.

Aramaki et al.[34] studied the interrelationship between SLS concentration and duration of exposure in irritant skin reaction. The influence of SLS concentration and duration of exposure was demonstrated with a standardized coefficient value β. For TEWL, the β value of the SLS concentration was 1.5-fold higher than that found for the exposure time. For the laser Doppler flowmetry (LD), the β value of concentration was 2.5-fold higher than that of exposure time. And they suggested that the skin reaction to SLS could be calculated by the following formulae: $\Delta\text{TEWL} = 14.36 \times \text{concentration} + 0.82 \times \text{duration (hours)} - 5.12$, and $\text{LD} = 30.81 \times \text{concentration} + 1.09 \times \text{duration} + 2.49$. This estimation is only valid for a patch application of $\leq$24 h.

Brasch et al.[35] have analyzed the synchronous reproducibility of patch tests with various concentrations of SLS aqueous solution (0.0625, 0.125, 0.25, 0.5, and 1.0%) using large Finn chamber, and they suggested that 1.0% SLS aqueous solution is appropriate for an irritant patch test as a positive control. Contamination with bacteria was found in the SLS solutions of lower concentrations resulting in decreased concentration of SLS, and the storage of SLS solutions of very low concentrations should be at low temperature and preferably in sterile vials.[36]

30.2.3 Evaporation and Temperature of Test Solution

The penetration of SLS through the skin barrier is significantly increased by the increase of the temperature of test solution.[37] Berardesca et al.[38] reported significantly different skin responses to the temperature of test solution (4, 20, and 40°C). Skin damage was higher in sites treated with warmer temperatures, and there was a highly significant correlation between irritation and temperature of test solution. Ohlenschlaeger et al.[39] also demonstrated increased irritation on the application site of warmer solution using repeated immersions in an SLS solution at 20 and 40°C. Transition from a packed gel state to a more fluid crystalline state in SC lipids occurs at temperatures between 38 and 40°C, and the fluidity of SC is important in the percutaneous penetration process as an explanation of increased irritancy at higher temperatures.[38] The evaporation rate of aqueous solutions from Finn chambers was reported as 1 mg/3 min.[40] Evaporation from the patch before application inhibits the inflammatory response, even though the relative concentration of the irritant is increased by the evaporation process.[41] This inhibition of skin irritation could be the result of decreased amount or lowered temperature owing to evaporation of test solution.

30.2.4 Time of Evaluation

When noninvasive measurements of the skin response are made, the interval between removal of the patch and the measurements should allow for a period of increased evaporation following occlusion. Equalization of water diffusion between the SC and the ambient air is settled after 20 min of patch removal.[42] For measurements of TEWL, in most papers, the interval was reported to be 30 min.[43–45] The time course of TEWL after SLS patch testing demonstrated significant reduction in TEWL values from 30 to 60 min after removal of the patch, but not from 60 to 180 min,[46] and they suggested that evaluation of irritant patch-test reactions by measurement of TEWL can naturally be made at any time after removal of the patches, as long as the time period is precisely accounted for. Others have argued that a minimum waiting period of 2 or 3 h should be allowed for evaporation of excessive water due to occlusion.[19,47] Recently, Aramaki et al.[34] suggested that TEWL measurement performed 30 min after patch removal is too early and measurement 24 h after patch removal should be done for practical reasons.

30.2.5 Guidelines on SLS Exposure Methods

High-purity (99%) SLS must be used in any study, dissolved water in occlusive and open testing, while tap water may be acceptable in immersion testing. Standard-sized occlusion chambers with filter paper disks corresponding to large (12 mm, 60 μL) and extralarge (18 mm, 200 μL) Finn chamber are recommended. The extralarge Finn chambers are recommended for repeated applications. For open exposures, 20 mm diameter plastic ring is advised. The volume of the solutions must be such that the total exposure area is covered (800 μL). Chambers should be applied to the skin immediately, i.e., within 1 min after preparation with the test solution. TEWL measurement should be performed a minimum of 1 h after removal of test chambers. European Society of Contact Dermatitis (ESCD) proposed new guidelines in terms of purposes and methods of SLS exposure tests (Table 30.1).[23]

30.3 BIOLOGIC ENDPOINTS

30.3.1 Clinical Appearance of SLS Reaction

Erythema, infiltration, superficial erosion can be seen during acute reaction to SLS. With higher concentrations vesicular and pustular reactions may be seen. During healing of acute reactions, scaling and fissuring will take over. The same appearance of erythema, scaling, and fissuring is seen during repeated application of SLS. The soap effect consisting of fine wrinkled surface or chapping is not commonly seen in SLS patch-test reaction.[23] Most recently reported literatures have used the modified visual scoring system of Frosch and Kligman[9] to evaluate clinical skin reaction to SLS. Tupker et al.[23] developed the guideline concerning about the visual scoring schemes for the acute and cumulative reactions to SLS (Tables 30.2 and 30.3).

TABLE 30.1
ESCD Guidelines on SLS Exposure Tests with TEWL Measurement

	Susceptibility Evaluation		Provocative Testing	
	Acute	Cumulative	Acute	Cumulative
One-time occlusion test				
Application time	24 h	Not	24 h	Not
Mode of application	Chamber 12 mm	applicable	Chamber 12 mm	applicable
SLS w/v%	0.5%		2%	
Repeated occlusion test				
Application time	Not	2 h 1 × daily	Not	2 h 1 × daily
Application period	applicable	3 weeks[a]	applicable	3 weeks[a]
Mode of application		Chamber 18 mm		Chamber 18 mm

TABLE 30.2
ESCD Guideline on Clinical Scoring of Acute SLS Irritant Reactions

Score	Qualification	Description
0	Negative	No reaction
1/2	Doubtful	Very weak erythema or minute scaling
1	Weak	Weak erythema, slight edema, slight scaling, and slight roughness
2	Moderate	Moderate degree of erythema, edema, scaling, roughness, erosions, vesicles, bullae, crusting, and fissuring
3	Strong	Marked degree of erythema, edema, scaling, roughness, erosions, vesicles, bullae, crusting, and fissuring
4	Very strong/caustic	As 3, with necrotic areas

Source: Tupker, R.A. et al., *Contact Dermatitis*, 37, 53, 1997.
Note: Reading 25–96 h after one-time exposure.

TABLE 30.3
ESCD Guideline on Clinical Scoring of Subacute/Cumulative SLS Irritant Reactions

Score	Qualification	Description
0	Negative	No reaction
½	Doubtful	Very weak erythema or shiny surface[a]
1	Weak	Weak erythema, diffuse or spotty, slight scaling, and slight roughness[b]
2	Moderate	Moderate degree of erythema, scaling, roughness, and weak edema and fine fissures
3	Strong	Marked degree of erythema, scaling, roughness, edema, fissures and presence of papules and erosions, and vesicles
4	Very strong/caustic	As 3, with necrotic areas

Source: Tupker, R.A. et al., *Contact Dermatitis*, 37, 53, 1997.

[a] The term shiny surface is used for those minimal reactions that can only be discerned when evaluated in skimming light as a "shiny area."

[b] The term roughness is used for reactions that can be felt as rough or dry, sometimes preceeded or followed by visible changes of the surface contour, in contrast to "scaling," which is accompanied by visible small flakes.

30.3.2 Pathogenesis of SLS Reaction

The histopathologic changes induced by SLS depend on various factors including concentration, mode of application, and time of evaluation. Acute reaction to SLS application in epidermis can include hyperkeratosis, parakeratosis, spongiosis, intracellular edema, hydropic degeneration of basal cells, and necrosis.[48–51] In dermis, there were variable degrees of inflammatory cell infiltration, edema, and collagen degeneration. T lymphocytes are the predominant infiltrating cells and CD4(+) cells outnumbered the CD8(+) cells.[52–56] The histological changes to cumulative SLS irritation were similar as in acute irritation, but repetitive mild irritation may evoke epidermal hyperplasia with minimal inflammatory infiltration.[48]

Many surfactants including SLS disrupt the skin barrier function resulting in increased TEWL,[57,58] and increased blood flow, clinically visible as erythema.[59] Leveque et al.[60] suggested that an increase in TEWL did not necessarily imply the alteration of SC and SLS-induced dry skin could hardly be interpreted in terms of lipid removal.[61] A disruption of the secondary and tertiary structure of keratin proteins may expose new water-binding sites resulting in SC hydration, and the most likely explanation of SLS-induced increase in TEWL lied in the hyperhydration of SC and a possible disorganization of lipid bilayers.[27] Forslind[62] proposed a domain mosaic model of skin barrier. SC lipids are not randomly distributed, but are organized in domains. Lipids with very long chain lengths are segregated in gel, impermeable to water, and separated by grain borders populated by lipids with short chain lengths, which are in fluid phase, permeable to water. Surfactants including SLS infiltrate the fluid phase permeable to water increasing the width of grain borders, and increase TEWL.

30.3.3 Noninvasive Bioengineering Techniques Assessing SLS Reaction

Several noninvasive bioengineering methods to quantify and to obtain information which is not detectable clinically have developed in recent decades (Table 30.4).[63] Measurement of TEWL as a technique to evaluate skin barrier function is widely used[64,65] and a positive dose–response relationship for skin response to SLS as measured by TEWL has been demonstrated.[66] When attempting to quantify irritant patch-test reactions by electrical conductance measurement, the intraindividual variation in the results was so high that the method was found unhelpful for this purpose.[67] A positive relationship was found between dose of SLS and blood flow values recorded by LD.[66,68] However, wide fluctuations in laser Doppler blood flow values in response to SLS patches were found due to spotty erythema.[44] The skin color is expressed in a three-dimensional coordinate system: a* (from green to red), b* (from blue to yellow), and L* (from black to white) values.[69] Color a* coordinates have been demonstrated to correlate well with visual scoring of erythema in inflammatory reactions caused by soap or SLS.[65,70,71] Ultrasound examination has the advantage that no preconditioning of the subjects is necessary before measurement. Ultrasound A-scan has been found suitable for quantification of patch-test reactions[72,73] and also a promising method for quantification of SLS-induced inflammatory response, being

TABLE 30.4
Noninvasive Bioengineering Techniques Used in the Evaluation of Cutaneous Irritation

Technique	Measured Skin Function	Informed Obtained
Evaporimeter	Transepidermal water loss	Positive dose–response relationship for skin response to SLS Most sensitive method for SLS-induced irritation
Laser-Doppler flowmeter	Blood flow	Positive relationship between applied dose of SLS and blood flows. Wide fluctuations in response to SLS due to spotty erythema
Ultrasound	Skin thickness	No preconditioning is necessary. Good relation to SLS concentrations, but minimal correlation with erythema or epidermal damage
Impedance, conductance, capacitance	Skin hydration	Correlation with epidermal damage, but intraindividual variation is so high, this method is unhelpful
Colorimeter	Skin colors	Positive correlation between changes in the a* color coordinates and doses of SLS, but not with epidermal damage

Source: Lee, C.H. and Maibach, H.I., *Contact Dermatitis*, 33, 1, 1995.

consistently more sensitive than measurement of skin color,[66] and Seidenari and di Nardo[74] demonstrated that B-scanning evaluation showed a good correlation with TEWL values in assessing superficial skin damage induced by SLS.

In a comparison among evaporimetry, LD, ultrasound A-scan, and measurement of skin color, evaporimetry was found to be the best suited method for evaluation of SLS-induced skin damage.[65,67] Lee et al.[75] also observed that measurement of erythema index using Dermaspectrometer was less sensitive than TEWL measurement. However, Wilhelm et al.[65] suggested that although TEWL measurements may be an accurate and sensitive method in evaluating skin irritation, color reflectance measurements may be a helpful complimentary tool for the clinician, because of its convenience. Serup[76] suggested that measurement of TEWL is sensitive and useful in the study of corrosive irritants, such as SLS, especially in the induction phase of irritant reaction, but does not have direct clinical relevance, and the results need to be backed up with other relevant measures. Fluhr et al.[77] suggested that, regarding the time-dependent effect, a positive discrimination was seen for TEWL, measuring the barrier function, and the perfusion parameter LD. The discriminatory ability of TEWL was superior to that of LD. However, when evaluating SLS patch testing by bioengineering methods, TEWL measurement appears more suitable to evaluate skin reaction to SLS concentration $<1.0\%$, whereas LD is more appropriate to evaluate pronounced skin reaction (SLS concentration $\geq 1\%$).[78]

Tupker et al.[79] found that the time course of TEWL after a 24-h SLS patch test varied between different subjects. Using SLS in varying concentrations, Serup and Staberg[73] found a delayed response only for reactions clinically scored as 1+, but not for more intense reactions, indicating that the kinetics of the response may depend on the severity of the reaction.[78,]

30.3.4 Recovery of SLS Reaction

Wilhelm et al.[80] studied the skin function during healing phase after single 24-h patch application of 0.5% SLS solution. Erythema was most increased directly after patch removal with a slow gradual decrease, but not completely resolved even 18 days after treatment. SC hydration evaluated by capacitance measurements did not return to baseline values before 17 days after surfactant exposure. The repair of the SC barrier function as indicated by TEWL measurements was completed 14 days after exposure. Freeman and Maibach[44] described augmented irritant response to repeated application of 2% SLS solution on the clinically improved irritant contact dermatitis site, and suggested that although skin may appear to be morphologically normal, it may not be functionally normal. Lee et al.[21] suggested that complete recovery of skin function after acute reaction induced by 1% SLS solution was achieved approximately 4 weeks later. Choi et al.[81] demonstrated that skin reactivity of chronically irritated sites with SLS solution showed hyperreactivity compared to normal skin even 10 weeks after chronic irritation, and suggested that chronically irritated skin required a longer recovery time than acutely irritated skin.

30.3.5 Comparison of SLS Reaction with Noncorrosive Irritants

Irritants could be divided into two types: corrosive and noncorrosive irritants.[76] Corrosive irritants induce impairment of skin barrier function even when in provoked weak or subclinical reaction. Corrosive irritants have shown linear dose–response curve. However, noncorrosive irritants that cause low degree of irritation do not induce barrier disruption, and noncorrosive irritants may show linear dose–response at lower concentrations and have a tendency to make a plateau at higher concentrations. SLS has been considered as the typical corrosive irritant, and nonanoic acid (NAA) is an example of noncorrosive irritant. There are many reports comparing the skin responses between SLS and NAA; these are clinical morphology, histopathological changes, and changes in skin function measured by noninvasive bioengineering techniques.

Reiche et al.[82] observed the clinical morphology of SLS and NAA patch-site reactions and showed that erythema decreased with time for all concentrations of NAA and at higher concentrations of SLS. Surface changes increased with time for SLS patch sites and at higher concentrations of NAA. Lindberg et al.[83] studied the differential effects of SLS and NAA on the expression of CD1a and intercellular

adhesion molecule 1 (ICAM-1) in human epidermis. ICAM-1 reactivity could not be detected in epidermis on the site of 20 and 80% of NAA solution, and there was a decrease in CD1a+ cells after 80% NAA application. However, SLS induced ICAM-1 expression on keratinocytes, and the effects on the number of CD1a+ cells were minimal. Forsey et al.[84] compared the effects of NAA and SLS on the LCs and keratinocytes of clinically normal skin in patients with chronic irritant contact dermatitis. SLS induced keratinocyte proliferation after 48 h of exposure; however, NAA decreased keratinocyte proliferation after 24 h of exposure, but this returned to basal levels after 48 h. SLS induced keratinocyte apoptosis after 24 and 48 h of exposure; however, NAA induced epidermal cell apoptosis after only 6 h of exposure. SLS had no effect on LC number, and no CD1a+ apoptotic cells were seen after exposure to SLS. NAA dramatically decreased LC number after 24 and 48 h of exposure, which was accompanied by basal redistribution. Most significantly, NAA induced apoptosis in over half of LCs present after 24 and 48 h of exposure. Boxman et al.[85] observed immunoreactive HSP27 in the upper cell layers of the epidermis after exposure to the higher (2%) concentration of SLS. However, HSP27 nuclear immunoreactivity was observed in the skin exposed to the lowest concentration of NAA tested (2.5%).

Seidenari[86] compared the irritant reactions induced by NAA and SLS using 20-MHz B-scan. A clear decrease in flexibility of the epidermis echo at 24 h was visible at SLS patch-test sites, whereas at patch-test sites with NAA, there was a trend toward an increase in values of hyperreflecting pixels. Fullerton et al.[87] studied the skin irritation typing and grading using laser Doppler perfusion imaging. For SLS, both mean perfusion and area were found to increase from day 2 to day 3. The values decreased on day 5. The NAA reactions had a more rapid onset, peaked at 24 h (day 2) and then gradually declined at 48 and 96 h. We applied the SLS and NAA solutions on the volar forearm skin for 24 h and measured TEWL values and erythema indices to compare the different features of irritant reactions between corrosive and noncorrosive irritation. In our study of TEWL measurements, SLS solutions caused higher TEWL values than NAA, and the slope of SLS curve was steeper than that of NAA curve in relation to the concentration of SLS and NAA solutions. There was a tendency for the TEWL values to make a plateau at the higher NAA concentrations. However, both SLS and NAA solutions showed very similar pattern of erythema indices. In the study of the time course of TEWL values and erythema indices, TEWL returned to baseline values after 3 weeks in areas patch tested with 50% NAA. But TEWL values did not recover baseline values until 3 weeks in the corresponding areas tested with 5% SLS. However, erythema index curve of 5% SLS and 50% NAA showed quite similar pattern.[88] Benzalkonium chloride (BKC), another typical noncorrosive irritant, showed much less damage to the skin barrier function compared to the concentration of SLS, while they showed a similar degree of erythema. The slope of BKC was between those of SLS curve and NAA curve in relation to the concentration of SLS, NAA, and BKC solutions.[89]

TABLE 30.5
Host-Related Factors in Cutaneous Irritation

Hyperirritable skin
Skin disease (atopic dermatitis, hand eczema, seborrheic dermatitis)

30.4 HOST-RELATED FACTORS

There are many host-related factors in cutaneous irritation: those that are considered as skin disease and those that represent variations from normal skin predisposed to irritation (Table 30.5).

30.4.1 Age

Increased susceptibility to SLS in young females compared to elderly females was reported, when assessed by visual scoring and TEWL, and the increase in TEWL values was found to be more persistent in the older group.[90,91] These findings imply less reaction to an irritant stimulus but a prolonged healing period in older people. There is no significant influence on skin susceptibility between the 18 and 50 years of age,[92] but significantly reduced irritant reactivity in older more than 55 years age group compared to various younger age groups.[93]

30.4.2 Sex

Hand eczema occurs more frequently among women than men. However, many investigators have found no sex correlation in skin susceptibility.[45,94–96] Reactivity to SLS at day 1 increased in the menstrual cycle compared to day 9–11, when tested on opposite arms in healthy women.[97] Since no cyclical variation was found in baseline TEWL, the increased reactivity of the skin at day 1 in the menstrual cycle probably reflects an increased inflammatory reactivity, rather than changes in the barrier function. Recently, Robinson[98] reported that the male subjects responded more rapidly, and there was a significant increase in response of the male subjects compared to female subjects.

30.4.3 Anatomic Region

Variation in skin responses within the same individual to identical irritant patch tests may be considerable. Van der Valk and Maibach[99] studied the differences in sensitivity of volar surface of the forearm to SLS and demonstrated that the potential for irritation increases from the wrist to the cubital fossa, and Panisset et al.[100] showed that TEWL values next to the wrist were found greater than on the other sites of volar

forearm. Cua et al.[90] reported that the thigh had the highest reactivity and the palm the lowest. Henry et al.[101] studied the regional variability to 1% SLS using corneosurfametry bioassay and found that the dorsal hand and volar forearm were the least reactive, the neck, forehead, back, and dorsal foot the most reactive sites. Dahl et al.[102] found that, for simultaneous Al-patch testing with SLS, the corresponding sites on the right and the left sides were scored identically in only 53% of cases. Using large Finn chambers (12 mm), 84% of SLS patches showed identical visual score when tested simultaneously on right and left arms.[67] Rogiers[103] suggested that measurement of TEWL should be carried out on identical anatomic sites for all subjects involved, and the volar forearm is a good measurement site and corresponding places on the right and left forearms exhibit the same TEWL.

30.4.4 Race and Skin Color

Bjornberg et al.[104] reported that fair skin and blue eyes showed the high intensity of the inflammatory response to a mechanical irritant. When skin color was assessed by a tristimulus colorimeter, an association between light reflection (L*) from the skin surface and susceptibility to SLS was found.[92] By determination of minimal erythema dose (MED) in Caucasians, the cutaneous sensitivity to UV light and to seven different chemical irritants was found to correlate positively, while skin phototype based on complexion and history of sunburn proved less reliable.[105] McFadden et al.[106] found no significant differences in irritation thresholds to SLS among six skin phototypes. In contrast to these reports, an inclination to increased susceptibility to SLS in black and Hispanic skin types as compared to white skin types was found when evaluated by measurement of TEWL.[43,64] There were more complex reports concerning the SLS susceptibility between Caucasian and Asian population. There was an increased cumulative irritation response in Japanese subjects versus Caucasian to various chemicals.[107] Foy et al.[108] demonstrated a greater acute irritant responses in Japanese women compared to Caucasian; however, cumulative irritation did not show significant increase in Japanese compared to Caucasian. Chinese displayed similar response profile in acute irritation test; however, they showed a slower and less-severe response in the cumulative irritation test compared to Caucasian or Japanese subjects.[98] Robinson et al.[109] failed to find significant differences in skin reactivity to SLS between Caucasians and Asians. However, there was a consistent trend toward increased reactivity, i.e., reduced time to respond, observed in the Asian versus Caucasian subjects.[93] Tanning may influence the susceptibility to irritants. A diminished reaction to SLS after UVB exposure was reported.[110]

30.4.5 Skin Hydration

In repetitive exposure to SLS, higher susceptibility was reported in dry skin than in clinically normal skin in eczematous subjects and controls.[79] Comparing winter and summer skin, decreased skin hydration was found in winter, when a higher reactivity to SLS was also found.[24] Low outdoor temperature and low relative humidity in the winter lead to decreased ability of the SC to retain water.[111] Thus, these studies indicate that a decreased hydration state of the skin may be associated with impaired barrier function and increased skin susceptibility. In contrast, Lammintausta et al.[112] found no relationship between clinically dry skin and the response to repeated SLS exposure.

30.4.6 Sensitive Skin

Frosch and Kligman[113] reported a significant correlation between the skin response to particular irritants in healthy volunteers and patients with skin diseases. Murahata et al.[114] suggested a relationship between skin susceptibility to detergents and high baseline TEWL, and a highly significant correlation between baseline TEWL and TEWL after a single or repeated exposure to SLS was reported.[19,96,97] However, other studies reported an absent or poor correlation between baseline TEWL and TEWL after SLS exposure.[43,44,115,116]

Sensitive skin is a skin type having higher reactivity than normal skin and developing exaggerated reactions when exposed to external factors.[117] The stinging test using lactic acid has been widely used for the selection of sensitive skin. However, this test is based on self-perceived assessment and lacks objectivity. Seidenari et al.[118] demonstrated a decrease of baseline capacitance values indicating the tendency to barrier impairment, and they suggested that dehydration can represent a basis for subjective sensations after exposure to water and soap. Lammintausta et al.[104] demonstrated reactivity to a 24-h SLS patch test using LD in stingers compared with nonstingers. Simion et al.[119] also showed the correlations between self-perceived sensory responses to cleansing products and TEWL and colorimeter a* values in stingers. However, other studies did not show correlation between self-assessed skin sensitivity or skin reactivity to chemosensory stimuli and skin reaction to SLS irritation.[93,109,120] Recently, we performed lactic acid sting test, dimethyl sulfoxide (DMSO), and SLS patch tests in 55 Koreans. There were no significant differences in the skin responses of lactic acid sting test, DMSO, and SLS patch tests between sensitive and nonsensitive skin.[121]

Loeffler et al.[122] propose the new classification of skin irritancy. People with sensitive skin are only individuals who stated their skin as sensitive. There is no possibility to prove the statement with objective methods. If individuals react repeatedly to a skin test with sensation induced by chemical irritants such as lactic acid, they are identified as a stinger. If individuals do have an increased skin susceptibility to irritation caused by chemical irritants, which objectively be measured using bioengineering methods, they are identified as individuals with an irritable skin.

30.4.7 Irritable or Hyperirritable Skin (Excited Skin Syndrome)

Mitchell[123] introduced the term *angry back* to describe the phenomenon of a single strong positive patch-test reaction

creating a back, which is hyperreactive to other patch-test applications. The excited skin syndrome was illustrated experimentally in guinea pigs, and increased susceptibility to an ointment containing 1% SLS was observed in animals stressed by inflammatory reactions in the neck area.[124] Bruynzeel et al.[125] attempted to use SLS patches as markers of hyperirritability. Agner[126] observed no increased skin reactivity to SLS in patients with chronic or healed eczema compared to controls, while hand eczema patients with acute eczema showed increased skin reactivity to SLS compared to controls. Shahidullah et al.[127] reported increased TEWL values in the clinically normal skin of patients with eczema. But there was no significant difference in baseline TEWL values between patients with eczema and in controls.[126,128]

30.4.8 Skin Diseases (Atopic Dermatitis, Hand Eczema, Seborrheic Dermatitis)

There is a marked abnormality in barrier function in the skin of patients with atopic dermatitis (AD), and high levels of sphingomyelin deacylase were demonstrated in the lesional and nonlesional skin of patients with AD leading to decrease of ceramide and abnormality in barrier function.[129] Di Nardo et al.[130] suggested that SC ceramide content may determine a proclivity to SLS-induced irritant contact dermatitis. There are many reports of increased baseline TEWL in clinically normal skin of patients with AD.[79,131–135] Agner[132] showed that the response to SLS was statistically significantly increased in atopics compared to controls, when evaluated by visual scoring and skin thickness, but not TEWL. Nassif et al.[134] suggested that AD patients, as well as those with a history of allergic rhinitis, had lower irritant threshold than controls. It has also been demonstrated that a significantly greater response to SLS,[79,126,134,136] as well as a tendency to increased skin susceptibility, is related to the degree of severity of the dermatitis.[137] There were no significant differences in TEWL between individuals who were classified as atopic but without active dermatitis, individuals with rhinoconjunctivitis or atopic asthma and healthy controls, either at the basal or at the post-SLS measurement. Enhanced skin susceptibility is only present in individuals with active dermatitis.[138] Basketter et al.[139] also could not find significant differences in skin reactions to SLS in the normal skin of AD compared to control group.

Baseline TEWL values in patients with localized, inactive, or healed eczema were not significantly higher than in controls.[15,126] Agner[126] observed no increased skin reactivity to SLS in patients with chronic or healed eczema compared to controls, while hand eczema patients with acute eczema showed increased skin reactivity to SLS compared to controls.

There were several reports that patients with seborrheic dermatitis showed could be easily irritated to some chemicals including SLS.[136,140] Tollesson and Frithz[141] observed increased TEWL values and abnormality in essential fatty acids in infantile seborrheic dermatitis, and they normalized TEWL values by applying the borage oil containing gamma-linoleic acid.

30.5 CONCLUSION

It is clear that SLS data do not provide a unanimous opinion on all points. Yet, the preponderance of the observations suggest that we are beginning to understand some of the parameters, such as purity, dose, patch, anatomic site, single versus multiple application, occluded versus open application, that influence diverse response of the skin irritation.

31 Factors Influencing Applied Amounts of Topical Preparations

Tanzima Islam, Nikolay V. Matveev, and Howard I. Maibach

CONTENTS

31.1 Preparation-Dependent Factors 295
31.1.1 The Form of Preparation 295
31.1.2 The Physical Characteristics of Preparation 295
31.1.3 Type of Container 296
31.2 Patient-Dependent Factors 296
31.2.1 Socially Mediated Factors 296
31.2.2 Factors Mediated by Medical Personnel 296
31.2.3 Factors Dependent on Patient's Condition 297
31.3 Conclusion 297
References 297

The effect of any medication depends on the applied dose. In case of topical medications, the applied amount is often uncertain and variable. The importance of proper dosage of topical medications in dermatology was seldom discussed, but accurate dosage of topical agents (e.g., calcipotriol) was demonstrated to provide better efficacy [1]. Additionally, to make any conclusion about the effectiveness of a topical preparation, it is preferable to have the amount of a topical preparation known and well controlled.

Unfortunately, only limited scientific data are available on the variability of amount of topical preparations applied to the skin of the patients in different conditions. Some studies concerned not pharmaceutical preparations, but sunscreens; others dealt with application of barrier creams. Nevertheless, with certain limitations, the data of sunscreen and barrier cream studies might be generalized to all topical preparations, including topical pharmaceuticals.

Our aim was to collect and analyze the available information on the factors influencing the amount of various topical agents applied to skin.

The analysis of the data demonstrated that the amount of applied topical agents depended on several factors, which can be divided into two main groups: (1) preparation-dependent, and (2) patient-dependent.

31.1 PREPARATION-DEPENDENT FACTORS

Preparation-dependent factors are: (1) form of a preparation (i.e., ointment, cream, lotion); (2) the physical characteristics of a preparation (e.g., its viscosity); and (3) type of container.

31.1.1 The Form of Preparation

When fixed amounts of ointment, cream, and solution are distributed on the skin of volunteers, the ointment was most evenly distributed [2]. Authors believed that this was due to higher viscosity of the ointment. Nevertheless, an additional explanation might be that the volunteers could have much better control (tactile and visual) over the ointment distribution, compared to creams and lotions. The application of the topical preparations, which either evaporate or is absorbed by the skin (lotions, creams), could not be as well controlled as an ointment, which usually stays on the site of application for at least several minutes.

Probably, if creams or lotions were more visible on the skin (e.g., due to added pigment, which could fade in several minutes postapplication), creams and lotions might be applied more evenly, as better control over their distribution could be achieved.

31.1.2 The Physical Characteristics of Preparation

If the amount of the applied topical agents was not fixed, the applied amounts strongly depended on the preparation's viscosity. For instance, a "chemical" type of sunscreen, which was easier to spread on the skin, was applied in amounts up to 50% higher than the "physical" sunscreens of higher viscosity (1.48 mg/cm^2 versus 0.94 mg/cm^2, respectively [3]). Meanwhile, the same study did not reveal statistically significant differences between the amounts of the applied chemical sunscreens with various sun-protective factors (SPF): 8, 15, and 25.

Modified with permission from Matveev, N.V. and Maibach, H. I., *Exog. Dermatol., 1*, 64–67, 2002.

Note that an earlier study [4] did not demonstrate a statistically significant difference between the amounts of applied cream, ointment, and lotion, in spite of their evidently different viscosity. Probably, this may be explained by more sensitive methods of investigations used in the later study.

31.1.3 Type of Container

A study demonstrated that the dispenser type may influence the amount of medication applied by the patients: the cream contained in an open jar was applied by volunteers much more readily than the same cream from a tube (1.7 mg/cm^2 versus 0.71 mg/cm^2, respectively [4]).

31.2 PATIENT-DEPENDENT FACTORS

Patient-dependent, or behavioral, factors influencing dosing might be divided into three groups: (1) socially mediated factors; (2) factors mediated by medical personnel; and (3) factors mediated by patient's condition.

31.2.1 Socially Mediated Factors

The socially mediated factors are mostly known regarding the use of sunscreens (although we might assume that in case of visible skin lesions, e.g., facial eczema, such factors may also play a role).

It is the social factors which may explain the fact that women use sunscreens more often than men and apply sunscreens more frequently on sun-exposed parts of the body [5,6]. Some associations were also found between use of sunscreens and also self-tanning products by undergraduate students and their close relatives (for facial sunscreens) and romantic partners (for self-tanning preparations) [7]. Household members encouragement increased the frequency of sunscreen use by postal workers of Southern California [6]. At the same time, the people who had relatives with a skin cancer history applied the sunscreens more readily than the people without a family history of skin cancer [6].

Nevertheless, another study [8] demonstrated no significant gender difference in the amount of sunscreen cream applied by students from several European countries—these amounts were uniformly low, the median quantity was 0.39 mg/cm^2, while the amount needed to obtain the nominal SPF must be 1.5 mg/cm^2 (according to the requirements of the German standardization authority—Deutsches Institut für Normung) or 2 mg/cm^2 (according to the requirements of American Standard Association).

No gender differences were also found in the study of application of pharmaceutical topical agents [4], probably because the use of medications was perceived as necessary by both male and female patients, while the use of sunscreens might be perceived more important by females as having a cosmetic effect.

31.2.2 Factors Mediated by Medical Personnel

There is an opinion that little attention is paid to the accurate dosage of topical preparations in terms of explicit instructions to the patient on the quantity of the agent to be applied per unit of time [9]. Other investigators demonstrated that the assistance of medical personnel may change the amount of preparations applied by the patients.

The amount of topical medication (cream) applied by nurses was significantly less (0.91 mg/cm^2) than the quantity of cream applied by patients themselves (1.71 mg/cm^2) [4]. The same authors demonstrated no significant differences between the amounts of topical preparations applied by uninstructed and instructed patients.

Operator-assisted (e.g., nurse) total-body application of cream/ointment resulted in less cream applied, but the cream was spread more equally than in the case of self-application [10]. It was interesting to compare the distribution of the cream/ointment applied by patients themselves at different anatomic sites and the surface areas of the sites (see Table 31.1). Significant differences existed between cream distribution over the region and the real surface of the region, for example, genitoanal area received more than sevenfold the amount of cream in comparison with its surface share.

The application of sunscreens and barrier creams, on the contrary, did reveal the influence of instructions provided by medical personnel.

Though sunscreens are supposed to be used with no instructions or assistance, Azurdia et al. [11] showed that self-applied sunscreens are spread in low mean amounts with great variability: from 0 to 1.2 mg/cm^2 at different anatomic sites (mean amount 0.5 mg/cm^2). Maximum thickness was found on the forehead, cheeks, nose, and chin (1.0 mg/cm^2 or greater), while the mean cream thickness on the temple, ears, lateral, and posterior neck approached zero.

Loesch and Kaplan [12] also showed that periorbital areas, perioral regions, and the ears are rarely covered by sunscreen properly; they suggested some rules for patients to enhance complete sun protection. Subsequently, Azurdia et al. [13] demonstrated that after special instructions the same patients applied 5- to 10-fold higher amounts of sunscreen than prior to instructions.

TABLE 31.1
Distribution of Cream/Ointment by Body Areas

Part of the Body	Cream Amount, %	Surface of Body Area of Adults, % of Total Body Surface
Head	7.6 ± 2.3	9
Arms	22.3 ± 1.6	19
Legs	43.6 ± 2.3	40
Trunk, anterior	14.1 ± 2.0	13
Trunk, posterior	12.4 ± 1.8	18
Genitoanal area	7.4 ± 1.0	1

Source: Schlagel C.A., and Sanborn E.C., *J. Invest. Dermatol.*, *42*, 253–256, 1964.

There was a thorough investigation of distribution of self-applied industrial protective cream in three groups of workers—metal workers, hospital cleaners, and construction workers [14]. Many areas of the hands and forearms were not covered properly by protective cream, which might result in a higher incidence of irritant dermatitis. The authors suggested a special educational program for workers to ensure the proper use of protective cream at the workplace.

Subsequent investigations showed that the uptake of barrier creams was significantly higher among German bakers, who received special training on skin protection, compared to those who did not receive it [15].

31.2.3 Factors Dependent on Patient's Condition

Severe cases of skin diseases may require larger amounts of topical medications, and this is well understood by the patients, so that the patients with more severe cases are ready to apply much larger amounts of topical agents.

It was also demonstrated that, for example, the postal workers with higher skin sensitivity to sun used sunscreens significantly more frequently than their colleagues with lower skin sensitivity [6].

31.3 CONCLUSION

Numerous factors may influence the applied amounts of topical preparations. It is important that the mentioned factors be considered if any conclusion is to be made on effectiveness of a topical preparation—either for a specific patient, or for a group of the patients.

The investigations failed to demonstrate the influence of medical instructions on self-application of topical medications [4]; but in case of preventive agents (barrier creams and sunscreens) such instructions were beneficial [13]. Further studies may provide additional information on the reasons for such a difference.

When clinical trials of topical agents are conducted, and no direct measurement of the applied amounts of the substances is provided, there should always be a proper control of the possible factors influencing the application of the substances on the skin. Otherwise, the obtained data may not be comparable.

Generally, we believe that there remains much room for innovations, which would be able to provide more precise dosing of topical preparations.

32.1 INTRODUCTION

Each day the skin is exposed to an infinite number of substances; some may be potentially irritants (e.g., surfactants, cutting oils, acids, and alkalis) or allergens (e.g., poison oak/ivy). Skin barrier function may be damaged due to contact with these materials. Consequentially, irritant contact dermatitis (ICD) and allergic contact dermatitis (ACD) may develop. Minimizing exposure is recommended but often not practicable. In many occupations, such as farmers, forest firefighters, outdoor activities, hospitals, and even households, such encounters are ubiquitous. Therefore, to prevent or reduce the risk of developing ICD and ACD, prophylactic measures are indicated. Application of barrier creams (BC) before or during work may play an important role in the prevention of occupational contact dermatitis and nature hand care as well.

Their efficacy in reducing the developing ICD and ACD has been documented *in vitro* and *in vivo* experimental studies (Frosch et al., 1993a; Lachapelle, 1996; Zhai and Maibach, 1996a, 1999, 2001, 2002; Wigger-Alberti and Elsner, 1998, 2000a,b; Maibach and Zhai, 2000). Yet inappropriate BC application may induce a deleterious rather than a beneficial effect (Goh, 1991a,b; Frosch et al., 1993a–d; Treffel et al., 1994; Zhai and Maibach, 1996b; Lachapelle, 1996). This updated chapter from Zhai and Maibach (2004) emphasizes on BC's terms, mechanism, and other relative topics in this field.

32.2 DEFINITION AND TERMS

BC are designed to prevent or reduce the penetration and absorption of various hazardous materials into skin, preventing skin lesions and other toxic effects from dermal exposure (Orchard, 1984; Frosch et al., 1993a; Lachapelle, 1996; Zhai and Maibach, 1996a,b). BC are also called "skin protective creams" (SPCs) or "protective creams" (PCs), as well as "protective ointments," "invisible glove," "barrier," "protective" or "prework" creams or gels (lotions), "antisolvent" gels, and so on (Guillemin et al., 1974; Mahmoud and Lachapelle, 1985; Loden, 1986; Goh, 1991b; Frosch et al., 1993a). Kresken and Klotz (2003) believe that the term "invisible glove" is incorrect and it might mislead the user. Frosch et al. (1993a) consider SPC a more appropriate terminology since most creams do not provide a real barrier, at least not comparable to stratum corneum. We utilize BC here because this term is in general usage in industry. BC may share characteristics with moisturizers. BC's target is the prevention of external noxious substances penetrating skin, and moisturizers are frequently used for "dry" skin conditions, as well as to maintain healthy skin (Zhai and Maibach, 1998). BC and moisturizers may overlap in chemistry and function.

32.3 REASONS TO UTILIZE BC

Occupational contact dermatitis is the most common work-related injury involving millions of workers worldwide. Avoidance of these irritants or allergens may not be practical for persons whose occupation or activities mandate their working in certain environments. Certain gloves provide protective effects for corrosive agents (acids, alkalis, etc.) (Boman et al., 1982; McClain and Storrs, 1992; Mellstrom et al., 1996; Wigger-Alberti and Elsner, 1998). Protective clothing, as well as other personal devices, also plays a critical role as an important measure in industries (Mathias, 1990; Davidson, 1994). But, protective clothing may trap moisture and occlude potentially damaging substances next to the skin for prolonged periods and increase the likelihood that dermatitis will develop (Mathias, 1990; Davidson, 1994). In practice, BC are recommended only for low-grade irritants (water, detergents, organic solvents, cutting oils) (Frosch et al., 1993a; Zhai and Maibach, 1996b; Wigger-Alberti and Elsner, 1998). The first line of defense against hand eczema

is to wear gloves, but in many professions this is impossible because of the loss of dexterity. In some instances, an alternative would be to utilize BC. BC are also used to protect the face and neck against chemical and resinous dust and vapors (Birmingham, 1969). Many prefer to use BC rather than gloves because they do not want the hand continuously sealed inside a glove that can inhibit skin barrier function (Wigger-Alberti and Elsner, 1998). In addition, many gloves do not resist the penetration of low molecular weight chemicals. Some allergens are soluble in rubber gloves and may penetrate the glove and produce severe dermatitis (Mathias, 1990; Estlander et al., 1996; Wigger-Alberti and Elsner, 1998). Allergy to rubber latex has become a growing problem (Estlander et al., 1996; Wigger-Alberti and Elsner, 1998). Furthermore, due to continuous wearing of gloves, workers can develop serious symptoms (i.e., contact urticaria syndrome) including generalized urticaria, conjunctivitis, rhinitis, and asthma (Amin and Maibach, 1997; Wigger-Alberti and Elsner, 1998).

In addition, BC can be used against the chemical warfare (Chilcott et al., 2005). This chapter focuses on the general occupational industries only.

32.4 MECHANISM OF ACTION AND DURATION

Minimal information exists on the mechanisms of BC's action. The frequently quoted general rule is that water in oil (W/O) emulsions are effective against aqueous solutions of irritants, and oil in water (O/W) emulsions are effective against lipophilic materials (Mathias, 1990; Frosch et al., 1993a; Davidson, 1994; Lachapelle, 1996); exceptions have demonstrated (Frosch et al., 1993c; Frosch and Kurte, 1994). BC may contain active ingredients presumed to work by trapping or transforming allergens or irritants (Frosch and Kurte, 1994; Lachapelle, 1996). Most believe they interfere with absorption and penetration of the allergen or irritants by physical blocking—forming a thin film that protects the skin (Orchard, 1984; Frosch and Kurte, 1994; Marks et al., 1995; Lachapelle, 1996).

To avoid frequent interruptions for reapplication, BC are expected to remain effective for 3 or 4 h. Most manufacturers claim that their products last ~ 4 h. Others suggest use "as often as necessary" (Davidson, 1994). Studies document duration of action—with varying results (Reiner et al., 1982; Boman et al., 1982; Zhai and Maibach, 1996b; Zhai et al., 1999).

32.5 APPLICATION METHODS AND EFFICACY

BC effectiveness may be influenced by application methods (Packham et al., 1994; Wigger-Alberti et al., 1997a,b). A study had been conducted to determine which areas of the hands were likely to be skipped on self-application of BC by a fluorescence technique at the workplace (Wigger-Alberti et al., 1997a); application of BC was incomplete, especially on the dorsal aspects of the hands. Most manufacturers suggest rubbing thoroughly onto skin; to pay special attention to cuticles and skin under nails; to let it dry approximately 5 min; to apply a thin layer of BC to all appropriate skin surfaces three to four times daily. We believe these suggestions are important for BC efficacy.

In vivo and *in vitro* methods have been developed to evaluate the efficacy of BC. Frosch et al. (1993a), Lachapelle (1996), Wigger-Alberti and Elsner (1998, 2000a,b), and Zhai and Maibach (1996a, 1999, 2000, 2001, 2004) have extensively reviewed their efficacy.

32.6 U.S. FOOD AND DRUG ADMINISTRATION MONOGRAPH "SKIN PROTECTANTS"

U.S. Food and Drug Administration (FDA) identified 13 skin protectants for over-the-counter (OTC) products and regulated in Federal Register (1983). These ingredients and concentrations are listed in Table 32.1. The lack of new ingredients suggests research stagnation.

In addition, an OTC lotion (containing quaternium-18 bentonite) against poison ivy, oak, or sumac has been approved as a new drug application by U.S. FDA.

32.7 CONCLUSION

The efficacy of BC in preventing or reducing ICD and ACD has been well documented in many experimental environments. A recent study has shown an excellent result that BC containing a zinc gel significantly reduced skin irritation in volunteers who exhibited type IV hypersensitivity when exposed to latex gloves (Modak et al., 2005). Obviously, BC may inhibit low-grade irritants, but should be not used as a primary protection against high-risk substances as well as corrosive agents. However, inappropriate BC application may exacerbate irritation rather than provide benefit. In particular, using BC

TABLE 32.1
U.S. Food and Drug Administration (FDA) Identified 13 Skin Protectants and Their Concentrations

Ingredients	Concentrations (%)
Allantoin	0.5–2
Aluminum hydroxide gel	0.15–5
Calamine	1–25
Cocoa butter	50–100
Dimethicone	1–30
Glycerin	20–45
Kaolin	4–20
Petrolatum	30–100
Shark liver oil	3
White petrolatum	30–100
Zinc acetate	0.1–2
Zinc carbonate	0.2–2
Zinc oxide	1–25

Note: Most of these entities have been available for decades and suggest research stagnation.

on diseased skin may lead to increased skin irritation (Mathias, 1990; Lachapelle, 1996). People utilizing water, soaps, and detergents daily may benefit by applying BC frequently. Furthermore, BC may also shield skin from chemicals, oils, and other substances, and to make them easier to clean at the end of the workday (Davidson, 1994). To achieve optimal protective effects, BC should be used with careful consideration of the types of substances they are designed to protect against based on specific exposure conditions; also, the proper use of BC should be instructed (Wigger-Alberti et al., 1997a,b).

The ideal BC should be nontoxic, noncomedogenic, nonirritating, nongreasy foam, and colorless. They should keep high efficacy, but not interfere with user's manual dexterity or sensitivity. They should be easy to apply and remove, cosmetically acceptable, and economical. They may be combined with cosmetic benefits, and contain a high proportion of fatty materials (lipids) and can, therefore, also be used for skin care, especially for rough, dry, or chapped skin. Furthermore, the mechanisms of BC's action should be further investigated when evaluating their efficacy. Recent investigative information will hopefully lead to controlled field trials (Berndt et al., 2000; Schnetz et al., 2000), so that we will have clearer insights into when and how to efficiently utilize them.

Taken together, the field now contains an almost critical mass of workers, ideas, and motivation. Considering the magnitude of irritant dermatitis in industry much remains to be done!

33.5 Adopted Test Guidelines 305
33.6 Draft Test Guidelines for Which Commenting Period has Expired and Which Are Being Revised or Finalized 305

33.1 INTRODUCTION

33.1.1 General

1. This publication contains an excerpt of the official OECD guidelines for testing chemicals as adopted by the OECD council.
2. The test guidelines have been developed initially under the OECD chemicals testing program (see points 10–16), and subsequently, since 1981, as provided by the council under the OECD updating program for test guidelines.
3. Whenever testing of chemicals is contemplated, the OECD test guidelines should be consulted. Since the test guidelines have been endorsed by the OECD member countries, their use in the generation of data provides a common basis for the acceptance of data internationally, together with the opportunity to reduce direct and indirect costs to governments and industry associated with testing and assessment of chemicals.
4. Other methods and guidelines not included in this publication may be judged to be appropriate in testing chemicals in certain scientific, legal, and administrative contexts.
5. The OECD council decision on mutual acceptance of data (May 12, 1981; C(81)30) affirms that data generated in one country in accordance with the OECD test guidelines—and additionally in accordance with the OECD principles of good laboratory practice—should be accepted in OECD countries for purposes of assessment and other uses relating to protection of man and the environment. The full text of this decision and the OECD principles of good laboratory practice may be found in the appendix to the OECD guidelines for testing of chemicals.
6. The OECD test guidelines contain generally formulated procedures for the laboratory testing of a property or effect deemed important for the evaluation of health and environment hazards of a chemical. The guidelines vary somewhat in respect of detail, but include all the essential elements, which, assuming good laboratory practice, should enable an operator to carry out the required test.
7. OECD test guidelines are not designed to serve as rigid test protocols. They are instead designed to allow flexibility for expert judgement and adjustments to new developments.
8. It is intended that the OECD test guidelines be used by experienced laboratory staff familiar with the type(s) of testing involved. Proper conduct of testing and associated interpretation of results can only be achieved by appropriately trained personnel with access to equipped laboratory facilities.
9. The loose-leaf system chosen for the guidelines allows for additions and changes to be made when necessary. Information will be circulated when such changes occur resulting from work under the updating program.

33.2 OECD CHEMICALS TESTING PROGRAM

10. The OECD chemicals testing program was launched by the chemicals group in November, 1977. It composed of six expert groups under the leadership of individual member countries. One of these groups, the step system group, worked on phased approaches

to testing and assessment of chemicals (see points 30–32).

11. Five of the groups reviewed the state-of-the-art of methods and produced draft test guidelines. The following areas were covered:
    i. Physicochemical properties (lead country—Germany)
    ii. Effects on biotic systems other than man (lead country—the Netherlands)
    iii. Degradation/accumulation (lead countries—Japan/Germany)
    iv. Long-term health effects (lead country—the United States)
    v. Short-term health effects (lead country—the United Kingdom)
12. Some 300 experts, drawn from academia, government, industry, international organizations, and other sectors, took part in the program. In all, some 50 meetings were held during 1978–1979 under the auspices of the OECD chemicals testing program.
13. To improve the international validation of tests, several methods were subjected to laboratory intercomparison exercises in the chemicals testing program. This work is being continued under the OECD updating program.
14. In December 1979, the five expert groups working on test methods submitted their reports to the OECD. The two groups on health effects submitted a combined report. The reports contained draft test guidelines and an analysis of approaches to testing within the respective areas.
15. During 1980, the draft test guidelines were subjected to an extensive commentary and review process. Member countries were invited to submit comments to the OECD, which were subsequently taken into account by a review panel, established to finalize the product for adoption and printing. The panel worked in close collaboration with the chairman of the expert groups.
16. The review process was concluded by the chemicals group and the environment committee of the organization that endorsed these test guidelines prior to their formal submission to the OECD council.
17. The subject areas covered by the expert groups under the chemicals testing program have largely been kept separate in this publication. Thus, the OECD test guidelines are presented under four different sections:
    i. Physicochemical properties
    ii. Effects on biotic systems other than man
    iii. Degradation/accumulation
    iv. Health effects
18. Each section is preceded by a summary of considerations raised in the individual expert group reports. These summaries reflect some of the major observations and explanations made at the scientific level during the preparatory process. Further, major portions of the expert group reports have been absorbed into the on-going activities of OECD on chemicals.

33.3 OECD UPDATING PROGRAM FOR TEST GUIDELINES

19. In 1981, the OECD updating program for test guidelines was established by member countries in consultation with the commission of the European communities. The aim was to ensure that OECD test guidelines will not become outdated as a result of major changes in the state-of-the-art or scientific advances.
20. The updating program is considering:
    i. Proposals for new or modified tests, which offer conspicuous advantages over those already adopted
    ii. New guidelines, which are being developed in areas not yet covered
    iii. Incorporation of results from the chemicals testing program into OECD test guidelines
    iv. Those matters that need further investigation and research

33.4 OECD PRINCIPLES FOR TESTING AND ASSESSMENT OF CHEMICALS

21. The OECD test guidelines are but one component in an OECD strategy to make testing of chemicals more systematic, relevant, and cost effective within an international framework, which could lead to increased exchange and acceptance of test data between countries. This strategy has been developed with vigor in the organisation during the 1970s, leaving several important questions yet to be resolved.
22. While the OECD test guidelines can properly be used in establishing one effect or property, the guidelines were developed under programs directed toward an integrated and comprehensive approach to testing and assessment. Thus, the OECD council, in 1974 and 1977, developed recommendations, which deal respectively with "The assessment of the potential environmental effects of chemicals" (C[74]215) and "Guidelines in respect to procedures and requirements for anticipating the effects of chemicals on man and in the environment" (C[77]97[Final]).
23. In 1974, the OECD council recommended that prior to marketing of chemicals their potential effects on man and his environment should be assessed.
24. This concern, that assessments should encompass both man and his environment, was reflected in the subject areas chosen for the OECD chemicals testing program, and is also reflected in the disposition of the test guidelines into sections.

25. Some outstanding features with respect to testing and assessment, which derive from the 1977 OECD council recommendations, can be summarized as follows:
    i. Chemical substances—with special emphasis on new substances—should be subjected to systematic assessment for potential effects, in relation to both human and environmental hazard.
    ii. It is possible to determine no more than the likelihood of adverse affects from chemicals, and this can only be done through the application of expert judgement based on methods that are technically practicable, as well as economically acceptable.
    iii. Responsibility for generating and assessing the data necessary to determine the potential effects of chemicals must be part of the overall function and liability of industry.
    iv. A phased approach should be applied in data gathering and assessments.
26. These four principles also provided guidance to the expert groups in their work in the chemicals testing program.
27. The need for expert judgement in testing and assessment has been emphasized throughout the work on chemicals in OECD. The expert groups under the OECD chemicals testing program reaffirmed this need when they selected methods that were regarded as technically practicable and economically acceptable for inclusion into OECD test guidelines.
28. The question of a phased approach to testing and assessment is an important concept, which is under continuing active consideration in OECD within the chemicals testing program. All the expert groups have contributed to the framework of an overall scheme for testing and assessment of chemicals.
29. In their work, the five expert groups on test methods identified steps in which testing and assessment might proceed. The early steps were usually simple in character with the objective of establishing a first indication of hazard. Further steps brought the testing and assessment into a sophisticated and time-consuming range of tests, characterized by increased confidence in the assessments.
30. The step systems group, the sixth expert group established under the chemicals testing program, draws upon the work of the other expert groups and is currently developing an integrated stepwise approach to testing and assessment of chemical hazard to man and his environment.
31. An important outcome of the work of the step systems group is the OECD minimum premarketing set of data (MPD).
32. MPD lists some 35 individual data components that normally would be sufficient to perform a meaningful first assessment of the potential hazard of a chemical.
33. Finally, it should be recognized that elaboration of principles for testing and assessment of chemicals is a continuing process within OECD. This process has been, and remains, possible only through the generous provision of time, knowledge, and enthusiasm from the participating experts, and the active support of member countries.

33.5 ADOPTED TEST GUIDELINES

The complete list of OECD guidelines is available on the OECD webpage (www.oecd.org). Following is a list of those guidelines pertaining to dermal and ocular toxicity.

402 Acute Dermal Toxicity (updated guideline, adopted on February 24, 1987)

404 Acute Dermal Irritation/Corrosion (updated guideline, adopted on April 24, 2002)

405 Acute Eye Irritation/Corrosion (updated guideline, adopted on April 24, 2002)

406 Skin Sensitisation (updated guideline, adopted on July 17, 1992)

410 Repeated Dose Dermal Toxicity: 21/28 day study (original guideline, adopted on May 12, 1981)

411 Subchronic Dermal Toxicity: 90 day Study (original guideline, adopted on May 12th, 1981)

427 Skin Absorption: *In Vivo* Method (original guideline, adopted on April 13, 2004)

428 Skin Absorption: *In Vitro* Method (original guideline, adopted on April 13, 2004)

429 Skin Sensitisation: Local Lymph Node Assay (updated guideline, adopted on April 24, 2002)

430 *In Vitro* Skin Corrosion: Transcutaneous Electrical Resistance Test (TER) (original guideline, adopted on April 13, 2004)

431 *In Vitro* Skin Corrosion: Human Skin Model Test (original guideline, adopted on April 13, 2004)

432 *In Vitro* 3T3 NRU Phototoxicity Test (original guideline, adopted on April 13, 2004)

451 Carcinogenicity Studies (original guideline, adopted on May 12, 1981)

33.6 DRAFT TEST GUIDELINES FOR WHICH COMMENTING PERIOD HAS EXPIRED AND WHICH ARE BEING REVISED OR FINALIZED

434 Acute Dermal Toxicity-Fixed Dose Procedure Draft New Guideline (May 2004)

(Deadline for public comments passed on July 16, 2004)

435 *In Vitro* Membrane Barrier Test Method for Skin Corrosion Draft New Guideline (May 2004)

(Deadline for public comments passed on July 16, 2004)

34 Methods for *In Vitro* Percutaneous Absorption

34.1 INTRODUCTION

In vitro percutaneous absorption methods are used for various reasons. Often it may be the only ethical way of obtaining human skin absorption data with potentially toxic chemicals. These studies also facilitate simultaneous measurement of skin metabolism, which can be examined without metabolic interference from systemic organs (see Chapter 42). The use of animals is also minimized with *in vitro* studies since many diffusion cells can be assembled from the skin of one animal.

It is important to conduct a study in a way that most closely simulates normal exposure to the chemical of interest. The length of exposure of a chemical in contact with the skin is often assumed to be 24 h unless it is washed off more quickly such as with a shampoo or hair color. Since the vehicle can play a major role in determining the absorption rate, the vehicle used in the absorption study should be similar to that found in normal exposure conditions.

34.2 PRELIMINARY STEPS

It is useful in the planning of studies to have knowledge of the test chemicals solubility and partitioning properties. The log of the octanol/water partition coefficient (Log P) has been used for years as an indicator of percutaneous absorption properties. It is an indicator of the lipophilicity of a chemical, which is a property necessary for it to permeate through the lipid-enriched stratum corneum layer. Water solubility is necessary for permeation through the more aqueous-viable epidermal and dermal tissue. Diminished skin absorption may start to be observed with chemicals of molecular weight above 500 Da (Bos and Meinardi, 2000).

34.3 DIFFUSION CELLS

There are two basic designs of one-chambered diffusion cells—the flow-through cell (Bronaugh and Stewart, 1985) and static cell (Franz, 1975). The one-chambered cell has a chamber (receptor) beneath the skin but is open to the environment above the skin to simulate many exposure conditions. Static diffusion cell systems are simpler in design and frequently based on the Franz diffusion cell. Receptor fluid beneath the skin is manually sampled by removing aliquots periodically for analysis. Besides the cost advantage, another important feature is their availability in a wide range of larger openings for skin that might be needed, for example, in studies with transdermal devices.

A flow-through diffusion cell has an advantage in receptor fluid sampling, which can be done automatically using a fraction collector. The maintenance of cell viability for metabolism studies is facilitated by the continual replacement of receptor fluid. Use of a flow-through cell helps prevent high concentrations of test compound in the receptor fluid that can reduce absorption, and the cell may facilitate partitioning of water-insoluble chemicals from skin.

Special attention may be necessary in measuring the permeability of highly volatile compounds when the skin is not occluded to prevent evaporation. The short walls on the top of some diffusion cells can protect the skin surface from air currents, and it has been suggested that this protection may be responsible for some differences observed between *in vivo* and *in vitro* results (Bronaugh and Maibach, 1985; Bronaugh et al., 1985). Diffusion cells have been designed to collect evaporating material above the surface of the skin (Spencer et al., 1979; Reifenrath and Robinson, 1982). These cells have

proven useful particularly in studies of the effectiveness of mosquito repellents and in studies of volatile compounds that require mass balance determinations.

A two-chambered cell has two chambers of equal volume (often from 2 to 10 mL) that are separated by the skin membrane. Variations of the two-chambered cell have been used for years to create conditions in which the diffusion of a compound in solution can be measured from one side of the membrane to the other (Scheuplein, 1965). An infinite dose (one that is large enough to maintain constant concentration during the course of an experiment) is added to one side of the membrane, and its rate of diffusion across a concentration gradient into a solution on the opposite side is determined. Usually, the solutions on both sides of the membrane are stirred to ensure uniform concentrations. Studies comparing permeation through skin to Fickian diffusion through a membrane are performed in this fashion. The two-chambered cell is useful for studying mechanisms of diffusion through skin. It is also applicable to the measurement of absorption from drug delivery devices where compounds are applied to skin at an infinite dose and a steady-state rate of delivery is desired.

34.4 PREPARATION OF SKIN

Skin that is harvested from human or animal sources may need to be washed prior to further preparation for the diffusion cells. Washing should be carefully conducted with a soap and water solution followed by a water rinse.

Full-thickness skin should generally not be used for absorption studies. All or most of the dermis should be removed to simulate the *in vivo* diffusional barrier layer. Chemicals that are systemically absorbed are taken up into the blood vessels of the papillary dermis directly beneath the epidermis. A dermatome is commonly used to prepare a split-thickness preparation of skin because it can be used for all types of skin and the viability of skin can be maintained (Bronaugh and Collier, 1991). Full-thickness skin (stratum corneum side up) is fixed to a styrofoam block with hypodermic needles. The dermatome is pushed across the skin surface to prepare a layer of skin with much of the dermis removed. A dermatome section of 200–300 μm is satisfactory since thinner preparations are difficult to make without damage to the skin.

Heat treatment is the only other practical method to remove the dermal tissue, but it must be used on nonhairy skin to avoid damage to the barrier during the separation process. Full-thickness skin is submerged in 60°C water for approximately 1 min, and the epidermal and dermal layers can be pulled apart with forceps (Scheuplein, 1965; Bronaugh et al., 1981). All but the most stable enzymes are destroyed by this process.

The use of full-thickness skin is really only then justifiable when using animal skin that is already very thin, such as that from the mouse (400 μm) (Behl et al., 1984) or rabbit. With the skin of other animals, such as the rat (800–870 μm) (Yang et al., 1986), guinea pig, monkey, and pig, full-thickness skin is almost 1 mm in thickness; and with human skin it can be several millimeter thick (Loden, 1985). Therefore, some means should be used to prepare a membrane that more accurately reflects the barrier layer in thickness. This is particularly important when examining a hydrophobic compound, which diffuses slowly through the aqueous viable tissue.

After the skin is assembled in the diffusion cells, barrier integrity should be verified by measuring the absorption of a standard compound, such as tritiated water. A number of laboratories have reported permeability constant (*K*p) values for tritiated water in normal skin (Bronaugh et al., 1986; Dugard et al., 1984), but this procedure requires dosing the skin for 4–5 h for determination of the steady-state absorption of tritiated water. Bronaugh and co-workers developed a 20-min test for tritiated water absorption to give more rapid results without hydration of skin samples (Bronaugh et al., 1986).

34.5 RECEPTOR FLUID

The selection of the receptor fluid has become an increasingly important decision as investigators strive to create *in vitro* conditions that can adequately duplicate the *in vivo* situation. For measuring the absorption of water-soluble compounds, the use of normal saline or an isotonic buffer solution may be sufficient. However, some chemicals are metabolized significantly during the percutaneous absorption process (Yourick and Bronaugh, 2000). The viability of skin can be maintained for 24 h in a flow-through diffusion cell using a physiological buffer as the receptor fluid (Collier et al., 1989). Metabolism and percutaneous absorption can be measured simultaneously as discussed in Chapter 42. The combined information gives a more complete picture of absorption since the actual permeating species are identified.

Sometimes surfactants (Bronaugh and Stewart, 1984) or organic solvents (Scott and Ramsey, 1987) have been added to the receptor fluid in nonviable skin studies to increase the solubility of lipophilic compounds, and thereby promote free partitioning of chemicals from skin into the receptor fluid. Care must be taken to insure that damage to the skin barrier does not occur. The effectiveness of these methods will likely vary with the solubility properties of the test compound.

More recently, studies have been conducted to examine the significance of test material left in the skin at the end of an absorption study (see Section 34.7).

34.6 TERMINATION OF EXPERIMENT

At the end of a study, the unabsorbed material is washed from skin surface usually using a soap and water solution. Organic solvents have sometimes been used for more lipophilic material. For cosmetic products, removal from the skin is normally accomplished with a soap and water wash.

Barrier integrity may be rechecked with tritiated water or other standard chemical if damage to the barrier is suspected.

The washing procedure itself may be damaging to the skin unless it is carefully accomplished.

34.7 DETERMINATION OF ABSORPTION

The determination of systemic percutaneous absorption is sometimes controversial in an *in vitro* diffusion cell study. Since the skin membrane can sometimes serve as a reservoir for absorbed material, measurement of the absorbed compound appearing in the receptor fluid alone may not be an accurate determination of systemic skin absorption. Both skin and receptor fluid levels should be measured at the end of a study. If determination of systemic absorption is desired, it is not sufficient to simply measure the receptor fluid levels. If significant amounts remain in skin, additional studies may be necessary to determine if the material in skin will eventually be systemically absorbed (see discussion later). Also, skin levels must be known to determine mass balance at the end of the experiment. Recoveries of at least 90% should be obtained unless the test compound is volatile.

Skin can be fractionated to observe localization in different layers. The stratum corneum layer can be removed from the surface of the skin by successive stripping with 10 or more pieces of cellophane tape (Kraeling and Bronaugh, 1997). Individual variation has been reported in the number of strips necessary presumably due to differences in the pressure applied to the tape and differences in the tape itself. The epidermal and dermal layers can be separated with heat as previously described in the preparation of skin.

The guidelines for skin absorption studies recommended by the European Union's Scientific Committee on Consumer Products (SCCP) require that material remaining in the viable skin levels (exclusive of stratum corneum) be considered as systemically absorbed (SCCP, 2006). An exception to this requirement could be made if documentation is provided that irreversible binding of an ingredient occurs to the viable epidermis and that the ingredient is subsequently eliminated by desquamation. The Organization for Economic and Cultural Development (OECD) guideline 428 for *in vitro* skin absorption studies states that all material remaining in skin (including the stratum corneum) may need to be considered as systemically absorbed unless additional studies show that there is no eventual absorption (OECD, 2004).

For example, the lipophilic fragrance ingredient, musk xylol, was shown to be absorbed through hairless guinea pig and human skin (Hood et al., 1996). However, substantial amounts of the fragrance were found in the skin at the end of the 24-h studies (Table 34.1). An additional study was conducted that showed that significant amounts of the material in the skin at 24 h diffused into the receptor fluid in the next 48 h. These results suggest that 24-h receptor fluid values alone do not adequately estimate systemic absorption of musk xylol.

Other compounds have been found to form extensive skin reservoirs of absorbed material during 24 h studies; however, in some instances, extended absorption studies conducted for an additional 48 h have found little or no additional penetration of test material from skin into the receptor fluid. At the end of a 24-h disperse blue 1 absorption study in human skin, 11.1% of the dose applied in a hair dye vehicle remained in skin, and only 0.2% of the applied dose had penetrated into the receptor fluid (Yourick et al., 2004). Only 0.7% of the applied dose of diethanolamine was absorbed through human skin in 24 h from a lotion vehicle while 11.9% was found remaining in skin at the end of the study (Table 34.2) (Kraeling et al., 2004). For both compounds, extended absorption studies suggested that the test material remaining in skin was not available for systemic absorption.

When a substantial reservoir of test material is found in skin at the end of an absorption study, it is important to determine the potential significance of this material for systemic absorption. Conducting an extended absorption study as mentioned above or performing an *in vivo* absorption study can help determine the systemic fate of material in the skin reservoir at the end of an absorption study.

TABLE 34.1
Percentage of Applied Dose Absorbed of Musk Xylol from Oil-in-Water Emulsion and Methanol Vehicles in 24 h

	Hairless Guinea Pig Skin[a]		Human Skin[b]	
	Oil-in-Water Emulsion	Methanol	Oil-in-Water Emulsion	Methanol
Receptor fluid	32.1 ± 1.3	25.8 ± 1.2	4.1 ± 0.7	1.0 ± 0.2
Skin	22.9 ± 2.7	18.8 ± 2.2	17.3 ± 2.3	21.3 ± 0.8
Total absorbed	55.0 ± 2.1	44.6 ± 2.4	21.5 ± 3.0	22.3 ± 0.8
24-h skin wash	24.9 ± 1.4	5.5 ± 0.3	46.9 ± 3.2	25.9 ± 1.3
Total recovery	80.5 ± 1.9	50.4 ± 2.5	68.5 ± 2.9	45.7 ± 3.3

[a] Values are the mean ± SE of four determinations in each of three animals.
[b] Values are the mean ± SE of four or five determinations from two human subjects.

TABLE 34.2
Diethanolamine Penetration in Human Skin from a Lotion Vehicle

	Percentage of Applied Dose Penetrated		
Time of study (h)	24	48	72
Receptor fluid	0.7 ± 0.1	1.2 ± 0.1	1.7 ± 0.5
Stratum corneum	4.2 ± 0.2	3.3 ± 0.1	3.7 ± 0.3
Epidermis and dermis	7.7 ± 0.9	7.4 ± 1.3	7.4 ± 0.9
Total in skin	11.9 ± 0.7	10.7 ± 1.3	11.1 ± 0.6
Total penetration	12.5 ± 0.5	11.9 ± 1.3	12.8 ± 1.1
Recovery	95.2 ± 3.0	93.3 ± 3.4	96.6 ± 3.0

Values are the mean ± SEM of three replicates in each of three donor pieces of human skin. Unabsorbed diethanolamine washed from the surface of skin at 24 h in all three studies. Corresponding values at the different study times are not significantly different (ANOVA, $p < 0.05$).

34.8 EXPRESSION OF PERCUTANEOUS ABSORPTION

Percutaneous absorption values are frequently expressed in terms of percentage of the applied dose absorbed. But these values are valid only at the concentration of the compound tested. Permeability constants are sometimes determined by dividing the steady-state absorption rate by the applied concentration of test compound. A permeability constant is, therefore, a normalized rate constant and is sometimes used to determine skin absorption at various doses. Errors can be introduced in these calculations if the initial lag-time in absorption is ignored and because absorption does not always increase in a linear fashion. Expression of absorption data in terms of rate of penetration (for example, $\mu g/h/cm^2$ skin) can also be useful information for evaluating skin penetration.

34.9 CONCLUSION

There are many methodological decisions to make in conducting an *in vitro* percutaneous absorption study. Careful attention to details should be given when developing a protocol so that the conditions necessary for the study of absorption (and possibly metabolism) of a particular test compound are included.

35.1 INTRODUCTION

Contamination of soil and water (ground and surface water) and the transfer of hazardous chemical is a major concern. When the large surface area of skin is exposed to contaminated soil and water (work, play, swim, daily bath), skin absorption may be significant. Brown et al. (1984) suggested that skin absorption of contaminants in water has been underestimated and that ingestion may not constitute the sole, or even the primary route of expense. Soil has become an environmental depository for potentially hazardous chemicals. Exposure through work in pesticide-sprayed areas on chemical dump sites seems obvious. However, there may be hidden dangers in weekend gardening or in the child's play area.

This chapter demonstrates potential risk from contaminated soil and water, and discusses potential error in dependence on model systems without validation.

35.2 PERCUTANEOUS ABSORPTION

35.2.1 Solvents

Numerous sites have significant levels of organic contaminants in soil, which are either slowly released or degraded, providing a potential long-term source for chemical exposures. Remediation clean-up cost varies dramatically with the level to which soil must be decontaminated. However, a difficulty in establishing soil clean-up level stems, in part, from our lack of knowledge of the dermal bioavailability of chemicals following exposure to environmental mediums. Compared to dermal exposures with neat or aqueous compound, little is understood about the dermal bioavailability of solvents in soil, dust, sludge, or sediment matrices. A method has been developed to determine dermal uptake of solvents under nonsteady state conditions using real-time breath analysis in rats, monkeys, and human volunteers. The exhaled breath was analyzed using an ion-trap mass spectrometer, which can continually quantitate chemicals in the exhaled breath stream in the 1–5 ppb range. The resulting exhaled breath data were evaluated using physiologically based pharmacokinetic (PBPK) models to estimate dermal permeability constants (K_p), under various exposure conditions. Exposures have been conducted comparing the impact of exposure matrix (soil versus water), occlusion versus nonocclusion, and species-differences on the percutaneous absorption of methyl chloroform, trichloroethylene (TCE), and pentachloroethylene. Studies have demonstrated that rat skin is roughly 40 times more permeable than human skin, that bioavailability is decreased when exposures are in a soil versus aqueous matrix, and that under nonoccluded exposure conditions, the majority of the compound is lost to volatilization and unavailable for absorption. These results have clearly illustrated that the methodology was sufficiently sensitive to enable the conduct of animal and human dermal studies at

low exposure concentrations over small body surface areas, for short periods of time.

Table 35.1 summarizes PBPK estimates for solvent human *in vivo* dermal absorption. Hand immersion treatment is a volunteer sitting comfortably with his/her hand immersed in a bucket of water or soil containing one of the solvents. The volunteer wears a facemask. The volunteer inhales fresh air from an air tank. The mask has a special device that switches between inhalation and exhalation. Thus the volunteer exhales through a different pathway such that the exhaled breath goes to a tandem ion-trap mass spectrometer (MS/MS) coupled to a computer which records and can display real time (every few second if wanted) the solvent concentration in the exhaled breath (Poet et al., 2000a,b, 2002).

Table 35.2 gives PBPK model estimates for the dermal absorption of TCE in rats. Estimated permeability constants are listed. Generally, solvent dermal absorption is less for humans than for rats. In both species, solvent absorption is less from soil than from water. This may be due to water's ability to retain solvent within a matrix on the skin better than with soil.

The combination of real-time breath analysis and PBPK modeling provides an opportunity to effectively follow the changing kinetics of uptake, distribution, and elimination phases of a compound throughout a dermal exposure. The sensitivity of the ASGDI-MS/MS system for exhaled-breath analysis is pivotal in enabling studies wherein human volunteers are exposed to low levels of compounds for short periods of time. This real-time, *in vivo* method is suitable for studying the percutaneous absorption of volatile chemicals, and allows exposures to be conducted under a variety of exposure conditions, including occluded versus nonoccluded, rat versus monkey versus human, and soil versus water matrices (Thrall et al., 2000).

TABLE 35.1
PBPK Model Estimates for Human *In Vivo* Dermal Absorption

Solvent	Treatment	K_p(cm/h)
Methylchloroform (TCA)	Water hand immersion	0.0063 ± 0.0006
Trichloroethylene (TCE)	Soil hand immersion	0.0015 ± 0.0005
	Water patch	0.019 ± 0.001
	Soil hand immersion	0.0074 ± 0.000
	Soil patch	0.0043 ± 0.002
Perchlorolthylene (PCE)	Soil hand immersion	0.0009 ± 0.0003

TABLE 35.2
PBPK Model Estimates for the Dermal Absorption of TCE in Rats

Exposure Concentration	K_p^a (cm/h)	Amount Absorbed (mg)	Total TCE Recovered[b] (%)
Occluded water (mg/L)			
1600	0.31 ± 0.018	7.5 ± 1.4	100 ± 5.2
600	0.30 ± 0.006	2.7 ± 0.4	103 ± 5.1
Average	0.31 ± 0.014	102 ± 5.6	
Nonoccluded soil (mg/kg)			
40,600	0.087 ± 0.002	1.5 ± 1.4	98 ± 8.8
20,300	0.085 ± 0.003	7.3 ± 2.7	97 ± 5.7
5000	0.085 ± 0.003	1.7 ± 0.8	101 ± 1.4
Average	0.086 ± 0.003	99 ± 6.0	
Occluded soil (mg/kg)			
15,600	0.090 ± 0.003	40 ± 15	99 ± 2.2
5300	0.089 ± 0.002	14 ± 3.7	99 ± 2.4
Average	0.090 ± 0.002	99 ± 1.0	

[a] Water K_p values are significant from soil ($p < .01$) for both occluded and nonoccluded studies. There is no significant difference in K_p between occluded and nonoccluded soil exposures.

[b] The total TCE recovered was calculated from percent absorbed (estimated from PBPK model), percent remaining in media (soil or water), and percent in charcoal path, where appropriate (as measured using GC headspace analysis) ± SD. The amount absorbed by the body for nonoccluded soil exposure is for a 3 h exposure ($n = 3$) ± SD.

35.2.2 Organic Chemicals

35.2.2.1 DDT, Benzo[a]pyrene, Chlordane, Pentachlorophenol, 2,4-D

Table 35.3 gives the *in vitro* (human skin) and *in vivo* (rhesus monkey) percutaneous absorption of organic chemicals from soil and a comparative vehicle (water or solvent, depending on vehicle). The soil is the same source (Yolo County) for all chemicals. For each chemical the concentration of mass (μg) per unit skin area (cm^2) is the same for each vehicle. It should be pointed out that chemical selection was done according to chemical interest, as expressed by Cal EPA and US EPA. Thus, the chemicals exhibit high log P octanol/water partition

TABLE 35.3
***In Vitro* and *In Vivo* Percutaneous Absorption of Organic Chemicals**

Compound	Vehicle	Percent Dose *In Vitro* Skin	Percent Dose *In Vitro* Receptor Fluid	*In Vivo*
DDT	Acetone	18.1 ± 13.4	0.08 ± 0.02	18.9 ± 9.4
	Soil	1.0 ± 0.7	0.04 ± 0.01	3.3 ± 0.5
Ben[a]pyrene	Acetone	23.7 ± 9.7	0.09 ± 0.06	51.0 ± 22.0
	Soil	1.4 ± 0.9	0.01 ± 0.06	13.2 ± 3.4

Aroclor 1242	(High log P)
Aroclor 1254	(High log P)

TABLE 35.5
***In Vitro* and *In Vivo* Percutaneous Absorption of PCBs**

Compound	Vehicle	Percentage Dose *In Vitro* Skin	*In Vitro* Receptor Fluid	*In Vivo*
PCBs (1242)	Acetone	–	–	21.4 ± 8.5
	TCB	–	–	18.0 ± 8.3
	Mineral oil	6.4 ± 6.3	0.3 ± 0.6	20.8 ± 8.3
	Soil	1.6 ± 1.1	0.04 ± 0.05	14.1 ± 1.0
PCB (1254)	Acetone	–	–	14.6 ± 3.6
	TCB	–	–	20.8 ± 8.3
	Mineral oil	10.0 ± 16.5	0.1 ± 0.07	20.4 ± 8.5
	Soil	2.8 ± 2.8	0.04 ± 0.05	13.8 ± 2.7

coefficients, rather than a range of log Ps (Table 35.4). The *in vivo* human skin percutaneous absorption is expressed as chemical percent dose in receptor fluid accumulation and skin content. Chemicals with higher log Ps are lipophilic and, therefore, are not soluble in biological fluid or receptor fluid (plasma, buffered saline) (Wester et al., 1990a,b, 1992a).

Receptor fluid (human plasma) accumulation of DDT was negligible in the *in vitro* study due to solubility restriction. Human skin content was 18.1% dose from acetone vehicle. *In vivo* absorption in the rhesus monkey was 18.9% dose from acetone vehicle. These values are comparable to the published 10% dose absorbed *in vivo* in man from acetone vehicle. Percutaneous absorption from soil was predicted to be 1.0% dose in human skin *in vitro* and a comparative 3.3% dose *in vivo* in rhesus monkey.

In vivo percutaneous absorption of benzo[a]pyrene is high—51.0% reported here for rhesus monkey and 48.3% (Bronaugh et al., 1986) and 35.3% (Yang et al., 1989) for rat. Benzo[a]pyrene absorption from soil was approximately one-fourth that of solvent vehicle (Wester et al., 1990a).

For chlordane, pentachlorophenol, and 2,4-D, the *in vivo* percutaneous absorption in rhesus monkey from soil was equal to or slightly less than that obtained from solvent vehicle (Table 35.3). Validation to man *in vivo* is available for 2,4-D, where the percutaneous absorption is the same for rhesus monkey and man. *In vitro* percutaneous absorption is variable, probably due to solubility problems relative to high lipophilicity.

35.2.3 PCBs

Table 35.5 gives the *in vitro* and *in vivo* percutaneous absorption of PCBs (Wester et al., 1993a). As with the other organic chemicals with high log P, receptor fluid accumulation *in vitro* was essentially nil. Skin accumulation *in vitro* did exhibit some PCB accumulation. *In vivo* PCB percutaneous absorption for both Aroclor 1242 and 1254 was (1) high, ranging from 14 to 21%, and (2) generally independent of formulation vehicle. Thus, PCBs have a strong affinity for skin and are relatively easily absorbed into and through skin. Figure 35.1 summarizes absorption from solvent and soil.

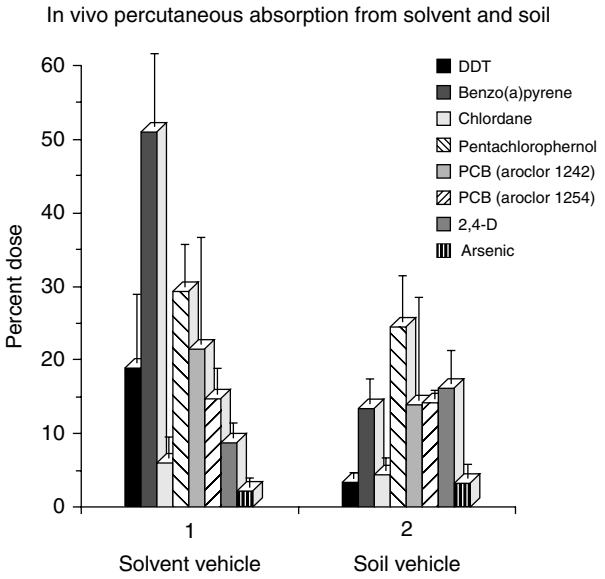

FIGURE 35.1 In percutaneous absorption of several hazardous substances from soil and solvent (either acetone or water), overall, soil reduced absorption to about 60%, compared to solvent. However, the absorption of some compounds is the same for soil and solvent.

35.2.4 Metals

35.2.4.1 Arsenic, Cadmium, Mercury

Selected salts of arsenic, cadmium, and mercury are soluble in water, and thus are amenable to *in vitro* percutaneous absorption with human skin. Arsenic absorption *in vitro* was 2.0% (1.0% skin plus 0.9% receptor fluid), and the same *in vivo* in rhesus monkey. Absorption from soil was equal to (*in vivo*) or approximately one-third (*in vitro*). Cadmium and mercury both accumulate in human skin, and are slowly absorbed into the body. (It should be noted that *in vivo* studies with cadmium and mercury are difficult to perform; cadmium accumulates in the body and mercury is not excreted via urine.) Note the high skin content with cadmium and mercury (Table 35.6) (Wester et al., 1992a, 1993b).

TABLE 35.6
***In Vitro* and *In Vivo* Percutaneous Absorption of Metals**

Compound	Vehicle	Skin	Percent Dose *In Vitro* Receptor Fluid	*In Vivo*
Arsenic	Water	1.0 ± 1.0	0.9 ± 1.1	2.0 ± 1.2
	Soil	0.3 ± 0.2	0.4 ± 0.5	3.2 ± 1.9
Cadmium	Water	6.7 ± 4.8	0.4 ± 0.2	–
	Soil	0.09 ± 0.03	0.03 ± 0.02	–
Mercury	Water	28.5 ± 6.3	0.07 ± 0.01	–
	Soil	7.9 ± 2.2	0.06 ± 0.01	–

TABLE 35.7
***In Vitro* Receptor Fluid versus *In Vivo* Percutaneous Absorption**

	Soil	0.03 ± 0.02	–
Mercury	Water	0.07 ± 0.01	–
	Soil	0.06 ± 0.01	–

35.3 *IN VITRO* DIFFUSION VERSUS *IN VIVO*

Regulatory agencies have developed an affinity for a calculated permeability coefficient (K_p) for risk assessment. Permeability coefficients are easily determined from the time course of chemical diffusion from a vehicle (water, soil) across the skin barrier into a receptor fluid. Table 35.7 compares *in vitro* diffusion receptor fluid absorption with *in vivo* percutaneous absorption. Receptor fluid accumulation for the higher log P chemicals (Table 35.4) is negligible. This is due to basic chemistry—the compounds are not soluble in the water-based receptor fluid. Based on these receptor fluid accumulations, these chemicals are not absorbed by skin. Risk assessment would contain an extreme false-negative component. That point where the diffusion system and receptor fluid accumulation gives a true K_p or manufactures a false K_p has not been determined. Regulatory agents should have some *in vivo* validation before blindly accepting an *in vitro* K_p.

35.4 SOIL LOAD

A popular assumption is that only the fine particles of soil stick to the skin transfer contaminants from the soil to the skin. This is the monolayer theory. If it was only the fine soil particles, then all of the data shown in this chapter could not exist, because the fine particles were not used (sieved out for laboratory personnel safety reasons). Besides, contaminants will transfer between large surfaces (table, couch, etc.) and skin, even between people. And, certainly, the first soil monolayer to contact the skin during planting of the first rose bush will not be the same monolayer after planting the 20th bush. However, the computer model needs the monolayer, therefore, it has to exist. Table 35.8 shows the effect of soil load. Note the chemical concentration was kept constant while soil load was varied.

35.5 DISCUSSION

The evolution of skin resulted in a tissue that protects precious body fluids and constituents from excessive uptake of water and contaminants in the external environment. The outermost surface of the skin that emerged for human is the stratum corneum, which restricts but does not prevent penetration of water and other molecules. This is a complex lipid–protein structure that is exposed to contaminants during bathing, swimming, and exposure to the environment. Industrial growth has resulted in the production of organic chemical and toxic metals whose disposal resulted in contamination. When an adult settles into a tub or a child sits

TABLE 35.8
Effect of Soil Load on 2,4-D Percutaneous Absorption

System	Soil Load[a] (mg/cm²)	Percent Dose Absorbed[b]
In vivo, rhesus monkey	1	9.8 ± 4.0
	40	15.9 ± 4.7
In vitro, human skin	5	1.8 ± 1.7
	10	1.7 ± 1.3
	40	1.4 ± 1.2

[a] Concentration of 2,4-D chemical per cm² skin area was kept constant, while soil load per cm² skin area was varied.

[b] *In vivo* percutaneous absorption measured by urinary ^{14}C accumulation; *in vitro* absorption determined by ^{14}C skin content.

in the dirt for a day of play, the skin (the largest organ of the body) acts as a lipid sink (stratum corneum) for the lipid-soluble contaminants. Skin also serves as transfer membrane for water and whatever contaminants may be dissolved in it. It is most important to note that (1) water transfers through skin and can carry chemicals, and (2) the outer layer of skin is lipid in nature. Thus, highly lipophilic chemicals such as DDT, PCBs, and chlordane residing in soil will quickly transfer to skin. Percutaneous absorption can be linear, orderly, and predictive (a measured flux from water). However, evidence exists that chemicals may transfer to skin with short-term exposure.

Regulators should be cautious as *in vitro* and computer models are developed for risk assessment. Validation is needed to avoid false negative assessment.

36.5 Enhancers of Percutaneous Absorption of Pesticides 322
36.6 Skin Decontamination 323
36.7 Discussion 324
References 324

36.1 INTRODUCTION

Percutaneous absorption is a primary focal point for dermatotoxicology and dermatopharmacology. Local and systemic toxicity depend on a chemical penetrating the skin. The skin is both a barrier to absorption and a primary route to the systemic circulation. The skin's barrier properties are impressive. Fluids and precious chemicals are reasonably retained within the body; at the same time hundreds of foreign chemicals are restricted from entering the systemic circulation. Even with these impressive barrier properties, the skin is a primary body organ that contacts the environment and is a route by which many chemicals enter the body. Some chemicals applied to the skin have proved to be toxic. These include pesticides, which in actuality are designed poisons.

Table 36.1 summarized the 30-year lesson with parathion. Absorption of parathion was established for human skin contact, but other species similarly absorb the compound. Mathematical models based on quantitative structure activity now can predict a human skin permeability coefficient, but the accuracy of the predicted coefficient is not fully validated to *in vivo* man. Skin absorption amounts combined with toxicity data can predict potential human health hazard. Figure 36.1 shows human systemic parathion from dermal exposure. Parathion is predicted to be lethal for not only total systemic absorption but also for exposure to limited regions. The LD_{50} used for parathion is 14 mg/kg. Given a body weight of 70 kg, the systemic absorption of 980 mg might result in 50% mortality. Thus, parathion lethal toxicity levels can be reached at 8 h and longer exposures. This was unfortunately validated in the agricultural fields of California and elsewhere.

36.2 PERCUTANEOUS ABSORPTION METHODOLOGY

36.2.1 Absolute Topical Bioavailability

The only way to determine the absolute bioavailability of topically applied compound is to measure the compound by specific assay in blood or urine after topical and intravenous administration. This is extremely difficult to do in plasma because concentrations after topical administration are often low. However, as advances in analytical methodology bring forth more sensitive assays, estimates of absolute topical bioavailability will become more available (Wester and Maibach, 1999).

36.2.2 Radioactivity in Excreta

Percutaneous absorption *in vivo* is usually determined by the indirect method of measuring radioactivity in excreta after topical application of the labeled compound. In human studies, plasma levels of compound are extremely low after

TABLE 36.1
Summary: Parathion Percutaneous Absorption

Parathion

O,O-diethyl O-(4-nitrophenyl) phosphorothioate
Other names: ethylparathione, parathion-ethyl
CAS: 56-38-2; Mol. Wt. 291.26
Molecular formula: $C_{10}H_{14}NO_5PS$
Nonsystemic contact and stomach-acting insecticide and acaricide with some fumigant action
Nonphytotoxic except to some ornamentals and under certain weather conditions. Absorption takes place readily through any portal. Fatal human poisoning has followed skin exposure

Skin Absorption (Species)

Human (forearm); solvent: acetone; 10%, 5 days (excretion analysis) (Feldmann and Maibach, 1974)
Human: solvent: acetone; forearm 8.6%, palm 11.8%, foot 13.5%, abdomen 18.5%, hand, dorsum 21%, forehead 36.3%, axilla 64%, jaw 33.9%, fossal cubitalis 28.4%, scalp 32.1%, ear cannal 46.6%, scrotum 101.6% (Maibach et al., 1974)
Rat (dermal); solvent: acetone; 59%, 1 h (patch) (Knaak et al., 1984)
Mouse (dermal); no solvent; 1.4%, 1 h (excretion analysis). Mouse (dermal); solvent: acetone; 32%, days (patch) (Marty, 1976)
Frog (dermal); solvent: acetone; 33%, 1 h (patch) (Shah et al., 1983)
Quail (dermal); solvent: acetone; 40%, 1 h (patch) (Shah et al., 1983)
Roach (dermal); solvent: acetone; 14%, 1 h (patch) (Shah et al., 1983)
Hornworm (dermal); solvent: acetone; 8%, 1 h (patch) (Shah et al., 1983)

Skin Absorption (Computer Model)

kp (cm/h)	Log P (K_{ow})
1.59×10^{-2}	3.83

Based on the formula: log kp = –2.74 + [0.71 × log P (K_{ow})] – [0.0061 × MW]; where kp = permeability coefficient, P (K_{ow}) = partition coefficient in octanol compared to water, MW = molecular weight (Guy and Plotts, 1992), and P (K_{ow}) = partition coefficient in octanol compared to water

Toxicity

Rat
Oral male LD50: 13–15 mg/kg [105,109]
Oral female LD50: 3–3.6 mg/kg [105,109]
Skin male LD50: 21 mg/kg [105]
Skin female LD50: 6.8 mg/kg [105]

topical application, often below assay detection level; so it is necessary to use trace methodology. The compound, usually labeled with ^{14}C or tritium, is applied and the total amount of radioactivity excreted in urine or urine plus feces is determined. The amount of radioactivity retained in the body or excreted by some route not assayed (CO_2, sweat) is corrected for by determining the amount of radioactivity excreted after parenteral administration. This final amount of radioactivity is then expressed as the percentage of applied dose that was absorbed (Feldmann and Maibach, 1974).

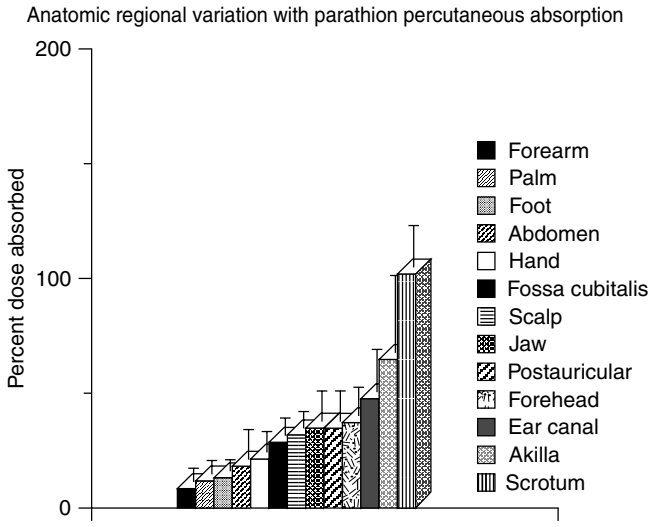

FIGURE 36.1 Simulated parathion human skin exposure to regions of the body. As early as 8 h following exposure lethality is possible. A 24 h lethality is possible if only certain body regions are exposed; example is head and neck to a field worker. (Adapted from Krieger, R. *Handbook of Pesticide Toxicology*, Academic Press, 2001. With permission.)

The equation used to determine percutaneous absorption is:

$$\text{Absorption (\%)} = \frac{\text{total radioactivity after topical administration}}{\text{total radioactivity after parenteral administration}} \times 100$$

36.2.3 Skin Flaps

The methodology is to surgically isolate a portion of skin so that a singular blood supply is created to collect blood containing the chemical that has been absorbed through skin. The skin flap can be used to study percutaneous absorption *in vivo* or *in vitro*. The absorption of chemicals through skin and metabolism within the skin can be determined by assay of the perfusate (Wester and Maibach, 1997).

36.2.4 Stripping Method

The stripping method determines the concentration of chemical in the stratum corneum during an application period and predicts the percutaneous absorption of that chemical. The chemical is applied to skin of animals or humans, and at various skin application times the stratum corneum is removed by successive tape application and removal. The tape strippings are assayed for chemical content. Pharmacokinetic Cmax, Tmax, and area-under-curve (AUC) parameters can be calculated for stratum corneum bioavailability.

36.2.5 Biological Response

Another *in vivo* method of estimating absorption is to use a biological or pharmacological response. Here, a biological assay is substituted for a chemical assay and absorption is estimated. An obvious disadvantage to the use of biological response is

that it is only good for compounds that will elicit an easily measurable response. An example of a biological response would be the vasoconstrictor assay in which the blanching effect of one compound is compared to that of a known compound. This method is perhaps more qualitative that quantitative. The best-known use of this method is in comparison of various hydrocortisone products for skin dermatitis (Wester and Maibach, 1997).

36.2.6 *In Vitro* Methodology

In vitro percutaneous absorption is best done with human skin. The skin should be used as soon as possible, and stored in the refrigerator no longer than 7 days. *In vitro* penetration into skin gives results suitable for distinguishing drug formulations, especially in cases where the drug will not partition into reservoir fluid. Material balance in an *in vitro* study design adds to the overall data presentation. *In vivo* verification of skin absorption, preferably in humans, adds relevance to the *in vitro* data. The human skin sample can be kept viable if stored properly in the refrigerator (freezing kills skin viability) and used appropriately (Wester et al., 1998).

Table 36.2 gives the *in vitro* human skin and *in vivo* percutaneous absorption of several chemicals from a variety of vehicles. The *in vitro* absorption is divided into skin content and receptor fluid (either buffered saline or human plasma) accumulation. Generally, receptor fluid accumulation does not agree with *in vivo* percutaneous absorption. The reason for this is lack of solubility in the receptor fluid. In some cases, skin content (see DDT) was a reflection of *in vivo* absorption because the chemical was able to penetrate skin (and lacking solubility, failed to partition into receptor fluid). Chemicals with high log P (octanol:water partition coefficient) will not partition into receptor fluid (Wester and Maibach, 1997, 1999).

36.3 REGIONAL VARIATION IN HUMAN AND ANIMAL PESTICIDE PERCUTANEOUS ABSORPTION

Feldmann and Maibach (1967) first explored the potential for regional variation in percutaneous absorption. The first absorption studies were done with ventral forearm,

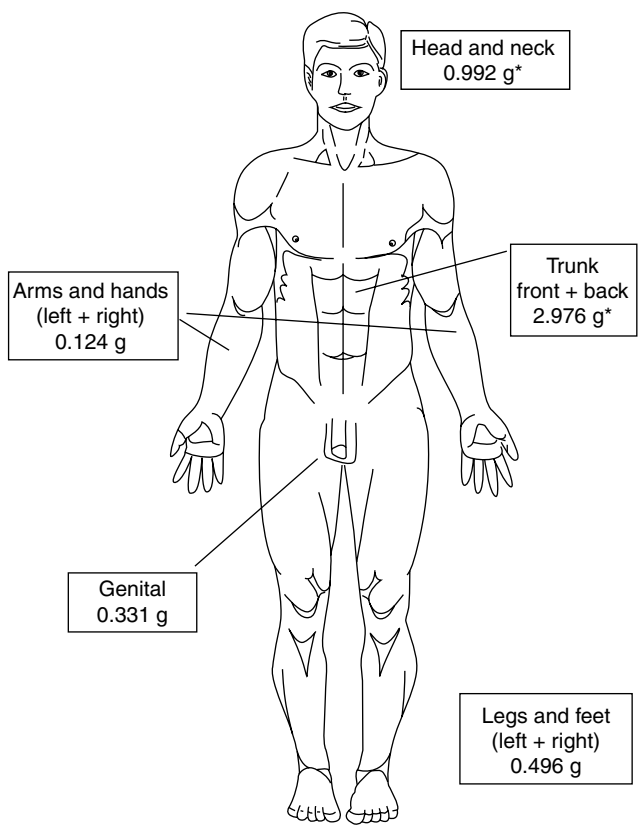

FIGURE 36.2 Different parts of the body vary in percutaneous absorption. This is an important consideration in risk assessment. (Adapted from Krieger, R. *Handbook of Pesticide Toxicology*, Academic Press, 2001. With permission.)

because this site is convenient to use. However, skin exposure to chemicals exists over the entire body. They first showed regional variation with the absorption of parathion (Figure 36.2). The scrotum was the highest absorbing skin site (scrotal cancer in chimney sweeps is the key). Skin absorption was the lowest for the sole, and highest around the head and face.

Table 36.3 gives the effect of anatomical region on the percutaneous absorption of pesticides in humans (Maibach et al., 1971). There are two major points in this study. First, regional variation was confirmed with the different chemicals; note that parathion and malathion are chemically related to some chemical warfare agents. Second, those skin areas that would be exposed to the pesticides, the head and face, were of the higher absorbing sites. Body areas most exposed to environmental contaminants are among the areas with the higher skin absorption.

Table 36.4 gives site variability for parathion skin absorption with time. Soap and water wash in the first few minutes after exposure is not a perfect decontaminant. Site variation is apparent early in skin exposure (Wester and Maibach, 1985). Decontamination is discussed later.

Guy and Maibach (1985) took the hydrocortisone and pesticide data and constructed penetration indices for five anatomical sites (Table 36.5). The indices might be used with their total surface areas (Table 36.6) when estimating systemic availability relative to body exposure sites.

Van Rooy et al. (1993) applied coal-tar ointment to various skin areas of volunteers and determined absorption of

polycyclic aromatic hydrocarbons (PAH) by surface disappearance of PAH and the excretion of urinary I-OH pyrene. Using PAH disappearance, skin ranking (highest to lowest) was shoulder > forearm > forehead > groin > hand (palmar) > ankle. Using I-OH pyrene excretion, skin ranking (highest to lowest) was neck > calf > forearm > trunk > hand. Table 36.7 compares their results with Guy and Maibach (1985).

Wester et al. (1984) determined the percutaneous absorption of paraquat in humans. Absorption was the same for the leg ($0.29 \pm 0.02\%$), hand ($0.23 \pm 0.1\%$), and forearms ($0.29 \pm 0.1\%$). Here, the chemical nature of the low-absorbing paraquat overcame regional variation.

Skin absorption in rhesus monkey is considered to be relevant to that of humans. Table 36.8 shows the percutaneous absorption of testosterone (Wester et al., 1980), fenitrothion, aminocard, and diethyltoluamide (DEET) (Moody and Franklin, 1987; Moody et al., 1988), in the rhesus monkey compared with the rat. What is interesting is that for the rhesus monkey, there is regional variation between forehead (scalp) and forearm. If one determines the ration of

forehead (scalp) to forearm for the rhesus monkey and compares the results with human, the results are found to be similar (Table 36.9). Therefore, the rhesus monkey can be a relevant animal model for human skin regional variation.

36.4 PERCUTANEOUS ABSORPTION FROM CHEMICALS IN CLOTHING

Chemicals in cloth cause cutaneous effects. For example, Hatch and Maibach (1986) reported that chemicals added to cloth in 10 finish categories (dye, wrinkle resistance, water repellency,

TABLE 36.10
***In Vitro* Percutaneous Absorption of Glyphosate and Malathion from Cloth through Human Skin**

Chemical	**Donor Conditions**	**Treatment**	**Percent Dose Absorbed**
Glyphosate	1% Solution (water)	None	1.42 ± 0.25
	1% Solution on cloth	0 h	0.74 ± 0.26
	1% Solution on cloth	24 h	0.08 ± 0.01
	1% Solution on cloth	48 h	0.08 ± 0.01
	1% Solution on cloth	Add water	0.36 ± 0.07
Malathion	1% Solution (water/ethanol)	None	8.77 ± 1.43
	1% Solution on cloth	0 h	3.92 ± 0.49
	1% Solution on cloth	24 h	0.62 ± 0.11
	1% Solution on cloth	48 h	0.60 ± 0.14
	1% Solution on cloth	Add water/ethanol	7.34 ± 0.61

Note: Both glyphosate and malathion in solution (treatment = none) area absorbed through human skin. Glyphosate and malathion on cotton cloth show absorption in skin; depending upon time chemical was added to cloth (treatment = 0, 24, 48 h). When the cloth was wetted (treatment = add water/ethanol), the transfer of glyphosate and malathion from cloth to human skin was increased. This suggests that sweating, skin oil, or even rain may facilitate transfer of chemicals from cloth to skin.

Source: Krieger, R. in *Handbook of Pesticide Toxicology*, Academic Press, 2001. With permission.

soil release, and so on) caused irritant and allergic contact dermatitis, atopic dermatitis exacerbation, and urticarial and phototoxic skin responses. This is qualitative information that chemicals will transfer from cloth to skin *in vivo* in humans. Quantitative data are lacking. Snodgrass (1992) studied permethrin transfer from treated cloth to rabbit skin *in vivo*. Transfer was quantitative but less than expected. Interestingly, permethrin remained within the cloth after detergent laundering.

In other studies (Wester et al., 1996), *in vitro* percutaneous absorption of glyphosate and malathion through human skin were decreased when added to cloth (the cloth then placed on skin), and this absorption decreased as time passed over 48 h (Table 36.10). It is assumed that with time, the chemical will sequester into deep empty spaces of the fabric, or some type of bonding is established between chemical and fabric. When water was added to glyphosate/cloth and water/ethanol to malathion/cloth, the percutaneous absorption increased (malathion to levels from solution). This perhaps reflects clinical situations where dermatitis occurs most frequently in human sweating areas (axilla, crotch). The clothing must not be a collection system for pesticides, and it cannot be assumed that laundry will remove the agents.

Obendorf et al. (2003) conducted a comprehensive study evaluating the different characteristics in clothing that affect pesticide absorption. Starching fabric reduced pesticide transport compared to those without starching while carboxymethylated fabrics showed higher transport of pesticides compared to the synthetic membrane. Bleached and mercerized fabrics showed much lower transport of pesticides compared to the synthetic membrane. Denim fabrics showed a much greater reduction in pesticide transport than shirt-weight fabrics.

36.5 ENHANCERS OF PERCUTANEOUS ABSORPTION OF PESTICIDES

Certain chemicals can actually lead to an enhanced absorption of pesticides. One such chemical that is used frequently among agricultural workers is sunscreen. Brand et al. (2002) showed that six of a total nine tested sunscreens in fact led to an increase in percutaneous absorption of 2,4-dichlorophenoxyacetic acid, a commonly used herbicide, when tested in hairless mice. More recently, Brand et al. (2003) showed that sunscreens containing chemical UV absorbers have enhanced absorption over those that do not contain these absorbers. However, these enhancement properties due to the chemical UV absorbers were mitigated when the researchers used phenyl trimethicone as a solvent.

Feldmann and Maibach studied the effect of stripping and occlusion on penetration of hydrocortisone in human skin. In skin that was stripped or occluded, there was a doubling in amount of hydrocortisone dose recovered in urine over a 10 days period and significantly altered hydrocortisone absorption rate curve. Nielsen (2005) studied this phenomenon in relation to pesticide absorption in slightly damaged skin. In their experiment, they exposed an *in vitro* sample of human skin to sodium lauryl sulfate, a commonly used detergent compound found in many household products and soaps, for 3 h to induce damage to the skin barrier and then exposed the skin to a group of pesticides. They concluded that skin damage affects the rate, lag time, and total penetration of chemicals with the most hydrophilic pesticides being most affected.

With the knowledge that topically applied ethanol is a dermal penetration enhancer, Brand et al. (2004) studied

whether chronic alcohol consumption would also lead to pesticide penetration enhancement. In a study on rats, Brand concluded that regular alcohol consumption led to altered properties of the dermal barrier and led to an increased penetration of pesticides through rat skin. However, this phenomenon has yet to be proven true in humans.

36.6 SKIN DECONTAMINATION

Although decontamination of a chemical from the skin is commonly done by washing with soap and water, as it has been assumed that washing will remove the chemical, recent evidence suggests that many times the skin and the body are unknowingly subjected to enhanced penetration and systemic absorption/toxicity because the decontamination procedure does not work or may actually enhance absorption.

Zendzian (2003) studied the effects of pesticide residue in washed skin and its contribution to dermal toxicity. Nine of 19 pesticides tested in rats showed an increase in systemic concentration after washing indicative of a postwash absorption and increased toxicity. Moody and Maibach (in press) proposes a mechanism for this wash-in effect in that by washing chemicals off of one's skin, some chemicals can actually be washed into the system and become bioavailable through the systemic cutaneous blood supply.

Figure 36.3 illustrates skin decontamination of alachlor with soap and water or water only over a 24 h dosing period, suing grid methodology. Note that the amount recovered decreases over time, which happens because this is an *in vivo* system and percutaneous absorption is taking place, decreasing the amount of chemical on the skin surface. There may also be loss due to skin desquamation. The second observation is that alachlor is more readily removed with soap-and-water wash than with water only. The reason is alachlor is lipid soluble and needs the surfactant system for more successful decontamination (Wester et al., 1991, 1992).

In the preceding illustration, decrease in alachlor wash recovery over time was thought to be due to ongoing absorption and loss due to skin desquamation. These factors are probably true, but probably not the main reason, which is soap-and-water wash effectiveness. In the home and workplace, decontamination of a chemical from skin is traditionally done with a soap-and-water wash, although some workplaces may have emergency showers. It has been assumed that these procedures are effective, yet workplace illness and even death occur from chemical contamination. Water, or soap and water, may not be the most effective means of skin decontamination, particularly for fat-soluble materials. A study was undertaken to help determine whether there are more effective means of removing methylene bisphenyl isocyanate (MDI) from the skin. MDI is an industrial chemical for which skin decontamination, using traditional soap and water and nontraditional polypropylene glycol, a polyglycol-based cleanser (DTAM), and corn oil were all tried *in vivo* on the rhesus monkey, over 8 h (Figure 36.4). Water, alone and with soap (5 and 50% soap), was partially effective in the first hour after exposure, removing 51–69% of the applied dose. However, decontamination fell to 40–52% at 4 h and 29–46% by 8 h. Thus, the majority of MDI was not removed by the traditional soap-and-water wash; skin tape stripping after washing confirmed that MDI was still on the skin. In contrast, polypropylene glycol, DTAM, and corn oil all removed 68–86% of the MDI in the first hour, 74–79% at 4 h, and 72–86% at 8 h. Statistically, polypropylene glycol, DTAM, and corn oil were all better ($p < 0.05$) than soap and water at 4 and 8 h after dose application. These results indicate that a traditional soap-and-water wash and the emergency water shower are relatively ineffective at removing

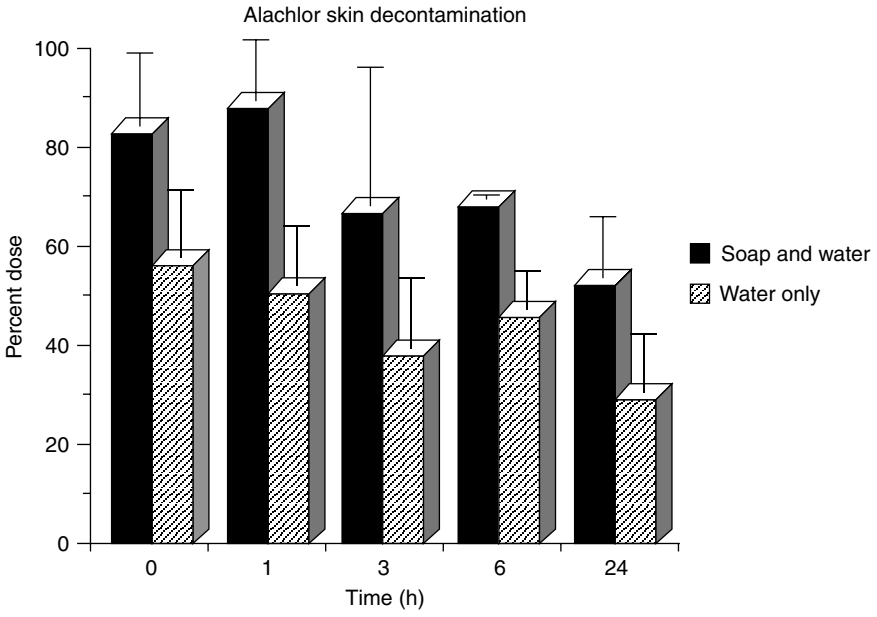

FIGURE 36.3 Alachlor is a lipophilic chemical, which is better removed from skin by soap and water than by water only. (Adapted from Krieger, R. *Handbook of Pesticide Toxicology*, Academic Press, 2001. With permission.)

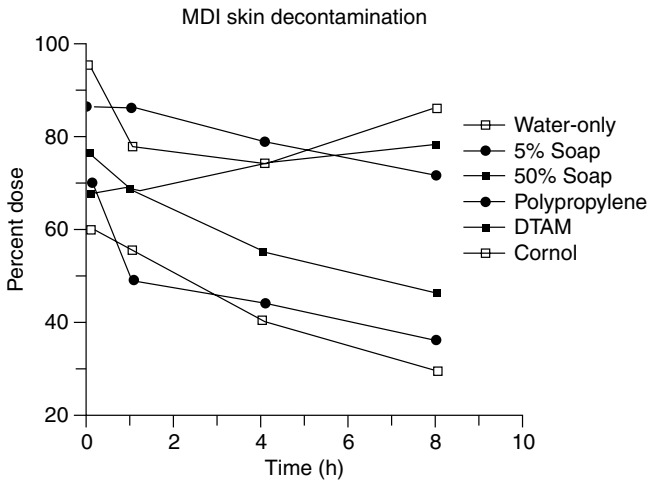

FIGURE 36.4 Mean percent applied dose of MDI removed with designated decontamination procedure at designated time period. Water, and soap and water are the least effective, especially at 4 and 8 h. (Adapted from Krieger, R. *Handbook of Pesticide Toxicology*, Academic Press, 2001. With permission.)

MDI from the skin. More effective decontamination procedures, as shown here, are available. These procedures are consistent with the partial miscibility of MDI in corn oil and polyglycols (Wester et al., 1999). Thus, if there is skin contamination with a pesticide and the skin is washed with soap and water, it cannot be assumed that the pesticide has been removed from the skin.

36.7 DISCUSSION

The lesson partially learned but still ongoing is that pesticide use can achieve its chemically intended goals, but that continued knowledge in human risk assessment needs to be achieved. Understanding percutaneous absorption as a major route of pesticides entering the body is an integral part of the risk assessment process. Data in humans can be achieved safely using trace methodology, and with low-risk doses coupled with high-tech analytical methodology. Data from animal and computer models are simpler to use. Safer is debatable if the models are not validated to man, because the resulting risk assessment may also be wrong.

37.1 INTRODUCTION

Tape stripping is a useful method for removing the stratum corneum (SC) and obtaining more information about function of this thin layer as a main barrier for skin penetration. Typically, an adhesive tape is pressed onto the test site and is subsequently abruptly detached. The number of tape strips need to remove the SC varies with age, sex, and possibly ethnicity (Palenske and Morhenn, 1999).

Tape stripping has been used to various dermatological and pharmaceutical fields to measure the SC mass and thickness (Bashir et al., 2001; Blank et al., 1984; Dreher et al., 1998; Herkenne et al., 2006; Jakasa et al., 2006; Kalia et al., 2001; Schwindt et al., 1998; Weigmann et al., 2005), to investigate percutaneous penetration and disposition of topically applied drug *in vivo* (Benfeldt and Serup, 1999; Benefeldt et al., 1999; Choi et al., 2003; Jacobi et al., 2003; Potard et al., 2000; Rougier et al., 1987), and to disrupt skin barrier function (Benfeldt and Serup, 1999; Benefeldt et al., 1999; Fluhr et al., 2002). Also, this technique has been used to collect SC lipids samples (Weerheim and Ponec, 2001), to detect proteolytic activity associated with the SC (Beisson et al., 2001), and to quantitatively estimate esterase activities in the SC (Mazereeuw-Hautier et al., 2000). Tape stripping is a quantitative and minimally invasive assay for the detection of metal on and in the skin (Cullander et al., 2000; Hostynek et al., 2001, 2006). Tape stripping has been used to disrupt the skin before percutaneous peptide (protein) and DNA immunization (Liu et al., 2001; Seo et al., 2000; Takigawa et al., 2001; Watabe et al., 2001).

Tape stripping is of sufficient utility to have been proposed by the FDA as part of a standard method to evaluate bioequivalence of topical dermatological dosage forms (Ikeda et al., 2005; Loden et al., 2004; Shah et al., 1998; Weigmann et al., 2005). Ikeda et al. (2005) reported the cutaneous bioavailability of topically applied maxacaltol ointment *in vivo* by tape stripping. Tape stripping is simple, inexpensive, and minimally invasive method; it has been the most frequently used method for investigation of the skin penetration, barrier function, and the involvement factors in skin pathologies. In addition, tape stripping is fast and easy to use in human studies.

This chapter reviews the stripping method, considering factors, analytic method of drug in the SC after stripping, and its application on the penetration enhancement into SC and topical vaccination and summarizes recent data.

37.2 STRATUM CORNEUM AND ITS FUNCTIONS

SC is a stratified squamous epithelium lining the body surface that plays an important antidesiccating role as a barrier function and a reservoir for topically applied substances (Pelchrzim et al., 2004). SC consists of nonviable cornified cells (corneocytes) embedded in lipid-rich intercellular domains (intercorneocyte spaces). Intercellular domains comprise free fatty acids (FFA), cholesterol (CHOL), and ceramides (CER), together with smaller amounts of cholesteryl sulfate, sterol, triglycerides, squalene, *n*-alkanes, and phospholipids. Nine different extractable CER have been detected in human SC, which are classified as CER1 to CER9 (Stewart and Downing, 1999; Wertz et al., 1985). The CER can be subdivided into three main groups, based on the nature of their head group architecture (sphingosine, phytosphingosine, or 6-hydroxysphingosine).

SC lipids localize mainly in the intercellular space with little in the corneocytes (Moghimi et al., 1999). These lipids

exist as a continuous lipid phase; occupying about 20% of the SC volume, arranged in multiple lamellar structures. All ceramides and fatty acids found in SC are rod and cylindrical in shape; this physical attribute makes them suitable for the formation of highly ordered gel phase membrane domains. CHOL is capable of either fluidizing membrane domains or of enhancing rigidity, depending on the physical properties of the other lipids and the proportion of CHOL relative to the other component (Wertz, 2000). Intracellular lipids that form the only continuous domain in the SC are required for a major competent barrier.

Efforts have been undertaken to characterize the lipid lamellar regions. X-ray diffraction studies on native SC have demonstrated that the SC lipids are organized in two coexisting crystalline lamellar phases: the short periodicity phase (SPP) with a periodicity of approximately 6 nm and the long periodicity phase (LPP) with a periodicity of approximately 13 nm (Bouwstra et al., 1991, 1995, 2003). The LPP and its predominantly orthorhombic lipid packing are considered to be crucial for the skin barrier function. SC lipids, CER, CHOL, and FFA form the orthorhombic lateral packing, a densely packed structure. However, in equimolar mixtures prepared for CHOL and CER, the major lipid fraction forms a lamellar phase (hexagonal lateral packing) with periodicity of 12.8 nm. Addition of FFA to CER/CHOL mixtures induced a transition from a hexagonal to orthorhombic lateral packing (Bouwstra and Honeywell-Nguyen, 2002). Therefore, the formation of the characteristic LPP depends on the presence of CHOL and specific CER, in particular CER1, whereas FFA are required for the crystalline (orthorhombic) character of the lateral lipid packing (Bouwstra et al., 1998, 2002; McIntosh et al., 1996).

Diseases such as atopic dermatitis, psoriasis, and contact dermatitis are associated with barrier dysfunction. Most skin disorders that have a diminished barrier function present a decrease in total CER content with some differences in their pattern (Choi and Maibach, 2005; Macheleidt et al., 2002; Matsumoto et al., 1999; Okamoto et al., 2003). Pilgram et al. (2001) reported that in case of diseased skin, an impaired barrier function is related to an altered lipid composition and organization. In atopic dermatitis SC, they found that, in comparison with healthy SC, the presence of the hexagonal lattice (gel phase) is increased with respect to the orthorhombic packing (crystalline phase). From lipid composition studies of atopic skin, it has been found that intercellular lipids, especially ceramides, play an important role in the barrier function and lipid organization. Man-Qiang et al. (1993) suggested that for the formation of a component SC barrier, the CER, CHOL, and FFA should be present in an equimolar ratio. Man et al. (1996) reported that three major SC lipids are required for permeability barrier homeostasis and equimolar composition of major lipids is increased up to threefold acceleration of barrier repair. Barrier repair creams including natural components of SC lipids have been used to treat skin disease (Chamlin et al., 2001; Mortensen et al., 2001). Chamlin et al. (2001) reported a phase I trial of a repair cream in childhood atopic dermatitis.

The physiology of SC differs from gender to gender. Only few studies on gender-related differences in skin physiology have been performed and they provided conflicting results (Blank, 1939; Ehlers et al., 2001; Ohman and Vahlquist, 1994; Wilhelm et al., 1991). Jacobi et al. (2005) investigated the effect of gender on the physiology of the SC. The skin of women was characterized by a significantly higher pH value (5.6 ± 0.4) than that of men (4.3 ± 0.4, $p < 0.05$). There were no significant differences between women and men volunteers in TEWL, SC hydration, and sebum content. Protein absorption was the only other parameter significantly dependent on gender. The difference of skin pH and protein absorption might be caused by differences in human biology, such as hormonal status.

37.3 SC REMOVAL METHODS AND EFFECT OF STRIPPING

To remove SC, tape stripping for mechanical removal of corneocytes and solvent-extraction method to remove both polar and nonpolar SC lipids is used. Tape stripping is a useful technique for selectively removing the skin's outermost layer, while solvent extraction is a delipidization process in SC.

In general, a clinical description of the barrier disruption differs depending on the disruption methods. For tape-stripped skin, the typical description was moderate erythema and a glistening surface due to total removal of the SC; for acetone-treated skin, the description was minimal or no erythema and slight superficial dryness; and for chloroform–methanol mixture, the description was deep erythema and edema (Benefeldt et al., 1999). Thus, an organic solvent method using chloroform–methanol mixing may be more aggressive than standard tape.

The change of skin condition after stripping differs depending on stripping (Table 37.1). Fluhr et al. (2002) investigated the barrier recovery pattern after tape stripping or acetone delipidization at five body sites in healthy volunteers. The fastest barrier recovery after tape stripping and acetone was observed on the forehead, followed by the back. But there are differences in SC capacitance values following acetone and tape stripping. In the case of acetone, there were no statistically significant differences in SC capacitance between body sites. In contrast, tape stripping produces significant differences in capacitance values between body sites. The capacitance increases are related to strong barrier damage by tape stripping. However, the decrease of capacitance appears related to lipid extraction. Benefeldt and Serup (1999) reported that salicylic acid penetration was greatly increased with the tape stripping, but not with acetone in the skin of hairless rats.

After barrier disruption, there are typically no adverse effects, such as infection or scaring. However, disruption of permeability barrier by tape stripping induces activation and maturation of epidermal Langerhans' cells (Nishijima et al., 1997). This process is important in inducing immune response *in vivo* and in immunizing with peptide and protein by a percutaneous method.

TABLE 37.1
Physiological Changes of the Human and Rat Skin after Stripping

Type of Skin	Barrier Perturbation	None	Tape Stripping[a]	Acetone[b]
Human	TEWL (g/cm^2/h)[c]	4.3 ± 2.2	30.6 ± 22.2	9.1 ± 7.5
	Erythema (arbitrary unit)[d]	8.7 ± 2.8	11.6 ± 2.8	9.2 ± 1.5
Rat	ΔTEWL[e]	0	69 ± 14	6 ± 3
	ΔErythema[e]	0	2.41 ± 0.87	0.95 ± 1.66

[a] Tape stripping was achieved by applying 2.5 × 5 cm (human) and 5 × 5 cm (rat) piece of Transpore tape with firm pressure and repeating the procedure 20 (human) and 10 (rat) times, respectively.

[b] Acetone was treated by gentle wiping with large cotton buds socked in 100% acetone for 3 min.

[c] Fifteen minutes after barrier perturbation procedures, TEWL was measured using an evaporimeter and recorded in triplicate.

[d] Colorimetry measures skin color by analyzing the light reflected from the skin surface according to the standardization protocol for the content of green-red (a^*) and yellow-blue (b^*) color and skin brightness (L^*). The a^* redness parameter is a measure of a erythema.

[e] TEWL and erythema from the barrier perturbed skin area minus the value from the untreated side.

37.4 STRIPPING FACTORS

When the tape stripping is employed, the following factors are important: (1) number of strips, (2) types and size of tapes, (3) the pressure applied to the strip prior to stripping and the peeling force applied for removal, and (4) anatomic site. Some parameters are summarized in Table 37.2. We summarize the effect of the type of tape and number of strips on the stripping.

Dreher et al. (1998) improved the method by quantifying the amount of human SC removed by each strip utilizing a colorimetric protein assay. With this method, Bashir et al. (2001) determined the physical and physiological effect of SC tape stripping, utilizing tapes with different physicochemical properties. Three commercial adhesive tapes utilized were D-Squame® (CuDerm, Dallas, Texas), Transpore® (3M, St. Paul, Minnesota, batch no. 2002-12 AP), and Micropore® (3M, St. Paul, Minnesota, batch no. 2001-08 AN). D-Squame is precut into disc shape. Transpore and Micropore are provided as a standard roll. Table 37.3 shows the components of three commercial adhesive tapes and the effect of tapes on the transepidermal water loss (TEWL) depending on the number of strip. Bashir et al. (2001) demonstrated that no significant difference was found in the kinetic parameters (mean water diffusion coefficient, SC thickness, and permeability) between the tapes. However, there are differences in the mean TEWL values. Mean TEWL increased significantly

TABLE 37.2
Comparison to Tape-Stripping Methods

Type of Tape	Stripping Number	Size	Applied Pressure	Time	Study
D-Squame	40	14 mm	10 Kpa	2 s	Bashir et al. (2001)
Transpore	40		10 Kpa	2 s	Bashir et al. (2001)
Micropore	40		10 Kpa	2 s	Bashir et al. (2001)
D-Squame	16	14 mm	80 g/cm^3	5 s	Potard et al. (2000)
Leukoflex	18–20	7.5 cm^2	Soft pressure		Weerheim and Ponec (2001)
3M invisible	7		Controlled condition	10 s	Fernandez et al. (2002)
Adhesif 3M 6204	10	20 cm^2		2 s	Mazereeuw-Hautier and Muller (2000)
Scotch Book tape 845	20		By rubbing six times		Alberti et al. (2001)
Scotch	7		1-kg-pressure		Wissing and Muller (2002)
Scotch 600	2–5	4 cm	By rubbing		Betz et al. (2001)
Blenderm 3M	6	4 cm^2			Couteau et al. (2001)
Transpore	20	12.5 cm^2	Firm pressure		Benfeldt et al. (1999)
Transpore	10	5 × 5 cm			Benfeldt and Serup (1999)
Teasfilm	20	4 cm^2			Fluhr et al. (2002)
D-Squame	20	3.8 cm^2	Uniform pressure	5 s	Dreher et al. (1998)
D-Squame	16	25 mm	0.365 N/cm^2		Chatelain et al. (2003)
D-Squame	25	25 mm	Uniform pressure	5 s	Simonsen et al. (2002)
D-Squame	20	2.2 cm	10 Kpa pressure	2 s	Bashir et al. (2005)
Tesa	20	3.0 cm^2	2-kg-pressure	10 s	Verma et al. (2003)
Tesa	26–28	1.9 cm	15 g–25 g/cm^2	15 s	Lademann et al. (2005)
Cover-Roll tape	5	10 cm^2	Uniform pressure	2 min	Chao and Nvlander French (2004)
Scotch Book tape 845	20	2.0 cm^2	Uniform pressure		Esposito et al. (2005)
					Ricci et al. (2005)

Note: Tape stripping is employed with different adhesive tape, size, number of strips, and the pressure applied to the strip prior to stripping and the peeling force applied for removal.

TABLE 37.3
Components of Three Commercial Tape and Precise TEWL (g/m²/h) Data per Number of Strips for Three Common Tapes at Dorsal Forearm Site

Number of Strips	Type of Tape		
	D-Squame	Transpore	Micropore
Components	Polyacrylate ester, super clear polymer	Iso-octyl acrylate, methyl acrylic acid copolymer	Iso-octyl acrylate, acrylic acid copolymer
Baseline	10.3	8.78	9.37
10	11.23	10.77	8.88
20	14.15	14.12	10.1
30	21.05	21.12	10.4
40	30.33	31.98	13.4

Note: The tape was applied to the test site with forceps and pressed onto the skin with a standardized 10 Kpa pressure for 2 s. The pressure was then removed and the tape was peeled from the skin unidirectionally.

Source: Bashir, Chew, Anigbogu, Dreher, and Maibach, Skin Res. Technol., 7, 40–48, 2005.

as the deeper layers of the SC reached by tape stripping for the D-Squame and Transpore, but not for the Micropore tape. Therefore, D-Squame and Transporore tapes induce a significant increase in the TEWL, while Micropore tape does not (Table 37.3). The value of TEWL differed depending on the tapes and the number of tape strips. Loffler et al. (2004) investigated the influences of stripping procedures (anatomical site, pressure, pressure duration, and tape removal rate) inherent in each stripping protocol on changes in skin physiology. They reported that stripping results were influenced dramatically by all investigated parameters.

The number of tape strips to remove SC differs by investigators and experimental methods such as *in vivo* and *in vitro* assay (Table 37.2). The FDA guideline recommends 10 tape strips after topical application of a substance. Weerheim and Ponec (2001) reported that the average number of tapes *in vivo* could be 18–20 strips. For some individuals, 40 adhesive tape strips, regardless of the type of tapes, do not disrupt the SC barrier to water (Bashir et al., 2001). Thus, we consider the factors such as the types of tape and number of strips when applying this method.

37.5 TAPE STRIPPING VERSUS PERCUTANEOUS ABSORPTION AND PENETRATION

Percutaneous absorption and penetration is a complex physical and physiological process. This process initiates a series of absorption and excretion that are influenced by a numerous factors. Percutaneous absorption of drug depends mainly on the permeability coefficient of the drug, which is affected by drug polarity, molecular size, the vehicle in which the drug is applied, and the skin barrier. Other important factors are application conditions (nonocclusion or occlusion) and skin integrity, which is affected by disease and trauma, body site, and age (Fang et al., 2001; Feldmann and Maibach, 1965, 1967; Morgan et al., 2003; Rougier et al., 1986, 1987, 1999; Wester and Maibach, 1983; White et al., 2002).

The intracellular lipid domain is a major pathway for permeation of most drugs through the SC and also acts as a major barrier for penetration. As a consequence of its hydrophobic nature, the SC barrier allows the penetration of lipid-soluble molecules more readily than water-soluble drugs. Generally, small, nonpolar, lipophilic molecules are the most readily absorbed, while high water solubility confers less percutaneous absorptive capacity through normal skin (Morgan et al., 2003). The way to overcome the properties of the corneal layer is by disrupting it with physical methods (ultrasound, low- and high-voltage electrical pulsing, and stripping) and chemical enhancers.

The tape-stripping method is mainly used to measure drug concentration and its concentration profile across the SC. The SC is progressively removed by serial adhesive tape stripping and consequently, percutaneous absorption and penetration was significantly increased in stripped skin (Table 37.4). Benfeldt and colleagues (Benfeldt et al., 1999; Benfeldt and Serup, 1999) reported that in microdialysis experiment salicylic acid was highly increased in tape-stripped skin in human and hairless rats at 157- and 170-fold, respectively. Morgan et al. (2003) reported that in microdialysis experiment tape stripping increased penciclovir absorption by 1300-fold and acyclovir absorption by 440-fold. Although tape stripping increased the penetration of drugs into the skin, this is not universal (Arima et al., 1998; Moon et al., 1990; Xiong et al., 1996). Physiological and pathological factors affect drug transport across the living human skin. Bos and Meinardi (2000) suggested the 500-Da rule for the skin penetration of chemical compounds and drugs. This size limit may be changed by the skin abnormalities such as atopic dermatitis and disrupted skin.

Abla et al. (2005) reported the effect of iontophoretic current on the acetaminophen and kyotorphin (peptide) delivery across intact and tape-stripped porcine ear skin. Passive permeation of acetaminophen and kyotorphin across intact porcine ear skin was negligible. After removal of the SC, there was a significant increase in passive permeation of acetaminophen ($294 \pm$ nmol/cm²/h) and kyotorphin peptide (98 ± 31 nmol/cm²/h). However, the application of an iontophoretic current across tape-stripped skin did not result in a further increase in acetaminophen (266 ± 71 nmol/cm²/h) and kyotorphin (100 ± 30 nmol/cm²/h). Iontophoretic studies into the transdermal delivery of lidocaine by Sekkar et al. (2004) and tacrine by Hirsch et al. (2005) across intact and tape-stripped skins have also observed the similar result as Abla et al. (2005). From these results, application of iontophoretic current in the impaired skin did not increase transdermal delivery of applied drugs.

In addition to organic drugs, tape striping increased the penetration of biological macromolecules such as peptide and DNA into viable skin (Liu et al., 2001; Seo et al., 2000;

[a] Penetration ratio varies among drugs and species investigated. Most of the studies used traditional radiolabeling and HPLC techniques. In case of salicylic acid, the study defined the cutaneous penetration and systemic absorption during 20 min intervals over a period of 4 h after drug administration.

Takigawa et al., 2001; Watabe et al., 2001). Topically applied oligonucleotides (ONs) and DNA do not penetrate normal human SC. But removal of SC by tape stripping led to extensive penetration of ONs and DNA throughout the epidermis. Regnier et al. (2000) compared ONs penetration through intact and stripped hairless rat skin. Stripping increased ONs concentration by 1 or 2 orders of magnitude (24- to 166-fold increase) (Table 37.4). In case of plasmid DNA, Yu et al. (1999) reported that transfer gene activity depends on the number of stripping. They applied a cytomegalovirus-chloramphenicol acetyltransferase expression plasmid to stripped area and found that the transfer gene expression was higher in the murine skin samples stripped five times prior to DNA application compared with those stripped three times prior to DNA application. This result indicated that abrasion of the skin prior to DNA application could improve cutaneous gene transfer and expression. Taken together, tape stripping is commonly used to enhance the delivery of chemical drugs and biological macromolecules.

The determination of penetration pathways of topically applied drugs into the skin has been well evaluated. However, a direct and noninvasive quantification of the amount of topically applied drugs penetrated into the hair follicular had not been available. Teichmann et al. (2005) reported differential stripping method to determine the amount of topically applied drug penetrated into the hair follicles. They used differential stripping techniques with a tape stripping and a cyanoacrylate skin surface biopsy. Tape stripping was used to remove the part of the SC that contained the topically applied dye. Subsequently, the follicular contents were ripped off by cyanoacrylate skin surface biopsy. Differential stripping technique is a new method that can be used to study the penetration of topically applied substances into the hair follicular infundibula noninvasively and selectively.

37.6 TAPE STRIPPING VERSUS ANALYTIC METHODS

To determine the drug concentration and profile into SC, analytical techniques are important. These techniques include skin extraction measurement, horizontal stripping and sectioning, quantitative autoradiography, mass spectrometry, optical microscopy, and spectroscopic methods. Penetration into SC is determined by tape stripping followed by skin extraction and spectroscopic methods. These methods are widely used in determination of drug concentration within skin. Skin extraction is necessary to extract the drug with a suitable solvent and then an appropriate, sensitive analytical such as high-performance lipid chromatography (HPLC), spectroscopy, and scintillation counting is used to quantify the extracted drug. The improving sensitivity of optical instrument has permitted the quantification of drugs in skin by spectroscopic methods. These methods are noninvasive and offer real-time data on penetrated drug localization. These techniques include attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy, fluorescence

TABLE 37.5
Description of the Techniques Available for Quantifying Drugs in the Skin

Technique	Penetrants Detected	Measuring Depth	Cost	Speed	Complementary Strategies
Skin extraction	Any	All strata	Inexpensive	Rapid	Separation of skin tissue Qualitative autoradiography
Horizontal sectioning	Any	All strata	Inexpensive	Rapid	Separation of follicles Use of follicle-free skin
Quantitative autoradiography	Radiolabelled only	All strata	Expensive	Slow	None
ATR-FTIR spectroscopy	IR-absorbing only	SC	Expensive	Very rapid	Tape stripping
Direct fluorescence spectroscopy	Self-fluorescent only	All strata	Medium	Rapid	Separation of follicles Quantitative fluorescent microscopy
Indirect fluorescence spectroscopy	UV-absorbing only	SC	Medium	Rapid	None
Remittance spectroscopy	UV-absorbing only	SC	Medium	Rapid	None
Photothermal spectroscopy	Strong UV-absorbing	SC	Medium	Rapid	None
Spectroscopy	UV/Visible	SC	Inexpensive	Rapid	Tape stripping
Microscopy	Common or laser	SC	Medium	Rapid	Tape stripping
Mass spectrometry	Metal	SC	Expensive	Rapid	Tape stripping

Source: Hostynek, Dreher, Nakada, Schwindt, Anigbogu, and Maibach, *Acta Derm. Venereol*., 212, 11–18, 2001; Lindemann, Weigmann, Schanzer, Richer, and Audring, *J. Biomed. Opt*., 8, 601–607, 2003; Touitou, Meiden, and Horwiwitz, *J. Control. Release*, 56, 7–21, 1998.

spectroscopy, remittance spectroscopy, confocal microscopy (laser-scanning microscopy), mass spectrometry, and photothermal spectroscopy (Hostynek et al., 2001; Lindemann et al., 2003; Pelchrzim et al., 2004; Touitou et al., 1998). Table 37.5 shows the characterization of the analysis method of drugs in the skin.

Tape stripping and optical spectroscopy are used as a suitable combined method to determine the honey layer profile (Ikeda et al., 2005; Lademann et al., 2005; Lindemann et al., 2003; Pelchrzim et al., 2004; Weigmann et al., 1999, 2001). The application of tape stripping in combination with analytical instruments (mass spectrometry, UV/VIS spectroscopy, microscopy) is checked to determine the local position of topically applied substances inside the SC, the penetration profile (Ikeda et al., 2005; Pelchrzim et al., 2004; Weigmann et al., 2005). The combined use of these analytical methods can test the validity of the dermatopharmacokinetic (DPK) method to assess bioequivalence and bioavailability of topical dermatological drugs.

In addition to drug detection methods, many methods detect metal into and on the skin: inductively coupled plasma-atomic emission spectroscopy (ICP-AES), inductively coupled plasma-mass spectrometry (ICP-MS), atomic absorption spectrometry (AAS), and particle-induced x-ray emission (PIXE) are widely used. ICP-AES permits detection of metals at the trace amount level, obviating the use of radioisotopes. ICP-MS is a technique applicable to microgram per liter (ppb) concentration of several elements in aqueous medium upon appropriate sample preparation of biological materials. AAS is the reference method accepted by the International Union of Pure and Applied Chemistry for trace element analysis. PIXE analysis with a proton microprobe allows the determination of trace elements in epidermal strata prepared by cryosection (Hostynek et al., 2002).

37.7 TAPE STRIPPING VERSUS TOPICAL VACCINATION

Why is the skin a major target for topical vaccination? The skin, an active immune surveillance site, is rich in potent antigen-presenting dendritic cells (DC) such as Langerhans' cells (LC) in the epidermis. LC plays a key role in the immune response to antigenic materials. Skin accessibility makes it an easy target for vaccination. Thus, skin is an attractive target site for topical vaccination and has become the focus of intense study for the induction of antigen-specific immune responses (Babiuk et al., 2000; Choi et al., 2006; Choi and Maibach, 2003; Godefroy et al., 2005). Wang et al. (1996) observed that protein penetrates SC barrier following occlusion by patch application, but immune responses generated in this way are Th2-predominant. This immune response does not elicit cytotoxic T lymphocytes (CTL) response that is important in preventing and therapy against viral infections and tumors.

In addition to disruption of the epidermal barrier, stripping enhances *in vitro* the T-cell-mediated immune response (Nishijima et al., 1997). Tape stripping is immunostimulatory and results in the production and release of IL-1α, IL-1β, TNF-α, IL-8, Il-10, and INF-γ (Nickoloff and Naidu, 1994; Nishijima et al., 1997; Takigawa et al., 2001). Skin barrier disruption by tape stripping also increases co-stimulatory molecule expression (CD86, CD54, CD40, and MHC class II) and the antigen-presenting capacity of epidermal DCs (Kahlon et al., 2003; Takigawa et al., 2001). In addition, tape-stripping facilitates the generation of Th1 immune responses and stimulates LCs migration to cutaneous lymph nodes (Kahlon et al., 2003).

Seo et al. (2000) reported that topical application of tumor-associated peptide onto the SC barrier disrupted by tape stripping in mice induces a protective antitumor response *in vivo*

and *in vitro*. They investigated induction of CTL response on tape-stripped earlobes of C57/BL6 mice by application of CTL epitope peptide onto the SC. The optimal condition for a CTL response was observed 12 and 24 h after tape stripping at peptide doses of 48 and 96 μg per mouse. However, CTL induction was virtually absent when peptide was applied to intact skin (Table 37.6). Kahlon et al. (2003) reported optimization of topical vaccination for the induction of CTL with peptide and protein antigens. They found that tape stripping significantly enhanced antigen-specific antibody (protein) and CTL responses (peptide and protein) measured at 3 and 2 weeks following immunization, respectively (Table 37.6). Stripping resulted in prolonged CTL responses at least 2 months after single immunization. Godefroy et al. (2005) reported the systemic and mucosal antibody responses to protein after its application onto the intact or tape-stripped skin. Application of protein antigen alone onto the intact or tape-stripped skin did not elicit any detectable antibody response. These results are inconsistent with Kahlon et al. (2003). However, when cholera toxin was used as an adjuvant good antigen-specific responses (systemic and mucosal) were measured in mice immunized with protein applied onto the tape-striped skin but not onto the intact skin. These results suggest that stripping can be widely used in inducing immune responses with topical vaccination *in vivo*.

TABLE 37.6
Comparison to CTL Activity of Peptide, Protein, and DNA Immunization with and without Stripping

Antigen	Immunization	Specific Lysis (%)
Peptide	Intact skin	11.0
	Stripped skin[a]	80.0
	Stripped skin + cholera toxin[b]	70.0
Protein[c]	Intact skin	8.0
	Stripped skin	46.0
DNA[d]	Intact Skin	12.7
	Stripped skin	37.0

[a] Cervical lymph node cells (effectors) obtained from mice immunized 10 days earlier with tyrosinase-related protein 2 peptide (VYDFFVWL, 96 μg per mouse) either through intact earlobes or earlobes tape stripped 12 hr earlier were subjected to CTL assay using Lkb target cells pulsed with tyrosinase peptide. CTL assays were performed at effector-to-target ratio of 10.

[b] C57BL/6 mice were immunized on the ear with 25 μg ovalbumin peptide (SIYRYYGL) and 25 μg cholera toxin following tape stripping. Mice were boosted in similar fashion at 1 week and sacrificed at 2 weeks. Ovalbumin expressing EG7 cells were used as target and CTL assays were performed at effector-to-target ratio of 50. The ear skin on the dorsal and ventral side was tape-stripped 10 times (using Scotch Brand 3710 adhesive tape).

[c] C57BL/6 mice were immunized on the ear with 250 μg ovalbumin protein and 25 μg cholera toxin following tape stripping. Mice were boosted in similar fashion at 1 week and sacrificed at 2 weeks. Ovalbumin expressing EG7 cells were used as target and CTL assays were performed at effector-to-target ratio of 50. The ear skin on the dorsal and ventral side was tape-stripped 10 times (using Scotch Brand 3710 adhesive tape).

[d] BALB/c mice were immunized with plasmid DNA coded influenza M protein. Lymphoid cells from each immunized group were restimulated for 5 days using influenza M peptide-pulsed syngenic spleen cells. The peptide pulsed p815 cells were used as targets. CTL assays were performed at effector-to-target ratio of 80. Fast-acting adhesive glue (Alon Alfa®) was smeared on a glass slide to cover the mouse. After an interval of 20–30 s, the slide was ripped off.

In addition to peptide and protein antigen, tape stripping increased the humoral and cellular immune responses of topical DNA antigens (Liu et al., 2001; Watabe et al., 2001). Comparing the immune response with and without stripping, topical application without stripping induced weak antibody response and did not elicit a sufficient CTL response. In contrast, topical application of this vaccine with stripping induced strong antibody responses and elicited substantial CTL responses. There was a significant difference between the results of topical application with and without stripping (Choi et al., 2006; Choi and Maibach, 2003; Liu et al., 2001).

To confirm the protective effect of topical vaccination, Watabe et al. (2001) and Seo et al. (2000) used an influenza and melanoma mouse model, respectively. Watabe et al. (2001) investigated the efficacy of a topical DNA vaccine that expressed the matrix gene of the influenza virus using a mouse model. They topically applied plasmid DNA onto the stripped skin on days 0, 7, and 14. After the third immunization, the mice were challenged with $5LD_{50}$ of influenza virus; 13 of 20 mice (65%) survived when they were topically immunized with plasmid DNA that expressed the matrix gene. When the mice were immunized with inactivated virus topically, only 18% of mice were protected and all mice were dead 7 days after virus inoculation in case of unimmunized control group. These results suggest that the topical administration of DNA vaccine induces a protective immunity against influenza challenge. Seo et al. (2000) investigated the efficacy of topical peptide vaccination for tumor immunotherapy. Mice were immunized twice with tumor-associated peptide at barrier-disrupted skin and were challenged with B16 melanoma tumor cells. B16 tumor cells were virtually completely rejected after epitope peptide immunization via a disrupted barrier. Also, when tumor-bearing mice were treated with epitope peptide on tape-stripped skin, tumor cells regressed with peptide application, and 100% of the mice survived for 1 month and 95% for over 60 days. However, mice treated with peptide application to intact skin died after 34 days. Thus, topical immunization provides a simple, nonadjuvant system, and noninvasive means of inducing potent antitumor immunity that may be exploited for cancer immunotherapy in human.

37.8 UNANSWERED QUESTION AND CONCERNS TO TAPE STRIPPING

Surber et al. (1999) reviewed the tape-stripping technique as standardized tape-stripping technique; many factors remain to be investigated. As shown in Table 37.2, the types and sizes of tapes utilized equally affect the method and the pressure

applied to the strip prior to stripping. A proposed FDA guideline describes serial tape stripping to determine the amount of drug within the skin. By the guidelines, the first tape strip is discarded and the drug is extracted from the remaining pooled strips and the quantified amount is expressed as a mass per unit area. From the guidelines, it is impossible to express the amount of drug substance per unit mass of SC and to determine the proportion of the SC that has been sampled by the tape-stripping method. Although tape stripping is relatively simple to execute, there are many opportunities for experimental artifacts to develop. Tape-stripping samples have a high surface-to-volume ratio, and losses by evaporation can be significant even for chemicals with relatively low volatility. In addition, the tape-stripping experiment is unsuitable for volatile chemicals (Reddy et al., 2002). Considering the current application and convenient of tape-stripping method, topical vaccination and clinical trials for the determination of bioequivalence of topical dermatological products could be improved by stripping standardization.

38 Parameters Influencing Stratum Corneum Removal by Tape Stripping

Harald Löffler, Caroline Weimer, Frank Dreher, and Howard I. Maibach

CONTENTS

38.1 Extrinsic Parameters Influencing Tape Stripping Test 339
38.1.1 Anatomic Sites 339
38.1.2 Pressure and Contact Time 340
38.1.3 Velocity of Removal 340
38.1.4 Type of Tapes 340
References 340

The stratum corneum (SC), the outermost layer of the epidermis, is the main barrier against xenobiotics and protects the body against dehydration. This several micrometer thin skin layer can be studied using a technique known as adhesive tape stripping. Tape stripping is a relatively less invasive method to remove the SC, either partially or entirely.

After its first mention by Pinkus,[1] tape stripping has become a frequently used method in many areas of research.[2] Tape stripping can be used to obtain a more susceptible skin, e.g., prior to the application of an irritant[3] or an allergen.[4–6] Similarly, tape stripping can be performed to induce a defined disruption of the (water) barrier, e.g., to evaluate the effect of a subsequently applied skin care product in barrier restoration.[7] It may be also used to obtain cells for mycological culture[8] or to investigate SC quality.[9] Moreover, it can be used to study skin's barrier function including the uptake of topically administered compounds into the SC.[7,10] Further, the tape stripping technique is currently considered as being a valuable method to assess bioequivalence of topical drug products.[11–14]

Bioengineering methods, such as the measurement of transepidermal water loss (TEWL), can be used to measure changes in barrier properties after tape stripping. To quantify the amount of SC removed by stripping, several methods can be used. Besides weighing of the tape before and after tape stripping,[15] spectroscopic analysis of the tape[16–18] or SC protein extraction from the tape followed by quantification using total protein assay[19,20] were proposed.

Tape stripping appears simple and easy to perform.[21,22] However, there are many parameters influencing the outcome. Various types of tapes exist. They differ in adhesive properties, composition, shape, surface area, and flexibility, indicating that the influence of the tape on the outcome seems apparent.[19,23] Besides adhesive properties, parameters which influence the SC removal can be subsumed in SC's intrinsic characteristics (anatomic site, skin condition, etc.),[24] the pressure with which the tape is applied onto the skin, the duration of pressure and its removal process, as well as other extrinsic factors.[25]

38.1 EXTRINSIC PARAMETERS INFLUENCING TAPE STRIPPING TEST

38.1.1 Anatomic Sites

When comparing changes in TEWL using a standardized tape stripping procedure on different skin sites, the forehead and the back showed a significant higher TEWL increase after removing the same number of strips as compared to the forearm.[25] This may be due to different reasons. The SC of face and trunk is less thick and is composed of less corneocyte layers than the forearm SC.[26,27] Since an equal number of tape strips removes a larger part of SC in face and trunk, tape stripping leads to a faster TEWL increase in these areas as compared to the thicker SC of the forearm.

Furthermore, there are site-dependent differences in spontaneous desquamation[28] and, therefore, probably also SC cohesion, which may additionally explain why the same number of tape strips does not necessarily result in the same TEWL change. The mechanism of spontaneous desquamation is far from completely elucidated, but is believed to depend on physiological and probably also anatomic site-dependent mechanisms, such as corneodesmosome physiology[29] including its proteolysis[30] as well as the composition and structure of the intercorneocyte lipids.[31,32]

A further parameter that may influence the anatomic dependency of SC removal is the pressure resistance when applying the tape, which is likely a function of the biomechanical properties or viscoelasticity of the directly underlying tissue. This seems to be particularly relevant for the forehead where the skull bone is just underneath the skin surface, which may affect the overall pressure on the tape. In what respect the biomechanical properties of the skin and

its underlying tissue influence SC removal by tape stripping remains, however, to be further investigated.

Consequently, tape stripping results obtained from different anatomic regions are not necessarily directly comparable and should be related to the amount of SC removed or, better, normalized with respect to the fraction of SC thickness removed.

38.1.2 Pressure and Contact Time

A longer pressure application period (e.g., from 2 to 10 s) led to an increased TEWL after a significantly smaller number of tape strips, indicating that a larger amount or fraction of SC has been removed.[33] Pressure-sensitive adhesives form a strong adhesive bond with substrates under application of a slight external pressure over a short time.[34,35] This property is known as "tack." As known for such adhesives, tack increases with contact time and pressure up to a plateau corresponding to the so-called critical contact time and contact pressure.[36–38] The critical parameters depend on the adhesive properties as well as the substrate properties. This may be related to the fact that the adhesive glue requires some time to close the gaps between tape and SC surface, leading to an increasing or improved contact area between tape and SC surface.[36]

Similarly, as for contact time, a higher pressure results in a higher tack of pressure sensitive adhesives.[36,37] Hence, as long as the critical contact pressure and time[37,38] is not reached, the amount of SC removed increases with the applied pressure and the period of applied pressure, which results in a corresponding barrier perturbation.

Interestingly, the type of pressure seems important when performing tape stripping since it may influence the homogeneous removal of SC layer. The existence of skin furrows is particularly discussed to influence the outcome of tape stripping.[39,40] Lademann and colleagues showed that the influence of furrows may be minimized when using a standardized roller to apply the tape onto the skin.[39,41] By using this roller the skin is stretched, which flattens the SC and allows, therefore, a more homogeneous SC removal.

38.1.3 Velocity of Removal

In addition to contact time and pressure, the velocity of tape removal was shown to further influence SC mass removed and, thus, barrier perturbation. When strips are removed in a rapid movement, a less pronounced increase of TEWL was observed.[33] In contrast, when the tape removal was performed with a slow movement, more corneocytes seem to adhere to the tape since the barrier was disturbed significantly more with fewer strips.[33] For a given adhesive, the force to remove a tape after application is influenced by the viscoelastic properties of its substrate.[37,38,42] Similarly as for medical adhesives,[43] the skin may become more extended during slow tape removal as compared to fast removal. It is possible that this extension may result in a more efficient SC removal per single tape strip probably due to the fact that corneodesmosomes, which are predominantly responsible for SC cohesion,[29] become more "stressed" during this removal procedure. This hypothesis remains to be studied in detail.

38.1.4 Type of Tapes

When comparing different tape brands, different brands removed differing amounts of SC under standardized conditions.[19] As previously mentioned, this can be explained by the different adhesive characteristics of the tapes.[44] Therefore, it is of importance to define the type of tape before performing a tape stripping test.

In conclusion, numerous parameters significantly affect SC removal when performing tape stripping. Hence, it is recommended that the most relevant tape stripping parameters (tape brand, pressure, time of pressure, removal process) are defined and controlled when a tape stripping study is performed. A definition of the procedure, as can be found in numerous scientific references, like "after application with a moderate pressure over a few seconds onto the skin, the tapes were removed," is not sufficient because the crucial parameter directly influencing SC removal has not been adequately defined or described.

Combining the different procedures in a single test protocol might represent a new dynamic SC stress test (DSCST). For instance, a DSCST may allow distinguishing small differences in intrinsic SC cohesion. Furthermore, DSCST may be a valuable test to investigate in a more dynamic way the effect of topically applied agents such as keratolytics, which influence the SC cohesion.

39.1 INTRODUCTION

The outermost skin layer, the stratum corneum (SC), can be removed sequentially by repeated application of appropriate adhesive tapes [1]. This technique, commonly known as "SC tape stripping," is a relatively noninvasive frequently used method to investigate the structure, properties, and functions of SC *in vivo* [2]. SC consists of corneocytes embedded in lipid layers and represents the main barrier for skin penetration of xenobiotics. Its thickness in healthy adults varies from 5 to 20 μm, except in the SC of the palm and sole, where SC is thicker. Other techniques to remove SC include skin surface biopsy using cyanoacrylate strips and diverse skin scraping techniques.

Since SC is known to be a reservoir for topically applied chemicals [3,4], its removal by tape stripping has provided useful data on their penetration into skin [5]. Tape stripping is therefore regarded as a valuable method to evaluate cutaneous bioavailability of topically applied chemicals, which may also provide helpful information to understand their dermatotoxicology profile. The possibility to use tape stripping as an alternative method to assess bioequivalence of certain topical drugs is still being debated [6]. Further, tape stripping can be successfully used to investigate intercorneocyte cohesion within the SC [7,8].

This chapter deals with the experimental procedure of tape stripping technique and reviews methods to quantify SC removal.

39.2 TAPE STRIPPING TECHNIQUE

39.2.1 Experimental Procedure

SC tape stripping is carried out by pressing an adhesive tape onto the skin surface, and further removing it by tearing off. The tape is placed to a previously delineated skin surface area according to a standardized procedure by applying a constant pressure (e.g., 100 g cm^{-2}), using a weight or spring system, over an appropriate time period (e.g., 5 s). Then the tape is removed with a single continuous motion. The application and removal procedure may be repeated up to more than 100 times at the same site. Commonly used tapes for skin tape stripping are stationary tapes (e.g., Tesa Film No. 5529, Beiersdorf, Germany), medical tapes (e.g., Transpore®, 3M Co., United States), or for such a purpose specially designed tapes (e.g., D-Squame®, CuDerm Inc., United States). Tapes differ in shape, size, composition, and adhesive properties. Following tape stripping, the solute contained in the SC can be extracted and measured using appropriate analytical methods such as HPLC.

39.2.2 Parameters Influencing SC Removal

Numerous parameters influence the amount of SC removed by a single tape strip. Differences in adhesive properties between [9] as well as within tape brands may result in different amounts of SC removed per surface unit. Pressure [10], time course between application and removal [11], as well

as velocity of tape removal process [10] also significantly influence the SC amount removed. Additionally, SC removal depends on intrinsic skin properties related to race, sex, age, skin site, as well as skin condition (e.g., moistened versus dry, healthy versus pathologic). Moreover, it has been recognized that the SC amount removed by tape stripping varies according to the depth. In general, the first strips remove the largest amounts of SC, because they remove the loosely packed squamous cells. Decreasing amounts of SC are removed with increasing strips due to the fact that the cohesiveness between corneocytes increases with depth [7]. In addition, product application prior to tape stripping should also be considered as a factor influencing the amount of SC removed by sequential tape stripping [12]. For instance, the vehicle components may alter both adhesive properties of the tape; at least for the very first strips, as well as cohesiveness between corneocytes.

39.2.3 Quantification of SC Removal

As described earlier, the amount of SC removed by tape stripping is highly variable and depends on the way the tape stripping procedure is performed, as well as on SC characteristics and conditions. As a consequence, the amount of SC removed by tape stripping is not proportional to the number of strips removed. The SC removal can be determined using various methods including weighing, protein quantification, and spectroscopy.

39.2.3.1 Weighing

Currently, weighing is commonly used to measure the amount of SC removed on a tape strip [13]. Thereby tapes are weighted before and after stripping and the amount of SC is given by weight difference. High precision balances are needed since a very low amount of SC is removed per square centimeter of tape. However, weighing is time consuming and may be biased by water absorption or desorption during weighing procedure before and after stripping [13]. Furthermore, after topical product application, the weighing of SC is only reliable to some extent since the tape strips may also contain applied vehicle and solute.

39.2.3.2 Protein Quantification

As an alternative to weighing, a simple colorimetric method based on commercially available protein assays was recently proposed [14]. Briefly, the total protein assay (e.g., according to Lowry or Bradford) was carried out after immersing the SC containing tapes in a one molar sodium hydroxide solution to extract the soluble SC protein fraction (SC is mainly composed of corneocytes filled with keratins) and neutralizing the solution with one molar hydrochloric acid. The neutralization was realized since most protein assays are not compatible with acidic conditions. Thereby the extracted SC proteins, or their hydrolysate, remain in solution. This quantification method makes it possible to determine accurately and reproducibly as little as a few micrograms of SC adhering to a single tape strip. Furthermore, with the exception of protein-containing products and some other compounds interfering with protein assay, the uptake of product ingredients into the SC after topical application does not interfere with this colorimetric method. In addition, water content of the SC tape strip has no influence on the colorimetric assay. Besides the D-Squame tape, other tapes can be used and are compatible with this assay. Besides performing the protein extraction with each tape strip, the extraction can also be performed with pooled strips such as with five strips [15]. In case it is sufficient to obtain data on pooled strips, this recently described procedure allows in significantly shortening the time of analysis. Alternatively, the protein assay can also be realized in 96 well microplates [16].

When performing bioavailability studies, the discussed method is particularly adapted for hydrophilic solutes, which are chemically stable under alkaline conditions (e.g., hydroxy acids). They can be easily extracted from the SC adhering to tape strips and may be analyzed in parallel. However, this method seems less suitable for hydrophobic and for compounds not stable under the conditions of SC extraction. In that case, tape strips can be divided into two parts: one part can be used for SC protein determination and the other for solute analysis.

A method whereby the SC proteins were directly stained with comassie brilliant blue on the tape without prior SC extraction followed by spectroscopic measurement of the colored tape was unsuccessful [13]. The results were shown to be variable, particularly since the absorbance of colored SC proteins is negligible as compared to light scattering of the SC material adhering to tape strips.

39.2.3.3 Spectroscopic Methods

A few years ago, a method based on the measure of UV/VIS-absorbance was reported to determine the SC amount adhering on tape strips [17]. Unlike methods through protein quantification, this technique does not require any preceding treatment of the SC. As a consequence, the entire tape strip can be used for subsequent analysis including solute extraction. Thereby SC determination is performed at 430 nm directly on the tape (Tesa Film no. 5529) using a double-beam UV/VIS-spectrophotometer, modified to obtain a 1×1 cm^2 light beam. The reference beam chamber contains an unused tape. The absorbance at this wavelength originates from light reflection, scattering, and diffraction by corneocyte aggregates on the tape and was reported to be directly related to SC weight removed by tape stripping. However, chemicals absorbing in the wavelength range of corneocyte absorbance at 430 nm may interfere with the measurement. Further, it remains to be verified whether potential changes in optical properties of corneocytes after topical product application (e.g., due to uptake of water) influence the accuracy of this spectroscopic measurement.

Recently, another spectroscopic (densitometric) method was described [18]. This method measures SC absorption at 850 nm with an instrument developed specifically for this

purpose (SquameScan™ 850A, Heiland Electronic GmbH, Germany). Absorption data were shown to correlate with protein content on the tape, which emphasizes the validity of this approach. Similar to the method measuring SC removal at 430 nm, it remains to be verified whether potential changes in optical (densitometric) properties of corneocytes after topical product application influence the accuracy of this measurement or not.

39.3 SUMMARY AND CONCLUSION

The application of tape stripping technique is well established in dermatopharmacological research, and the technique is appreciated as one of the most useful methods to remove SC allowing investigation of its structure, properties, and functions. However, despite apparent simplicity, the tape stripping technique entails several technical problems and care has to be taken to avoid misleading conclusions when interpreting data. For instance, results given as a function of tape strip number or pooled tape strips have to be interpreted with care, since the amount of SC removed by tape stripping may be highly variable and may depend on numerous factors related to tape stripping procedure and SC properties. Therefore, SC removal by tape stripping should be determined using accurate and reliable methods. Today, weighing still seems to be the most commonly used method for such a purpose. But, due to possible artifacts associated with weighing procedure, SC amounts removed by tape stripping may be more accurately determined through protein quantification of extracted SC proteins or spectroscopic (or densitometric) methods. The currently described alternative methods of weighing require, however, further validation before considering that they indeed provide an adequate and more accurate measure for SC removal by tape stripping.

40.1 INTRODUCTION

There are numerous methods that have been employed to assess the percutaneous absorption of toxic chemicals using both *in vitro* and *in vivo* animal models. There is little debate that *in vivo* human studies are optimal for predicting the absorption of topically applied chemicals in man. However, for highly toxic or carcinogenic chemicals, ethics preclude conducting such studies when a risk analysis is to be conducted. Similar considerations apply to the humane use of animal surrogates. For chemicals that pose little direct adverse risk to man or animals, experimental design and sampling limitations often apply to any *in vivo* study. An important limitation is the inability to noninvasively sample the venous drainage of a topical application site to determine the true cutaneous flux for use as an input into systemic risk assessment models. Although microdialysis provides one approach to this dilemma, it does not allow recovery of all absorbed compound since the dermal vasculature is still intact. Similarly, extensive biopsies may not be taken to quantitate subtle, preclinical morphological or biochemical manifestations of dermatotoxicity.

The next alternative in the hierarchy of model systems would be *in vitro* diffusion cell studies using human skin. Although in most cases these methods may appear to be preferred, there are limitations that may seriously detract from their usefulness. These include studies where vasoactive compounds are being used or where the magnitude or distribution of cutaneous blood flow would affect the subsequent rate and extent of compound absorption or pattern of cutaneous distribution. Vascular changes could result from compound-induced cutaneous irritation where released inflammatory mediators could directly modulate vascular physiology. Some *in vitro* models are not optimal for studying the kinetics of cutaneous metabolism. Another problem is availability of disease-free, fresh human skin from the same individual and body region. Variability in tissue sources may introduce an unacceptably high degree of intersample variation. If the effects of chemical or physical pretreatment on subsequent chemical absorption are to be studied, ethical considerations may preclude these studies being done in man. These limitations also apply to the recently developed living skin equivalent (LSE) models and *in vitro* animal studies.

Isolated perfused skin studies, such as the isolated perfused porcine skin flap (IPPSF) developed in our laboratory and described in this chapter, may be the "missing link" in the hierarchy of classic *in vitro* and *in vivo* models. The primary advantages of isolated perfused systems relate to:

1. The presence of a functional cutaneous vascular system.
2. The ease of continuously sampling venous perfusate.
3. The ability to conduct mass-balance and metabolism studies.
4. The availability of a large dosing surface area.
5. The capability of simultaneously assessing transdermal chemical flux and biomarkers of cutaneous toxicity.
6. The ability to conduct morphological evaluations at the end of a study in the same preparation that an absorption study was conducted.

7. The ease with which experimental conditions (temperature, humidity, perfusate flow and composition) can be manipulated and controlled without being concerned with interference from systemic feedback processes as is usually seen *in vivo*.

Isolated kidney, liver, and lung perfusions have been recognized as mainstay models for toxicology and pharmacology for many decades. Part of their acceptance relates to the ease of harvest since these organs are all characterized by having "closed" vascular systems with anatomically identifiable arterial inputs and venous outputs, both amenable to catheterizations with minimal expertise in surgery. In contrast, outside of the possible exception of ears, skin does not possess such a closed vascular system.

Rabbit and pig ears have been used as perfused skin systems to assess percutaneous absorption of topically applied compounds (Behrendt and Kampffmeyer, 1989; de Lange et al., 1992; Celesti et al., 1992). We feel that a fundamental problem with these systems is that the skin of the pinna is different (hair density, adnexial structures) than other body sites and has a much greater degree of blood perfusion (Monteiro-Riviere et al., 1990; Monteiro-Riviere, 1993). Additionally, the vasculature is specialized because of the unique thermoregulatory demands placed on this appendage. Auricular arteries perfuse a complex tissue bed consisting of skin, subcutaneous tissue, muscle, and cartilage. We believe that these additional factors outweigh the obvious economic benefits of obtaining ears from laboratory animals or abattoirs. Also, reports have appeared sporadically in the literature on perfused pieces of animal and human skin being used in various studies (Feldberg and Paton, 1951; Kjaersgaard, 1954; Hiernickel, 1985; Kietzmann et al., 1991); however, none have ever been optimized or validated for percutaneous absorption studies.

40.2 OVERVIEW OF METHOD

40.2.1 Surgical Preparation and Perfusion

The IPPSF is a single pedicle axial pattern tubed skin flap created from the abdominal skin of weanling pigs. This area was selected because it is perfused by direct cutaneous arteries (superficial epigastric artery) and drained by the associated paired venous commitantes. This allows a tube of skin to be created whose sole vascular supply may be cannulated and perfused *ex vivo*. The formation of a tubed flap allows the wound edges to be apposed and after a short healing period of 2 days, the preparation only drains via the venous system. This area of skin has also been used to create the *in situ* rat/human skin flap system (Kreuger et al., 1985) and recently an isolated perfused human nontubed skin flap model (Kreidstein et al., 1991). The IPPSF is fully described in the original publications describing its use (Riviere et al., 1986; Monteiro-Riviere et al., 1987; Riviere and Monteiro-Riviere, 1991). In addition, our group has developed an isolated perfused equine skin flap for use in assessing percutaneous absorption of chemicals across horse skin (Bristol et al., 1991) and a perfused human tumor bearing flap for use in anticancer drug targeting investigations (Vaden et al., 1993).

The IPPSF is created in a two-stage surgical procedure (Figure 40.1) (Bowman et al., 1991). Two flaps are created on each pig using the right and left caudal superficial epigastric

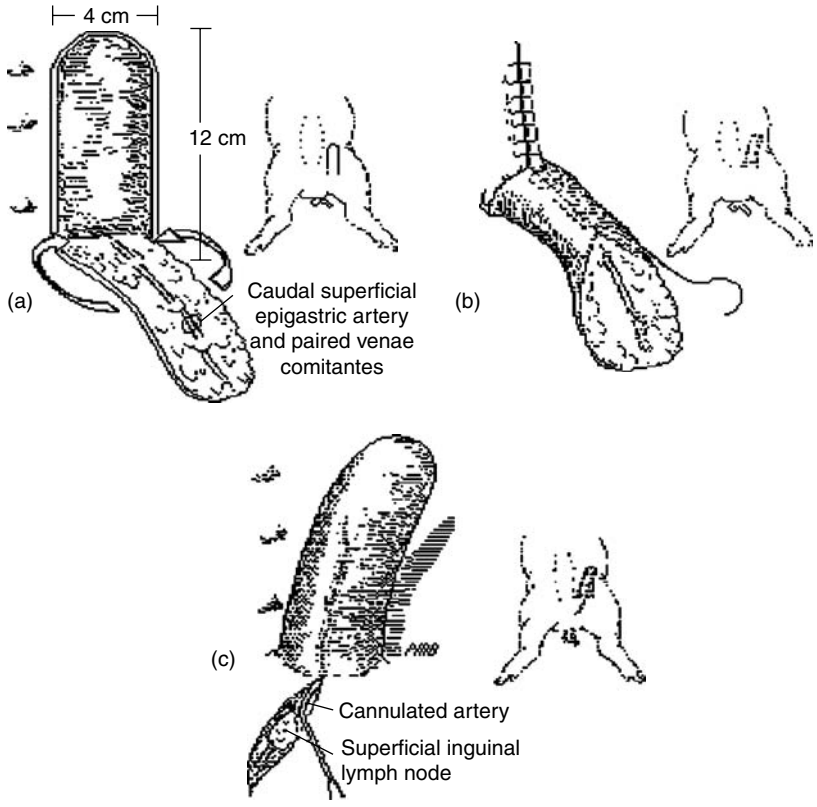

FIGURE 40.1 Two-stage surgical procedure used to create isolated perfused porcine skin flaps. A single pedicle axial pattern tubed skin flap is created in stage I (a and b) and harvested 2 days later in the stage II (c) procedure.

arteries. Depending on the experimental design, this allows one flap to serve as a control for the other during perfusion studies so as to minimize interflap variability. In stage I surgery, conducted aseptically and under inhalational anesthesia, a 4×12 cm area of skin previously shown to be perfused by this artery is demarcated, excised, tubed, and allowed to remain on the pig. Two days later, a time found to be optimal based on morphological criteria (Monteiro-Riviere et al., 1987), the flap is excised and the artery cannulated in a simpler stage II procedure. Both flaps are then removed and placed in the isolated perfusion chambers described later. The small incision remaining on the pig is allowed to heal and then the pig can be returned to its prior disposition (sale, other uses).

The isolated perfusion apparatus depicted in Figure 40.2 is a custom Plexiglas chamber designed to maintain the skin flap in a temperature- and humidity-regulated environment. Perfusion pressure, flow, pH, and temperature are set for desired conditions dictated by the experimental design and continuously monitored. The perfusion media is a modified Krebs–Ringer bicarbonate buffer (pH 7.4, 350 mOsm/kg) containing albumin (45 g/L) and supplied with glucose (80–120 mg/dL) as the primary energy source. Albumin is added to provide the oncotic pressure required to maintain capillary patency as dictated by Starling's laws, and to facilitate the absorption of lipophilic penetrants that otherwise would not be soluble in a pure aqueous buffer system. Normal perfusate flow through the skin is maintained at 1 mL/min/flap (3–7 mL/min/100 g) with a mean arterial cannula pressure ranging from 30 to 70 mmHG. With this system, flaps may be maintained biochemically and morphologically viable for up to 24 h. Two experimental configurations are possible for flap perfusion: recirculating and nonrecirculating. For most studies, the single pass nonrecirculating system is used. Our laboratory has perfused over 3200 IPPSFs and several hundred more have also been independently perfused in nonacademic laboratories to which the technique has been transferred.

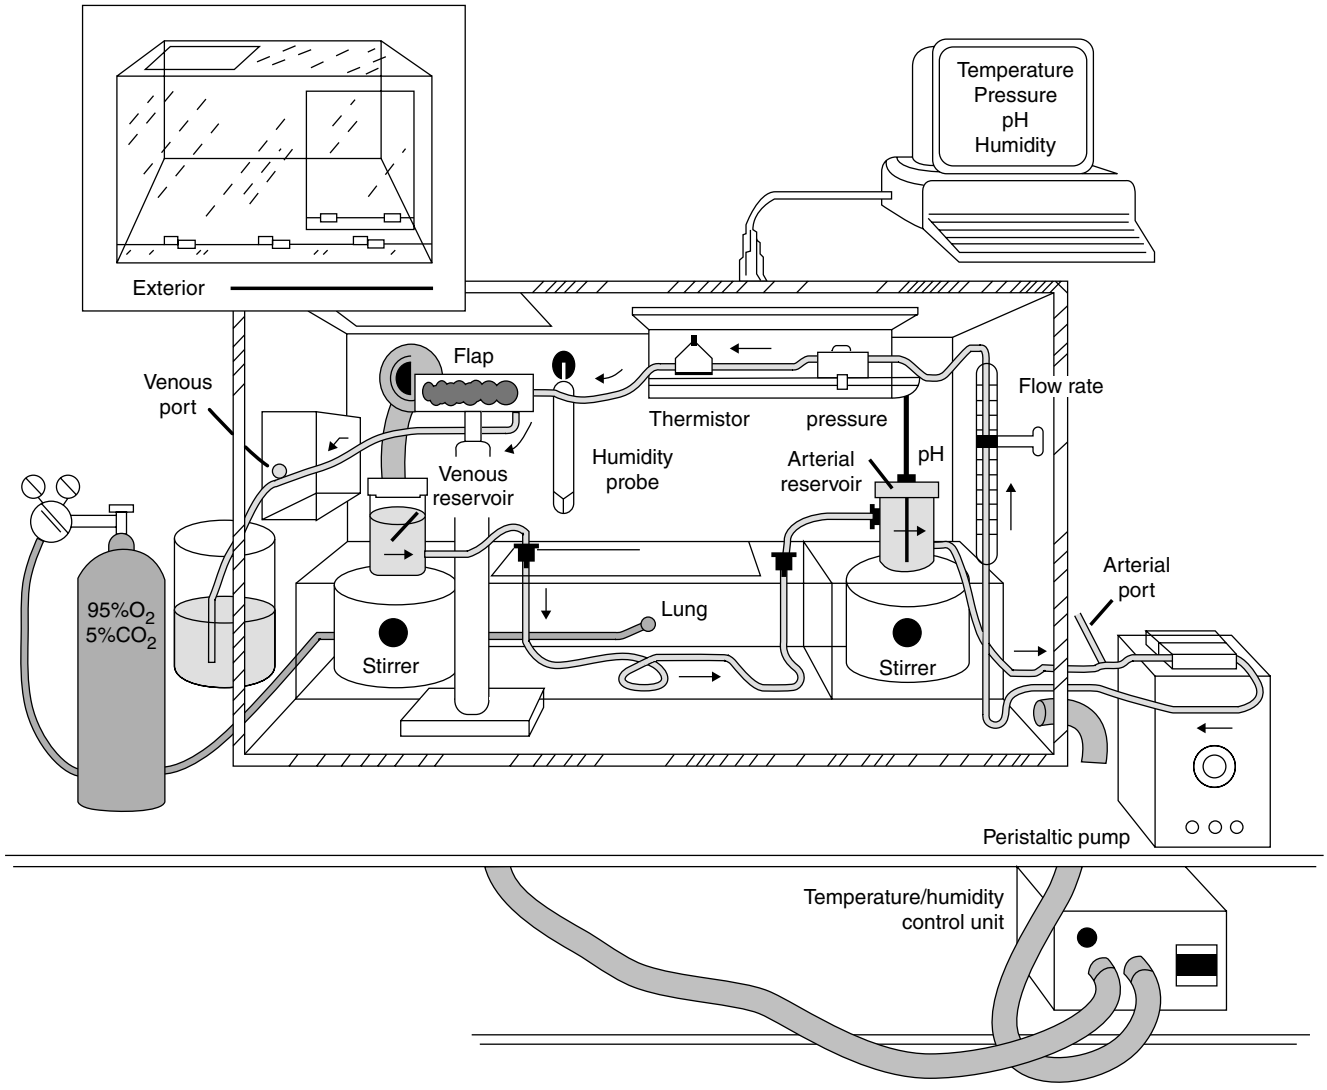

FIGURE 40.2 Temperature- and humidity-controlled chamber used to maintain IPPSF viability and environmental conditions throughout an experiment.

40.3 APPLICATIONS

There have been three general types of studies conducted in the IPPSF: toxicology, percutaneous absorption (including biotransformation and pharmacokinetic modeling), and cutaneous drug distribution (drug administered by intra-arterial infusion) studies. Intra-arterial drug distribution studies have been conducted to model the mechanism of drug distribution out of the capillary bed into the skin (Williams and Riviere, 1989a). The first two of these will be addressed in this chapter.

40.3.1 Assessment of Flap Viability and Development of Biomarkers for Toxicity Assessment

Viability of the preparations is monitored real time by assessing perfusate pressure and glucose utilization. We have found that during perfusion of a normal IPPSF, the most sensitive indicator of vascular function, and thus of vascular toxicity in dermatotoxicology experiments, is the parameter of vascular resistance calculated as perfusate pressure divided by flow. This parameter has also been used as an endpoint in pharmacological experiments when autonomic drug activity has been studied (Rogers and Riviere, 1994). Glucose utilization, calculated from the arterial-venous extraction ratio and perfusate flow, has been used as a marker of direct cutaneous toxicity of chemicals (King and Monteiro-Riviere, 1990; King et al., 1992; Monteiro-Riviere, 1992; Srikrishna et al., 1992) with decreases in cumulative glucose utilization being suggestive of direct chemical toxicity. However, glucose utilization may also be dependent on the extent of capillary perfusion, since only cells that are being perfused are capable of extracting glucose from the arterial perfusate (Rogers and Riviere, 1994). A decrease in glucose utilization is definitely a manifestation of chemical activity; however, a chemical-induced decrease in epidermal glucose utilization may be blunted by increased capillary perfusion.

Depending on the experimental design, a number of more specialized markers of viability, or loss thereof, may be assessed. Previously, we have assessed lactate production as a marker of epidermal glucose utilization and have observed decreased lactate production coexistent with decreased glucose utilization. Also, we have monitored the release of inflammatory mediators into the perfusate as biomarkers for physical- or chemical-induced toxicity. These have included PGE_2, $PGF_2\alpha$, and interleukins 1 and 8 as indicators of cutaneous inflammation (Monteiro-Riviere, 1992; Zhang et al., 1995a,b). Prostaglandin fluxes changed with compounds that altered vascular resistance. We have used these prostaglandin fluxes as endpoints in pharmacologic intervention studies designed to block a cutaneous toxicant's effect by preexposure infusion of a specific antagonist. For example, to dissect out the role of prostaglandins in sulfur mustard (HD)-induced cutaneous vesication, we demonstrated that perfusion with the nonsteroidal anti-inflammatory drug (NSAID) indomethacin blunted both PGE_2 release and altered vascular resistance, but did not completely prevent blister formation (Zhang et al., 1995b). Similarly, infusion of pyridostigmine bromide modulated interleukin 8 and PGE_2 release was seen after exposure to topical irritants (Monteiro-Riviere et al., 2002).

The final markers of dermatotoxicity are the myriad of morphological endpoints, which may be assessed easily at the termination of an experiment. Specimens are routinely collected for light microscopy to evaluate skin viability and integrity (Monteiro-Riviere et al., 1987). These studies are pivotal in assessing the nature of cutaneous toxicity produced (Monteiro-Riviere, 1992; Monteiro-Riviere et al., 2001). For a more specific insight into the mechanism of an observed effect, transmission electron microscopy may also be performed (Monteiro-Riviere et al., 1987; Monteiro-Riviere, 1990). These studies give a better indication of what is actually occurring within the epidermal cells at a level before light microscopy or gross observation indicate an adverse effect. For even more specific details, specialized morphological procedures may be conducted. These have included enzyme histochemistry to probe biochemical pathways affected by cutaneous toxicants (King et al., 1992; Srikrishna et al., 1992), immunohistochemistry, and immunoelectron microscopy to study the specific molecular targets involved in vesication secondary to chemical alkylation (King et al., 1994; Monteiro-Riviere and Inman, 1995; Zhang et al., 1995c) or topical jet fuel exposure (Rhyne et al., 2002), and x-ray diffraction microscopy to probe path ways of metal penetration (Monteiro-Riviere et al., 1994a).

Although every one of the aforementioned biomarkers may be assessed in other skin models, the unique strength of the IPPSF is that all may be simultaneously evaluated in the same preparation. For example, we have demonstrated the utility of the IPPSF to serve as a humane *in vitro* model for UVB phototoxicity (Monteiro-Riviere et al., 1994b). In these studies, physiological parameters such as vascular resistance, glucose utilization, and prostaglandin (PGE_2) efflux could be simultaneously evaluated in the same preparation as morphometric quantitation of pyknotic "sunburn" cells and estimation of epidermal growth fraction using histochemical staining for the proliferating cell nuclear antigen (PCNA). In chemical-induced dermatotoxicity, compound flux through the skin can simultaneously be determined in the same preparation that physiological and morphological endpoints are being evaluated. Such studies have been conducted with paraquat (Srikrishna et al., 1992), lewisite (King et al., 1992), 2-chloroethyl methyl sulfide (King and Monteiro-Riviere, 1990), lidocaine iontophoresis (Monteiro-Riviere, 1990), and electroporation (Riviere et al., 1995).

This approach offers many unique advantages. First, it guarantees that cutaneous exposure to a penetrating molecule actually occurred. Second, it allows quantitation of this exposure and subsequent correlation to severity of toxicity observed. Finally, it would allow the development of linked toxicokinetic–toxicodynamic models to be developed, which should shed insight into the mechanisms of cutaneous toxicity.

40.3.2 Absorption Studies

The IPPSF has also been extensively utilized to quantitate the cutaneous penetration and absorption of topically applied

compounds for which systemic exposure could result in toxicity. There are a number of levels of sophistication which can be employed depending on the nature of the penetrant and the precision desired. The simplest approach is to measure compound flux into the venous perfusate and express this as the percent of applied dose absorbed (Figure 40.3). The compound remaining on the skin surface and within the skin can be easily assessed, especially if radiolabelled chemical was employed. This method is accurate if most of the absorption is complete at the end of an experiment (e.g., venous fluxes are approaching background). The amount of penetrated chemical in the venous effluent may then be determined as the area under the curve (AUC) of the venous efflux profile.

Numerous IPPSF absorption studies have been conducted and are referenced in manuscripts included in the reference section of this chapter. Recent IPPSF absorption studies have been conducted on 2,6-Di-*tert*-butyl-4-nitrophenol (DBNP) (Inman et al., 2003), nonylphenol and nonylphenol ethoxylates (Monteiro-Riviere et al., 2003), the jet fuel JP-8(+100) (Muhammad et al., 2004) as well as Gulf Way syndrome related chemicals discussed later. A great deal of very recent work has been done with complex chemical mixtures (Riviere and Brooks, 2007), a topic covered in Chapter 6 of this test, which presents details on some of these IPPSF studies.

At the end of a topical treatment, additional studies may be conducted to determine the amount and distribution of penetrated compound within local tissues. The most precise technique available for this purpose is to take a core biopsy through the dosing site, snap freeze it in liquid nitrogen, and then cut serial sections to precisely localize chemical distribution within the skin as a function of penetration depth. In these studies, which are fully described in the literature (Riviere et al., 1992a; Monteiro-Riviere et al., 1993), the surface of the application site is first gently washed with a mild soap solution and then dried with gauze. Cellophane tape is then applied to "strip" is stratum corneum. A biopsy punch is used to take the core of tissue, which is then embedded in OCT compound, quenched in an isopentane well cooled by liquid nitrogen and immediately stored at −80ºC until it is sectioned in a cryostat. Each tissue section (representing a disc of skin containing radiolabelled compound), along with the washes and tape strips, is then combusted and radioactivity determined using liquid scintillation spectroscopy. The resulting data are a depth penetration profile for the compound under study (Figure 40.4). Although similar studies may be conducted *in vivo*, the advantage of the IPPSF is that this data are obtained in the same preparation that venous flux of the compound is determined, allowing the investigator to assess factors that modulate tissue penetration separate from absorption into the vasculature. Figures 40.3 and 40.4 show the different pattern seen from these two perspectives. This approach was also utilized to assess the effect of various environmental exposure variables on the absorption of TCB (Qiao and Riviere, 2000). Finally, a technique was recently

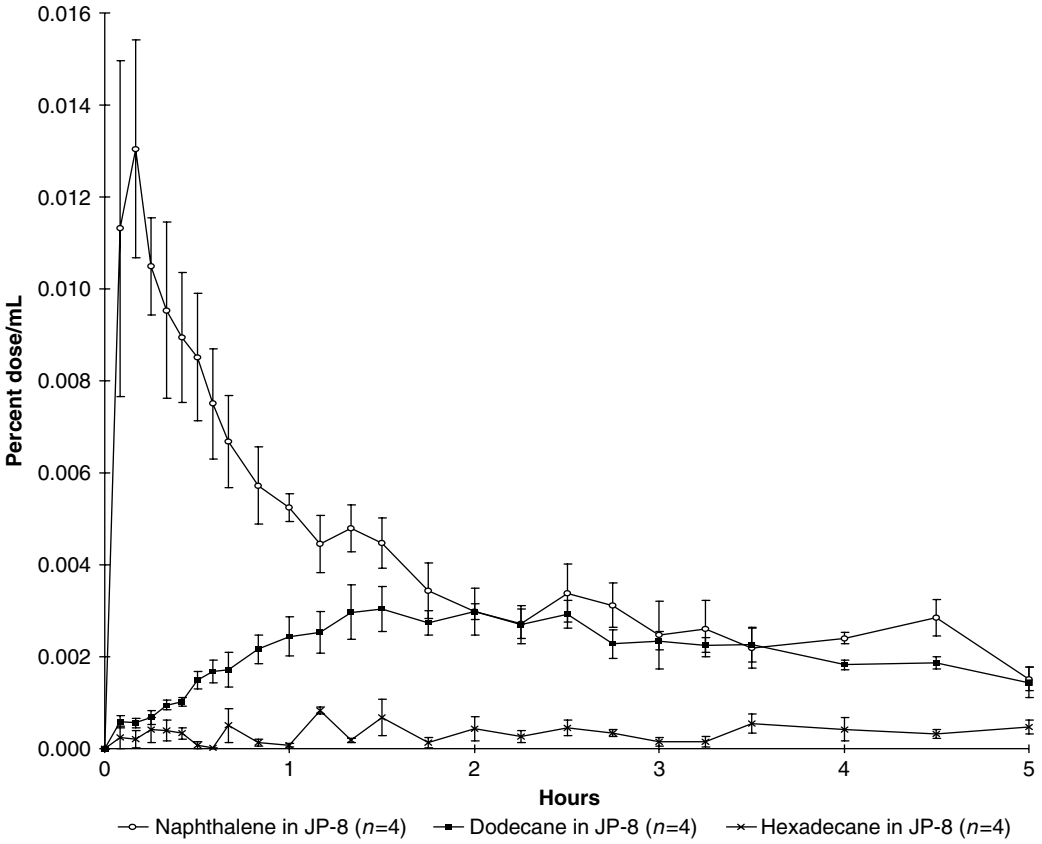

FIGURE 40.3 IPPSF venous flux profiles (naphthalene, dodecane, hexadecane) for a percutaneous absorption experiment (mean ± SD).

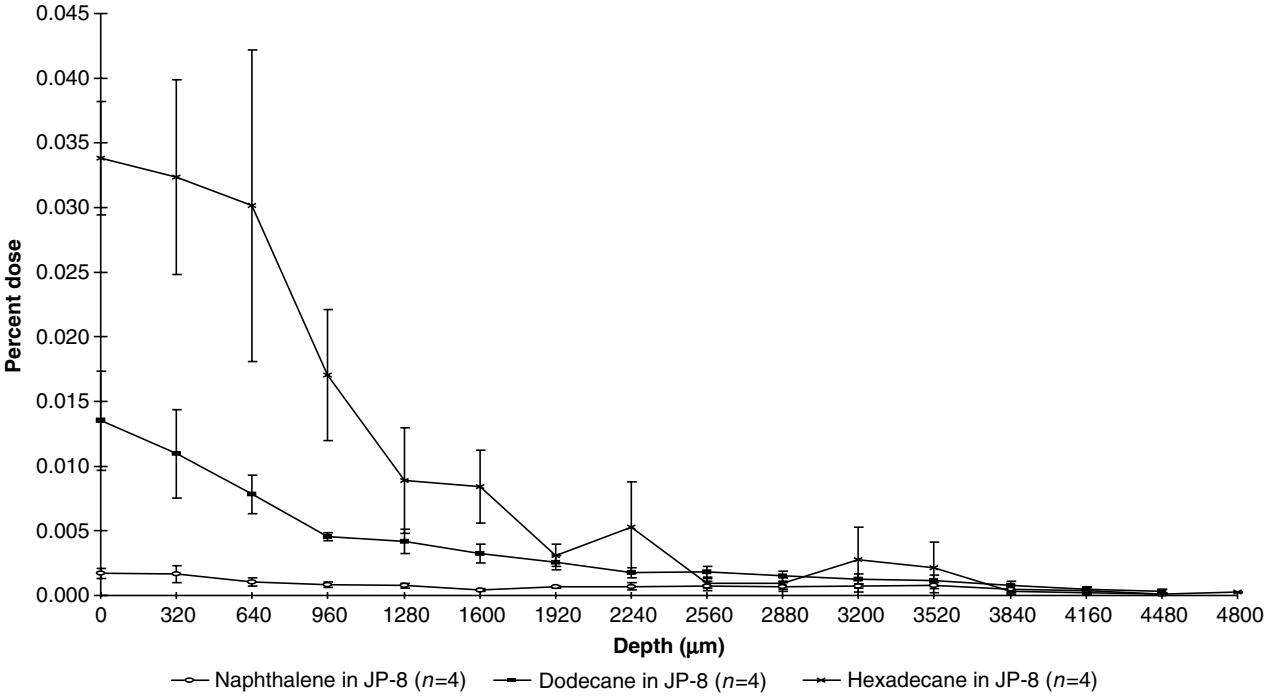

FIGURE 40.4 IPPSF tissue distribution profile at the end of an experiment for the same compounds as in Figure 40.3 (naphthalene, dodecane, hexadecane), seen after topical administration (mean ± SD).

developed to assess the absorption of volatile compounds in this IPPSF (Riviere et al., 2000).

Percutaneous absorption in the IPPSF was correlated ($r^2 \approx 0.8$) to *in vivo* human absorption for five diverse compounds (Wester et al., 1998). The IPPSF estimate for absorption used was the amount absorbed into the perfusate plus the amounts penetrated into the skin. Comparative absorption values (% Dose; Mean ± SD) were:

Compound	Human	IPPSF
Salicylic acid	6.5 ± 5	7.5 ± 2.6
Theophylline	16.9 ± 11.3	11.8 ± 3.8
2,4-Dimethylamine	1.1 ± 0.3	3.8 ± 0.6
Diethyl hexyl phthalic acid	1.8 ± 0.5	3.9 ± 2.4
ρ-Aminobenzoic acid	11.5 ± 6.3	5.9 ± 3.7

Figure 40.5 illustrates the IPPSF to *in vivo* human correlation for all compounds studied to date for which both sets of data exist.

40.3.3 Dermatopharmacokinetic Studies

The greatest level of precision that may be achieved with this system is to apply pharmacokinetic models to either extrapolate to the *in vivo* situation or quantitate the fate of drug within the skin. These are especially adaptable to a system such as the IPPSF because venous drug efflux can be readily determined, which is the starting point for the analysis. These strategies are outlined in Figure 40.6. If the goal of the study is to predict *in vivo* disposition, then one should view the IPPSF as a "living" infusion pump whose output

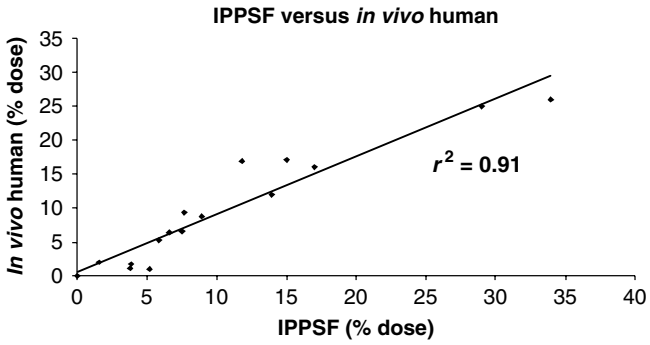

FIGURE 40.5 IPPSF predicted versus *in vivo* human dermal absorption for 16 compounds for which data sets are available.

flux (venous efflux) is actually the input into the systemic circulation. First, this approach allows one to use porcine skin data to model human skin penetration with human systemic pharmacokinetic data to avoid interspecies differences in drug distribution, metabolism, or elimination. Second, this strategy allows one to predict the actual serum drug concentration-time profile that may be seen *in vivo*. This approach has been used to predict the *in vivo* disposition of a number of drugs, including arbutamine and LHRH (Riviere et al., 1992b; Heit et al., 1993; Williams and Riviere, 1994). The systemic input may either be the observed IPPSF venous efflux profile or the pharmacokinetic simulation of this profile.

This brings us to the second use of pharmacokinetic modeling, which is to predict the shape of the cutaneous efflux profile based on factors governing the absorption and distribution of the drug. Our group initiated these studies using drug infused into the arterial cannula whereby arterial and venous

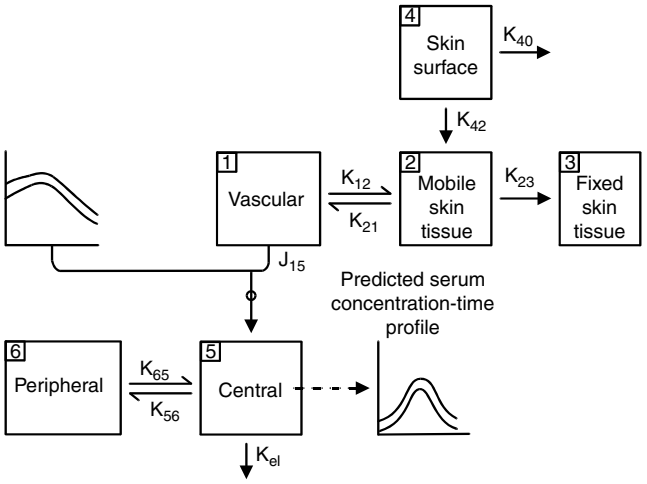

FIGURE 40.6 Conceptual approach to using IPPSF absorption profile (upper left) or dermatopharmacokinetic model (upper right) as input into a systemic pharmacokinetic model (lower left) to predict an *in vivo* serum concentration-time profile.

extraction of the drug could be determined. This approach allowed the basic structure of our IPPSF model to be determined (Williams and Riviere, 1989a). The specific volumes of the extracellular and intracellular spaces were then validated using dual radiolabelled albumin and inulin infusions (Williams and Riviere, 1989b). The next step was to add a percutaneous absorption component (Williams et al., 1990; Carver et al., 1989), which is the basic model depicted in Figure 40.6. This approach allows one to conduct an experiment over an 8 h period and use the venous efflux profile to determine the parameters of the pharmacokinetic model. If the venous efflux profiles demonstrated a peak or beginning of a plateau phase, then using the model parameters, the 8 h data may be extrapolated to extended time points. Such correlations ($r^2 \approx 0.9$) were determined between extrapolated IPPSF profiles and observed 6 day absorptions for a number of diverse compounds, further demonstrating both the utility of the IPPSF to predict percutaneous absorption in humans, as well as the underlying similarity between pig and human skin (Riviere and Monteiro-Riviere, 1991). Since only the total fraction of a topically applied dose absorbed was predicted in these situations, *in vivo* pharmacokinetic data were not needed because a blood concentration-time profile was not available.

The only data used in the models presented earlier are actual venous efflux profiles and residual compound recovered at the end of an experiment (e.g., unabsorbed chemical bound to dosing device, skin surface wipes, and drug in the flap). The precision of such models may be greatly improved if the tissue penetration data described (stratum corneum residues by tape strips, serial sections of biopsy cores) are also included in the data analysis. Additionally, if other *in vitro* data such as stratum corneum partition coefficients and rates of evaporation are independently determined in porcine skin (Williams et al., 1994), more sophisticated models may be developed, which can shed much greater insight into the mechanisms governing chemical absorption and penetration. Figure 40.7 depicts such a model

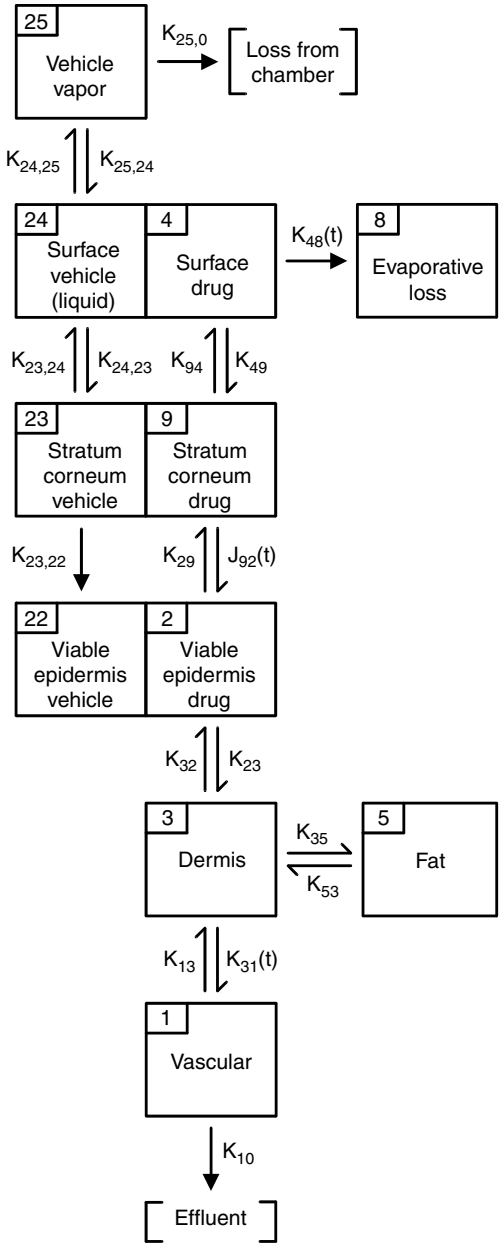

FIGURE 40.7 Complete dermatopharmacokinetic model of a penetrant and its vehicle (shaded), utilizing multiple data points obtained from IPPSF experiments (venous effluent profiles and tissue samples as seen in Figures 40.3 and 40.4) and parameters from parallel *in vitro* studies.

which incorporates the fate of the vehicle used to apply the drug, since it is widely acknowledged (but seldomly modeled) that vehicle affects the rate and extent of penetration of many compounds (Williams and Riviere, 1995). This approach allows one to take into account penetrating chemical or vehicle interactions with stratum corneum lipids (e.g., enhancers such as Azone®), which could alter permeability, to be directly incorporated into the analysis. The work has been extended to study the simultaneous absorption of multiple (>2) penetrants so that a mechanistic approach to assessing exposure to chemical mixtures may be developed (Riviere et al., 1995). This approach is now being applied to the complex

absorption patterns seen in topical jet fuel exposure (Riviere et al., 1999). Finally, the absorption of toxic compounds which may alter their own absorption, secondary to cutaneous toxicity of the penetrant, has been studied using the chemical vesicant sulfur mustard (Riviere et al., 1995). In this model, absorption profiles could only be precisely described if the vascular compartment was modulated as a function of sulfur mustard in the skin. This was independently correlated to vascular volume/permeability using inulin infusions to measure vascular space.

The major limitation to all pharmacokinetic approaches such as these relate to the large data requirements needed to solve model parameters. A full solution for a model, such as presented in Figure 40.7, requires a series of replicated experiments using a single chemical applied at different doses and experiments terminated at various time points. As mentioned earlier, *in vitro* studies would be conducted to obtain specific biophysical parameter estimates. All data are simultaneously analyzed. For many compounds, specific components of the full model may not be required and thus in reality, the actual model fitted is simpler. Statistical algorithms are presently being developed to select the optimum model for the specific compound being studied and collapse the remainder of the model structure into a matrix from which individual rate parameters cannot be extracted (Smith et al., 1995). This work has now resulted in the collapse of an equation that describes an IPPSF efflux profile to a three parameter equation: $Y(t) = A\ (e^{-bt} - e^{-dt})$, which adequately describes most IPPSF flux profiles (Riviere et al., 2001). This approach allows emphasis to be placed only on those compartments or processes that are important for the chemical being studied, yet retains the general structure of the model for all compounds so that future extrapolations are facilitated.

40.3.4 Cutaneous Biotransformation

The final aspect of assessing percutaneous absorption, which has not been considered up to this point, is cutaneous biotransformation. The IPPSF is ideally suited for this purpose and has been used to study metabolism of pesticides, drugs, and endogenous compounds (Bikle et al., 1994; Carver et al., 1990; Chang et al., 1994; Riviere et al., 1996). Specific pharmacokinetic models which incorporate IPPSF data and *in vivo* disposition have been constructed (Qiao et al., 1994; Qiao and Riviere, 1995). These studies demonstrate a number of important features of percutaneous absorption of chemicals which are biotransformed during passage through the skin. The method of dose application significantly affects the metabolic profile observed in the venous efflux. Occlusion enhances the fraction of parathion metabolized to para-nitrophenol both in the IPPSF and the *in vivo* pig. The mechanism of this effect has not been determined, although it illustrates the inherent complexity of skin relative to assessing the fate of chemicals applied on its surface. By constructing dermatopharmacokinetic models to address these phenomena, quantitative parameters describing absorption and cutaneous distribution independent of biotransformation may be used as experimental endpoints.

The primary implication of biotransformation to risk assessment is that the *in vitro* to *in vivo* extrapolation strategy outlined in Figure 40.6 is actually oversimplified since it assumes that all inputs from the skin to the general circulation are in the form of parent chemical. In reality, multiple inputs from the skin to systemic circulation are required in making the extrapolation process more complex. *In vivo* work requires that studies be done both intravenously and topically so that systemic and cutaneous metabolism may be separated. Dosing methods must also be assessed if effects such as occlusion are to be quantitated.

40.3.5 Percutaneous Absorption of Vasoactive Chemicals

One of the major advantages of using an isolated perfused tissue preparation is the presence of an intact vascular system with dermal microcirculation. This is important from the perspective of assessing the effect of altered blood flow on compound disposition, as well as determining how a penetrating chemical's inherent vasoactivity affects its own fate. Unlike other organ systems, the range of blood flow possible through mammalian skin is tremendous because of its role in thermoregulation. The primary impact of altered dermal perfusion on the disposition of penetrated chemical may be on the surface area of the exchanging capillaries being perfused, which determines the actual volume of dermis that is perfused and is thus available for systemic absorption (Riviere and Williams, 1992; Williams and Riviere, 1995). Alternatively, changes in dermal perfusion resulting from modulation of arterial-venous shunt activity may completely bypass areas of skin or result in deeper dermal penetration, a phenomenon observed *in vivo* with piroxicam (Monteiro-Riviere et al., 1993). Changes in dermal perfusion may be initiated by physiological homeostatic mechanisms, by exposure to vasoactive drugs or secondarily by chemical-induced irritation with concomitant release of vasoactive inflammatory mediators (e.g., prostaglandins). Using glucose utilization as a measurement of exchanging capillary perfusion, we have recently begun to map out the IPPSF vascular response to the infusion of vasoactive drugs in an attempt to experimentally define the pharmacodynamics of vasoactive drugs in this system for future integration into a comprehensive pharmacokinetic–pharmacodynamic model (Rogers and Riviere, 1994).

The impact of a drug's vasoactivity on its rate and extent of percutaneous absorption and distribution within skin can best be illustrated with IPPSF studies on the iontophoretic transdermal delivery of lidocaine coadministered with the vasodilator tolazoline or the vasoconstrictor norepinephrine (Riviere et al., 1991, 1992a). Coiontophoresis of both these compounds using *in vitro* diffusion cell systems resulted in essentially no effect on lidocaine flux. However, identical *in vivo* dosing conditions resulted in increased blood concentrations when tolazoline was present. As can be seen in Figure 40.8, tolazoline enhanced and norepinephrine decreased lidocaine flux in IPPSF studies. When one examined the concentrations in the skin underlying these electrodes, the opposite

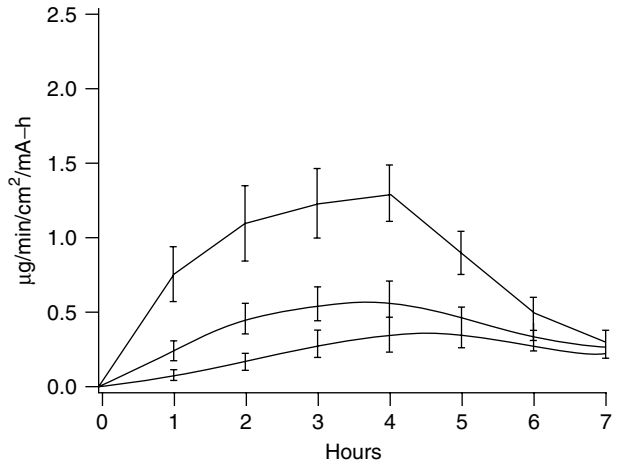

FIGURE 40.8 IPPSF venous efflux profile of iontophoretically delivered lidocaine (—) demonstrating vascular effect with enhanced delivery after tolazoline (——) and reduced delivery after norepinephrine (———) coadministration.

pattern was seen. These vascular effects have now been incorporated into our dermatopharmacokinetic model (Williams and Riviere, 1993). These studies clearly demonstrate the importance of the microcirculation on determining the nonsteady state profile of drug delivery and dermal disposition.

40.3.6 Effect of Mixtures and Vascular Drug Infusions on Dermal Absorption

One recent series of studies nicely illustrates the strength of a perfused skin model such as the IPPSF. These investigations focused on the mutual interactions among DEET, permethrin, and pyridostigmine bromide, as well as other military exposure scenarios (pesticides, CW agents) on DEET and permethrin dermal absorption relative to their potential role in the Gulf War syndrome (Baynes et al., 2002; Monteiro-Riviere et al., 2003; Riviere et al., 2002, 2003; Baynes, 2006). These studies clearly demonstrated interactions between topically applied DEET and permethrin on each other's dermal absorption. However, the most interesting finding was that systemic infusion with pyridostigmine bromide, in contrast to the other agents studied, significantly increased permethrin dermal absorption almost eightfold, and modified cytokine release seen after topical mixture exposure. Few percutaneous absorption studies have studied the effect of systemic exposure on subsequent dermal absorption. These studies also documented the effect of these complex exposure scenarios on drug masses in the epidermis and dermis, in some cases resulting in patterns different from what was transported into the perfusate, similar to what was previously depicted in Figures 40.3 and 40.4 for jet fuel aliphatic hydrocarbons.

40.4 DISCUSSION

The earlier presentation provides the reader with an overview of the uses of a perfused skin model such as the IPPSF in percutaneous absorption and dermatotoxicokinetic studies. One of its major advantages is that both absorption and toxicity may be assessed in the same preparation. The pharmacokinetic models developed are experimentally verifiable. The major limitations are centered on the cost of the preparation and the technical expertise required to successfully conduct the studies. The overall cost is significantly greater than *in vitro* diffusion cell studies or *in vivo* rodent experiments, comparable to human skin equivalent and larger mammal (dog, pig, primate) *in vivo* work, and is much less expensive than human trials. However, cost alone is not a sufficient criterion. These studies are humane; and more information may be gathered than is obtainable with either *in vitro* or *in vivo* work. Optimal benefit may be achieved if these studies serve as a bridge between *in vitro* human/animal and *in vivo* animal work and the ultimate *in vivo* human exposure scenario.

40.4.1 Integrated Approach to Dermal Risk Assessment Using a Dermatopharmacokinetic Template

The optimal method to assess all of the aforementioned complex events is to use a hierarchy of experimental model systems ranging from *in vitro* diffusion cells for animals and humans to perfused skin studies such as the IPPSF to *in vivo* animal and human studies. By designing such experiments using a comprehensive dermatopharmacokinetic model as a template, the limitations of each system may be delineated and a complete understanding of the rate-limiting steps in the process defined. For example, there is general consensus that the major biological differences between humans and other species in regard to a chemical's percutaneous absorption is the nature of the stratum corneum lipids and patterns of biotransformation. As others have documented, the lipids of the stratum corneum of the pig are very similar to man and may be the primary reason that with *in vivo* comparisons, pigs and humans are often very similar. Such data are often not available relative to biotransformation. However, patterns of biotransformation may be determined from *in vitro* human diffusion cell or skin-equivalent studies and can be directly compared to *in vitro* pig data collected under identical conditions. Any differences observed may then be incorporated into the dermatopharmacokinetic model. The limitations to solely rely on the *in vitro* human data relate to the lack of proper anatomical orientation and microcirculation, which could alter the rate of parent chemical and metabolite penetration and thus pattern of biotransformation.

Any prediction errors purely inherent to the *in vitro* to *in vivo* extrapolation may be studied directly in the pig and a correction vector incorporated into the kinetic template. With these limitations defined, reasonable extrapolations to humans may then be made. Importantly, physiological or pathological processes which have been theoretically or experimentally shown to be important in either *in vitro* human or *in vivo* animal studies may be simulated. Using this approach, these hypotheses may then be tested in a reduced number of human clinical studies. More importantly, for many extremely toxic chemicals, human studies are never possible due to ethical

limitations. This makes the pharmacokinetic approach, capable of synthesizing and integrating data from many levels of experimentation, an optimal strategy for human risk assessment. The same holds for drugs in very early stages of preclinical development.

In conclusion, the IPPSF appears to be a useful humane experimental model system for assessing both a chemical's percutaneous absorption profile and dermatotoxic potential. The IPPSF's greatest strength is the ability to experimentally characterize both phenomena simultaneously. By utilizing a fixed template to guide experimental design, one is assured that maximum information may be obtained from each individual study while maintaining the ability to extrapolate across chemicals.

41.1 INTRODUCTION

Understanding and quantifying the penetration of chemicals into and through the skin is important in both pharmacology and toxicology. In nearly every case, the species of interest is the human species, although laboratory animals are often used as surrogates, particularly in the case of toxicological studies. Appropriate use of laboratory animals necessitates understanding differences between species so that the process of extrapolation to humans is meaningful. This is vital for *in vivo* animal studies, which are often more complex than *in vitro* animal studies. *In vivo* studies have the advantage of intact skin that has blood flow, is alive, and is responsive. Metabolism, nervous, and humoral responses are also present and, therefore, living skin more accurately reflects human exposure scenarios. Traditionally, the analysis of *in vivo* skin penetration in laboratory animals has involved estimation of the amount of chemical that has penetrated using either blood concentrations or the amount of chemical excreted after a dermal exposure. These methods are descriptive; applicability of the results is limited by the appropriateness of the specific experimental design and the similarities between the laboratory species chosen and humans.

Owing to the increase in the availability of computer hardware and software over the last three decades, methods that are based on physiological and pharmacokinetic principles are now feasible alternatives for analysis of *in vivo* skin penetration. These physiologically based pharmacokinetic (PB-PK) approaches mathematically describe the dynamics of chemicals in the body in terms of rates of blood flow, permeability of membranes, and partitioning of chemicals into tissues. Characterizing absorption in terms of parameters, which are measurable and species specific, facilitates extrapolations to the real species of interest, providing these parameters are known or can be determined for humans. This chapter describes PB-PK models, their use as a tool to quantify and understand the process of dermal absorption and penetration, and their suitability for dose, route, and species extrapolation.

41.2 WHY USE PB-PK MODELS?

One of the big advantages of dermal PB-PK models over traditional *in vivo* methods is the ability to accurately describe nonlinear biochemical and physical processes. Describing skin penetration based on blood concentrations or excretion rates, as "percent absorbed," assumes that all processes have a simple linear relationship with the exposure concentration. When nonlinear processes occur in the absorption, distribution, metabolism, or elimination of a chemical, describing penetration as "percent absorbed" does not provide information that can be applied to situations other than the experimental situation. Skin penetration may not be linear when there is binding or metabolism in the skin or when skin blood flow is a limiting factor. Many biochemical processes in the body are nonlinear, for example the percent of chemical metabolized per hour at a low liver concentration may be much greater than the percent metabolized per hour at a high liver concentration. A quantitative description of saturable kinetics in the model may allow it to be predictive of blood or tissue concentrations from various doses. A complete mathematical description of dermal pharmacokinetics takes mass balance throughout the animal into account, and makes it possible to estimate fluxes (amount/time) and permeability constants (distance/time). These expressions of the penetration process are required to accurately predict penetration in other situations (that is, different exposure area, time, or concentration) when nonlinear processes are present.

A properly validated PB-PK description of the skin will provide more information from each experiment than is possible without it. For example, if it is the chemical concentration in an organ or tissue that is important, by understanding the quantitative relationship between blood concentrations and tissue concentrations, serial blood sampling may provide the estimate of the tissue dose that is required without the need for an invasive procedure to sample tissue concentrations. Another good example would be the estimation of rate of metabolism in the skin. Proper comparison of a PB-PK description of metabolite production after an intravenous infusion with the rates of metabolite production after application to the skin at several concentrations allows the metabolic parameters in the skin to be estimated.

In this age of increased concern over the use of animals in research, it is important to try to reduce animal use and get maximum information from each animal that must be used. Before any experimentation, PB-PK models can often be used to form predictions that will help in designing experimental doses and sampling times, thus avoiding "range finding" experiments. During the experiment, PB-PK descriptions may allow the use of fewer animals because it may not be necessary to sacrifice animals at various time points to get tissue concentrations. After the study is complete, PB-PK models allow one to extrapolate results to other exposure areas, times, or concentrations, possibly eliminating the need to repeat an experiment under different conditions.

Another important reason for using PB-PK modeling of skin penetration is to acquire the experience necessary to extrapolate to other species. Classical pharmacokinetic modeling assumes that the body can be adequately described by one to three compartments based on the shape of the semilogarithmic plot of plasma concentration versus time (Gibaldi and Perrier, 1982). The most common classical description is a two-compartment linear system where one compartment is the plasma and the other all the remaining body water and tissues. Using this type of model, the plasma concentration curve can be fit by a distributive phase and a postdistributive phase. This type of model is useful in clinical situations for determining dose or dose regimen. Classical modeling has occasionally been used in skin penetration studies (Cooper, 1976; Wallace and Barnett, 1978; Peck et al., 1981; Chandrasekaran et al., 1978; Birmingham et al., 1979; Guy et al., 1982; Kubota and Ishizaki, 1986).

Figure 41.1 is a schematic representation of the classical two-compartment pharmacokinetic model having a body compartment connected with the plasma. The first-order transfer rates (K_{12}, K_{21}, K_{10}) are descriptive of a particular situation (Gibaldi and Perrier, 1982) but do not allow extrapolation to other exposure conditions or species because their physiological basis is obscure. PB-PK models are better suited for extrapolation because their physiological basis is well defined. It has been shown that a PB-PK model for the inhalation of styrene in rats can be predictive of blood and exhaled air concentrations of styrene in humans after scaling-up the physiological and metabolic constants (Ramsey and Andersen, 1984). Extrapolation with a PB-PK model is only limited

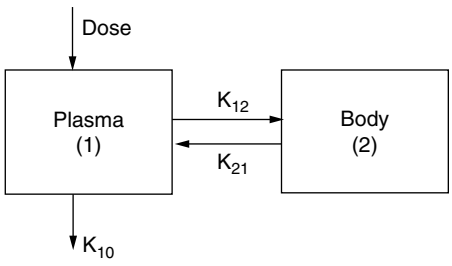

FIGURE 41.1 Classical pharmacokinetic model with two compartments and first-order transfer and elimination rates.

by the ability of the modeler to quantitatively describe the species differences in the pharmacokinetic and physiological processes involved.

41.3 WHEN CAN PB-PK MODELS BE USED?

PB-PK models can be used in nearly any *in vivo* experimental situation in which the physiological and pharmacokinetic processes can be described adequately for the purposes of the scientific question to be answered. It is often not necessary to have an exhaustive description of the animal to be studied—only the simplest description that "works." It is possible to imagine a PB-PK model that describes blood flow, partition coefficients, and metabolic characteristics for each organ in a specific mammal, but a single scientific question that would require such an exhaustive description could not be imagined! Normally it is sufficient to combine many organs into several lumped compartments that have similar blood flows and partition coefficients. The requirement for quantitative understanding of these conceptual processes is both the strong point and the Achilles heel of PB-PK modeling. Quantitative descriptions are the strong point because of their basis in underlying principles, but they are the weak point because the level of understanding required is not easy to achieve. Often the initial description of a particular process is not adequate but through experimentation and more careful description, based on sound pharmacokinetic and physiological principles, the fundamental understanding of the processes involved can be increased.

41.4 WHAT ARE THE COMPONENTS OF A PB-PK MODEL?

Simply speaking, a mammalian organism is comprised of diverse, sometimes metabolically active, pools of fluid separated by membranes which prohibit, permit, or promote passage of the fluids and their dissolved contents. These fluids and membranes obey and can, therefore, be described by the physical laws of fluid dynamics, transport, and diffusion. Skin is one of the most important membranes because it separates and protects animals from their environment. The major fluids, which contribute 60% of body weight, are blood plasma, interstitial fluids, and intracellular fluids. Plasma, the most important fluid because of its continuous motion, transports the red cells, white cells, platelets, and soluble components in the blood. Interstitial fluid, which bathes cells with three times the volume of the plasma, is diffuse and separated from the plasma only by capillary walls. The comparatively static intracellular fluid is separated from the extracellular fluids by specialized cell membranes with sophisticated transport systems. The membranes in the tissues that keep these fluids organized are protein–lipid structures of varying thicknesses, which may contain alterable apertures and carry metabolic enzymes. With this uncomplicated description as a basis, most pharmacokinetic processes can be simplified and described in terms of flows, volumes, solubilities, diffusion, and metabolic rates. When these physiological and biochemical processes can be quantified, a mathematical description can be constructed and compared with experiments to accurately describe the processes involved (see reviews by Himmelstein and Lutz, 1979; Lutz et al., 1980; Gerlowski and Jain, 1983; Clewell and Andersen, 1989).

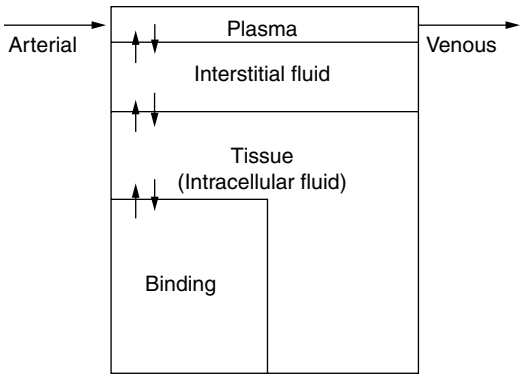

FIGURE 41.2 Diagrammatic description of a lumped compartment with three subcompartments and binding in the tissue subcompartment.

41.4.1 Tissue Compartments

The building block of a PB-PK model is the compartment. A compartment is a collection of fluids or tissues or organs that are grouped together because of similar physiological and pharmacokinetic characteristics rather than anatomical considerations (Lutz et al., 1980). Each lumped compartment receives inward flux of chemical in the blood flow, has a volume, and may incorporate binding or loss of chemical through outward flux or metabolism. Subcompartments may be necessary to accurately describe barriers to movement or sequestration of chemical. Figure 41.2 illustrates a lumped compartment.

Even this level of complexity is not always necessary to adequately describe the processes that are occurring. The transport of chemical across the thin capillary wall may be so rapid that the plasma and interstitial fluid have equivalent concentrations and, therefore, it may be possible to combine the plasma and interstitial fluid subcompartments into one extracellular fluid subcompartment. Diffusion across cellular membranes into the intracellular fluid may be so rapid that flow of the blood to the compartment is the rate-limiting factor affecting uptake of a chemical and, therefore, it may be possible to avoid subcompartments completely. The free concentration of chemical in the plasma, interstitial fluid, or intracellular fluid subcompartments will depend on whether binding or metabolism occurs in the subcompartment.

41.4.2 General PB-PK Model

Penetration of the skin is a process that lends itself to PB-PK modeling. Compartments are chosen based on an understanding of the pharmacokinetics of the chemical and the purpose for the model. Figure 41.3 shows a model with five simple compartments that was designed for predicting blood concentrations from different exposure times and concentrations

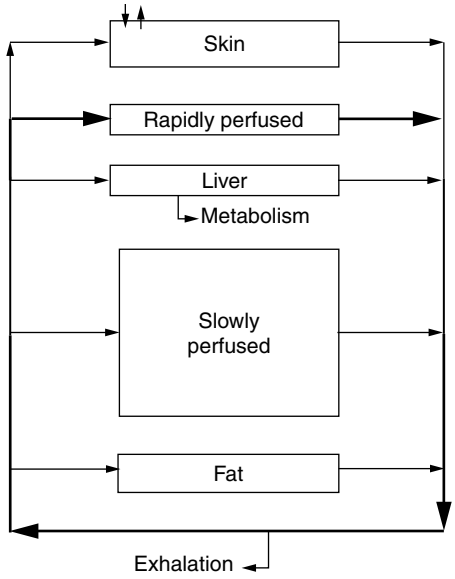

FIGURE 41.3 Diagrammatic representation of a PB-PK model with five simple compartments connected by blood flow. Compartment volumes and blood flows are approximately to scale.

on the skin. Each compartment is assumed to be well stirred, flow limited, and have no subcompartments. Potential losses of chemical are by evaporation from the skin, hepatic metabolism, and exhalation. The description is of the venous equilibration type, without blood volume being specified.

The skin compartment is discussed in detail in the next subsection. The rapidly perfused compartment lumps tissues with high blood flow and high affinity for the chemical. It represents kidney, viscera, brain, and other richly perfused organs. The slowly perfused compartment has low blood flow, low affinity for the chemical, and represents muscle and other poorly perfused tissues and organs. The fat compartment has low blood flow, high affinity for the chemical, and represents various types of fat. These characteristics are important criteria in choosing the compartments. According to this description, the sole route of entry for the chemical is the skin and elimination is by way of diffusion out of the skin followed by metabolism in the liver, and exhalation if the chemical is volatile. Additional compartments would be required for a chemical that is eliminated in the kidney, or if concentration in a target organ (e.g., testis) is of particular interest.

41.4.3 Skin Compartment

A skin compartment is just a special subset of tissue compartments that, because it is the defined portal of entry and has definable anatomy and physiology, needs to be further elaborated. Figure 41.4 illustrates a skin compartment that contains most of the anatomical detail that may be important in skin penetration (Bookout et al., 1996, 1997). Most of this detail will not be necessary for any particular chemical, but is described here for completeness. Each subcompartment communicates in both directions with adjacent compartments

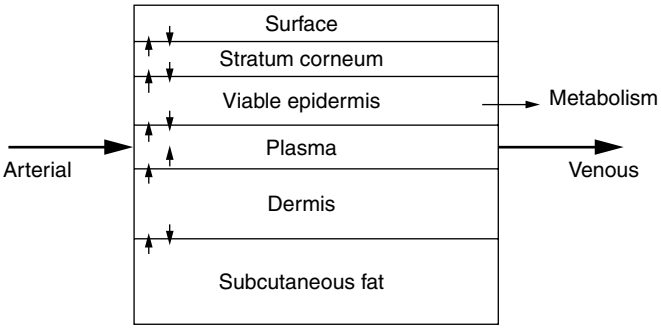

FIGURE 41.4 Diagrammatic representation of a skin compartment with six subcompartments and metabolism occurring in the viable epidermis.

and each has a concentration, volume, and affinity for the chemical of interest. The surface subcompartment, although not strictly part of the skin, is crucial to making the PB-PK model functional. The surface area exposed, exposure concentration, amount applied to skin, and affinity of the chemical for the vehicle (if any) are all incorporated into this subcompartment. If evaporation is occurring or if the chemical is applied in a vehicle and the vehicle has a penetration rate of its own, terms characterizing these events must be incorporated into the description, so that the concentration in the surface subcompartment, which is the driving force for penetration, can be accurately described.

The stratum corneum subcompartment represents the thin, densely packed, fully differentiated keratinocytes. This layer is the principal barrier to penetration for most chemicals due to the compactness of its lipid–protein matrix (Marzulli and Tregear, 1961; Scheuplein, 1967; Mershon, 1975; Elias and Friend, 1975; Dugard and Scott, 1984). The stratum corneum has the potential to act as a reservoir for lipophilic chemicals and may provide binding sites. There is little, if any, metabolic activity and no active transport processes (Scheuplein, 1967) associated with this lifeless layer. In this description, the stratum corneum is treated as if it were homogeneous and well stirred. This gross over-simplification will not apply for all chemicals. For other types of chemicals, it may be necessary to model the stratum corneum as the multilayered structure that it actually is (Blank and Sheuplein, 1964; Odland, 1983). Partial differential equations can be written to describe the skin if the concentration gradient within the skin is significant.

The viable epidermis subcompartment contains cells formed in the basal layer, which become keratinized and more compact as they migrate toward the surface to form the stratum corneum. The majority of the metabolic activity of the skin is found in this layer and it may provide binding sites (Marzulli et al., 1969; Pannatier et al., 1978; Finnen and Shuster, 1985). The plasma subcompartment in the skin provides blood flow to the dermis. Its vasculature is neurally regulated, provides nutrients and other essential chemicals to the skin, and affords a means for dissipation of body heat from the extremities. Pharmacokinetically, the plasma

subcompartment receives chemicals that penetrate the skin, but it also receives chemicals from arterial blood. Chemicals leave the skin via the venous blood or by metabolism. In this simplified description, the plasma subcompartment is between the viable epidermis and the dermis when, in fact, it is imbedded in the papillary dermis (Braverman and Keh-Yen, 1983; Odland, 1983).

The dermis subcompartment provides structural support for the epidermal layers above. It consists of a thick fibrous matrix of elastin and collagen and is more porous than the other compartments. Chemicals may bind to these structural components as they transit through the skin. The collagen in the dermis constitutes approximately 77% of the dry mass of the skin (Odland, 1983). The upper part of the dermis contains capillaries that provide nutrients to the viable epidermis.

The subcutaneous fat subcompartment represents a layer of variable thickness, which is poorly perfused but may provide a reservoir for lipophilic chemicals. Because it has perfusion, it could be an important compartment in its own right, even though it is below the level of the capillary beds.

Although the subcompartments make this skin compartment fairly complex for modeling purposes, it is still an obvious oversimplification of the actual intricacy of mammalian skin. Notably missing are appendages (sweat glands, hair follicles, and sebaceous glands), which have been suggested to be contributing pathways for absorption at early times with slowly diffusing electrically charged chemicals (Scheuplein, 1967; Mershon, 1975). Bookout and collaborators (1997) have described physiologically based modeling of appendages.

41.4.4 Flux Equations

Flux equations are the key to an appropriate model (see Flynn et al., 1974, for an excellent review of mass transport). The rate of change of amount (expressed as a product of volume and concentration) in a subcompartment at any time is a balance between inward flux and outward flux:

$$V\frac{dC}{dt} = \text{Influx}_{\text{total}} - \text{Efflux}_{\text{total}} \tag{41.1}$$

where V is the volume, C the free concentration (mass/volume), and Influx and Efflux are sums of the fluxes (mass/time) in each direction (Equations 41.2–41.4). The general form for the equation describing unidirectional flux where transportation of a chemical is occurring because of bulk flow of the medium is

$$\text{Flux} = QC \tag{41.2}$$

where Q is flow (volume/time) of the medium.

When the membrane between subcompartments (e.g., capillary or cell membrane) acts as a barrier to simple diffusion or when adjacent compartments such as the viable epidermis and dermis in Figure 41.4 act like there is a membrane between them, the flux from outside to inside is described by the permeability-area product and the concentration difference across the membrane:

$$\text{Flux} = PA(C_{\text{out}} - C_{\text{in}}) \tag{41.3}$$

where P is the permeability (distance/time), A the area (distance^2), and C_{out}, C_{in} the free concentrations at the outer and inner surfaces of the membrane. The thermodynamic activity differential actually drives the transport process and, if the chemicals across the barrier are in different media, it is the effective concentration at the interface that must be used in the calculation. Therefore, the concentration must be adjusted for partitioning between the media.

In some cases, movement across a barrier between subcompartments may not be by simple diffusion. If there is a saturable, active process involved, the description for flux is often represented by

$$\text{Flux} = \frac{kVC}{K_T + C} \tag{41.4}$$

where k is the maximum transport rate (mass/volume × time) and K_T the Michaelis-like transport constant (mass/volume).

41.4.5 Binding, Metabolism, and Excretion

The free concentration of a chemical in a subcompartment can also be reduced by binding to proteins or cellular macromolecules, by several types of metabolic processes, and by excretion (Lutz et al., 1980; Gerlowski and Jain, 1983). Normally, these processes are either first-order, saturable, or some combination of the two. If the process is first-order, the general equation is

$$\text{Loss} = rCV \tag{41.5}$$

where Loss has the same units as Flux (mass/time) and r is a proportionality constant (time^{-1}). This description of loss will have the same form regardless of whether the first-order loss is due to irreversible binding, metabolism, or excretion.

When the binding, metabolism, or excretion is saturable, the loss can be described by an equation of the same form as Equation 41.4 (Lutz et al., 1980; Gerlowski and Jain, 1983). The equation for saturable metabolism is

$$\text{Loss} = \frac{V_{\max}C}{K_m + C} \tag{41.6}$$

where $V_{\max}$ is the maximum reaction velocity (mass/time) and K_m the Michaelis metabolic constant.

41.4.6 Mass Balance Equations

41.4.6.1 Each Lumped Compartment

In general, for each subcompartment in Figure 41.2 a differential equation in the form of Equation 41.1 can be constructed. Equations 41.7–41.9 are for plasma, interstitial fluid, and intercellular fluid in tissues, respectively:

$$V_p \frac{dC_p}{dt} = Q_t(C_a - C_v) + P_{is}A_{is}\left(\frac{C_{is}}{R_{is/p}} - C_p\right) \quad (41.7)$$

$$V_{is} \frac{dC_{is}}{dt} = P_{is}A_{is}\left(C_P - \frac{C_{is}}{R_{is/P}}\right) + P_tA_t\left(\frac{C_t}{R_{t/is}} - C_{is}\right) \quad (41.8)$$

$$V_t \frac{dC_t}{dt} = P_tA_t\left(C_{is} - \frac{C_t}{R_{t/is}}\right) - rC_tV_t \quad (41.9)$$

where subscripts p, is, and t refer to the plasma, interstitial, and tissue (intercellular fluid) subcompartments, respectively (see Nomenclature). C_a is concentration in the arterial blood, C_v is concentration in venous blood, and R is partition coefficient between the media indicated by its subscripts. The concentration in the lumped compartment is the volume average of the concentration of the subcompartments:

$$C_i = \frac{C_pV_p + C_{is}V_{is} + C_tV_t}{V_p + V_{is} + V_t} \quad (41.10)$$

Each of the compartments in the general model shown in Figure 41.3 could require treatment as a diffusion limited lumped compartment as described in Equations 41.7 to 41.9; however, the simplification shown in Equation 41.18 will adequately describe the pharmacokinetic behavior of many lipid-soluble organic chemicals.

41.4.6.2 Skin Compartment

For skin subcompartments in Figure 41.4, Equations 41.11–41.17 account for mass fluxes within each subcompartment:

$$V_{sfc} \frac{dC_{sfc}}{dt} = P_{sc}A_{sc}\left(\frac{C_{sc}}{R_{sc/sfc}} - C_{sfc}\right) \quad (41.11)$$

$$V_{sc} \frac{dC_{sc}}{dt} = P_{sc}A_{sc}\left(C_{sfc} - \frac{C_{sc}}{R_{sc/sfc}}\right) + P_{ve}A_{ve}\left(\frac{C_{ve}}{R_{ve/sc}} - C_{sc}\right) \quad (41.12)$$

$$V_{ve} \frac{dC_{ve}}{dt} = P_{ve}A_{ve}\left(C_{sc} - \frac{C_{ve}}{R_{ve/sc}}\right) + P_pA_p\left(\frac{C_p}{R_{p/ve}} - C_{ve}\right) - \frac{V_{max}C_{ve}}{K_m + C_{ve}} \quad (41.13)$$

$$V_d \frac{dC_p}{dt} = Q_{sk}(C_a - C_v) + P_pA_p\left(C_{ve} - \frac{C_p}{R_{p/ve}}\right) + P_dA_d\left(\frac{C_d}{R_{d/p}} - C_p\right) \quad (41.14)$$

$$V_p \frac{dC_d}{dt} = P_dA_d\left(C_p - \frac{C_d}{R_{d/p}}\right) + P_{sf}A_{sf}\left(\frac{C_{sf}}{R_{sf/p}} - C_d\right) \quad (41.15)$$

$$V_{sf} \frac{dC_{sf}}{dt} = P_{sf}A_{sf}\left(C_d - \frac{C_{sf}}{R_{sf/d}}\right) \quad (41.16)$$

where the subscripts sfc, sc, ve, d, p, sf, and sk stand for surface, stratum corneum, viable epidermis, dermis, plasma, subcutaneous fat, and skin, respectively. The concentration in the skin as a whole is the volume average of the concentration of the subcompartments:

$$C_{sk} = \frac{C_{sc}V_{sc} + C_{ve}V_{ve} + C_pV_p + C_dV_d + C_{sf}V_{sf}}{V_{sc} + V_{ve} + V_p + V_d + V_{sf}} \quad (41.17)$$

It must be emphasized that these are theoretical descriptions of the process of skin penetration. These compartments have been chosen based on the current understanding of what may be the most important structural components involved. Exploration and understanding of these concepts will determine which are important subcompartments for each specific chemical to be studied.

41.4.6.3 Simplifying Assumptions

For completeness, the hypothetical compartments in Figures 41.3 and 41.4 have been relatively rigorously described using the PB-PK approach to diffusion limitation in each subcompartment; however, until methods are developed to measure the permeability-area products (PA) for the subcompartment interfaces, many simplifications must be made to make the description useful for extrapolation. One simplifying approach has been to lump P and A together into a single term, which has units of volume/time and is estimated or fit (Lutz et al., 1980; Miller et al., 1981; Angelo et al., 1984; Gabrielsson et al., 1985). A problem with the combined term is the lack of knowledge about how to scale this term so that it can be applied to another species. It has been assumed that the permeability term is related to a constant physical process across species, and the area can be scaled according to body weight (Gabrielsson et al., 1985).

There are several assumptions that have been used to collapse the subcompartments shown in Figures 41.2–41.4 and, therefore, reduce the complexity of the problem. When transfer across the cell membrane is the rate limiting step, the plasma and interstitial subcompartments can be combined into a single extracellular compartment (Lutz et al., 1980;

Gerlowski and Jain, 1983). When blood flow to the tissue is the rate limiting step (i.e., delivery of the chemical in the blood flow is much less than diffusion into the tissue), all subcompartments can be collapsed into a single well-stirred compartment where the rate of change in amount of chemical in the compartment as a whole is related to blood flow and the difference between arterial blood and venous blood concentrations (Lutz et al., 1977; Mintun et al., 1980; Andersen, 1981; Lutz et al., 1984; Matthews and Dedrick, 1984; Clewell and Andersen, 1985; Andersen et al., 1987; Leung et al., 1988; Fisher et al., 1989), which is a consolidation of Equations 41.1 and 41.2:

$$V_i \frac{dC_i}{dt} = Q_i\left(C_a - \frac{C_i}{R_{i/b}}\right) \tag{41.18}$$

where the i subscript refers to any compartment and $R_{i/b}$ is the partition coefficient between the tissue and blood. It has also been assumed that the concentration of chemical in tissue is in equilibrium with mixed venous blood. The second concentration term, tissue concentration (C_i) divided by the tissue to blood partition coefficient, is substituted for the concentration in venous blood, assuming the equilibrium condition:

$$R_{i/b} = \frac{C_i}{C_v} \tag{41.19}$$

where C_v is the concentration in venous blood leaving the tissue.

41.4.6.4 Full PB-PK Model

When differential equations are written for the skin and body compartments, they need to be connected in a way that total mass in the whole organism is conserved. The mass balance in the liver compartment is the same as Equation 41.18 except for the addition of saturable metabolism (Equation 41.6):

$$V_l \frac{dC_l}{dt} = Q_l\left(C_a - \frac{C_l}{R_{l/b}}\right) - \frac{V_{max}\dfrac{C_l}{R_{l/b}}}{K_m + \dfrac{C_l}{R_{l/B}}} \tag{41.20}$$

where C_l is the concentration in the liver. The simple skin compartment in Figure 41.3 can be described as a single well-stirred compartment with simple diffusion:

$$V_{sk} \frac{dC_{sk}}{dt} = Q_{sk}\left(C_a - \frac{C_{sk}}{R_{sk/b}}\right) + P_{sk}A_{sk}\left(C_{sfc} - \frac{C_{sk}}{R_{sk/sfc}}\right) \tag{41.21}$$

The first term on the right side of the equation describes the effect of blood flow, the second term is the net flux of chemical into the skin from the skin surface.

The concentration of chemical in mixed venous blood is the flow weighted average of all the concentrations leaving a compartment:

$$C_v = \frac{\Sigma_i(Q_i C_i)}{Q_c} \tag{41.22}$$

where Q_c is cardiac output (total blood flow).

41.4.7 Parameters of a Model

The parameters required for the model will depend on the compartments that have been chosen based on pharmacokinetics. It is important to know which parameters are available, or can be determined, because they may be the limiting factors in the structure of the model. Physiological parameters for rats with a model for volatile lipophilic chemicals (McDougal et al., 1986) are shown in Table 41.1.

It is important that the sum of the individual blood flows equals the total cardiac output. The sum of the volumes of the compartments only accounts for 91% of the body weight. The other 9% that is not accounted for is nonperfused tissue such as fur, crystalline bone, cartilage, and teeth.

Chemical-specific parameters of a model are partition coefficients, binding coefficients, and metabolic rates. Partition coefficients describe the ratio of chemical concentrations in different materials at equilibrium. They reflect the solubility of a chemical in biological fluids and tissues and are essential components of physiologically based models. Some of the partition coefficients determined by Gargas et al. (1989) that have been used for a PB-PK model of dermal absorption of organic vapors (McDougal et al., 1990) are shown in Table 41.2. These partition coefficients for volatile chemicals

TABLE 41.1
Physiological Parameters from a PB-PK Model for Rats

Lumped Compartment	Blood Flow (%Cardiac Output)	Volume (%Body Weight)
Rapidly perfused	56	5
Liver	20	4
Slowly perfused	10	65
Fat	9	7
Skin	5	10

TABLE 41.2
Partition Coefficients for Some Organic Chemicals

Chemical	Muscle/Air	Fat/Air	Liver/Air	Blood/Air
Styrene	46.7	3476	140.7	40.2
m-Xylene	41.9	1859	92.0	46.0
Toluene	27.7	1021	82.8	18.0
Perchloroethylene	20.0	1638	69.9	19.9
Benzene	10.3	499	17.8	17.8
Halothane	4.5	182	7.6	5.3
Hexane	2.9	159	12.0	2.3

TABLE 41.3
Metabolic Constants for Some Organic Chemicals

Chemical	V_{max} (mg/kg/h)	K_m (mg/L)	K_{fo} (kg/h)
Styrene	8.4	0.4	0.0
m-Xylene	4.2	0.4	2.0
Toluene	4.7	1.0	0.0
Perchloroethylene	0.0	0.0	0.3
Benzene	3.3	0.6	0.0
Halothane	7.0	0.2	0.0
Hexane	6.0	0.4	3.4

were measured by determining, at equilibrium, the ratio of concentrations in the blood or tissue to the concentration in air. Tissue/blood partition coefficients can be estimated by dividing the tissue/air partition coefficient by the blood/air partition coefficient. Jepson et al. (1994) developed a method to measure blood/saline and tissue/saline partition coefficients for nonvolatile chemicals (<1 mm Hg at 20°C) using filtration under pressure. In this case, tissue/blood partition coefficients can be estimated by dividing the tissue/saline partition coefficient by the blood/saline partition coefficient.

Metabolic constants describe the rate of loss of chemical from a lumped compartment. Table 41.3 shows saturable (V_{max} and K_m) and first-order (K_{fo}) metabolic constants for several volatile organics from McDougal et al. (1990). Most of these metabolic constants for rats were determined *in vivo* by gas uptake techniques (Gargas et al., 1986), but they can also be determined *in vitro* (Reitz et al., 1988; Sato and Nakajima, 1979; Dedrick et al., 1972). Kedderis (1997) has evaluated the extrapolation of *in vitro* enzyme induction to humans.

41.4.8 Computer Simulations

PB-PK models are sets of time dependent, nonlinear simultaneous differential equations such as those described above. Most common computer programming languages, such as FORTRAN, BASIC, and C, could be used to solve these differential equations simultaneously although the ease at which it could be done would be greatly improved with add-on integration routines and plotting packages. Continuous system simulation languages such as advanced continuous simulation language (ACSL) (AEgis Technology Group Inc., Huntsville, AL) and MATLAB® (The Math Works Inc., Natick, MA), Berkley Madona™ (Kagi, Emeryville, CA), ModelMaker (Borland®, Scotts Valley, CA), which were designed for engineering simulations, make the process of coding, debugging, modifying, and running a PB-PK model much easier. Simulation languages are interactive and allow easy data entry, on-line changes of model parameters, and plotting of the results. These simulation languages have been the most important factor influencing the increased use of PB-PK models.

41.5 HOW DO YOU DEVELOP PB-PK MODELS?

PB-PK models are unlike "canned" computer programs that can be used for various purposes once they are written. They are radically different from such multipurpose programs as statistical routines, spreadsheets, and databases because the structure of a PB-PK model is dependent on the interaction of a specific chemical with a specific species. The result of using a PB-PK model for a chemical other than that for which it was intended would be like using an Ohio state tax preparation package to prepare a California state tax return. Each unique chemical–species interaction requires that the salient physiological and pharmacokinetic principles be understood and quantitatively described. Development of a PB-PK model is an iterative process that requires insight, trial and error, and careful laboratory investigation. PB-PK models can and should be developed before the first laboratory experiment. As knowledge is gained in the laboratory, each new understanding should be quantitatively described in the model. Simulation and experimentation should be accomplished concurrently. Simulation prior to experimentation will allow appropriate data to be collected. Experimentation will confirm or increase the understanding that is quantified in the model. The key is understanding at the appropriate level as opposed to description on a superficial level.

41.5.1 Choose Compartments

Decisions about the form of the skin compartment are related to the behavior of the chemical in the skin. Lag time (the time before steady state penetration rate is achieved) is the single most important determining factor. If lag time prior to achieving steady state absorption is short, i.e., 15 min, a simple well-stirred homogeneous skin compartment (Figure 41.3) may be an adequate description. If the lag time is longer, which is more common, it will be necessary to include part or all of the skin subcompartments shown in Figure 41.4. Distribution of the chemical in the skin will determine which compartments are important to describe explicitly. Many of the methods that have been developed to study the skin will be useful for increasing the understanding required for an appropriate mathematical description. These include *in vitro* methods for metabolism and penetration, laser Doppler velocimetry, tape stripping, and ultrastructural analysis by light or electron microscopy.

Deciding which compartments, in addition to a skin, to be included in a model requires knowledge of the pharmacokinetics of the chemical of interest. Depending on the chemical, pharmacokinetic information may be available from the literature, or it may need to be determined in the laboratory before determining the structure of the model. Compartments must be included in a model to represent the major organs of metabolism and excretion. For example, a chemical that is primarily eliminated in the urine by an active process would require a kidney compartment, but a chemical that is eliminated primarily by exhalation would require a lung compartment. Metabolism studies with radiolabeled chemicals or other analytical methods, such as gas chromatography or

high-performance liquid chromatography, will provide the kinetic data required to choose the important compartments for loss of parent chemical. Additional lumped compartments must be included to account for distribution of the chemical in the animal. A lipophilic chemical would require a fat compartment or compartments while a chemical that does not distribute to the fat would not. Distribution studies with radiolabeled or nonlabeled chemicals provide the details necessary for appropriate choices of compartments. New analytical methods such as positron emission tomography or nuclear magnetic resonance imaging appear promising and may provide valuable distribution information in the whole animal. Organs in which the chemical has similar distribution may be lumped together if the organs have similar blood flow per weight of tissue. Blood flow to organs can be determined from the literature or from microsphere techniques. Other compartments that may be desired in the model would be representative of target organs for toxicity or therapeutic effect.

Decisions about the form of a lumped compartment and the requirement for subcompartments depend on the relationship between blood flow to the compartment, volume of the compartment, and solubility of the chemical in the compartment. Deciding whether the limiting factor in transfer of chemical from blood to the compartment is flow or diffusion is not always simple experimentally (Riggs, 1963). It is probably best to assume that blood flow is the limiting factor unless there is evidence otherwise or flow-limitation does not adequately describe the behavior of a compartment. The most important principle in PB-PK modeling is to use the simplest description that adequately describes the behavior of the chemical.

41.5.2 Determine Physiological Parameters

Species-specific physiological parameters, i.e., blood flow and volumes of organs, are often available in the physiology handbooks or reviews (USEPA, 1988; Fiserova-Bergerova and Huges, 1983; Gerlowski and Jain, 1983; Snyder et al., 1974) or from published PB-PK models (Adolf, 1949; Dedrick, 1973; Lutz et al., 1980; Ramsey and Andersen, 1984; Corley et al., 1990, 2000; Bouchard et al., 2001; Timchalk et al., 2002). It is necessary to make decisions about which physiological parameters to use from the literature because there will undoubtedly be a range of values available. One must avoid the temptation to change the physiological parameters to fall outside this normal range to obtain agreement between prediction and observation. If this temptation is not resisted, the result will be the loss of the ability to extrapolate. The physiological parameters in a PB-PK model for any species should be robust and not change when a different chemical is modeled, unless there is sound evidence that the chemical specifically causes changes, e.g., blood flow. When prediction and observation do not agree, there are two explanations: either the results of the experiment are not accurate or the model assumptions are inadequate. Once experimental calculations have been checked, the best approach is to determine if the structure of the model is adequate. In some cases, an important compartment has been overlooked or a diffusion limitation has been described as a flow limitation.

41.5.3 Determine Chemical Parameters

Metabolic constants, partition coefficients, and binding coefficients are much less available in the literature than the physiological parameters and they must often be determined experimentally. Metabolic constants can be determined in many ways, both *in vitro* and *in vivo*. Methods used specifically for PB-PK modeling are the tissue homogenate methods of Dedrick et al. (1972) and *in vivo* gas uptake methods for measuring metabolism of volatile chemicals (Gargas et al., 1986). Partition coefficients for volatile chemicals in blood and tissue homogenates can be determined by the vial equilibration technique (Gargas et al., 1989). Partition coefficients for nonvolatile chemicals can be determined by measuring tissue and blood concentrations after continuous dosing to achieve equilibrium. Binding, which is distinguished from partitioning because it is not linearly related to concentration, can be determined by various methods (Dedrick and Bischoff, 1968; Lin et al., 1982). The same caveat about changing physiological parameters to fit the data applies to the chemical parameters. Halving the blood/air partition coefficient because it fits the experimental results better may solve an immediate problem at the expense of the general applicability of the model.

41.5.4 Validate Model Where Absorption Is Absent

Before a PB-PK model can be used to describe the process of absorption through the skin, it is necessary to gain some confidence in the quantitative description of pharmacokinetics when absorption is absent. The model should successfully simulate blood concentrations, tissue concentrations, or expired breath after intravenous exposures at several concentrations. Urinary or fecal excretion could also be used for validation, but they are not optimum because sampling times are critical. Ideally, prolonged intravenous infusions at several concentrations and intravenous boluses at several concentrations should be used to make sure that the physiological and pharmacokinetic parameters chosen will adequately describe the processes of distribution, metabolism, and excretion for a wide range of concentrations. An alternative approach would be to achieve the same confidence with subcutaneous infusions using minipumps.

41.5.5 Validate Model with Dermal Absorption

Once the parameters not involved in absorption are fixed, then the model can be used to understand the process of absorption through the skin. Parent chemical distribution in the body after absorption through the skin and hepatic metabolism will follow the same principles independent of the absorption process. When these processes are understood and quantified, the rate of absorption through the skin can be determined based on blood, tissue, breath, or excreta concentrations.

Permeability constants can be determined by using the model to determine total chemical absorbed as long as the concentration on the skin and the surface area are known (McDougal et al., 1986).

41.5.6 Extrapolation to Humans

The ability to extrapolate from laboratory species to man is one of the most important reasons for using PB-PK models. Ramsey and Andersen (1984) have shown that a PB-PK model for inhalation of styrene vapors in rodents can predict the pharmacokinetic behavior of inhaled styrene in humans by changing the blood flows, organ volumes, and partition coefficients to those of humans. The same principles could be used to extrapolate dermal absorption studies to humans if differences in skin structure are taken into account. It will be possible to quantify the species differences in blood flow, differences in stratum corneum, epidermal and subcutaneous fat thickness and composition, as well as the effect of the type and number of appendages on skin penetration in various species.

It has been shown that organic vapor penetration rates determined in rats using a PB-PK model are two to four times greater than penetration rates in humans calculated from the literature based on the total absorbed after whole-body exposures (McDougal et al., 1990). The consistency of these comparisons suggests that differences in permeability may be due to physical differences in the skin. Using this as an example, it is important to understand some of the approaches and limitations involved in extrapolation to humans. It is not possible to directly extrapolate, with any confidence, the published PB-PK model for organic vapors in rats to the published human studies. This is because the human studies were based on urinary output and exhaled breath, and the rat studies were based on blood concentrations. It would be fairly easy to make the rat model capable of predicting exhaled breath and urinary output by adding urinary output and validating the rat model for these routes of excretion.

Once the rat model accurately predicted experimental results for urinary output and exhaled breath, the rat model could be used to address the human data by changing the physiological, pharmacokinetic, and biochemical parameters in the model to those of the human. For example, alveolar ventilation rates, blood flows, organ volumes, and urine volumes would need to be changed to those of the human. Partition coefficients, metabolic rates, and urinary excretion rates would need to be found or determined for each chemical of interest and changed in the model. With the published rat description, permeability constants were determined with confidence because the model was validated with a route where complex absorption was absent, i.e., inhalation. If the scaled-up rat model did not predict the dermal exposures in humans, it could be because the permeability constant in humans is different (as suspected) or because the physiological or pharmacokinetic parameters used for humans were incorrect. It would be necessary to make sure that these parameters were correct in humans with a route of absorption other than dermal.

Providing the rest of the description was correct, any inaccuracy in the prediction would be due to differences in permeability constant in the skin, and the permeability constant could be estimated by determining the constant required to fit the data. If the simple skin compartment (Equation 41.21) were descriptive for this chemical in the rat, it would most likely be descriptive of the same chemical in the human. Other types of chemicals, which penetrate more slowly than organic vapors, may require that the skin be broken into some or all of the subcompartments described in (Equations 41.11–41.16). In such a case, the subcompartments would also require that the structural differences in the skin between species be understood and quantified.

Other types of skin models that use first order rate constants to describe the transfer of chemicals between subcompartments have been developed. They are excellent descriptive models but do not extrapolate to other species well, because the first order rate constant is a composite of the permeability, area exposed, and the partition coefficient. These models have been reviewed and compared with PB-PK models by Roberts et al. (1999) and McCarley and Bunge (2001).

41.5.7 When the Model Fails

Paradoxically, models are often most useful when they fail to adequately describe the experimental data. During the process of developing a more adequate description of the pharmacokinetic processes involved, insight can be gained which will apply to other situations and increase the understanding of the skin, specifically, and pharmacokinetics, in general. It is the physiological foundation of the description that forces an investigator to design experiments to determine where the description is inaccurate. When frustration occurs, it is important to remember that the behavior of chemicals in living systems is not arbitrary. Chemicals and biological systems interact in accordance with physicochemical principles, which once understood are very reasonable and reliable. PB-PK modeling is an iterative process that requires theory and observation to come closer together until the final result is achieved.

41.5.8 Value of PB-PK Skin Models

PB-PK modeling can increase the understanding of the effect of vehicles on penetration rates and penetration enhancement. Jepson and McDougal (1999) showed the importance of the skin/vehicle partition coefficient by demonstrating that permeability, measured *in vivo*, could be extrapolated between different vehicles (water, corn oil, and mineral oil) with a reasonable degree of accuracy. Traditionally, flux measurements must be made on a system that is at or near steady state. Jepson and McDougal (1997) demonstrated that a PB-PK model could be used as a tool to estimate *in vivo* permeability in a situation such as an organic chemical in a

small volume of water where steady state is never achieved. These models have also been shown to accurately describe *in vitro* skin and receptor solution concentrations in the first 20 min of organic chemical in aqueous vehicle (McDougal and Jurgens, 2001). Real time breath analysis has been linked with PB-PK modeling as a tool to investigate human dermal absorption of volatile chemicals from water (Poet et al., 2000; Thrall et al., 2000) and soil (Thrall et al., 2000; Poet et al., 2002). This noninvasive approach would not be available without a PB-PK model to estimate body burden.

41.5.9 Future of PB-PK Skin Models

Improved skin compartments can be developed and validated, which include some of the subcompartments shown in Figure 41.4 to be predictive of penetration rates of chemicals that have more complicated absorption profiles. Pharmacodynamic models that quantitatively describe the molecular events that occur in the skin with local toxicity (for example, psoriasis, contact dermatitis, or skin cancer) can be developed. These models might describe tissue levels, production, and turnover rates of important proteins, signaling molecules, and mRNA levels that are responsible for deleterious changes in skin function. With appropriate biologically based models, it is possible to make the connection between amount of chemical on the surface and the therapeutic or toxic effect. When validated, these validated models could be applied to the development of biomarkers and prophylaxis.

41.6 CONCLUSION

Physiologically based pharmacokinetic models provide tremendous capacity to increase the understanding of skin absorption and the effects of chemicals in the skin. The ability to extrapolate between *in vivo* exposure conditions, doses, and species allows laboratory animal studies to provide a wealth of information applicable to human exposure situations that can be used for exposure and risk assessment. The ability to apply quantitative descriptions to processes occurring in the skin is limited only by our ability to understand the processes involved.

NOMENCLATURE

C	Concentration (mass/volume)
V	Volume
A	Area (distance^2)
Q	Flow (volume/time)
P	Permeability (distance/time)
K_m	Michaelis metabolic constant (mass/volume)
K_T	Michaelis-like transport constant (mass/volume)
K	Maximum transport rate (mass/volume $\times$ time)
R	Proportionality constant (time^{-1})
R	Partition coefficient (unitless, ratio of concentrations)
V_{max}	Maximum velocity (mass/time)

42.1 INTRODUCTION

It has been known for years that enzymes in skin catalyze a wide variety of metabolic reactions (Pannatier et al., 1978; Bickers, 1980; Kappus, 1989). All the major enzymes important for systemic metabolism in the liver and other tissues have been identified in skin (Pannatier et al., 1978). Often enzyme activity has been found to be lower in skin (on a per mg tissue basis) when compared to the liver (Bronaugh et al., 1989; Mukhtar and Bickers, 1981). However, the skin is the largest organ in the body with a surface area of 2 m^2 and total weight estimated at 4 kg—about three times that of the liver (Pannatier et al., 1978). Therefore, the skin can play an important role as a portal of entry of chemicals into the body.

Some chemical groups such as esters, primary amines, alcohols, and acids are particularly susceptible to metabolism in skin. Many esters are hydrolyzed by esterase to their parent alcohol and acid molecules (Boehnlein et al., 1994; Kenney et al., 1995). Primary amines are frequently acetylated during percutaneous absorption through skin (Nathan et al., 1990; Kraeling et al., 1996; Yourick and Bronaugh, 2000). Oxidation/reduction and conjugation of alcohols and acids are commonly observed in skin (Nathan et al., 1990; Boehnlein et al., 1994).

Chemicals that undergo significant metabolism in skin may exhibit greater or lesser biological activity than predicted simply from skin penetration studies. A more thorough examination of the safety or efficacy of these compounds can be determined by evaluating skin absorption and metabolism simultaneously using *in vitro* techniques.

42.2 REASONS FOR DOING *IN VITRO* STUDIES

Skin metabolism studies are difficult to accurately conduct *in vivo* because of systemic metabolism that takes place before samples are collected in the blood, urine, or other site. *In vitro* studies isolate the skin from the metabolic activity in the rest of the body. When studies are conducted using viable skin in diffusion cells, metabolites can be measured in skin homogenates or in the receptor fluid directly beneath the skin. Also, *in vitro* studies may be the only ethical way to obtain human skin metabolism data for chemicals with safety concerns.

42.3 MAINTENANCE OF SKIN VIABILITY IN DIFFUSION CELLS

The assembly of skin in diffusion cells is described in general terms in Chapter 34. This chapter discusses methods for maintaining viable skin in metabolism studies.

Human or animal skin should be freshly obtained. Skin previously frozen for shipping or storage is unsuitable for metabolism studies. Enzyme activity with some stable enzymes can sometimes be still observed in nonviable skin but the activity may be at a reduced level as observed for esterase activity (Boehnlein et al., 1994; Kenney et al., 1995).

The viability of rat skin was maintained for at least 24 h in flow-through diffusion cells using several physiological buffers as the receptor fluid (Collier et al., 1989). For 24 h studies, the use of flow-through cells is required likely, so that nutrients are continually provided to the skin.

Although a tissue culture media (minimal essential media [MEM]) was satisfactory in maintaining skin viability, it was not required. Simpler balanced salt solutions such as HEPES-buffered Hanks' balanced salt solution (HHBSS) or Dulbecco-modified phosphate-buffered saline worked just as well and are potentially less problematic for analytical reasons. Some of the vitamins, cofactors, and amino acids contained in MEM absorb in UV light and can interfere with UV detection during HPLC analysis. Bovine serum albumin (BSA) has been added to the receptor fluid to enhance the

partitioning of lipophilic test compounds from skin into the receptor fluid.

42.4 SKIN VIABILITY ASSAYS

Viability of skin was primarily assessed in our initial studies by measuring aerobic and anaerobic glucose utilization (Collier et al., 1989). Anaerobic metabolism of glucose to lactic acid predominates in skin and so this assay has been commonly used. Glucose is the primary energy source for skin cells and has been monitored by tissue banks to assess skin viability for transplants (May and DeClement, 1981). We used electron and light microscopy techniques to assess viability by demonstrating that the cellular organelles were still intact at the end of 24 h studies. Skin metabolism of estradiol and testosterone was also maintained for 24 h.

We have observed that the addition of 4% BSA to HHBSS results in a lowering of lactate levels measured in the skin viability assay (Hood and Bronaugh, 1999). Therefore, the 3-[4,5-dimethylthiazol-2yl]-2,5-diphenyltetra-zolium bromide (MTT) assay was adapted to assess skin viability when BSA was required in the receptor fluid. The MTT assay of skin viability was not affected by addition of BSA to the receptor fluid. The viability of human, fuzzy rat, and hairless guinea pig skin was found to be maintained for 24 h. However, the assay can only be conducted at the end of a study when skin can be removed from the diffusion cell. The lactate measurement of glucose utilization can be conducted during the course of an experiment.

42.5 SKIN METABOLISM DURING *IN VITRO* ABSORPTION STUDIES

Early studies from our laboratory used intact viable dermatome skin sections from mice, rats, hairless guinea pigs, and humans in flow-through diffusion cells to study the penetration and metabolism of estradiol and testosterone (Collier et al., 1989), acetyl ethyl tetramethytetralin (AETT) and butylated hydroxytoluene (BHT) (Bronaugh et al., 1989), benzo[a]pyrene and 7-ethoxycoumarin (Storm et al., 1990), and azo colors (Collier et al., 1993).

The percutaneous absorption and metabolism of three structurally related compounds, benzoic acid, *p*-aminobenzoic acid (PABA), and ethyl amino-benzoate (benzocaine), were determined *in vitro* with hairless guinea pig and human skin (Nathan et al., 1990). Approximately 7% of the absorbed benzoic acid was conjugated with glycine to form hippuric acid. Acetylation of primary amines was found to be an important metabolic step in skin. For benzocaine, a molecule susceptible to both *N*-acetylation and ester hydrolysis, 80% of the absorbed material was acetylated, while less than 10% of the absorbed ester was hydrolyzed. PABA was much more slowly absorbed than benzocaine and was also less extensively *N*-acetylated. Acetyl-PABA was found primarily in the receptor fluid at the end of the experiments, but the receptor fluid contained only 20% of the absorbed dose. Much of the absorbed PABA remained unmetabolized and in the skin as might be expected for an effective sunscreen agent. The compound in the skin would probably not have been exposed to *N*-acetylating enzymes if it was localized primarily in the stratum corneum. A similar pattern of benzocaine metabolism was observed in human and hairless guinea pig skin; however, there appeared to be less enzyme activity in human skin.

The effect of benzocaine dose on its absorption and metabolism was determined in the hairless guinea pig (Kraeling et al., 1996). It was of interest to determine if metabolism of absorbed benzocaine remained extensive when the radiotracer doses used in our earlier studies were increased to doses simulating human use conditions as a local anesthetic. Percutaneous penetration of benzocaine increased 50-fold when the applied dose increased from 2 to 200 μg/cm^2. Metabolism of benzocaine to acetylbenzocaine was reduced at the higher dose but still, approximately, one-third of the absorbed dose was metabolized (Table 42.1). The metabolism of benzocaine in skin may not affect the local anesthetic activity of a topical commercial product since benzocaine and acetylbenzocaine were found to have similar potencies in reducing conductance in the isolated squid giant axon (Kraeling et al., 1996).

Esterase activity and alcohol dehydrogenase activity were characterized in hairless guinea pig skin with the model compounds methyl salicylate and benzyl alcohol (Boehnlein et al., 1994). Subsequently, the absorption and metabolism of the cosmetic ingredient retinyl palmitate was determined in human and hairless guinea pig skin.

TABLE 42.1
Effect of Benzocaine Dose on its Metabolism; Percentage Distribution of Benzocaine and Metabolites in Receptor Fluid and Skin in 24 h

Location and Compound	Dose Level		
	2 μg/cm^2	40 μg/cm^2	200 μg/cm^2
Receptor fluid			
Benzocaine	9.6 ± 4.2	50.7 ± 6.6	54.0 ± 5.2
AcBenz	83.8 ± 4.4	43.8 ± 5.7	37.9 ± 3.6
PABA	1.0 ± 0.3	0.1 ± 0.1	0.9 ± 0.5
AcPABA	5.1 ± 1.0	5.8 ± 0.9	7.2 ± 1.7
Skin			
Benzocaine	26.7 ± 14.2	2.4 ± 2.4	62.7 ± 12.2
AcBenz	6.9 ± 6.9	34.4 ± 20.3	20.9 ± 11.7
PABA	4.3 ± 4.3	3.2 ± 3.2	1.5 ± 1.3
AcPABA	24.7 ± 14.9	15.2 ± 16.0	14.9 ± 1.2
Total			
Benzocaine	10.7 ± 3.3	49.9 ± 6.5	57.3 ± 3.7
AcBenz	80.5 ± 3.8	43.6 ± 5.6	34.3 ± 3.4
PABA	1.4 ± 0.2	0.1 ± 0.1	0.9 ± 0.5
AcPABA	6.5 ± 1.0	5.9 ± 1.0	7.6 ± 2.0

Note: Values are the mean ± S.E. for 1–6 determinations in each of the three animals. The 40 μg/cm^2 dose level values are the mean ± S.E. of 2–3 determinations in each of the four animals. The dosing vehicle was acetone. AcBenz = acetylbenzocaine; PABA = *p*-aminobenzoic acid; and AcPABA = acetylPABA.

The metabolism of methyl salicylate was determined in viable and nonviable hairless guinea pig skin. In viable skin over 50% of the absorbed compound was hydrolyzed by esterases in skin to salicylic acid. Twenty-one percent of the absorbed compound was further conjugated with glycine to form salicyluric acid. Greater esterase activity was observed in male skin. Esterase is a stable enzyme and hydrolysis of methyl salicylate also occurred in nonviable skin. However, no conjugation of salicylic acid was observed in nonviable skin.

Oxidation of benzyl alcohol was also observed in hairless guinea pig skin. Approximately 50% of the absorbed benzyl alcohol was oxidized to benzoic acid in viable skin with a small portion of this compound being further metabolized to the glycine conjugate—hippuric acid. As with the ester, significant activity was also observed in nonviable skin and greater oxidation of the alcohol was obtained with male skin.

The absorption and metabolism of retinyl palmitate was measured to see if ester hydrolysis and alcohol oxidation occurred with this cosmetic ingredient. Most of the absorbed radioactivity remained in the skin. A substantial amount of the absorbed compound was hydrolyzed to retinol but no oxidation of the alcohol to retinoic acid was observed. Any effects of retinyl palmitate on the structure of skin may be due to the formation of retinol during percutaneous absorption.

Absorption values from *in vitro* studies with viable hairless guinea pig skin have been found to compare closely with *in vivo* results for phenanthrene (Ng et al., 1991) and for pyrene, benzo[a]pyrene, and di(2-ethylhexyl) phthalate (Ng et al., 1992). Also, significant metabolism was observed *in vitro* during the absorption of all four compounds.

Phenanthrene was metabolized *in vitro* to 9,10-dihydrodiol, 3,4-dihydrodiol, 1,2-dihydrodiol, and traces of hydroxy phenanthrenes (Ng et al., 1991). Following topical administration of phenanthrene, approximately 7% of the percutaneously absorbed material was converted to the dihydrodiol metabolites.

Numerous metabolites of benzo[a]pyrene were formed during percutaneous absorption through hairless guinea pig skin (Ng et al., 1992). Of particular interest was the identification of benzo[a]pyrene 7,8,9,10 tetrahydrotetrol in the diffusion cell receptor fluid. This metabolite is the hydrolysis product of the ultimate carcinogen, 7,8-dihydroxy, 9,10-epoxy-7,8,9,10-tetrahydro-benzo[a]pyrene. This study demonstrates that skin metabolism is likely responsible for skin tumors formed following topical benzo[a]pyrene administration. In the earlier phenanthrene study (Ng et al., 1991), no known carcinogenic metabolites were formed during skin permeation. This finding is consistent with the lack of tumorigenicity of phenanthrene in rodents.

Since the systemic toxicity of topically applied compounds is sometimes evaluated by the oral route of administration, the effect of route of administration on metabolism of (^{14}C) 2 nitro-*p*-phenylenediamine (2NPPD) was examined *in vitro* in the fuzzy rat (Yourick and Bronaugh, 2000). Rat skin dermatomed to approximately 250 μm and full thickness rat intestinal tissue (from the jejunum) were assembled into flow-through diffusion cells perfused with HHBSS to maintain viability. 2NPPD was applied for 30 min to skin in a semipermanent hair dye formulation and to intestine in HHBSS (pH 6.5). Similar amounts of radioactivity penetrated into the receptor fluid from each tissue during the 24 h studies.

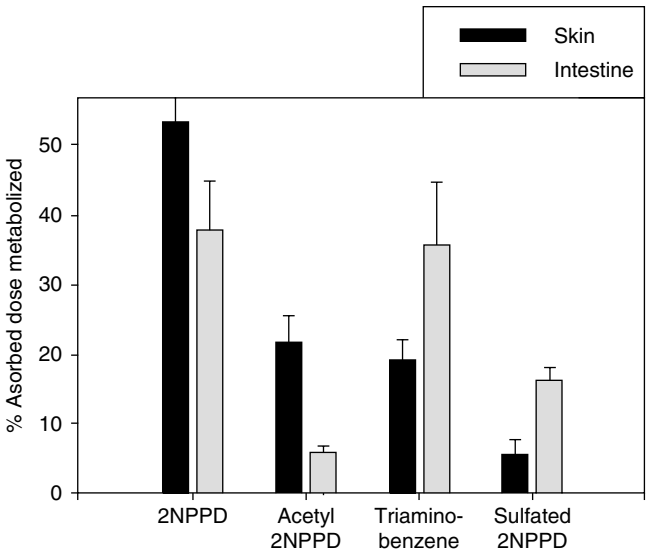

FIGURE 42.1 Metabolism of 2NPPD during absorption through rat skin and intestinal tissue. Values are the mean ± S.E. of three individual rat studies ($n = 3$).

The metabolism of 2NPPD was determined in receptor fluid fractions using an HPLC method. More than 50% of the 2NPPD applied to skin remained unmetabolized while only 40% of 2NPPD was unmetabolized by intestine (Figure 42.1). Substantially more acetylation of 2NPPD to N4-acetyl-2NPPD occurred during absorption through skin. However, triaminobenzene was formed to a greater extent in intestine. The amount of sulfated 2NPPD or metabolites (actual compound or compounds not determined) was also greater in effluent from intestinal tissue. The extent of metabolism of 2NPPD in human skin (semipermanent hair dye vehicle) was also determined. Approximately 60% of the absorbed radioactivity was metabolized to equal amounts of triaminobenzene and N4-acetyl-2NPPD. No sulfated compounds were found in effluents from human skin. These studies showed significant differences in metabolism during penetration through human and rat skin, as well as differences in metabolism through rat skin and intestinal tissue.

Predicting potential toxicologic responses to transdermal delivery is a complex procedure, involving both traditional toxicology protocols for evaluating results of systemic exposure and topical studies assessing skin–drug interactions and reactions. Evaluation of individual drug and system components is followed by final system testing to assess possible interactions. Risk is estimated by analyzing toxicologic data quantitatively, with estimation of human exposure based on dose–response extrapolations. Formulation or system changes designed to minimize risk are evaluated. In some instances, local intolerance to a compound—either due to irritation or sensitization—may preclude development of a transdermal product despite efficacious plasma levels. For viable projects with acceptable toxicologic profiles, a strategy is implemented to manage the risk of irritation and sensitization. In addition to the usual drug-specific systemic toxicology and regulatory issues, a toxicology evaluation plan for transdermal dosage forms must include primary and cumulative irritation and sensitization testing. The plan must also take into account the U.S. Food and Drug Administration's (FDA) categorization of new transdermal systems and novel excipients as new chemical entities (NCEs), subject to standard nonclinical testing procedures.

43.1 TOXICOLOGY EVALUATION PLAN

Development of a toxicology evaluation plan for a transdermal system involves two major stages: assessment of previous experience with both the drug(s) and system components, and selection of necessary and appropriate tests. Assessment of previous experience includes review of data in the literature and in regulatory submissions available through the Freedom of Information Act (1996). Substantial published knowledge of the drug allows analysis of the effects of various doses, plasma drug levels, and regimens, and generally reduces testing requirements. Information about oral, intravenous, and especially subcutaneous administration may be used for comparison or to support the safety and efficacy of transdermal delivery when equivalent plasma levels are achieved and no significant biotransformation occurs. Literature and other available data about compounds previously cleared by the FDA may be useful in determining areas for additional study. Similarly, evaluations of proposed system materials in the literature and previous FDA submissions may provide valuable information about individual system components or possible interactions of materials.

An additional factor in the evaluation plan is the categorization by the FDA of new transdermal systems as NCEs, subject to standard nonclinical testing procedures. A complete toxicology profile—including subchronic, chronic, carcinogenic, and genotoxic assays—is required for all compounds delivered transdermally. This requirement may be reduced when systems incorporate a compound already marketed in another dosage form. Transdermal systems that achieve lower plasma drug levels than other marketed forms of the drug and transdermal systems that incorporate drugs or components previously evaluated for irritation or topical sensitization may require few nonclinical studies. Additional toxicology studies for topical products may include photosafety studies and irritation and sensitization studies (see the following discussion) with the components.

The pharmacokinetic analysis of plasma drug levels in an acceptable animal model is recommended prior to clinical use of the transdermal system. This will not only support

the proposed toxicology plan, but also, because transdermal systems typically contain much more drug than will be delivered, provide safety data to the FDA that there is controlled delivery of drug. Some divisions of the FDA have required the demonstration that no immediate release or higher than anticipated drug delivery rates were observed from any of the systems tested, and only a fraction of the total drug content in the patch was delivered over the wearing period.

Toxicokinetic analysis—pharmacokinetic analysis applied to dose-ranging and definitive toxicity testing—is increasingly important to determine drug exposure in nonclinical toxicology protocols for transdermal and other dosage forms, and is included in guidelines drafted by the International Conference on Harmonisation (Federal Register, 1995). Toxicokinetic studies describe the relationship between systemic exposure, dose administered, and time, providing data to support safety claims at various doses. Results of these studies contribute to the design of subsequent nonclinical studies. (For additional details about toxicokinetic studies, see Dixit, 2006 and Kantrowitz and Yacobi, 1994.) Because transdermal delivery of drugs bypasses the first-pass effect, the drug-to-metabolite ratio changes. If a drug has an active major metabolite, measurement of both the parent and major metabolite may be indicated during the pharmacokinetic/toxicokinetic analysis.

Studies of skin metabolism may also be required. Although transdermal administration bypasses hepatic circulation, molecules absorbed through the skin will come into contact with the skin's metabolic system (Hikima et al., 2005). (For a comprehensive review of the skin's enzymatic activity, see Baron and Merk, 2001; Steinstrasser and Merkle, 1995; Noonan and Wester, 1985.) Skin metabolism may alter the delivery profile and pharmacological effects of some percutaneously absorbed compounds (Boehnlein et al., 1994; Guy and Hadgraft, 1982; Hashiguchi et al., 1998; Tang-Liu et al., 1999; see also Chapter 9 of this book). The effects of first-pass skin metabolism of transdermally delivered compounds can be predicted by *in vitro* biotransformation studies (Brand et al., 2000; Cormier et al., 1991; Friedberg, 1998; Sintov et al., 2002; Smith et al., 2000). The toxicology profile of compounds may be altered by the quantitative modification of metabolic pathways caused by skin metabolism (Cleary et al., 1984; Bucks, 1984). These changes, which are sometimes measured by comparison with oral or intravenous data, may result in local irritation, sensitization, or adverse systemic effects. Changes resulting from skin metabolism may also transform inactive prodrugs with favorable permeation characteristics into metabolically active parent drugs (Sintov et al., 2002; Imoto et al., 1996, Tauber, 1989). Skin metabolism and subsequent formation of protein conjugates may assist in prediction and evaluation of skin sensitization assays (Dimitrov et al., 2005; Wilson et al., 2003; Divkovic et al., 2003, 2005; Gerberick et al., 2004). In addition, genetic variations in the skin's enzymatic activity may account for differences in therapeutic efficacy among patients. Generally, however, the effect of the skin's first-pass metabolism is slight since skin cells have lower intrinsic metabolic activity than hepatocytes, and only a few cell layers within a limited area are perfused by a transdermally delivered compound. For example, skin metabolism of propranolol, which is metabolized extensively by the liver, was almost negligible (Cormier et al., 1991).

Phototoxicity issues may also need to be addressed with transdermal drug delivery. Although phototoxicity testing is conducted primarily with humans, both the FDA and the Organisation for Economic Co-operation and Development (OECD) have draft guidelines for photosafety testing (including phototoxicity, photoallergy, photogenotoxicity, photocarcinogenicity), which provide decision trees to assist in the evaluation. According to the OECD, photosafety testing is indicated if the drug absorbs light between 270 and 700 nm on the ultraviolet (UV)-visible light absorption spectrum, and if the drug is applied topically or accumulates in light-exposed areas. The OECD considers the *in vitro* 3T3 neutral red uptake (NRU) phototoxicity assay validated and provides a test guideline. This assay can be used to evaluate the drug substance, but other testing may be required on the finished drug product. If additional *in vivo* testing is warranted, a controlled clinical trial is suggested. The FDA has stated that testing only the drug substance may be acceptable, but that the drug product (final formulation) should be tested if the product absorbs light between 290 and 700 nm, as well as if the product is "applied to the skin or eyes, or persist or accumulate in one of these areas, or 2) are known to affect the skin or eyes." The FDA does not specify how to test for photosafety, but acknowledges the use of *in vitro* studies, *in vivo* nonclinical studies, and human clinical studies, and encourages "the submission of specific data that may help in evaluating the regulatory acceptance of such assays." The interagency coordinating committee on the validation of alternative methods (ICCVAM) is expected to evaluate the 3T3 *in vitro* assay, but no information is available as of this writing. The communication of risk is key; factors to consider include the half-life, acute or chronic use, pharmacologic class, and persistence in the skin (especially in areas exposed to sunlight). If the risk is sufficient, additional tests may evaluate photoallergy, photogenotoxicity, and photocarcinogenicity.

Polymers and permeation enhancers used in transdermal systems need to be evaluated for potential adverse effects before testing the drug delivery system in humans. Polymers used in transdermal drug delivery systems may not penetrate the skin themselves, but components of the polymer, such as residual monomers, reactive agents, or processing additives, may migrate. The effects of polymers or extracts will depend on unique chemical characteristics and the amount (or dose) of polymer/extract administered. To assist in the selection of materials, literature from the manufacturer and data from published studies should be reviewed for clinical and nonclinical safety information (Venkatraman et al., 2000).

The polymer and extracts should be biocompatible since they are in contact with components that penetrate the skin. If necessary, *in vitro* and *in vivo* tests are conducted to evaluate the biocompatibility of the polymer or extract and of the drug delivery system and thus to assess the safety of the system. *In vitro* studies should be conducted before initiating *in vivo*

studies. The tests listed in the International Standards Organization/American National Standards Institute/Association for the Advacement of Medical Instrumentation (ISO/ANSI/AAMI) Standard 10993, Biological Evaluation of Medical Devices, are intended to provide testing strategies for medical devices. There are similar guidelines in the U.S. Pharmacopeia (USP) 29—National Formulary 24 for plastics used as drug containers. These tests may also be used to test biocompatibility of polymers used in transdermal drug delivery systems.

Extracts may also be tested for the potential to cause topical sensitization. Preparation of polymer extracts is defined by guidelines, but the choice of conditions should come close to the conditions of manufacture of the drug delivery system. Extracts are evaluated using *in vitro* cytotoxicity tests as well as *in vivo* irritation, intracutaneous injection, systemic injection, and implantation studies. A sample of the polymer may also be evaluated in these *in vivo* tests. The final transdermal drug delivery system must also be evaluated in standard nonclinical toxicology studies to evaluate safety of the system.

If there is systemic absorption of a polymer or a permeation enhancer that is not an NCE, manufacturer information and published scientific literature should be reviewed. If data indicate that blood levels are acceptable based on historical exposure or existing toxicology data, then conducting irritation and sensitization studies with the final formulation and providing a written review and justification of the use of the polymer or permeation enhancer may be all that is necessary.

If the polymer or permeation enhancer is released systemically and is an NCE, the FDA Guidance for Industry: Nonclinical Studies for Development of Pharmaceutical Excipients should be reviewed. The new excipient may require a full toxicology package consisting of acute, chronic, reproduction, and carcinogenicity testing to establish safe limits for the compound. The FDA will consider reduced programs based on the availability of adequate prior human exposure and short durations of clinical use.

New adhesives should also be tested for biocompatibility. Extracts may be evaluated using *in vitro* cytotoxicity tests and *in vivo* irritation, intracutaneous injection, systemic injection, and implantation studies. Placebo transdermal systems may be tested in irritation studies to evaluate the contribution of the adhesive to irritation. Sensitization studies should always include placebos to differentiate reactions between the drug and the excipients.

Beyond these general toxicology considerations, irritation and sensitization tests are a primary focus for evaluating a transdermal dosage form.

43.2 IRRITATION

43.2.1 *In Vivo* Irritation Testing

The New Zealand white rabbit or guinea pig (Hartley or hairless strains) are the most often used species to test transdermal systems for irritation, but the pig (including mini- and microstrains) have also been used. Evaluation of the primary irritation potential of transdermal systems should be tested prior to single application in humans, including prototypes and the final formulation. Evaluation of the cumulative irritation potential of transdermal systems should be tested prior to multiple applications in humans.

Primary irritation (one application of a transdermal system irrespective of duration of wear) is most often tested by modifications of the original Draize test. Draize type tests have been used by several government bodies, including the department of transportation, the consumer product safety commission, the environmental protection agency, and the OECD (Patrick and Maibach, 1994). Transdermal systems should be applied for the intended dosing interval in humans (e.g., for a 7-day transdermal system, apply for 7 days).

Additional tests on the components of a transdermal system, as well as on the final formulation and placebo, may include a cumulative/subchronic irritation study (more than one application, each for the intended clinical wear) and dermal toxicity study (Robinson and Perkins, 2002; Steinberg et al., 1975). The duration of subchronic irritation studies should be confirmed with the FDA, but is typically 28 days (e.g., four applications of a weekly application) or 90 days in duration, depending on the active ingredient and the intended use. Plasma concentrations are determined on the first and last day to substantiate systemic exposure during these studies (28–90 days). Release of drug from the transdermal system may also be determined by measuring residual drug in used systems. For both active and placebo systems, erythema and edema of the skin sites are also monitored, and clinical pathology and histology observations are made to establish dose-related drug effects. Here again, the system should be applied for the intended dosing interval in humans. Typically, transdermal systems are not applied to the same skin site on people, and therefore, applications should be rotated among two to four skin sites on the toxicology animal model (guinea pigs, rabbits, pigs). Comparative testing using a novel human 4 h patch has also been proposed for acute skin irritation testing (Basketter et al., 2004; Robinson et al., 2005).

43.3 SENSITIZATION

Skin sensitization, or contact sensitization, is a delayed type immune response mediated by T cells. Each transdermal system formulation should be tested in the guinea pig model prior to multiple applications in humans.

Numerous *in vivo* tests and strategies are available, developed, and have been adopted by several regulatory agencies to identify potential skin sensitizers (Basketter et al., 1995; Gerberick et al., 2000; Kimber et al., 2001a,b; Maurer et al., 1994; Ryan et al., 2000, 2001). Each transdermal system formulation should be tested in the guinea pig model prior to multiple applications in humans. The European Economic Community (EEC) suggests the guinea pig maximization test as the first test, based on the original literature and its validation with moderate or weak allergens.

43.3.1 Guinea Pig Model

The guinea pig is the animal most frequently used to evaluate the potential for transdermal systems to produce contact sensitization. The hairless guinea pig is also used as a predictive model to study irritation and sensitization. Hairless guinea pigs are derived from a natural mutation, are euthymic, and are hairless except for continuous growth of hair at the nose and feet. The hairless guinea pig strain offers a cost-effective alternative to the Hartley guinea pig strain, since depilation or shaving is not required. In addition, undue irritation during removal of bandages is reduced, and application sites are not obscured by hair growth during scoring. Hairless guinea pigs have been evaluated in primary skin irritation and sensitization studies (Buehler and Kreuzman, 1990; Chester et al., 1988).

Delayed contact hypersensitivity testing of transdermal delivery systems must not underpredict potential toxic effects. Protocols designed to test products that wash off the skin may not be optimal for systems that deliver drugs through the skin. The sensitization potential of the drug is assessed early in the development program, before the development of the transdermal product. This evaluation of the inherent sensitization potential of the compound may be done by intradermal injection models; for evaluation of compounds with good transdermal flux, intermediate formulations, or final formulations, a modified Buehler protocol may be used (Tsuchiya et al., 1982). This modified protocol may use five or more 24-h occlusive applications of materials over a 3-week period (Chester et al., 1988). Topical applications can be augmented by Freund's Complete Adjuvant (FCA) injections, with or without drug, to the shoulder region. Treatment sites for the first and last inductions are scored for erythema/edema at 2 and 24 h after removal of the test article. Approximately 2 weeks after the last topical application of the induction period, all groups are challenged with 24-h occlusive topical application of appropriate test and control formulations.

Modifications of these standard methods have been adopted to test transdermal systems. For example, transdermal systems are applied three times a week for 3 weeks. The protocol should include at least three groups: one group of at least 10 guinea pigs induced with the placebo formulation (final formulation with permeation enhancers if appropriate, but no drug), one group of 10 guinea pigs induced with the final formulation with drug, and a positive control group. The positive control group animals are typically induced with a topical application, not a transdermal system, of a known moderate to severe sensitizer to demonstrate that the animals can mount a sensitization response. This group may require only five animals. As with topical applications, transdermal applications can be augmented by FCA injections, with or without drug, to the shoulder region. After a rest period of 2 weeks, each animal in the transdermal group is challenged with both the placebo and active systems. This will differentiate any sensitization reactions to drug from those to excipient(s). If the intended dosing interval of the transdermal system is greater than 24 h, the design of sensitization studies may be modified, for example, each induction application may be 48 h instead of 24 h. If a second challenge is needed to confirm responses, the transdermal animals can be rechallenged 2 weeks after the first challenge. Challenges may include intradermal injections of the drug or each excipient/permeation enhancer to differentiate the causative compound. For each additional challenge, the challenge materials should be applied in the same manner to an additional group of five naïve guinea pigs to act as an irritation control group. For all challenges, skin sites are evaluated at 2, 24, and 48 h (or longer if indicated) after the test compound or the transdermal system is removed. The scoring system remains the same, and a reaction is generally considered positive when a combined erythema and edema score of 2 or greater is still present 48 h after removal of the system. Sensitization potential is characterized based on the number of animals exhibiting reactions (0–8% [weak] to 81–100% [extreme]).

43.3.2 Murine Models

When testing a component and not the transdermal system, murine models such as the Mouse Car Sensitivity Test (MEST) and Local Lymph Node Assays (LLNAs) have objective endpoints and allow evaluation of pigmented materials. A quantitative relationship among LLNA, guinea pig, and human skin sensitization assays has been established (Yamano et al., 2005; Schneider and Akkan, 2004; Basketter et al., 2005). Murine assays also reduce cost, test duration, number of animals used, and required care space.

43.3.3 Regulatory Position

In 1992, both the OECD and EEC reduced the number of primary recommended tests and accepted primarily the Buehler and the maximization tests; the EEC favors the maximization test as the first test (Maurer et al., 1994). It was recommended that tests be based on the original literature. In addition, validation should occur with moderate or weak allergens. Other validated protocols are acceptable in certain cases, and the OECD accepts the MEST and LLNA as screening tests. Positive results in these *in vitro* tests are sufficient, but negative results in mouse tests must be confirmed in guinea pig tests.

43.4 SUMMARY

The results of animal sensitization studies must be related to potential human hazards. Unfortunately, human populations show greater variability than animal test systems. This is particularly problematic because a negative sensitizer in the test does not guarantee that the compound will not sensitize humans. For example, standard predictive tests in guinea pigs indicated that clonidine was not a sensitizer. This observation was confirmed in clinical trials. Following introduction in the marketplace, a large number of users (19%) became sensitized to transdermal clonidine after prolonged use. Conversely, a weak sensitizer with good potential utility for therapy may not need to be abandoned, but may need to be patch tested in humans. This chapter describes toxicity

tests used for establishing the safety of a transdermal delivery system. In addition to sensitization and irritation potentials, standard preclinical testing procedures are required for any new drug to be approved for marketing. In the United States, the FDA treats all new transdermal dosage forms as NCEs; however, a transdermal system incorporating a drug or compound already approved in a different dosage form may have a swifter approval process. Systemic safety may not be an issue if the dosage for drugs to be delivered transdermally produces plasma levels far lower than those produced by marketed forms of the same drug. If systemic safety has already been adequately demonstrated, nonclinical studies, beyond evaluation of acute and cumulative irritation and sensitization, may be minimal or not required.

44.1 INTRODUCTION

Contact with external irritating agents, such as dishwashing liquid, enzymes, or raw meat, can result in irritant contact dermatitis (ICD), a localized nonimmunologic condition. ICD ensues when irritant stimuli overpower the defense and repair capacities of the skin (Goldner and Jackson, 1994; Walle, 2000). Exposure to potent irritants or exposure to mild irritants for an extended period of time will increase the likelihood of developing ICD.

Preventive measures, including the utilization of proper skin care, the avoidance of harsh soaps, and the use of protective garments such as gloves, will decrease the risk of irritant dermatitis occurring. In addition, it is of crucial importance to test the irritant potential of any substance that will be applied to human skin, so that its likelihood of inducing irritant dermatitis is known. Federal regulatory agencies require toxicity testing to determine the safety or hazard of various chemicals and products prior to human exposure. This information is used to properly classify and label products according to their potential hazard (Bashir and Maibach, 2000).

No one assay is able to accurately portray irritation in its entirety. This is because irritant dermatitis may result from either acute or cumulative injury, and may involve inflammation or skin necrosis (corrosive). A number of animal, human, and *in vitro* test methods have been developed, each portraying some but not all aspects of irritation. Each model has its unique benefits and limitations.

44.2 ANIMAL MODELS

44.2.1 Draize Rabbit Assay

To evaluate primary irritation and corrosion, the Draize animal model or one of its modifications is utilized. The Draize rabbit test was developed in 1944, and has since been adopted in the U.S. Federal Hazardous Substance Act (FHSA) (code of FR) (Patrick and Maibach, 1989). The test involves two (1 in.^{2}) test sites on the dorsal skin of six albino rabbits. One site is abraded (through use of a hypodermic needle across the rabbit skin) and the other site remains intact. The stratum corneum is broken on the abraded site, without loss of blood. The undiluted "irritant" materials (0.5 g for solids or 0.5 mL for liquids) are placed on a patch and applied to the test sites. They are secured with two layers of surgical gauze (1 in. [2.5 cm] squared) and tape. The animal is wrapped in cloth so that the

patches are secure for a 24-h period. Assessment of erythema and edema, utilizing the scale noted in Table 44.1, takes place 24 and 72 h following patch application. Severe reactions are again assessed on days 7 or 14. Radiolabeled tracers or biochemical techniques to monitor skin healing is also utilized by some investigators. Other investigators supplement with histological evaluation of skin tissue (Mezei et al., 1966; Murphy et al., 1979).

The Draize test ultimately quantifies irritation with the primary irritation index (PII), which averages the erythema and edema scores of each test site and then adds the averages together. Materials producing a PII of <2 are considered nonirritating, 2–5 mildly irritating, >5 severely irritating and require precautionary labeling. Subsequent studies have demonstrated that the PII is somewhat subjective because the scoring of erythema and edema require clinical judgment (Patil et al., 1998).

Main critics of the Draize test oppose the harsh treatment of animals. They argue that the Draize test is unreliable in distinguishing between mild and moderate irritants. Furthermore, they believe the Draize is not an accurate predictor of skin irritancy as it does not include vesiculation, severe eschar formation, or ulceration in evaluating the PII. Finally, they argue that the Draize procedure is not reproducible (Weil and Scala, 1971) and they question its relevance with regard to human experience (Edwards, 1972; Nixon et al., 1975; Shillaker et al., 1989). Proponents of the Draize test point out that the test is somewhat inaccurate but it generally overpredicts the severity of skin damage produced by chemicals, and thereby errs on the side of safety for the consumer (Patil et al., 1996). This topic is hotly debated. In the meantime, the Draize assays are recommended by regulatory bodies.

44.2.2 Modified Draize Models

The Draize test has been modified in response to harsh criticisms over the past years. Alterations include changing the preferred species, use of fewer animals, testing on only intact skin and reduction of the exposure period to irritants. Please note Table 44.2 for a comparison of the modified Draize tests.

44.2.3 Cumulative Irritation Assays

Frequently, ICD is produced through cumulative exposure to a weak irritant. While the Draize assay assesses acute exposure to a strong irritant, there have been many assays developed to measure repetitive, cumulative irritation. One such assay was developed by Justice et al. (1961). They measured epidermal erosion through a repeat animal patch (RAP) test for comparing irritant potential of surfactants. In their study, solutions were occlusively applied to the clipped dorsum of albino mice for a 10-min interval. The process was repeated seven times and the skin was subsequently examined microscopically for epidermal erosion.

The repetitive irritation test (RIT), as described by Frosch et al. (1993), utilizes guinea pigs as the animal model in determining the protective efficacy of creams against various chemical irritants. In one study, the irritants sodium hydroxide (NaOH), sodium lauryl sulfate (SLS), and toluene were administered daily for 2 weeks to shaved dorsal skin of guinea pigs. Barrier creams were applied 2 h prior to and immediately following irritant exposure. Visual scoring, laser Doppler flowmetry (LDF), and transepidermal water loss (TEWL) quantified resultant erythema. The study found one barrier cream effective against SLS and toluene injury, while another barrier cream studied did not show any efficacy. In general, the RIT is most useful in evaluating the efficacy of barrier creams in preventing cumulative irritation.

To rank products for their irritant potential, repeat application patch tests have been developed. Diluted potential irritants are occlusively applied to the same site for 15–21 days. The sensitivity of the test is influenced by both the duration

of occlusion and the type of patch used to apply the irritants. In general, a longer occlusive period will result in enhanced percutaneous penetration. Similarly, the Draize-type gauze dressing will produce less percutaneous penetration as compared to the Duhring metal chambers. To facilitate interpretation of test results, a reference material that is of similar use or which produces a known effect is incorporated into the test. Rabbits and guinea pigs are the most commonly used animal species in the repeat application test (Phillips et al., 1972; Wahlberg, 1993). In a recent study, Kobayashi et al. (1999) studied the effects of propranolol as an irritant utilizing both primary and cumulative irritation assays. In both assays, skin irritation and histopathological changes were observed in all guinea pigs treated with propranolol, and those tended to increase with the increase of propranolol dosage. The skin reactions increased with the application times of propranolol up to 7 days in the cumulative skin irritation study. Scoring of the test sites were made in accordance with the following scale: 0 = no reaction, 1+ = mild erythema covering the entire patch area, 2+ = erythema and edema, 3+ = erythema, edema, and vesicles, 4+ = erythema, edema, and bullae.

One variation of the repeat application patch test involves measuring the edema-producing capacity of irritants utilizing a guinea pig model. Visual inspection and Harpenden calipers measure skin thickness following application of irritants for 3–21 days. This model demonstrates clear dose–response relationships and discriminating power for all irritants, excluding acids and alkalis (Wahlberg, 1993).

Open application assays, developed by Marzulli and Maibach (1975), involve application of irritants onto the backs of rabbits 16 times over a 3-week period. Visual scoring of erythema and skin thickness measurements are utilized to quantify results. A high degree of correlation has been observed when comparing erythema and skin thickness data. In addition, the results of 60 test substances in rabbits strongly correlated with the results of cumulative irritation studies in man, suggesting that the rabbit assay is a useful model.

A modified open application assay was performed by Anderson et al. (1986). In his assay, irritants are applied once a day for 3 days to a 1-cm^2 test site on the backs of guinea pigs. Sites are evaluated visually for erythema and edema. In addition, biopsies are taken and skin samples are stained with May–Grunward–Giemsa under oil immersion, to evaluate epidermal thickness and dermal infiltration. Irritants are compared with the standard irritant, 2% SLS, and their potency is ranked. Extensive processing involved in properly performing this assay may limit its usefulness.

44.2.4 Immersion Assay

Aqueous detergent solutions and other surfactant-based products are evaluated for irritancy using the guinea pig immersion assay (Calandra, 1971; MacMillan et al., 1975; Gupta et al., 1992). This assay involves placing 10 guinea pigs in a restraining device that is immersed in a 40°C test solution for 4 h daily for a total of 3 days (Kooyman and Snyder, 1942). The restraining apparatus allows the guinea pig's head to be above the solution. Twenty-four hours following the final immersion, the animals' flanks are shaved and evaluated for erythema, edema, and fissures. In one study, the dermatotoxic effects of detergents in guinea pigs and humans were concomitantly tested (Gupta et al., 1992). The immersion assay was utilized to test guinea pigs, while the patch assay tested humans. Irritation of guinea pig skin led to epidermal erosion and a 40–60% increase in histamine content. Seven of eight human subjects had a positive patch test to the same irritants, indicating a strong correlation between the guinea pig and human models.

44.2.5 Mouse Ear Model

The mouse ear model is used to evaluate the degree of inflammation associated with shampoos or surfactant-based products. Uttley and Van Abbe (1973) first described the mouse model when they applied undiluted shampoos to one ear of mice daily for 4 days. They visually assessed the erythema, vessel dilation, and edema. However, the anesthetic used to anesthetize the mice in this study may have altered the development of inflammation and confounded results.

More recently, Patrick and Maibach (1987) applied surfactants to measure mouse ear thickness at various time points following irritant application. Pretreating the ear with croton oil or 12-*O*-tetradecanoylphorbol 13-acetate 72 h prior to irritant application increased the sensitivity of the assay. This assay was most useful in testing surfactant-based products and had little efficacy with oily or highly perfumed materials.

44.2.6 Recent Assays

Recent animal assays have been developed to quantify irritant response. Humphrey et al. (1993) measured Evans blue dye recovered from rat skin after exposing the skin to inflammatory agents. Trush et al. (1994) assessed the dermal inflammatory response to numerous irritants by measuring the level of myeloperoxidase enzyme in polymorphonuclear leukocytes in young CD-1 mice.

44.2.7 Conclusion

Animal assays must be interpreted with caution. Dose–response measurements must be followed. Draize scores are most accurate when compared to related compounds with a record of human exposure. It is important to note that occlusive application does not enhance percutaneous penetration for all materials.

Responses in animal models, particularly the guinea pig and the rabbit, have a high degree of correlation to those of humans, but some inconsistencies have occurred. Major discrepancies in irritant response between different animal species tested under identical conditions have occurred (Llewellyn et al., 1972; Gilman et al., 1978), particularly with regard to weak irritants and colored materials. Subjective visual scoring techniques have accounted for some of these discrepancies. It is prudent to utilize other methodologies in addition to the animal model when evaluating a putative irritant.

44.3 *IN VITRO* ASSAYS

In vitro skin irritation assays are of potential benefit in addressing humane concerns associated with animal testing. These "alternative" methods may potentially reduce the number of animals needed in irritation testing, or in some cases may fully replace the need to use animals. In recent years, a number of *in vitro* skin irritation assays have been developed. However, most of these have not been evaluated in validation studies to determine their usefulness, limitations, and compliance with regulatory testing requirements. Furthermore, dose–response relationships have not been established for *in vitro* methods.

Studies evaluating *in vitro* testing thus far indicate usefulness in predicting starting doses for *in vivo* studies, potentially reducing the number of animals used for such determinations. Additionally, other studies suggest an association between *in vitro* cytotoxicity and human lethal blood concentrations. The U.S. Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) and the U.S. National Toxicology Program Center for the Evaluation of Alternative Toxicological Methods (NICEATM) were established to evaluate *in vitro* irritant testing. To date, there are four approved irritation assays, namely, Corrositex®, EpiDerm™, EPISKIN™, and Rat Skin Transcutaneous Electrical Resistance (TER) Assays.

Corrositex is a collagen matrix acting as synthetic skin, and is used to assess the dermal corrosivity potential of chemicals. Should a chemical pass through the biobarrier by diffusion or destruction, Corrositex elicits a color change in the underlying liquid chemical detection system (CDS). Corrositex is currently used by the U.S. Department of Transportation (U.S. DOT) to assign categories of corrosivity for labeling purposes according to United Nations (UN) guidelines. However, its use is limited to specific chemical classes, including acids, acid derivatives, acylhalides, alkylamines and polyalkyamines, bases, cholorosilanes, metal halides, and oxyhalides.

A peer review panel of NICEATM and ICCVAM elucidated some of the advantages to Corrositex, including its possible usefulness in replacing or reducing the number of animals required. Positive test results often eliminate the need for animal testing. When further animal testing is necessary, often only one animal is required to confirm a corrosive chemical. The panel also concluded that most of the chemicals identified as negative by Corrositex or nonqualifying in the detection system are unlikely to be corrosive when tested on animals for irritation potential.

EpiDerm(EPI-200) is a three-dimensional human skin model that uses cell viability as a measure of corrosivity. It has been utilized with several common tests of cytotoxicity and irritancy, including MTT, IL-la, PGE_2, LDH, and sodium fluorescein permeability.

EPISKIN is a three-dimensional human skin model comprised of a reconstructed epidermis and a functional stratum corneum. In a study supported by the European Center for the Validation of Alternative Methods (ECVAM), EPISKIN was useful in testing all types of potential irritants, including organic acids, organic bases, neutral organics, inorganic acids, inorganic bases, inorganic salts, electrophiles, phenols and soaps/surfactants. With both EPISKIN and EpiDerm, the test material is topically applied to the skin for up to 4 h with subsequent assessment of the effects on cell viability.

***In Vitro* Assays**

Assay	Description	Methodology
Corrositex	Collagen matrix acting as synthetic skin	A color change in the underlying liquid chemical detection system when irritant passes through matrix
EpiDerm	Three-dimensional matrix acting as synthetic skin	Cell viability as a measure of corrosivity
EPISKIN	Three-dimensional matrix acting as synthetic skin	Cell viability as a measure of corrosivity
TER	Skin disks taken from the pelts of humanely killed young rats	Significantly lower inherent transcutaneous electrical resistance when skin barrier is compromised

In the TER Assay, irritants will portray a loss of normal stratum corneum integrity and barrier function. A reduced barrier function will exhibit a significantly lower inherent transcutaneous electrical resistance. TER involves up to 24 h application of test material to the epidermal surfaces of skin disks taken from the pelts of humanely killed young rats. Comparing EpiDerm, EPISKIN, and TER, only EPISKIN was able to significantly distinguish between two particular types of chemicals. Currently, the ICCVAM recommends that EpiDerm, EPISKIN, and TER are used to assess the dermal corrosivity potential of chemicals in a "weight-of-evidence" approach. In general, positive corrosivity tests will not require further testing, while negative corrosivity will.

In vitro assays are promising and have significant interest to toxicologists. The future promises a greater use for *in vitro* irritancy testing.

44.4 HUMAN MODELS

Following the development of the patch test, Draize et al. suggested a 24-h single-application patch test in humans. Human testing facilitates extrapolation of data to the clinical setting. Many variations of the single-application test have been developed. Testing is often performed on undiseased skin (Skog, 1960) of the dorsal upper arm or back. The required test area is small and up to 10 materials may be tested simultaneously and compared. A reference irritant substance is often included to account for variability in test responses. In general, screening of new materials involves open application on the back or dorsal upper arm for a short amount of time (30 min to 1 h) to minimize potential adverse events in subjects.

44.4.1 Single-Application Patch Testing

The National Academy of Sciences (National Academy of Sciences and Committee for the Revision of NAS Publication 1138, 1977) recommended a 4-h single-application patch test protocol for routine testing of skin irritation in humans. In general, patches are occluded onto the dorsal upper arm or back skin of patients. The degree of occlusion varies according to the type of occlusive device; the Hilltop or Duhring chambers or an occlusive tape will enhance percutaneous penetration as compared to a nonocclusive tape or cotton bandage (Patil et al., 1996). Potentially volatile materials should always be tested with a nonocclusive tape.

Exposure time to the putative irritant varies greatly, and is often customized by the investigator. Volatile chemicals are generally applied for 30 min to 1 h while some chemicals have been applied for more than 24 h.

Following patch removal, skin is rinsed with water to remove residue. Skin responses are evaluated 30 min to 1 h following patch removal to allow hydration and pressure effects of the patch to subside. Another evaluation is performed 24 h following patch removal. The animal Draize scale is used to analyze test results (see Table 44.1). The Draize scale does not include papular, vesicular, or bullous responses; other scales have been developed to address these needs.

Single-application patch tests generally heal within 1 week. Depigmentation at the test site results in some subjects.

44.4.2 Cumulative Irritation Test

Utilizing statistical analysis of test data, Kligman and Wooding (1967) calculated the IT50 (time to produce irritation in 50% of subjects) and ID50 (dose required to produce irritation in 50% of subjects following a 24-h exposure). Their work formed the basis for the 21-day cumulative irritation assay. The "21 day assay" is used to screen new formulas prior to marketing. The original assay involved application of an 1-in. (2.5 cm) square of Webril saturated with the test material (either liquid or 0.5 g of viscous substance) to the skin of the undamaged upper back. Occlusive tape secured the patch. Twenty-four hours after patch application, the test site is examined and the patch is reapplied. The test is repeated for 21 days.

Two modifications of the cumulative irritation test were studied by Wigger-Alberti et al. (1997a). One assay involved Finn chamber application of metal-working fluids onto the midback of volunteers for 1 day. The sites were evaluated and the fluids were then reapplied for an additional 2 days. In the other assay, a 2-week, 6-h/day repetitive irritation test (excluding weekends) was utilized. Better discrimination of irritancy and shorter duration was observed with the 3-day model.

44.4.3 Chamber Scarification Test

The chamber scarification test assesses the irritancy potential of materials on damaged skin (Frosch and Kligman, 1976; 1977). Subjects included in this assay are highly sensitive to 24 h exposure to 5% SLS (they form vesicles, severe erythema, and edema postapplication). Six to eight 10 mm^2 areas on the volar forearms are scratched eight times with a 30-gage needle. Scarification damages the epidermal layer without drawing blood. Four scratches are parallel and the other four are perpendicular to the test site. 0.1 g of test material (or 0.1 mL of liquid) is then applied to the scarified area for 24 h via Duhring chambers. Nonocclusive tape is used to secure the chambers in place. With fresh specimens, patches are applied daily for 3 days. A visual scoring scale is used to quantify test results 30 min following patch removal. An analogous area of intact skin must be scored as well, so that evaluation is based upon comparison between compromised and intact skin. The visual score of scarified test sites divided by the score of intact test sites, known as the scaarification index, allows this comparison to be made. The relationship of this assay to prediction of irritant response from routine use has yet to be established.

44.4.4 Immersion Tests

Patch tests often overpredict the irritant potential of some materials. Immersion tests were established to improve irritancy prediction by mimicking consumer use. Kooyman and Snyder (1942) developed the arm immersion technique to compare the relative irritancy of two soap or detergent products. Soap solutions of up to 3% are prepared in troughs and subjects immersed one hand and forearm in each trough, comparing different products or concentrations. Temperature is maintained at 41°C (105°F). The exposure period varies between 10 and 15 min a day for a total of 5 days or until observable irritation is produced on both arms. The antecubital fossa is generally the first area to experience irritation, followed by the hands (Justice et al., 1961; Kooyman and Snyder, 1942).

More recently, variations on the arm immersion technique have developed so that the antecubital fossa and the hands are separately tested. Variations incorporate different dosing regimens or measuring different endpoints. Clarys et al. (1997) and Clarys and Barel (1997) investigated the effects of temperature and anionic character on the degree of irritation caused by detergents. TEWL, erythema (colorimetry, a* parameter), and skin dryness (capacitance) were used to quantify test results. The irritant response was increased by higher temperature and higher anionic content. Utilizing a modified arm immersion technique, Allenby et al. (1993) noticed that once skin had been compromised (erythema of 1+ on a visual scale), irritants applied to the forearm and back caused an exaggerated response.

44.4.5 Soap Chamber Technique

The "chapping" potential of bar soaps is evaluated with the soap chamber technique, developed by Frosch and Kligman (1979). While patch testing is useful in predicting erythema, it does not address the dryness, flaking, and fissuring observed with bar soap use. Using this method, 0.1 mL of an 8% soap solution is applied to the forearm via Duhring chambers fitted

with Webril pads. Nonocclusive tape is used to secure the chambers. Patches are applied for 24 h on day 1 and 6 h on days 2–5. If severe erythema at the test site occurs, the investigator must discontinue the study. Skin responses are evaluated with visual scoring of erythema, scaling, and fissures. This test correlates well with skin-washing procedures but tends to overpredict irritant response of some materials.

44.4.6 Protective Barrier Assessment

The skin barrier function assays test the efficacy of protective creams in preventing an irritant response. Zhai et al. (1998) studied the effect of barrier creams in reducing erythema, edema, vesiculation, and maceration. Subjects were given creams and then irritated with either SLS or ammonium hydroxide. Paraffin wax in cetyl alcohol was the most effective in preventing irritation. In another study by Wigger-Alberti and Elsner (1997a), petrolatum was applied to the backs of 20 subjects. Subjects were then exposed to SLS, NaOH, toluene, and lactic acid. Irritation was assessed by visual scoring, TEWL, and colorimetry. Petrolatum was found to be an effective barrier cream against SLS, NaOH, and lactic acid and moderately effective against toluene.

Frosch et al. (1993) revised the RIT (see Section 44.2) to evaluate the effect of two barrier creams in preventing SLS-induced irritation. The irritant was applied to the ventral forearms of human subjects for 30 min daily for 2 weeks. Visual scoring, LDF, colorimetry, and TEWL were utilized to assess resultant erythema. TEWL was found most useful in quantifying results, while colorimetry was the least beneficial.

44.4.7 Bioengineering Methods

Modern bioengineering methods utilized to quantify test results include TEWL, capacitance, ultrasound, LDF, spectroscopy, and chromametry (colorimetry). Most of the assays described were developed before the introduction of these bioengineering methods. These methods allow a more precise quantification of test results. These techniques are described in detail by Patil et al. (1998).

45.1 INTRODUCTION

Evaluation of skin irritancy is important because it may be useful in the prevention of irritant contact dermatitis. Irritant contact dermatitis is a multifactorial disease and it embraces a wide spectrum of reactions where different mechanisms are involved. Therefore, there is no single method to evaluate and predict all kinds of irritant contact dermatitis.

When irritancy is strong, visible inflammatory changes (acute irritant contact dermatitis) occur on the skin, and the evaluation of strong irritancy is relatively easy. When irritancy is weak, no visible reaction is induced. However, repeated and damaging insults to the skin by weak irritants often cause skin barrier dysfunction and cumulative irritant dermatitis. It is difficult to predict such weak irritation to the skin. Using recent bioengineering techniques such as evaporimeter, laser-Doppler flowmetry, ultrasound, impedance meter, colorimeter, etc., several investigators have tried to evaluate nonvisible cutaneous changes due to weak skin irritancy. As these methods apparently give information about different aspects in cutaneous irritation and skin function,[1] weak skin irritancy cannot be fully evaluated by any single method.

Kawai's method/nitrocellulose replica method is used to predict weak skin irritancy. To observe such a subtle skin damage, Kawai[2] observed replicas of stratum corneum microscopically and reported several skin surface changes occurring after irritant application in spite of no visible inflammatory changes. Using the replica method, we have evaluated over 18,000 commercial products including new chemicals, cosmetics, textiles, etc., and discovered that the incidence of complaints for skin irritation against tested products correlated well with our evaluations for skin safety.[3] In this chapter, we address Kawai's method/nitrocellulose replica method concisely.

45.2 METHOD

45.2.1 Subjects

A panel for a test consists of 20 healthy adults with no less than one-third belonging to either sex. They have no past or present history of skin disease. Informed consent is obtained from all subjects in each test. About 140 people are registered for the test and people who have participated in a test performed within the past month are not eligible for another test.

45.2.2 Test Samples and Control Substance

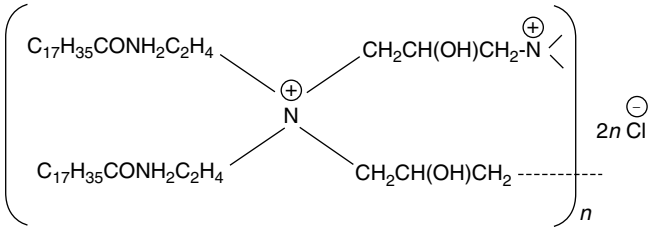
The test is applied to substances to be used in contact with the skin such as textiles, cosmetics, detergents, drugs, etc. As the aim for the Kawai method is to evaluate weak irritancy, as is the case with daily commodities, final products rather than raw materials are usually tested. For the safety of the human volunteer, unknown chemicals and known corrosive and severe irritants are not applied to the test.

Susceptibility to irritants differs by individual. Thus, there may be differences of susceptibility among each panel and the irritancy measured using one panel may be different from the irritancy measured using another panel. To avoid this, we use the same control substance in all tests. Every time we test, the reaction of the control substance is observed. The control substance and its preparation method are as shown in Table 45.1.

45.2.3 Irritant Application

Test substances are applied on the inner sides of the upper arm by semi-open test (Figure 45.1): they are applied directly onto a 1.5 cm^2 area of skin, and then two pieces of 2 cm^2 gauze are put on each sample and fixed gently with paper plaster. Thus, the substances are not completely occluded as closed patch tests and they approach a natural condition as found in daily life (for example, clothing, cosmetics, medicaments, etc.). The patches are removed after 24 h and the skin replicas are taken 30 min later.

Recently, we showed that occlusive patch tests can cause significant skin surface changes by observing the replicas microscopically.[4] Lindberg and Forslind[5] reported that simple occlusion for 3, 6, 24, and 48 h with aluminum cups used for patch testing causes morphological alterations in Langerhans cells, apposition of mononuclear cells, and increased number of mononuclear cells in the epidermis. Kligman[6] also mentioned that occlusion of the skin by polyethylene films can induce cytologic damage to the epidermis and dermis in as little as 48 h. Thus, closed patch tests are not appropriate for the replica method. We confirmed that the semi-open test for 24 h did not cause morphological changes on the skin surface.



45.2.4 Obtaining the Skin Replica

The procedure of taking skin replicas is shown in Figure 45.2. Specifically, a nitrocellulose disk, which is a round and translucent plate 21 mm in diameter, is coated evenly with *n*-butyl acetate on the site of the patch tests, so that the disk surface becomes softened. Then, the disk is applied carefully to the skin surface. After 1–2 min, when the disk surface is solidified, the disk is removed gently from the skin surface and is attached onto a mount.

TABLE 45.1
Control Substance—Di(Stearo Amino Ethylene)Amide Epichlor Hydrine Condensate

Ingredients

Octadecanamid *N N′* -(imino diethylene) bis, polymer with 1-chloro-2,3-epoxypropane

Preparation

Cloth used: Gauze of Japanese pharmacopia (washed by rubbing in warm water and dried)
Concentration of treatment: 2.5% aqueous solution

Soaking: 1 dip 1 nip (at 40°C for 20 s)
Wet pick up: 100%

Drying: 100°C for 7 min
Target add-on: 1% (to the pure fibrous content)

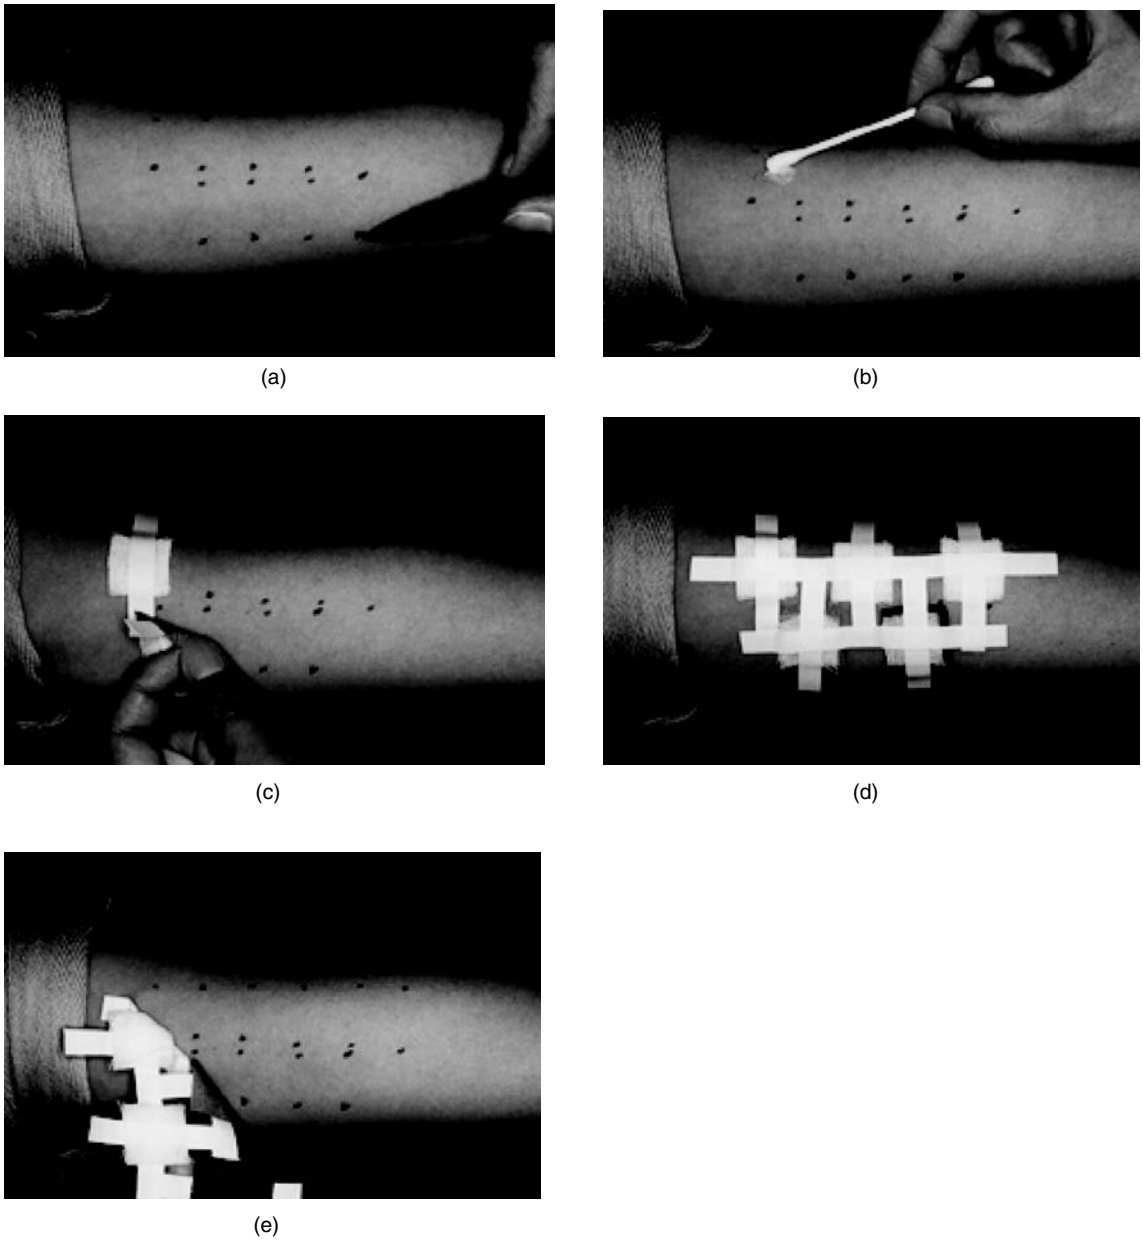


FIGURE 45.1 Irritant application. (a) Indicate the test sites with a marker. (b) A 1.5 cm^2 patch is applied per test sample. (c) Two pieces of gauze, 2 cm^2, are put on each sample and secured by paper plaster. (d) One test consists of four points each on the right and left forearms: eight patches in total of which one is a control sample. (e) After 24 h of application, the patches are removed. The test sites for this method are *the inner sides of the upper arm*.

45.2.5 Observation

The specimens are observed from all fields carefully under a microscope with a 50× magnification. We use a binocular microscope and a stereomicroscope.

45.3 OBSERVED REPLICA PICTURES UNDER MICROSCOPE

A replica finding of the normal skin of the inner side of the arm is shown in Figure 45.3. Several skin surface changes are observed after an irritant patch testing, including round ridges (Figure 45.4), the appearance of deepened skin furrows (Figure 45.5), membranous desquamation (Figure 45.6, a phenomenon in which the corneum is detached as a thick membrane), and loss of normal triangular configuration of the skin furrow pattern (Figure 45.7).

45.3.1 Normal Skin

In normal cases, the skin replica of the inner sides of the upper arm shows a triangular configuration of skin furrows

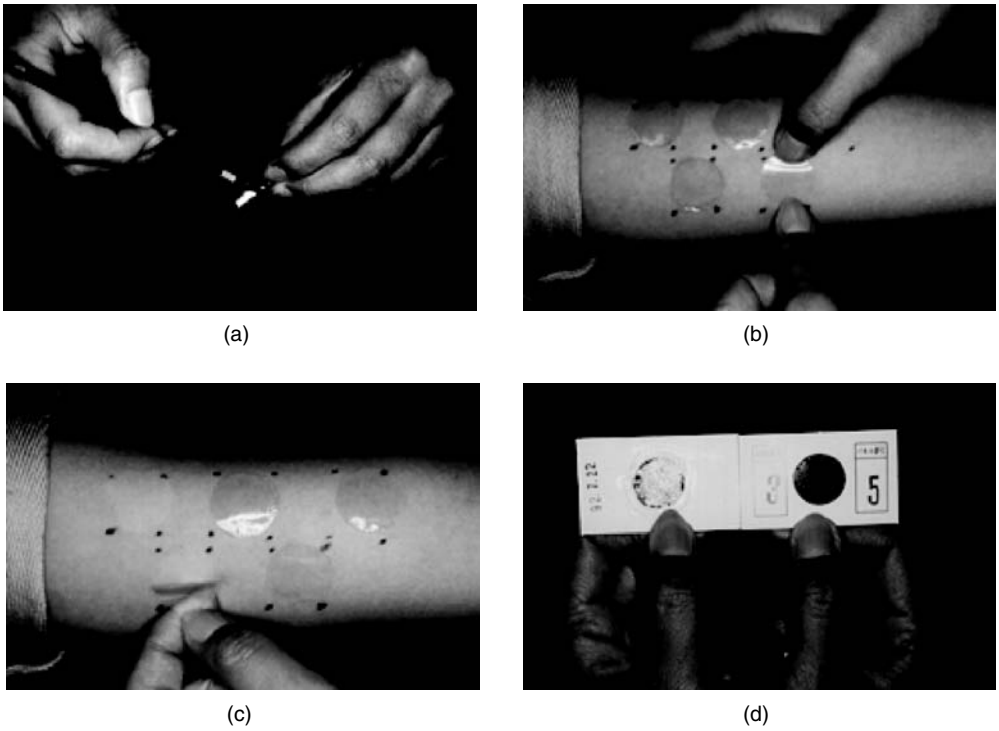

FIGURE 45.2 Obtaining the skin replica. (a) A nitrocellulose disk is coated evenly with *n*-butyl acetate. (b) The disk is applied carefully to the skin surface. (c) After 1–2 min, the disk is removed gently from the skin surface. (d) The resulting skin replica is attached to a mount with a hollow center. (Note that care should be taken not to touch the replica surface.)

seen as a thin line at low magnification (×10–×50). Under stronger magnification (×100), the tertiary lines, which are the limits of the corneocytes, can be seen.

Structural relief of skin replicas from various body sites is not constant. We believe that the inner side of the upper arm is the best site for irritant application, because structural relief of the replicas and the resulting data from the inner sides of the upper arm is most constant and reproducible.[7]

45.3.2 Round Ridges

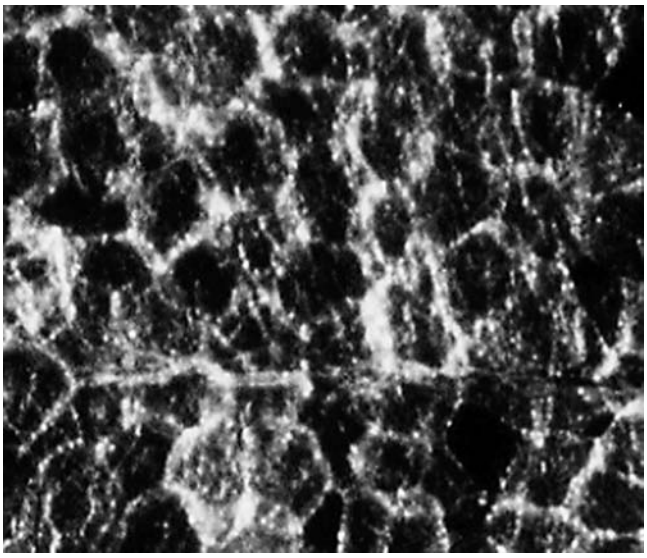
Round ridges are a phenomenon in which round or curved lines are observed in the triangular ridges (Figure 45.4). It is considered that this change is due to transient, microscopic edema of the horny layer of the skin. Round ridges are seen in skin, which has been wiped with diluted soap solution or alcohol, and can also be seen in about 40% of generally healthy individuals.

45.3.3 Deepened Skin Furrows

The appearance of deepened skin furrows is the most frequent and sensitive change which occurs on the skin after irritant application. This change is well observed under a stereomicroscope. As shown in Figure 45.5, normal skin shows thin lines running along skin furrows, whereas an abnormal region shows wide translucent bands, which indicates deepened skin furrows.

Although skin with the change of deepened skin furrows develops no visible inflammatory changes such as erythema and edema, it shows intercellular edema in the epidermis and exocytosis of mononuclear cells microscopically (Figure 45.8). This means epidermal inflammatory changes occur before the damage becomes clinically evident. Interestingly, there is no significant change in the horny layer.

45.3.4 Membranous Scale



This is a phenomenon in which the corneum is detached as a thick membrane (Figures 45.6 and 45.9). This change is thought to be the result of severe damage of the stratum corneum. It is observed after strong irritant application or after adhesive tape is removed from the skin.

45.3.5 The Loss of the Triangle Configuration of the Skin Furrow Pattern

The loss of the triangle configuration of the skin furrow pattern is caused by two different mechanisms (Figure 45.9): one is the result of destructive changes of the skin furrows by severe damage of the stratum corneum. Membranous desquamation is frequently observed with this destructive change. Thus it may be observed when the replica is taken after the removal of

(×50 under a microscope)

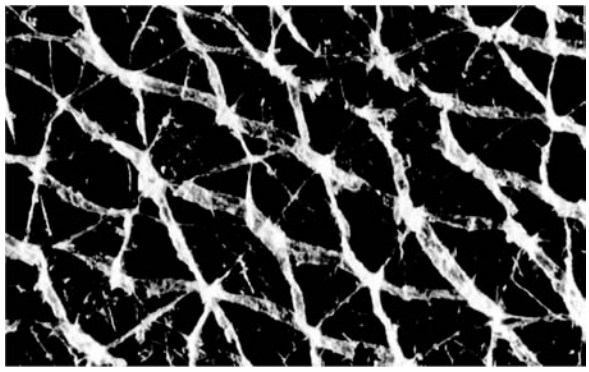
FIGURE 45.3 Normal replica picture of the skin. In normal cases, the skin replica shows triangular configuration of skin furrows seen as thin lines. Under higher magnification (×100), the tertiary lines, which are the limits of the corneocytes, can be seen.

membranous scale. It may also be the result of severe dermal edema. Contact urticaria to balsam of Peru caused the loss of the skin furrow pattern.[8] As the skin furrows are pushed up by dermal edema, they become shallow or disappear. The change by the urticaria, however, does not cause the loss of the normal triangular pattern, and it occurs only after severe urticaria. Probably loss of triangular minor furrows by the destructive change of the horny layer is much more frequently observed in irritant patch testings than those by dermal edema.



45.3.6 Replica Pictures and the Degree of Skin Irritancy

Figure 45.10 summarizes the relationship between replica pictures and the degree of skin irritancy. Round ridges and deepened skin furrows are thought to be reversible changes

(×50 under a microscope)

FIGURE 45.4 Round ridges. Round ridges are a phenomenon in which round or curved lines are observed in the triangular ridges. It is considered that this change is due to transient, microscopic edema of the horny layer of the skin. and the results of mild damage of the skin, while membranous desquamation and loss of normal triangular configuration of the skin furrow pattern are thought to be irreversible changes and the results of more severe damage.

45.4 EVALUATION OF REPLICA PICTURES

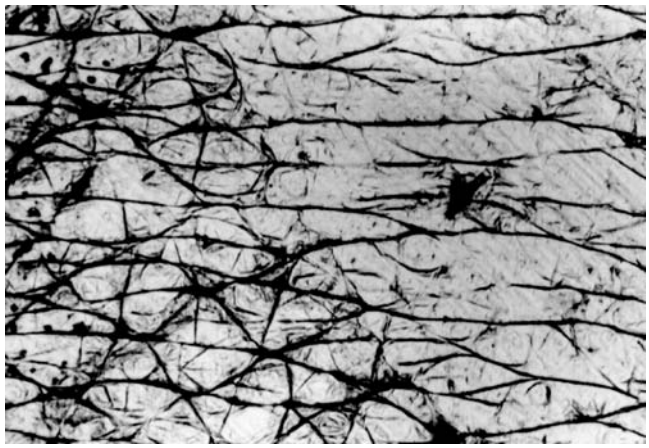
45.4.1 Criteria for Judgment of Skin Irritancy

We have evaluated skin irritancy of products, which come into contact with the skin by a specific criterion for more than 30 years.

The replicas taken from the 20 subjects, after a 24-h semiopen patch test, are observed microscopically and the abnormal changes, including round ridges, deepened skin furrows, membranous desquamation, and loss of triangular configuration of the furrow, are recorded. According to the degree of abnormal reaction as observed in the replica, there are four ranks of judgment of skin irritancy. Criteria for this are as follows.

45.4.1.1 Negative

No change is observed both microscopically and macroscopically, or the abnormal reaction is less severe than the reaction to the control substance. As 40% of the normal skin shows round ridges, this change is not thought to be irritant reaction.



45.4.1.2 Grade 1 (Almost Negative)

B score is defined as the number of subjects who show deepened skin furrows from the control substance, subtracted from the number of subjects who show the same reaction from the test substance. In this case, B score is counted only when the replica shows deepened skin furrows for more than 50% of the area of the sample.

If the B score is <2, and there are no other changes such as loss of the triangle configuration of the skin furrows, membranous desquamation on the replica, or visible changes on the skin, the judgment is "grade 1 (almost negative)."

(×50 under a microscope)

(×50 under a microscope)

FIGURE 45.7 The loss of the triangle configuration of the skin furrow pattern. In Figure 45.7, the normal structure of the skin surface was destroyed and the triangular skin furrow pattern was lost. This is caused by two different mechanisms: one is the result of destructive changes of the skin furrows by severe damage of the stratum corneum. Membranous desquamation is frequently observed with this destructive change. Thus, this may be observed when the replica is taken after the removal of membranous scale. The other is the result of dermal edema. Actually, urticaria shows similar changes on the replica. As the skin furrows are pushed up by dermal edema, they become shallow or disappear. The change by urticaria, however, does not cause the loss of the normal triangular pattern. The loss of triangular minor furrows by the destructive change of the horny layer is much more frequently observed than those by dermal edema in irritant patch testings.

45.4.1.3 Grade 2 (Almost Positive)

When the B score is 3, and there are no other changes such as loss of the triangle configuration of the skin furrows, membranous desquamation on the replica, or visible change on the skin, the judgment is "grade 2 (almost positive)."

45.4.1.4 Grade 3 (Positive)

When the B score is >4, or if one or more subjects show loss of the triangle configuration of the skin furrow pattern or membranous desquamation, the judgment is "grade 3 (positive)."

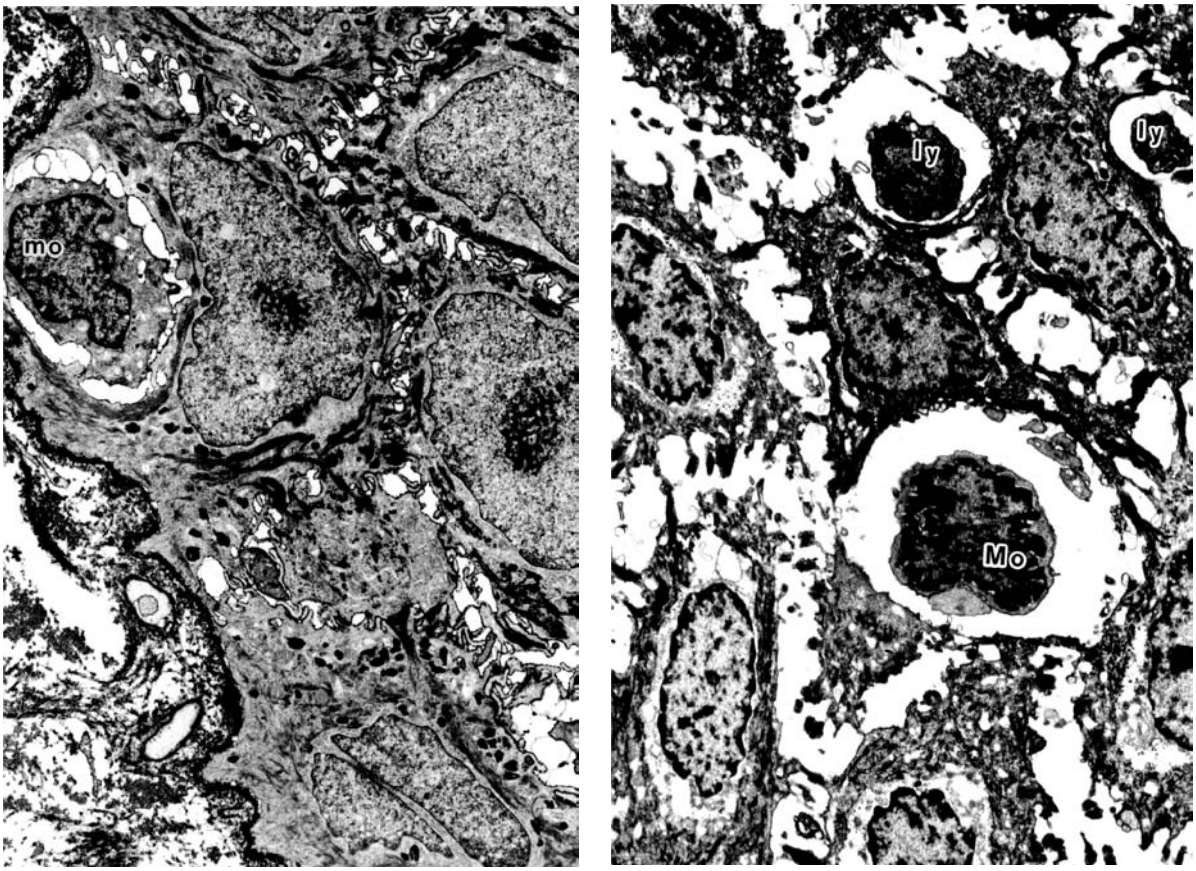


FIGURE 45.8 Histologic finding of the normal skin and the skin with deepened furrows. Epidermal intercellular edema and infiltration of mononuclear cells were found in the skin with deepened furrows.

45.4.1.5 Grade 4 (Positive Macroscopically)

When the skin shows any macroscopic inflammatory change (redness, swelling, etc.), the judgment is "positive macroscopically."

The judgment of "negative" and "grade 1 (almost negative)" means the test product has relatively weak subclinical irritancy, "grade 2 (almost positive)," and "grade 3 (positive)" mean it has relatively strong subclinical irritancy. Grade 4 means that the test product has clinically overt irritancy.

45.4.2 Follow-Up Study

Using the Kawai method, in the past 30 years we have evaluated more than 18,000 commercial products based on the criteria mentioned above. We have reviewed the incidence of complaints of skin irritation against tested products three times and the results were similar each time. From the results[3] of the third follow-up study, which investigated 2796 products tested from 1980 to 1991, the incidence of claims against products judged negative or grade 1 was 4.2%, and the incidence of claims against products judged grade 2 or grade 3 was 12.1%. Therefore, our judgments correlated well with the incidence of claims. We believe that the replica method can be used as a product test for screening skin irritancy.

45.4.3 Scoring of Deepened Skin Furrows and Experimental Investigations of Weak Skin Irritancy

The appearance of deepened skin furrows is the most frequent and sensitive change which occurs on the skin after irritant application. Thus, evaluation of this change is most important to judge the irritancy of products. The degree of appearance of the change was not considered in the criteria mentioned above. Only the number of subjects whose replicas show deepened skin furrows for more than 50% of the area of the sample is counted. Changes below 50% of the area are neglected. To adjust this neglection, reactions of deepened skin furrows are scored as follows (Figure 45.11): no skin furrow change scores 0, skin furrows which were deepened up to 25% of the area of the sample scores 0.5, from 25 to 50% scores 1, for more than 50% scores 2.

We have used the scoring system for several experimental investigations of skin irritancy. Studying the dose–response relationship for Sodium Lauryl Sulfate (SLS) in humans, the scoring of deepened skin furrows was a much more sensitive method than the visual scoring system using patch testings.[7] Similarly, several weak irritants for cosmetic materials such as liquid oil,[9] carboxylic acids, alcohols,

esters, and aldehyde with different chain length[10] have been evaluated. These studies showed that although no macroscopic alterations were found on the tested skin sites by closed patch testing, subclinical irritation could be evaluated by the scoring of deepened skin furrows. Recently, we demonstrated by using the scoring system of deepened skin furrows that subclinical irritation from liquid oil used as cosmetic ingredients is highly correlated with a reciprocal of molecular radius.[10]

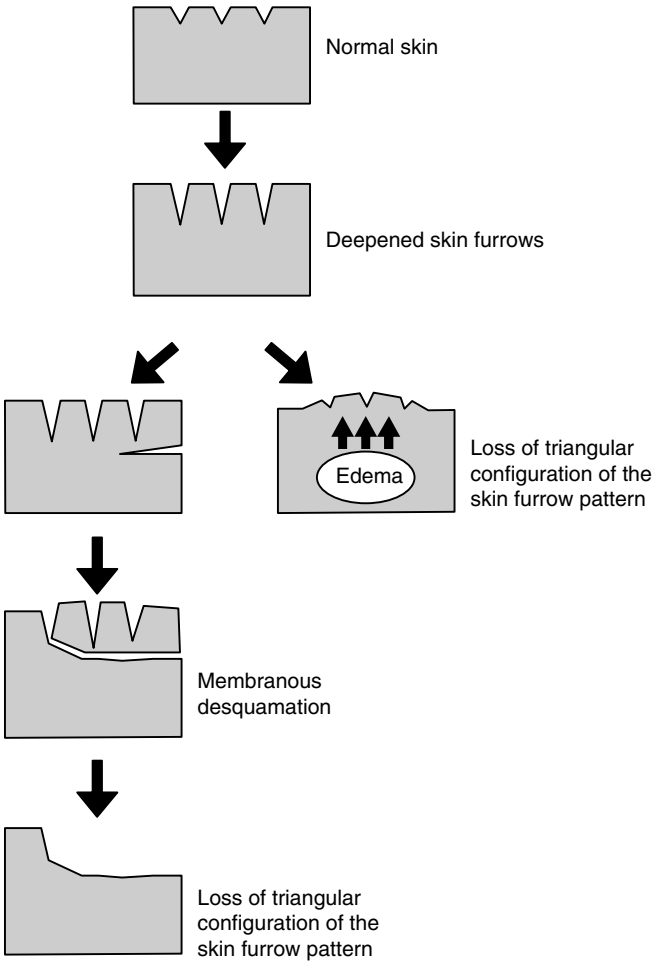

FIGURE 45.9 Possible mechanism of skin surface changes after irritant applications.

Not only chemical irritation but also physical irritation can be evaluated by the Kawai method. By using the Kawai method, Kondo et al.[11] reported that the physical skin irritation was dependent on fiber cross-sectional shape, fiber thickness, and yarn twist. Moreover, they have shown that the measurement of fabric mechanical properties and handles of hard-finished fabrics were closely related with their skin irritation (the degree of hardness of the fabric correlated to skin irritancy).[12] Tokumura et al.[13] showed that the cumulative amount of stripped corneocytes by repetitive application of adhesive tape correlated well with the appearance of deepened skin furrows on the tested skin.

45.5 SUMMARY

The Kawai method is discussed in this chapter. The Kawai method is used to predict weak skin irritancy. Using this method, we have evaluated the effects of commercial products on the skin, and our judgments based on the changes of replicas correlated well with the incidence of claims for skin troubles. Thus, we believe that the replica method can be used as a product test for screening skin irritancy. However, any predictive method, including this method, cannot be a precise method to assess skin irritancy, because the development of skin irritancy depends on various factors such as concentration or exposure time, chemical or physical property, cumulative effect with other irritants, environmental conditions, individual susceptibility, and so forth. As the replica method is merely evaluating skin surface changes after weak irritancy, this method can only evaluate the irritants which mainly affect the horny layer. Thus, several different methods must be combined for more precise prediction of skin irritancy.

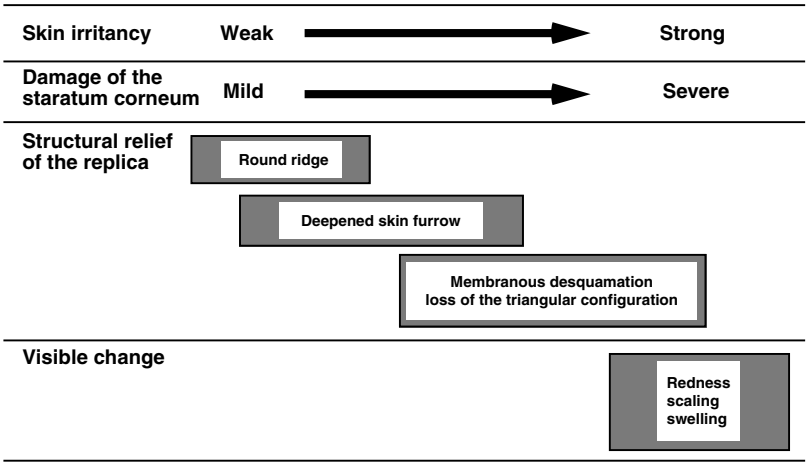

FIGURE 45.10 Replica pictures and the degree of skin irritancy.

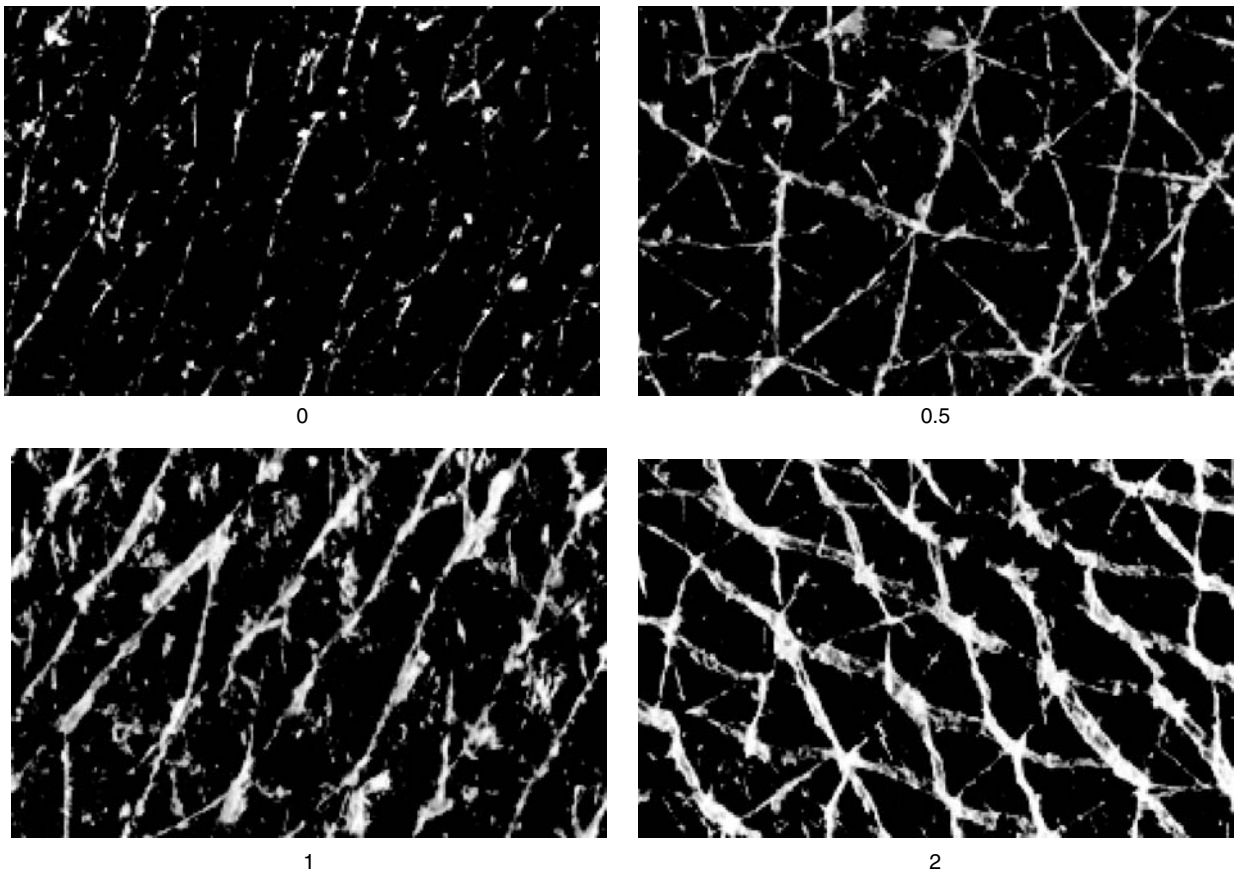

FIGURE 45.11 Scoring system for deepened skin furrow. The skin reactions were scored according to the degree of appearance of deepened skin furrows. No skin furrow change: 0, skin furrows which were deepened up to 25% of the area of the sample: 0.5, from 25 to 50%: 1, for more than 50%: 2.

46.1 INTRODUCTION

The human skin is the largest organ in the body and serves the major function of protecting the underlying tissues from external elements. The skin offers a formidable barrier in the form of a multilayered stratum corneum, which is renewed continuously by the underlying epidermis. With increasing use of cosmetics and cleansing products, the human skin is brought into contact with the variety of excipients used in these topical formulations. Many of these contain surfactants, which can have toxic and irritating effects on skin. In addition, these amphiphilic molecules can partition into the stratum corneum and compromise the epidermal barrier function.

The intercellular lipid lamellae in the stratum corneum constitute the main epidermal barrier to the diffusion of water and other solutes (Elias and Friend, 1975; Elias, 1981, 1983; Wertz and Downing, 1982; Landman, 1986). These lipids, arranged in multiple layers between the corneocytes (Swartzendruber et al., 1989; Wertz et al., 1989), consist of ceramides (40–50%), free fatty acids (15–25%), cholesterol (15–25%), and cholesterol sulfate (5–10%) (Swartzendruber et al., 1987; Gray et al., 1982; Long et al., 1985). Information on the molecular structure of these lipids is important in elaborating a rational design for effective penetration enhancers in transdermal drug delivery (Woodford and Barry, 1986) and to understand the mechanism of irritant dermatitis and other stratum corneum diseases. This information has been obtained by thermal analysis (Van Duzee, 1975; Golden et al., 1987a; Bouwstra et al., 1992), x-ray diffraction study (Vilkes et al., 1973; White et al., 1988; Bouwstra et al., 1991a,b; Garson et al., 1991;

Bouwstra et al., 1994), FTIR spectroscopy (Bommannann et al., 1990; Krill et al., 1992), and electron paramagnetic resonance spectroscopy (EPR) (Rehfeld et al., 1988, 1990).

Several investigators (Imokawa et al., 1975; Faucher and Goddard, 1978; Imokawa, 1980; Fulmer and Kramer, 1986; Rhein et al., 1986, 1990; Froebe et al., 1990; Barker et al., 1991; Giridhar and Acosta, 1993; Wilmer et al., 1994) have demonstrated that stratum corneum swelling, protein denaturation, lipid removal, inhibition of cellular proliferation, and chemical mediator release contribute to irritation reactions. However, the mechanism of irritant dermatitis has not yet been understood and defined completely.

Whereas, permeability is increased by an increase in fluidity both in biological and artificial membranes, suggesting a correlation between flux and fluidity (Knutson et al., 1985; Golden et al., 1987b). The dynamic properties of intercellular lipids in the stratum corneum are incompletely characterized; the effect of surfactants has not been studied in detail.

Electron paramagnetic resonance (EPR) employing nitroxide spin probes, known as the spin labeling method, has been utilized as a valuable spectroscopic method for providing information about the dynamic structure of membranes (Sauerheber et al., 1977; Curtain and Gorden, 1984). Spin probes are specifically incorporated into the lipid or lipid part of biological membranes. Thus, each label reflects the properties of different membrane regions. EPR spectra of membrane-incorporated spin probes are sensitive to the rotational mobility and orientation of the probes, and to the polarity of the environment surrounding the probes.

In this chapter, the influence of surfactants on the intercellular lipid structure of cadaver stratum corneum and the stripped stratum corneum will be discussed, based on spin-label EPR spectroscopy. Techniques used to investigate fluidity of intercellular lipid layers of human stratum corneum will also be reviewed. In the meantime, we will also show the correlation between EPR spectral data and human clinical data such as transepidermal water loss (TEWL).

46.2 WHAT IS ELECTRON PARAMAGNETIC RESONANCE SPECTROSCOPY?

EPR, also known as electron spin resonance (ESR), is the name given to the process of resonant absorption of microwave radiation by paramagnetic ions or molecules, with at least one unpaired electron spin in the presence of a static magnetic field. EPR was discovered by Zavoisky in 1944. It has a wide range of applications in chemistry, physics, biology, and medicine: it may be used to probe the "static" structure of solid and liquid systems, and is also very useful in investigating dynamic processes.

Most biological systems give no intrinsic EPR signal because they have no unpaired electrons. Therefore, if EPR is to be used in studying these systems such as lipid membranes or macromolecules, one or more radicals known as spin labels must be coupled to the system under investigation. The spin label thus is an extrinsic probe or reporter group providing information that reflects the state of the biological system.

46.2.1 Principles

The detailed principles of EPR are explained in the book written by Wertz and Bolton (1972). Here, EPR principles are introduced in brief.

The principles of EPR are similar to those of NMR (nuclear magnetic resonance). The magnetic moment of an unpaired electron is given by

$$m = -g_e(eh/4\pi m_e)m_s(\mathrm{SI})$$

in which g_e is the electronic g-factor (a number very nearly equal to 2). $-e$ and m_e are, respectively, the electronic charge and mass, and m_s the spin quantum number (equal to $\pm 1/2$). The quantity in parentheses in the first equation is called the *Bohr magneton* and has the value of 9.2732×10^{-24} J T^{-1} in SI units (9.2732×10^{-21} erg G^{-1}). In an applied magnetic field of strength B, the transition of an electron from ground to the excited state requires energy:

$$\Delta E = g_e(eh/4\pi m_e)B(\mathrm{SI})$$

In a magnetic field of 2 T (20 kG), this energy corresponds to the absorption of radiation of the frequency:

$$\upsilon = \Delta E/h = 2\times(9.273\times10^{-24}\,\mathrm{J\,T^{-1}})\,(2\,\mathrm{T})/6.62\times10^{-34}\,\mathrm{Js}$$

$$= 5.6\times10^{10}\,\mathrm{Hz}$$

which is in the microwave region of the spectrum.

Paramagnetic substances are detected readily by EPR. About 10^{-13} mole of a substance gives an observable signal, so this technique is one of the most sensitive of all spectroscopic tools (Eisenberg and Crothers, 1979).

The effect of a neighboring nuclear spin on the resonance of an unpaired electron is called hyperfine coupling. For an electron in a magnetic field, there are two orientations and two quantum states (Figure 46.1a), giving a possible combination of four quantum states for the electron–nucleus pair. Nuclear spin "splits" each electron quantum state into two states. Because the selection rules for transitions in hyperfine coupling are $\Delta m_s = \pm 1$ and $\Delta m_I = 0$, there can only be two transitions among these four states for which electromagnetic radiation can be absorbed. Vertical arrows in Figure 46.1b show these two transitions.

For the ^{14}N nucleus, for example, $I = 1$, so there are three nuclear spin quantum states. Thus, a nearby ^{14}N nucleus splits the electronic levels into six levels. Three transitions are allowed among the six levels; consequently, the spectrum consists of three absorption bands.

46.2.2 Electron Spin Resonance Spectrometer

A modern ESR instrument consists of three basic units: (1) a microwave bridge and resonator, (2) a variable field magnet, and (3) signal amplification circuitry (Figure 46.2).

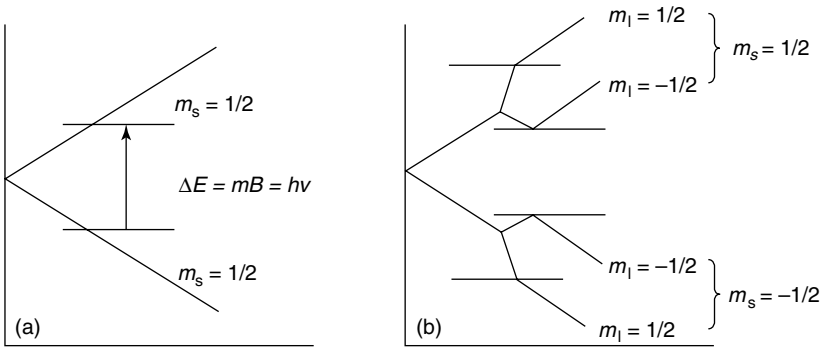

FIGURE 46.1 Energy levels of an unpaired electron with spin quantum states $m_s = 1/2$: (a) in a magnetic field; and (b) in a magnetic field and coupled to a nuclear spin of $I = 1/2$, with nuclear spin quantum.

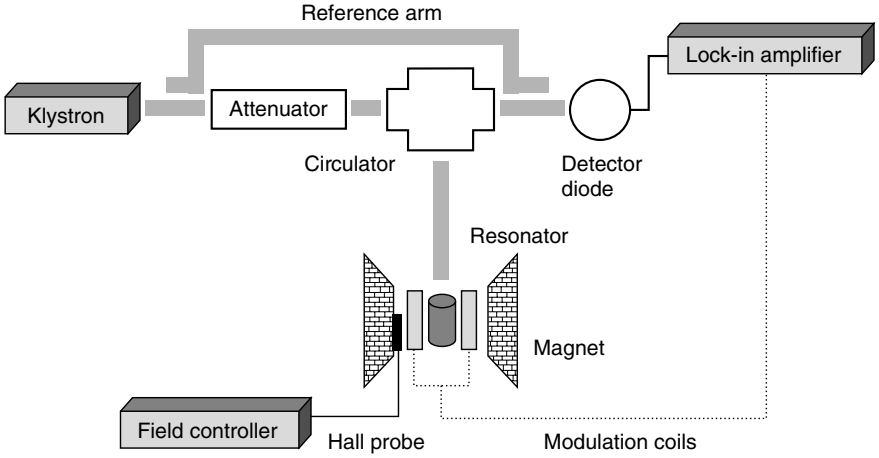

FIGURE 46.2 Block diagram of a typical EPR spectrometer.

Microwaves of the desired frequency are generated by either a klystron or Gunn diode. Their intensity is adjusted by an attenuator and transmitted via a waveguide to the sample chamber/resonator. During resonance, a small amount of microwave is reflected from the resonator and detected by a Shottky diode. To separate the reflected and incident microwaves, a circulator is placed between the attenuator and resonator. The circulator channels the microwaves in a forward direction: incident microwaves to the resonator and reflected microwaves to the detector. The bridge often contains an additional pathway—a reference arm which taps off a small fraction of the microwaves from the source—which bypasses the resonator and falls onto the detector to ensure its bias for the optimal detection of small intensity changes during resonance.

A static magnetic field is provided by an electromagnet stabilized by a Hall probe. The field is slowly swept by varying the amount of current passing through the electromagnet.

46.2.3 Spin Labeling Method; Paramagnetic Nitroxide Molecules That Serve as Probes in Membranes

McConnell et al. (1972) showed that significant information could be derived about macromolecules and membranes

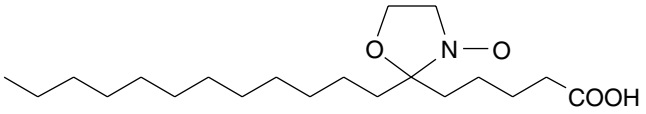

FIGURE 46.3 Chemical structure of spin probe; 5-Doxyl Stearic Acid (-DSA).

from the EPR spectra of bound nitroxide molecules. These are stable molecules that possess an unpaired $2p$ electron. The unpaired electron endows the molecules with strong EPR spectra. 5-Doxyl stearic acid (5-DSA) is one of the most commonly used spin probes and its structure is shown in Figure 46.3. A nitroxide molecule bound to a macromolecule is called a spin label.

Because the ^{14}N nucleus in a nitroxide molecule is near the unpaired electron, there is an interaction between them, thereby producing hyperfine splitting in the EPR spectrum. The ^{14}N nucleus has a spin of one, and consequently three absorption bands appear in the EPR spectra. The EPR spectra are usually recorded as the first derivative of the absorption spectrum, so instead of three bands there are three rise-and-dip spikes, which are the derivatives of the three bands. Triplet signals, which are sharp, can be observed when the spin probe moves freely, as shown in Figure 46.4. However, the spectrum becomes broader when spin probe mobility is restricted by interaction with other

components. When the spin probe is incorporated into the highly oriented intercellular lipid structure of normal skin, the probe cannot move freely due to the rigidity of the lipid structure, and its EPR spectrum represents the broad profile as seen in Figure 46.5a. Once the normal structure is completely destroyed by chemical or physical stress, there is nothing to inhibit probe mobility, and the EPR spectrum profiles become sharp, as in Figure 46.5b. The EPR spectral profile represents the rigidity of the environment of the spin probe. To express the rigidity quantitatively, an order parameter S is calculated from the EPR spectrum.

Spin labels provide information about the molecules to which they are bound. They can report the rate of motion of the molecule to which they have been covalently bound, or the amount of thermal motion in a membrane into which they have been inserted. The principle is that the bands of the EPR spectrum are broadened when the spin label is immobilized and narrowed when it is tumbling rapidly. The narrowing comes from the more rapid relaxation of the spin when neighboring groups are moving rapidly with respect to the spin label.

A second type of information is the polarity of the local environment surrounding the spin probe. The extent of splitting of the side bands from the central band depends on the dielectric constant of the medium in which the spin label is dissolved. Solvents of high dielectric constant augment the polarity of the N–O bond and increase the splitting. By measuring the splitting, an estimate can be made of the polarity of the surroundings of the spin label. This is of interest, for example, when a spin label is bound to a membrane, since it allows one to determine if the label is bound near the polar head groups or near the nonpolar hydrocarbon chains (Mehlhorn and Keith, 1972).

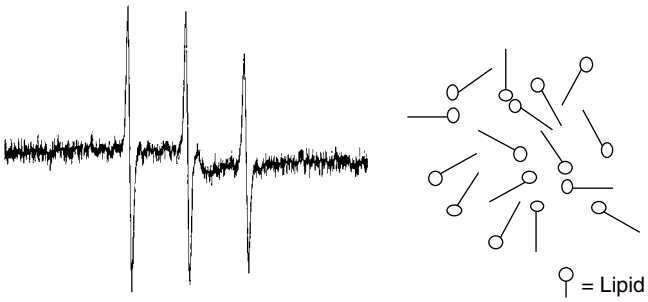

FIGURE 46.4 EPR spectrum of 5-DSA in aqueous solution.

46.2.4 How to Read the EPR Spectrum; Calculation of Order Parameter *S*

Order parameters were calculated according to Griffith and Jost (1976), Hubbel and McConnell (1971), and Marsh (1981):

$$S = (A\,||\,-A\,\perp)/[A_{ZZ} - 1/2(A_{XX} + A_{YY})](a_0/a_0')$$

where 2 A|| is identified with the outer maximum hyperfine splitting A_{max}, and A⊥ is obtained from the inner minimum hyperfine splitting A_{min} (Figure 46.5).

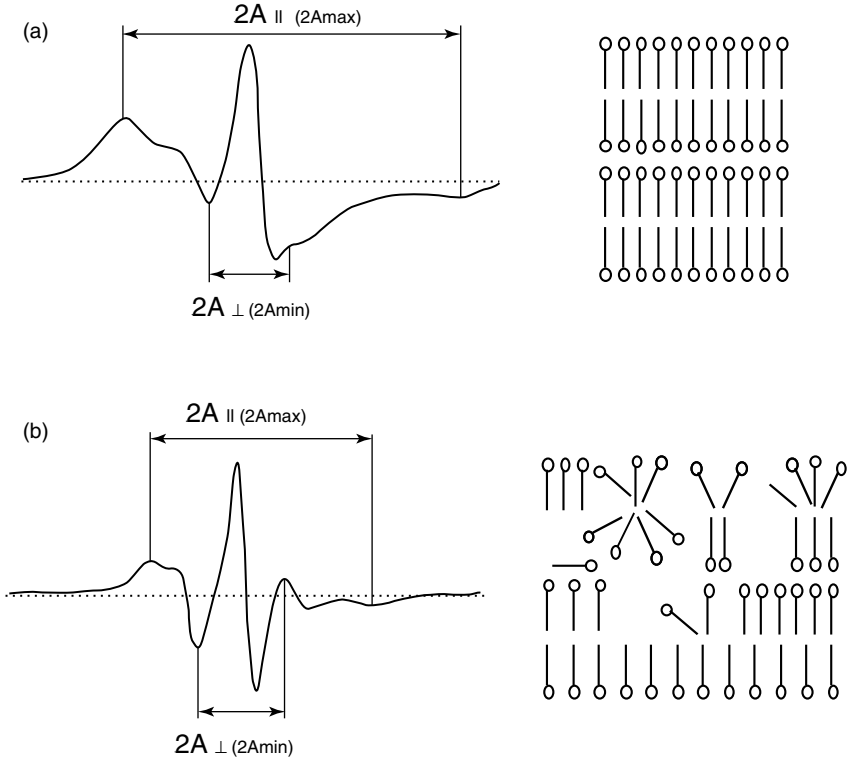

FIGURE 46.5 EPR spectrum of 5-DSA labeled stratum corneum from cadaver, (a) nontreatment (control), (b) treated with 1%wt SLS (sodium lauryl sulfate) for 24 h.

a_0 is the isotropic hyperfine splitting constant for nitroxide molecules in the crystal state.

$$a_0 = (A_{XX} + A_{YY} + A_{ZZ})/3$$

The values used to describe the rapid anisotropic motion of membrane-incorporated probes of the fatty acid type are

$$(A_{XX}, A_{YY}, A_{ZZ}) = (6.1, 6.1, 32.4) \text{ Gauss}$$

Similarly the isotropic hyperfine coupling constant for the spin label in the membrane (a_0') is given by

$$a_0' = (A \,||\, + 2A \perp)/3$$

a_0' values are sensitive to the polarity in the environment of the spin labels since increases in a_0' value reflect an increase in the polarity of the medium.

The order parameter provides a measure of the flexibility of the spin labels in the membrane. It follows that $S = 1$ for highly oriented (rigid) states and $S = 0$ for completely isotropic motion (liquid). Increases of order parameter reflect decreases in the segmental flexibility of the spin label, and conversely decreases in the order parameter *S* reflect increases in the flexibility (Curtain and Gorden, 1984).

46.3 EXPERIMENTAL DESIGN

46.3.1 EPR Measurement of Stratum Corneum from Cadaver; Spin Labeling and Surfactant Treatment Procedure

Human abdominal skin was obtained from a fresh cadaver with a dermatome. Epidermis was separated from dermis by immersing the skin in a 60°C water bath set for 2 min followed by mechanical removal. Then, the epidermis was placed, stratum corneum side up, on the filter paper and floated on 0.5%wt trypsin (type II; Sigma) in a Tris-HCl buffer solution (pH 7.4) for 2 h at 37°C. After incubation, any softened epidermis was removed by mild agitation of the stratum corneum sheet. Stratum corneum was dried and stored in a desiccator at –70°C for 3–4 days. Details are described by Quan (Quan and Maibach, 1994; Quan et al., 1995).

One slice of dry stratum corneum sheet (approximately 0.5 cm^2; ~0.7 cm × ~0.7 cm) was incubated in a 1.0 mg/dL 5-DSA aqueous solution (2.6×10^{-5} M; FW = 384.6) for 2 h at 37°C and washed gently with deionized water to remove the excess spin label.

Surfactant treatment was as follows: a spin-labeled section of stratum corneum was immersed in surfactant aqueous solution and incubated at 37°C for 1 h. The stratum corneum was taken out of the surfactant solution at indicated times. After rinsing with deionized water and removing the excess water, the stratum corneum was mounted on a flat surface EPR cell and EPR spectra were recorded.

The control EPR spectrum was recorded for the spin-labeled section of stratum corneum kept in the deionized water at 37°C instead of that kept in the surfactant solution.

46.3.2 EPR Measurement of Stripped Human Stratum Corneum; Spin Labeling and Surfactant Treatment Procedure

Two hundred microliters of aqueous solution of 1.00%wt surfactants was applied to the midvolar forearm using occlusive polypropylene chambers (1.8 cm diameter; Hilltop Laboratory, Cincinnati, OH, USA) for 24 h. Deionized water served as vehicle controls. Application sites for the different treatments were rotated to avoid an anatomical selection bias (Van der Valk and Maibach, 1989; Cua et al., 1990; Lee et al., 1994). Each site was examined visually by the same investigator and using following instrumental methods: TEWL, electrical conductance, and chromametry.

After these noninvasive measurements, patch site stratum corneum was removed from the volar side of the forearm skin by a single stripping with one drop of cyanoacrylate resin onto a quartz glass in accordance with the method of Imokawa et al. (1991). Stripped stratum corneum attached to a quartz glass was spin labeled with a drop (approximately 30 μL) of 1.0 mg/dL 5-DSA solution for 30 min at 37°C, then washed with deionized water to remove excess spin probe on the stripped skin surface.

Stripped stratum corneum was attached to a quartz cell, and EPR measurement was similarly conducted for cadaver stratum corneum.

46.4 RESULTS AND DISCUSSION

46.4.1 Effect of Surfactants on the Intercellular Lipid Fluidity of Cadaver Stratum Corneum

Kawasaki et al. (1995, 1997, 1999) and Mizushima et al. (2000) have examined the influence of surfactants on human stratum corneum obtained from cadaver (Table 46.1).

The surfactant molecule, which is amphiphilic to water and lipid, may be incorporated into structured lipids (lamellar structure). The order parameter calculated from 1.00%wt sodium lauryl sulfate (SLS)-treated stratum corneum was 0.47, indicating a disordering of the lipid structure. On the contrary, the high-order parameter value (0.73) for 1.00%wt monosodium lauryl glutamate (SLG) meant less of an effect on the structured lipid compared to the control-order parameter value (0.89). Treatment with 1.00%wt solution of SL, SLES, and SLEC revealed intermediate levels between SLG and SLS. Lipid disorder induced by MSAC and HEA, which are classified into a category different from anionic surfactants, also revealed intermediate levels between SLS and SLG. Note that 1.00%wt MSAC and 1.00%wt HEA, which are quaternary and amphoteric compounds, respectively, lead to less disorder in lipid structure than 1.00%wt SLS, although the irritation potential of surfactants is widely assumed to

follow the given pattern in which quaternaries are the most irritating; quaternaries > amphoterics > anionics > nonionics (Rieger, 1997). These two compounds (1.00%wt MSAC and 1.00%wt HEA) have plus charges. Their interaction with stratum corneum may be different from that of anionics such as SLS. A plus charge might have more attractive interaction with proteins electrically because proteins are generally thought to be negatively charged.

The change of order parameter corresponds to the structural changes in lipid layers. We can speculate that there are two phases in the increase of fluidity in lipid structure (decreasing the order parameter). The first phase is an effect of surfactants incorporated into the lamellar structures. If the surfactant interferes with or decreases lateral interactions between lipids, mobility increases in a way similar to the phase conversion from liquid crystal to gel in the lamellar layers. The second phase is the destruction of lamellar structure by micellization or solubilization of lipids by the surfactant. In this case, lipids no longer have dimensional restrictions and gain much higher mobility.

TABLE 46.1
Order Parameters of Stratum Corneum Treated with Surfactants and Clinical Observations

Category	Sample Name	Concentration (%wt)	Order Parameter *S*	Visual Scores (Average ± SD)	Visual Scores (Average ± SD) g/m²/h
Control	Water		0.89 ± 0.04	0.00 ± 0.00	5.0 ± 1.1
Anionic	SLS (Sodium lauryl sulfate)	1.0	0.47 ± 0.05	0.79 ± 0.30	13.6 ± 3.1
	SL (Sodium laurate)	1.0	0.65 ± 0.06	0.08 ± 0.20	7.1 ± 3.9
		5.0	0.52 ± 0.04	0.67 ± 0.30	13.3 ± 3.7

1.00%wt SLS + 1.00%wt SLG	0.66 ± 0.05	NA	NA
1.00%wt SLG	0.82 ± 0.02	0.67 ± 0.08	15.8 ± 1.1

Note: Error bars: mean ± SD, $n = 3$ for order parameters, mean ± SD, $n = 15$ for clinical data; NA: not available in Imokawa et al. (1991).

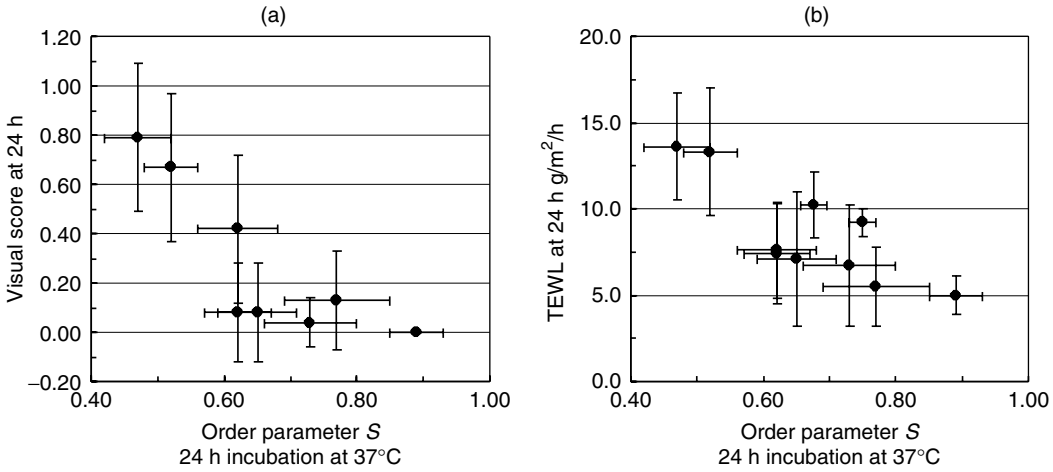

FIGURE 46.6 Correlation between clinical data of 24 h patch and order parameter *S* of 5-DSA labeled cadaver stratum corneum incubated in surfactant solution for 1 h at 37°C: (a) Correlation between order parameters and visual scores; (b) Correlation between order parameters and TEWL (error bars: mean ± SD, $n = 3$ for order parameter; mean ± SD, $n = 14$ for clinical data).

The results shown in Table 46.2 indicate that mobility increase induced by SLG can be attributed to phase-one structural changes in the lipid layers and that SLS might cause further disruption of the structures of lipid layers. The role of water in the stratum corneum must also be considered in an examination of the effects of surfactants on lipid layers. Treatment with anionic surfactants might influence water penetration and skin swelling (Takino et al., 1996). Rhein et al. (1986, 1990) examined the swelling of stratum corneum caused by surfactants and reported that the swelling effect of surfactants suggests a mechanism of action as the basis for *in vivo* irritation potential.

Figure 46.6 shows the correlation between the order parameter obtained from an EPR spectrum and the clinical readings. The correlation coefficients (r^2) of visual score and TEWL values were 0.76 and 0.83, respectively. The order parameter correlates to TEWL values better than to visual scores. This difference may be explainable in that TEWL is a direct measure of water barrier function, while visual scores represent total skin reactions including physical or structural changes of skin tissue due to physiological or biological reactions with surfactants. The visual score and colorimetry showed similar correlation coefficients, which mainly reflect reactions of the skin including edema of the epidermis and upper dermis, perivascular infiltrates, and vasodilation. The order parameter might not predict subsequent skin reactions after a disorder of the lipid structure caused by the denaturation of proteins or mucosaccarides in the dermis.

Order parameter measurement of stratum corneum may predict the minimal difference in irritation potential among a range of surfactants.

46.4.2 Effect of Surfactant Mixtures (SLS/SLG) on Intercellular Lipid Fluidity of Cadaver Stratum Corneum

As discussed previously, SLS was the most severely irritating and SLG the mildest amongst the anionic surfactants tested. Kawasaki et al. (1999) examined the influence of surfactant mixtures (SLS/SLG) on the intercellular lipid fluidity of stratum corneum obtained from cadaver skin.

The order parameter of water-treated stratum corneum (vehicle control) was 0.86 ± 0.03. Anionic surfactants as amphiphilic molecules may be incorporated into structured lipids (the lamellar structure). The order parameter calculated from 1.00%wt SLS-treated stratum corneum was 0.56 ± 0.03, indicating disorder in the lipid structure. On the contrary, the high-order parameter value (0.82 ± 0.02) for 1.00%wt SLG meant that less lipid structure was disordered; 1.00%wt SLG was almost equal to water. Treatment with 0.25%wt, 0.50%wt, and 0.75%wt SLS solutions revealed intermediate levels between 1.00%wt SLG and 1.00%wt SLS.

Each order parameter of 5-DSA labeled stratum corneum treated with SLS/SLG mixtures (the total concentration was constant at 1.00%wt) showed higher values than those of 0.25%wt, 0.50%wt, and 0.75%wt SLS, respectively. There were no statistically significant differences between 0.50%wt SLS and 0.50%wt SLS/0.50%wt SLG, and between 0.75%wt SLS and 0.75%wt SLS/0.25%wt SLG ($p > .05$). These profiles are also supported by the results of Kanari et al. (1993).

These results suggest that SLG inhibited SLS-induced lipid fluidization. To confirm the antifluidization of SLG, SLS/SLG mixture solutions were prepared with the SLG concentration constant at 1.00%wt, and 5-DSA labeled stratum corneum was treated with them. Then the EPR spectra were measured. The calculated order parameters are plotted in Figure 46.7.

Order parameters at each SLS concentration (0.25, 0.50, 0.75, and 1.00%wt SLS) with 1.00%wt SLG showed higher values than those of SLS-only solutions. There were statistically significant differences between solutions with and without 1.00%wt SLG ($p < .05$), suggesting that the addition of 1.00%wt SLG inhibits the fluidization of intercellular lipids induced by SLS. It may be hypothesized that the direct interactions between SLS and intercellular lipids would be interrupted by SLG and the log *P* (partition coefficient;

log {$[SLS]_{lipid}/[SLS]_{bulk}$}) of SLS into the intercellular lipid may be decreased.

The role of water in the stratum corneum must also be considered in analyzing the effects of surfactants on lipid layers. Alonso et al. (1995, 1996) reported that water increases the fluidity of the intercellular lipids of rat stratum corneum in the region closer to the hydrophilic area but not in the lipophillic area, deep inside the intercellular lipid layer.

The order parameter correlated to the clinical readings (Figure 46.8). The correlation coefficients (r^2) of visual score and TEWL values were 0.73 and 0.83, respectively. The order parameter correlates to TEWL values better than to visual scores, which is same as the result shown in the previous section.

The order parameters represent the disorder of stratum corneum induced by short-term surfactant contact. However, the clinical data represent skin irritation reactions induced by 24-h occlusive contact with surfactants. Order parameter measurement of stratum corneum may predict the minimal difference in irritation potential among a range of surfactants.

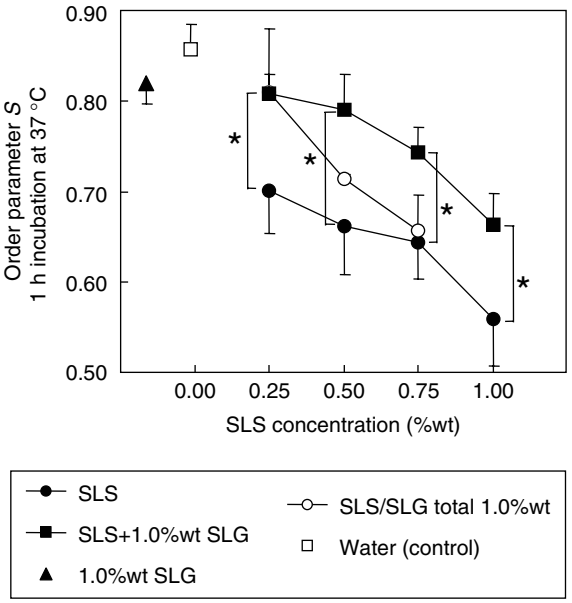

FIGURE 46.7 Order parameter of 5-DSA labeled cadaver stratum corneum treated with water, SLS, SLG, and SLS/SLG mixtures (total concentration 1.00%wt, 1.00%wt SLG addition to the SLS solutions; error bars: mean ± SD, $n = 3$; * indicates that $p < .05$).

46.4.3 Correlation Between CMC and Intercellular Lipid Fluidization for SLS

1.00%wt SLS causes more fluidization than other anionic surfactants. We still must ask: how long must there be contact with severe anionic surfactant SLS before fluidization happens in lipids? How much alteration is induced by how much concentration of SLS?

Figure 46.9 (unpublished data) shows the incubation time dependence of an EPR spectrum with different SLS concentrations. With increasing incubation time, the order parameter was decreased. However, each profile of incubation time dependence had a plateau at the region of 6 h and thereafter. The skin lipid alteration induced by SLS was typically completed within 6 h at a given concentration. However, each alteration level in intercellular lipids depended on its SLS concentration.

As the concentration of SLS increases, the order parameter at 24-h incubation decreases drastically in the range of 0–0.25%wt of SLS (Figure 46.10). However, the order parameters calculated from the stratum corneum treated with SLS at more than 0.5%wt had no significant difference, showing around 0.45~0.49. This critical point between 0.25 and 0.5%wt (8.7~17.3 mM) may correspond to the CMC (critical micelle concentration) for SLS at 37°C.

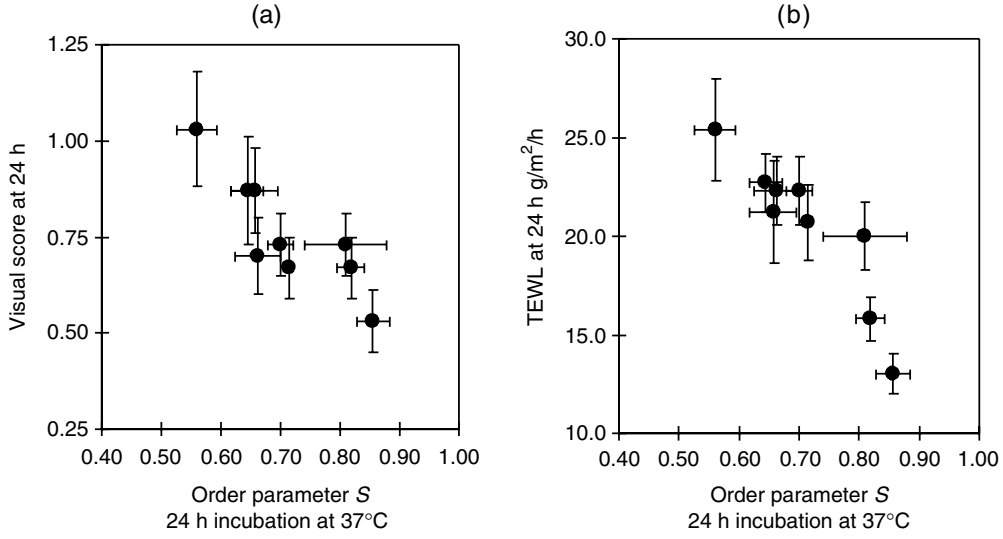

FIGURE 46.8 Correlation between clinical data of 24 h patch and order parameter *S* of 5-DSA labeled cadaver stratum corneum incubated in surfactant solution for 1 h at 37°C: (a) Correlation between order parameters and visual scores; (b) Correlation between order parameters and TEWL (error bars: mean ± SD, $n = 3$ for order parameter; mean ± SD, $n = 15$ for clinical data).

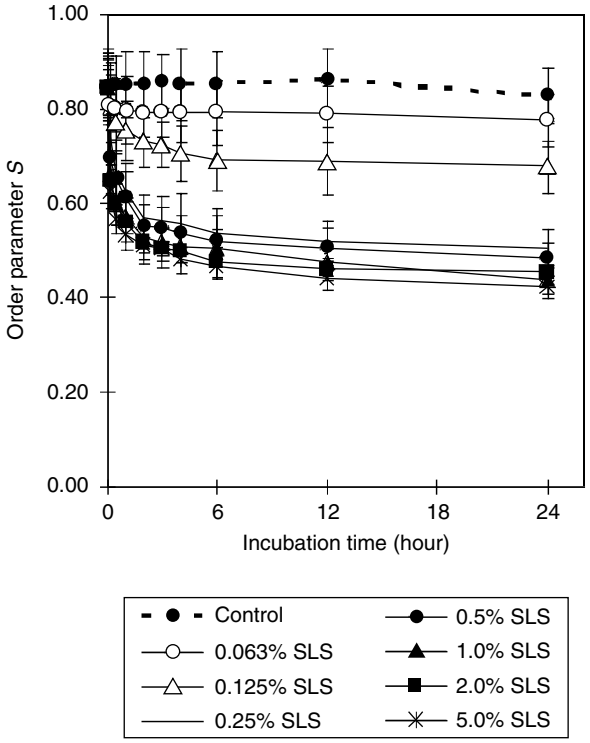

FIGURE 46.9 Time dependence of order parameters of 5-DSA labeled stratum corneum in SLS solution at various concentrations (error bars: mean ± SD, $n = 5$).

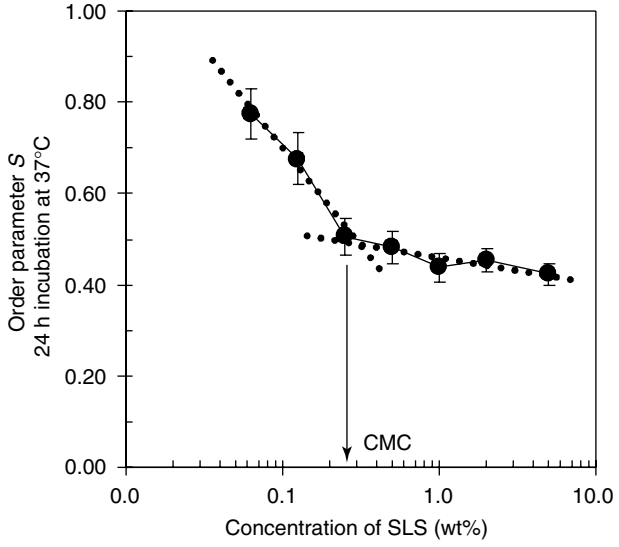

FIGURE 46.10 Correlation between SLS concentration and order parameters of 5-DSA labeled cadaver stratum corneum incubated at 37°C for 24 h (error bars: mean ± SD for $n = 5$).

Rosen (1978) reported that the CMC of SLS is 8.6 mM at 40°C and 8.2 mM at 25°C.

This behavior is consistent with the following general concerns among experts: monomeric surfactants can penetrate the skin. Monomeric molecules are also the species that are initially adsorbed into the various surfaces within the skin; we cannot ignore secondary bonding due to hydrophobic effects. Thus, the concentration of monomeric species probably plays a major role in skin and surfactant interactions (Rieger, 1995).

46.4.4 EPR Study Utilizing Human Stripped Stratum Corneum

All the previous data are based on human stratum corneum obtained from cadaver skin. To define the structural changes in intercellular lipids induced by the topical application of surfactants and to discuss the correlation between lipid alteration and skin irritation reactions, choosing human stratum corneum from cadavers for a substrate as a model site of skin irritation is much better than using animal skins such as those of guinea pigs and rats, or using lecithin liposomes. But stratum corneum is not sufficient for discussing the mechanism of irritant dermatitis. Cadaver stratum corneum is just a substrate, not a living system, which has a recovery system induced by signals such as chemical mediators. With the new procedure for measuring EPR spectra on human stripped stratum corneum, information on the dynamics of living skin may be provided.

Mizushima et al. (2000) examined EPR spectral data on stratum corneum from cadaver skin and stripped skin treated with three types of surfactants.

The correlation between order parameters of 5-DSA labeled cadaver stratum corneum treated with surfactants and those of 5-DSA labeled stripped stratum corneum was summarized in Figure 46.11.

Although the order parameters obtained from stripped stratum corneum are larger than those of cadaver stratum corneum, a high correlation between them is observed. It suggests that the order parameters of cadaver stratum

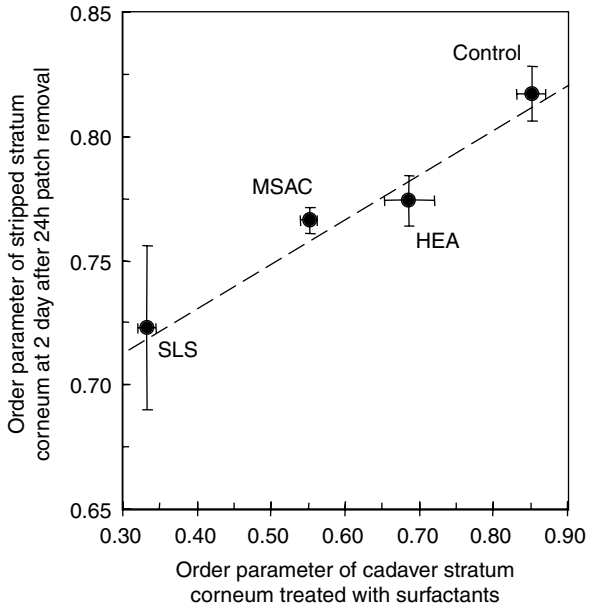

FIGURE 46.11 Correlation of order parameters between cadaver stratum corneum and stripped stratum corneum (error bars: mean ± SD for $n = 5$). Cadaver stratum corneum = −3.883 + 5.833 × stripped stratum corneum.

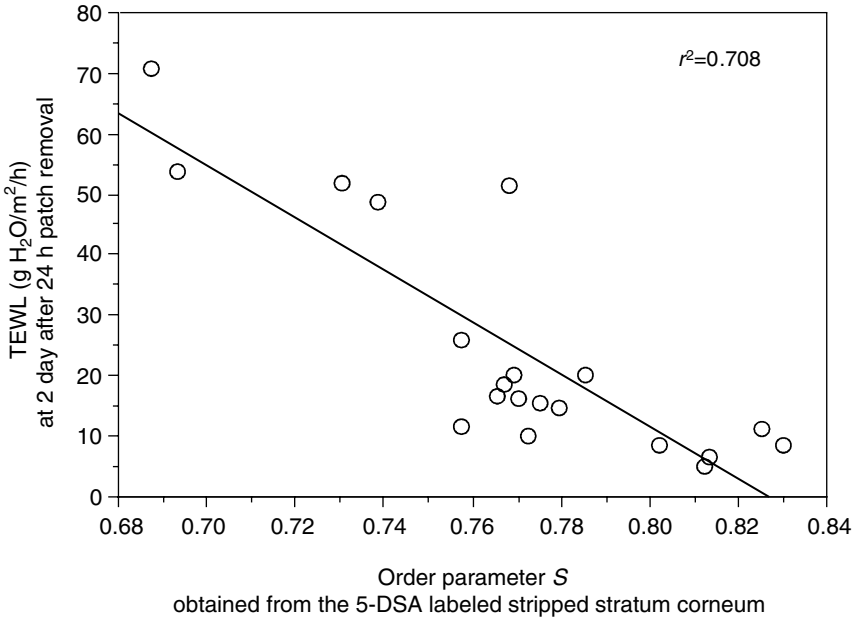

FIGURE 46.12 The correlation between TEWL and order parameters on the second day after 24 h patch removal.

corneum reflect the fluidity of the intercellular lipids in the irritaed skin.

The order parameter of SLS-treated cadaver stratum corneum is smaller than that of stripped stratum corneum. This difference may be due to the barrier-reconstruction property of skin itself. The epidermis can synthesize lipid immediately after barrier disruption (Grubauer et al., 1989). Skin barrier function was 80% repaired by 6–8 h, when skin was treated with acetone (Elias and Feingold, 1992).

The correlation between the order parameter of stripped stratum corneum and clinical readings is as follows: the correlation coefficient between order parameter and visual score, TEWL values on the second day after patch removal, were 0.526 and 0.708, respectively. The correlation with TEWL is high, as shown in Figure 46.12. This result consists of *in vitro* data based on cadaver stratum corneum.

46.4.5 Water May Affect the Order Parameter *S*

The role of water in the stratum corneum must be also considered for an understanding of the effects of surfactants on lipid layers. Alonso et al. (1995, 1996) reported that water increases the fluidity of intercellular lipids of rat stratum corneum at the region close to the hydrophilic area, but not in the lipophilic area, deep inside the intercellular lipid layer. Treatment with anionic surfactants may influence water penetration into stratum corneum. In case that the stratum corneum from a cadaver is treated with SLS and SLG for 1 h, the order parameter decreases with the dose dependency of the surfactants. When order parameter is followed over time under dry conditions, those values increase. After 24 h, the order parameter becomes higher than in the control (Kawasaki et al., 1997). It is suggested that the altering of water content in cadaver stratum corneum affects the order parameter. This does not simply mean loss of water, because after the untreated control stratum corneum dries, the order parameter still shows a minimal order parameter change.

To investigate such effects of surfactants, Mizushima et al. (2001) measured the EPR spectra on cadaver stratum corneum treated with four concentrations of SLS under wet conditions just after incubation. The EPR spectra were measured again on the same samples after they were dried at room temperature for 1 h. They also weighed each cadaver stratum corneum sample three times as follows: (1) before labeling (initial weight of each stratum corneum), (2) just after the treatment/EPR measurement of stratum corneum under wet conditions, and (3) after the second EPR measurement of stratum corneum under dry conditions.

As shown in Table 46.3, under wet conditions, the order parameter *S* decreased and the weight of each cadaver stratum corneum increased with SLS dose dependency. On the contrary, under dry conditions, the order parameter increased with the dose dependency of SLS compared to the untreated control, which meant that the fluidity of the stratum corneum increased greatly before surfactant treatment. The weight of each cadaver stratum corneum sheet decreased with SLS dose dependency. So we can say that the effect of SLS on stratum corneum is not only to alter the fluidity of the lipid bilayer, but also to change the water-holding capacity of the lipid bilayer. This might be due to depletion of or change in the intercellular lipid lamellae such as fatty acids, cholesterol derivatives, and materials, which cooperate with the keratin protein and amino acids as natural moisturizing factors.

Two phases can be hypothesized in the increase of fluidity in lipid structures. The first phase is in the effect of surfactants incorporated into the lamellar structures. If the surfactant interferes with or decreases lateral interactions between lipids, mobility increases in a way similar to the

TABLE 46.3
The Order Parameters *S* Obtained from SLS-Treated Cadaver Stratum Corneum ($n = 3$) and Its Weight, Measured under Wet and Dry Conditions

SLS Concentration (%wt)	Order Parameter		Weight Increase (%)	
	Wet Condition	Dry Condition	Wet Condition	Dry Condition
0.00	0.81 ± 0.01	0.82 ± 0.01	155.2 ± 4.3	95.2 ± 4.9
0.13	0.79 ± 0.01	0.83 ± 0.01	195.0 ± 9.8	87.1 ± 11.5
0.25	0.71 ± 0.01	0.84 ± 0.01	289.5 ± 47.7	82.5 ± 6.4
0.50	0.63 ± 0.02	0.84 ± 0.01	337.7 ± 28.8	81.6 ± 5.3
1.00	0.59 ± 0.01	0.84 ± 0.01	351.9 ± 21.3	80.3 ± 14.2

Note: The weight of the stratum corneum sheet is defined as 100 (%) just before labeling with 5-DSA aqueous solution.

phase conversion from liquid crystal to gel in the lamellar layers. The second phase is the destruction of the lamellar structure by means of micellization or solubilization of the lipid layer by the surfactant. In this case, lipids no longer have dimensional restrictions and gain much higher mobility. The surfactant might have changed the water-holding capacity of the stratum corneum, and the water content may change the fluidity of stratum corneum lipids. We have to consider the water content of stratum corneum because it will alter the fluidity of intercellular lipids. To evaluate the effects of chemicals such as surfactants on stratum corneum lipids, which may change the water-holding capacity, we have to consider the existing water content of stratum corneum in measuring the EPR spectra.

46.5 CONCLUSION

The toxic manifestations of topically applied substances may induce immediate phenomena (such as corrosion or primary irritation), delayed phenomena (such as sensitization), phenomena that require an additional vector (such as phototoxicity), and systemic phenomena (paraquat toxicity). Such reactions cannot occur unless the toxic agent reaches a viable part of the skin by going through the stratum corneum with accompanying intercellular lipid structure disruption. If the toxicant can be stored in or absorbed by a skin layer without any alteration in lipid structure, it may not reach the viable tissues at all or may be released relatively slowly, thus effectively prolonging the symptoms.

EPR spin labeling is a robust method for monitoring the structural change in intercellular lipids induced by topically applied surfactants. We have shown that order parameter is an easy to use and quantifiable method for predicting irritation reactions in the skin. In particular, EPR measurement on stripped stratum corneum may reflect the actual skin condition with regard to lipid structure. It may also aid in investigating the irritation potential of general chemicals, effects of topical penetration enhancers, drug delivery systems, and skin diseases such as xerosis and atopic dermatitis.
